

Proceedings of the Eightth Congress
of the European Society for Research
in Mathematics Education

Editors

Behiye Ubuz, Çiğdem Haser, Maria Alessandra Mariotti

Organized by

Middle East Technical University, Ankara

Editors

Behiye Ubuz, Middle East Technical University, Turkey

Çiğdem Haser, Middle East Technical University, Turkey

Maria Alessandra Mariotti, University of Sienna, Italy

Editorial Board

Paul Andrews, Samuele Antonini, Pedro Arteaga, Arthur Bakker, Mariolina Bartolini Bussi, Veronique Battie, Claire Berg, Irene Biza, Mariana Bosch, Richard Cabassut, Maria C. Cañadas, Susana Carreira, Charalambos Charalambous, Kathy Clark, Sarah Crafter, Pietro Di Martino, Therese Dooley, Viviane Durand-Guerrier, Andreas Eichler, Lisser Rye Ejersbo, Ingvald Erfjord, Alejandro S. González-Martin, Ghislaine Gueudet, Corinne Hahn, Jeremy Hodgen, Eva Jablonka, Uffe Thomas Jankvist, Gabriele Kaiser, Alexander Karp, Ivy Kidron, Christine Knipping, Snezana Lawrence, Roza Leikin, Esther Levenson, Thomas Lingefjärd, Mirko Maracci, Michela Maschietto, Alain Mercier, Mônica Mesquita, Joris Mithalal, John Monaghan, Elena Nardi, Jarmila Novotna, Reinhard Oldenburg, Cecile Ouvrier-Bufferet, Alexandre Pais, Marilena Pantziara, Kirsten Pfeiffer, Nuria Planas, Despina Potari, Giorgos Psycharis, Luis Radford, Sebastian Rezat, C. Miguel Ribeiro, Philippe R. Richard, Bettina Roesken, Frode Rønning, Leonor Santos, Florence Mihaela Singer, Jeppe Skott, Hauke Straehler-Pohl, Gabriel Stylianides, Ewa Swoboda, Konstantinos Tatsis, Jana Trgalova, Jan van Maanen, Kjersti Waege, Geoff Wake, Hans Georg Weigand, Carl Winsløw

The proceedings are published by Middle East Technical University, Ankara, Turkey
on behalf of the European Society for Research in Mathematics Education

ISBN 978-975-429-315-9

TABLE OF CONTENTS

General Introduction	1
<i>Maria Alessandro Mariotti, Ferdinando Arzarello</i>	
Editorial Introduction	5
<i>Behiye Ubuz, Çiğdem Haser, Maria Alessandro Mariotti</i>	
I. PLENARY LECTURES	
Plenary Lecture 1	
Mathematics Education Today: Scientific Advancements and Societal Needs	8
<i>Paolo Boero</i>	
Plenary Lecture 2	
Teaching and Learning Geometry and Beyond ...	33
<i>Alain Kuzniak</i>	
Plenary Lecture 3	
Language and Mathematics: A Field without Boundaries	50
<i>Candia Morgan</i>	
II. WORKING GROUPS	
Working Group 1 - Argumentation and Proof	
Introduction to the Papers and Posters of WG1	69
Research Papers	
Proof in Algebra at the University Level: Analysis of Students Difficulties	76
<i>Nadia Azrou</i>	
Students` Use of Variables and Examples In Their Transition From Generic Proof To Formal Proof	86
<i>Rolf Biehler & Leander Kempen</i>	

Use of Formalism in Mathematical Activity Case Study: The Concept of Continuity in Higher Education <i>Faïza Chellougui & Rahim Kouki</i>	96
The Making of a Proof-Chain: Epistemological and Didactical Perspectives <i>Renaud Chorlay</i>	106
Possible Language Barriers in Processes of Mathematical Reasoning <i>Jenny Christine Cramer</i>	116
The Presentation and Setting Up Of a Model of Analysis of Reasoning Processes in Mathematics Lessons in Primary Schools <i>Patrick Gibel</i>	126
Research Situations to Learn Logic and Various Types of Mathematical Reasonings and Proofs <i>Denise Grenier</i>	136
The Width of a Proof <i>Gila Hanna</i>	146
Multiple Proofs and In-Service Teachers' Training <i>Margo Kondratieva</i>	156
New Objectives for the Notions of Logic Teaching in High School in France: A Complex Request for Teachers <i>Zoe Mesnil</i>	166
Approaching Algebraic Proof at Lower Secondary School Level: Developing and Testing an Analytical Toolkit <i>Francesca Morselli</i>	176
The Epistemic Status of Formalizable Proof and Formalizability as a Meta-Discursive Rule <i>Eva Müller-Hill</i>	186
$0, 999\dots = 1$ An Equality Questioning The Relationships Between Truth and Validity <i>Judith Njomgang Ngansop & Viviane Durand-Guerrier</i>	196
The Biological Basis for Deductive Reasoning <i>David A. Reid</i>	206

Multimodal Proof in Arithmetic	216
<i>Reinert A. Rinvold & Andreas Lorange</i>	
Ways of Analogical Reasoning – Thought Processes in an Example Based Learning Environment	226
<i>Markus Ruppert</i>	
A Case Study of the Enactment of Proof Tasks in High School Geometry	236
<i>Ruthmae Sears</i>	
The Roles of Behavioral Schemas, Persistence, and Self-Efficacy in Proof Construction	246
<i>Annie Selden & John Selden</i>	
The Nature of Argumentation in School Texts in Different Contexts	256
<i>Chrissavgi Triantafillou, Vasiliki Spiliotopoulo & Despina Potari</i>	
Posters	
Modelling Algorithmic Thinking: The Fundamental Notion of Problem	266
<i>Simon Modeste</i>	
Working Group 2 – Arithmetic and Number Systems	
Introduction to the Papers and Posters of WG2	268
Research Papers	
The (Relativity of the) Whole as a Fundamental Dimension in the Conceptualization of Fractions	273
<i>Nadine Bednarz & Jérôme Proulx</i>	
Students’ Mental Computation Strategies with Fractions	283
<i>Renata Carvalho & João Pedro da Ponte</i>	
Performance on Ratio in Realistic Discount Task	293
<i>Bernardo Gómez, Javier Monje, Patricia Pérez-Tyteca & Mirela Rigo</i>	
Replacing Counting Strategies: Children’s Constructs Working On Number Sequences	303
<i>Uta Häsel-Weide & Marcus Nührenbörger</i>	

Why and How to Introduce Numbers Units in 1 st -and 2 nd -Grades <i>Catherine Houdement & Christine Chambris</i>	313
Levels of Objectification in Students' Strategies <i>Andreas Lorange & Reinert Rinvold</i>	323
Mental Computation Strategies in Subtraction Problem Solving <i>Cristina Morais & Lurdes Serrazina</i>	333
Focusing Structural Relations in the Bar Board – A Design Research Study for Fostering All Students' Conceptual Understanding of Fractions <i>Susanne Prediger</i>	343
Flexibility in Mental Calculation in Elementary Students from Different Math Classes <i>Elisabeth Rathgeb-Schnierer & Michael Green</i>	353
Different Praxeologies for Rational Numbers in Decimal System – The $0,\bar{9}$ Case <i>Benoit Rittaud & Laurent Vivier</i>	363
About Students' Individual Concepts of Negative Integer – In Terms of the Order Relation <i>Maike Schindler & Stephan Hufßmann</i>	373
Representations and Reasoning Strategies of Grade 3 Students in Problem Solving <i>Isabel Velez & João Pedro da Ponte</i>	383
The Consistency of Students' Error Patterns in Solving Computational Problems with Fractions <i>Gerald Wittmann</i>	393
Posters	
Transformations via Fractions, Decimals, and Percents <i>Regina Reinup</i>	403
To Measure with a Broken Ruler to Understand the Common Technique of The Substraction <i>Anne-Marie Rinaldi</i>	405

Working Group 3 – Algebraic Thinking

Introduction to the Papers and Posters of WG3	407
Research Papers	
An Analysis of Turkish Mathematics Teachers' Self-Reported Preparedness to Teach Algebra in TIMSS 2007 <i>Kübra Çelikdemir & Ayhan Kürşat Erbaş</i>	411
Young Pupils' Generalisation Strategies for the 'Handshakes' Problem <i>Thérèse Dooley</i>	420
How Arithmetic Education Influences the Learning of Symbolic Algebra <i>Sandra Gerhard</i>	430
Hidden Differences in Teachers' Approach to Algebra – A Comparative Case Study of Two Lessons <i>Cecilia Kilhamn</i>	440
Limit of the Syntactical Methods in Secondary School Algebra <i>Rahim Kouki & Faiza Chellougui</i>	450
Covariation, Embodied Cognition, Symbolism and Software Design in Teaching/Learning about Functions: The Case of Casyopée <i>Jean-Baptiste Lagrange</i>	460
From Recursive to Explicit Formula for the N -th Member of a Sequence Mapped from a Shape Pattern <i>Heidi Strømskag Måsøval</i>	470
Different Ways of Grasping Structure in Arithmetical Tasks, as Steps toward Algebra <i>Maria Mellone, Piera Romano & Roberto Tortora</i>	480
Generalising Through Quasi-Variable Thinking: A Study with Grade 4 Students <i>Célia Mestre & Helia Oliveira</i>	490
Syntactic and Semantic Items in Algebra Tests – A Conceptual and Empirical View <i>Reinhard Oldenburg, Jeremy Hodgen, & Dietmar Küchemann</i>	500

Implicit Learning in the Teaching of Algebra: Designing a Task to Address the Equivalence of Expressions	510
<i>Julia Pilet</i>	
Students' Difficulties with the Cartesian Connection	520
<i>Valentina Postelnicu</i>	
Mental Mathematics & Algebra Equation Solving	530
<i>Jérôme Proulx</i>	
The Effects of a Teaching Method Supporting Metacognition on 7th Grade Students' Conceptual and Procedural Knowledge on Algebraic Expressions and Equations	540
<i>Sevgi Sari & Elif Yetkin Özdemir</i>	
Relational Understanding when Introducing Early Algebra in Portuguese School	550
<i>Leonel Vieira, Pedro Palhare, & Joaquin Gimenez</i>	
Conceptual Challenges for Understanding the Equivalence of Expressions – a Case Study	558
<i>Larissa Zwetzscher & Susanne Prediger</i>	
Posters	
How Experts Graph Formulas	568
<i>Peter Kop, Fred Janssen, & Paul Drijvers</i>	
Generalizing and Justifying Properties of Real Numbers: A Study at Grade 9	570
<i>Joana Mata-Pereira & Joao Pedro da Ponte</i>	
Improving the Covariational Thinking Ability of Secondary School Students	572
<i>Tobias Rolfes, Jürgen Roth & Wolfgang Schnotz</i>	
Introduction to Equations: Three Cases as Part of a Video Study	574
<i>Ann-Sofi Røj-Lindberg, Anna-Maija Partanen, & Ole Björkqvist</i>	
Introductory lessons on algebra: A video study (Videomat)	576
<i>Unni Wathne, Jorunn Reinhardtzen & Maria Luiza Cestari</i>	

Working Group 4 - Geometrical Thinking

Introduction to the Papers and Posters of WG4	578
Research Papers	
Using Origami to Enhance Geometric Reasoning and Achievement <i>Sevil Arici & Fatma Aslan-Tutak</i>	585
Learning and Teaching Geometry at the Transition from Primary to Secondary School in France: The Cases of Axial Symmetry and Angle <i>Aurelie Chesnais & Valérie Munier</i>	595
Which Geometrical Working Spaces for the Primary School Preservice Teachers? <i>Annette Braconne-Michoux</i>	605
(Dis)Orientation and Spatial Sense: Topological Thinking in the Middle Grades <i>Elizabeth de Freitas & Mary Jean Mccarthy</i>	615
Close Your Eyes and See...An Approach to Spatial Geometry <i>Francesca Ferrara & Maria Flavia Mammana</i>	625
Are Mathematics Students Thinking As Kepler? Conics And Mathematical Machines <i>Francesca Ferrara & Michela Maschietto</i>	635
Synergy Between Visual and Analytical Languages in Mathematical Thinking <i>Juan D. Godino, Teresa Fernández, Margherita Gonzato & Miguel R. Wilhelmi</i>	645
Characterising Triangle Congruency in Lower Secondary School: The Case of Japan <i>Keith Jones & Taro Fujita</i>	655
An Investigation on Students' Degree of Acquisition Related to Van Hiele Level of Geometric Reasoning: A Case of 6-8 th Graders in Turkey <i>Yusuf Koç, Mine Işıksal, Şerife Seviş, Aslıhan Osmanoğlu, Bülent Çetinkaya, Cengiz Aşkun & Safure Bulut</i>	665

Constructions with Various Tools in Two Geometry Didactics Courses in the United States and Germany	675
<i>Ana Kuzle</i>	
Investigating Manipulations in the Course of Creating Symmetrical Pattern by 4-6 Year Old Children	685
<i>Eva Swoboda</i>	
An Activity Entailing Exactness and Approximation of Angle Measurement in a DGS	695
<i>Denis Tanguay, Loic Geeraerts, Mireille Saboya, Fabienne Venant, Lourdes Guerrero & Christian Morales</i>	
Mathematics Teachers' Perceptions of Quadrilaterals and Understanding the Inclusion Relations	705
<i>Elif Türnüklü, Elif Nur Akkaş & Funda Gündoğdu Alaylı</i>	
Plane Geometry: Diagnostics and Individual Support of Children through Guided Interviews – A Preliminary Study on the Case of Line Symmetry and Axial Reflection	715
<i>Seval Yetiş & Matthias Ludwig</i>	
Posters	
Developing Spatial Sense: A Suggestion of Activities	725
<i>Annette Braconne-Michoux & Patricia Marchand</i>	
Role of Symmetry Axes ; Undergraduate Students' Experience of Impossible Figures as Plane Symmetry Groups	727
<i>Özlem Çeziktürk-Kipel</i>	
Geometrical Aspects of Generalization	729
<i>Marta Pytlak</i>	
Working Group 5 – Stochastic Thinking	
Introduction to the Papers and Posters of WG5	731
Research Papers	
What Does It Mean To Do Stochastics? Ideas, Symbols and Procedures	736
<i>Chiara Andrà & Judith Stanja</i>	

Prospective Primary School Teachers' Errors in Building Statistical Graphs	746
<i>Pedro Arteaga, Carmen Batanero, Gustavo R. Cañadas & J. Miguel Contreras</i>	
Psychology Students' Strategies and Semiotic Conflicts When Assessing Independence	756
<i>Carmen Batanero, Gustavo R. Cañadas, Pedro Arteaga & Maria M. Gea</i>	
Contextualizing Sampling – Teaching Challenges and Possibilities	766
<i>Andreas Eckert & Per Nilsson</i>	
Principles of Tasks' Construction Regarding Mental Models of Statistical Situations	777
<i>Andreas Eichler & Marcus Vogel</i>	
Using Applets for Training Statistics with Future Primary Teachers	787
<i>Assumpta Estrada, Maria Manuel Nascimento & Jose Alexandre Martins</i>	
Design and Exploratory Evaluation of a Learning Trajectory Leading to Do Randomization Tests Facilitated by Tinkerplots	798
<i>Daniel Frischemeier & Rolf Biehler</i>	
Conceptualizing and Assessing Secondary Mathematics Teachers' Professional Competencies for Effective Teaching of Variability-Related Ideas	809
<i>Orlando González</i>	
Bridging Policy Debates on Risk Assessments And Mathematical Literacy	819
<i>Kjellrun Hiis Hauge</i>	
Students' Informal Inferential Reasoning When Working With The Sampling Distribution	829
<i>Bridgette Jacob & Helen M. Doerr</i>	
Assessing Statistical Literacy: What Do Freshmen Know?	840
<i>Eugenia Koleza & Aristoula Kontogianni</i>	
Evaluating the Efficacy of Training Activities for Improving Probability and Statistics Learning in Introductory Statistics Courses	850
<i>Caterina Primi & Francesca Chiesi</i>	

The Didactical Knowledge of One Secondary Mathematics Teacher on Statistical Variation	860
<i>Sandra Quintas, Helia Oliveira & Rosa Thomas Ferreira</i>	
Prospective Elementary School Teachers' Interpretation Of Central Tendency Measures During A Statistical Investigation	870
<i>Raquel Santos & Joao Pedro da Ponte</i>	
Coping With Patterns and Variability - Reconstructing Learning Pathways Towards Chance	880
<i>Susanne Schnell</i>	
Metaphorical Random Walks: A Royal Road to Stochastic Thinking?	890
<i>Jorge Soto-Andrade</i>	
Statistical Understanding and Language - A Qualitative Analysis	901
<i>Ute Sproesser & Sebastian Kuntze</i>	
8 th Grade Students' Statistical Literacy of Average And Variation Concepts	912
<i>Ayşe Yolcu & Çiğdem Haser</i>	
Posters	
Understanding of Statistical Graphs in Primary: Results of a Teaching Unit	922
<i>Ana Henriques & Ana Michele Cruz</i>	
Diagrams, Graphs and Charts in Biological Courses a System of Categories in the Overlap of Mathematics and Biology	924
<i>Christine Plicht</i>	
 Working Group 6 - Applications and Modelling	
Introduction to the Papers and Posters of WG6	926
Research Papers	
Fermi Problems Involving Big Numbers: Adapting a Model to Different Situations	930
<i>Lluís Albarracín & Nuria Gorgorió</i>	

Students' Emerging Models of Average Rates of Change in Context <i>Jonas B. Ärlebäck, Helen Doerr & AnnMarie O'Neil</i>	940
Creating Necessary Conditions for Mathematical Modelling at University Level <i>Berta Barquero, Lidia Serrano & Vanessa Serrano</i>	950
Diversity in Middle School Mathematics Teachers' Ideas about Mathematical Models: The Role of Educational Background <i>Alfredo Bautista, Michelle H. Wilkerson-Jerde, Roger Tobin & Barbara Brizuela</i>	960
Excel Modelling in Upper Secondary Mathematics - A Few Tips for Learning Functions and Calculus <i>Jan Benacka & Sona Ceretkova</i>	970
Mathematical Modelling in Teacher Education Courses: Style of Thought in the International Community – ICTMA <i>Maria Salett Biembengut & Emilia MeloVieira</i>	980
The Use of Theory in Teachers' Modelling Projects – Experiences from an In-Service Course <i>Morten Blomhøj & Tinne Hoff Kjeldsen</i>	990
Barriers and Motivations of Primary Teachers for Implementing Modelling in Mathematics Lessons <i>Rita Borromeo Ferri & Werner Blum</i>	1000
Project Teaching and Mathematical Modelling in Stem Subjects: A Design Based Research Study <i>Wolfgang Bock & Martin Bracke</i>	1010
Themes for Mathematical Modeling that Interest Dutch Students in Secondary Education <i>Cor Willem Buizert, Jeroen Spandaw, Martin Jacobs & Marc de Vries</i>	1021
Students' Modelling of Linear Functions: How Geogebra Stimulates a Geometrical Approach <i>Susana Carreira, Nelia Amado & Fatima Canário</i>	1031
Teaching Practices and Modelling Changing Phenomena <i>Helen Doerr, Jonas B. Ärlebäck & AnnMarie O'Neil</i>	1041

Developing a Criterion for Optimal in Mathematical Modelling <i>Ole Eley</i>	1052
Mathematical Modelling Discussed By Mathematical Modellers <i>Peter Frejd</i>	1060
Investigating Students' Modeling Competency through Grade, Gender and Location <i>Abolfazl Rafiepour Gatabi & Kazem Abdolahpour</i>	1070
Solution Aids for Modelling Problems <i>Gilbert Greefrath & Michael Riess</i>	1078
Merging Educational and Applied Mathematics: The Example of Locating Bus Stops <i>Horst W. Hamacher & Jana Kreußler</i>	1087
About Mathematical Modeling in the Reality of the Cybernetic World <i>Marcus Vinicius Maltempi & Rodrigo Dalla-Vecchia</i>	1097
Parental Engagement in Modeling-Based Learning in Mathematics: An Investigation of Teachers' and Parents' Beliefs <i>Nicholas Mousoulides</i>	1107
Students' Discussions on a Workplace Related Task <i>Trude Sundtjønn</i>	1117
Teacher Behaviour in Modelling Classes <i>Katrin Vorhölter, Susanne Grünewald, Nadine Krosanke, Maria Beutel & Natalie Meyer</i>	1127
Posters	
Studying the Teaching/Learning of Algorithms at Upper Secondary Level: First Steps <i>Dominique Laval</i>	1137
The Role of Modeling on Effects of Iranian Students <i>Abolfazl Rafiepour Gatabi & Fereshteh Esmaili</i>	1139

Working Group 7 – Mathematical Potential, Creativity and Talent

Introduction to the Papers and Posters of WG7	1141
Research Papers	
Memory and Speed of Processing in General Gifted and Excelling in Mathematics Students <i>Nurit Baruch-Paz, Mark Leikin & Roza Leikin</i>	1146
Students' Picture of and Comparative Attitude towards Mathematics in Different Settings of Fostering <i>Matthias Brandl</i>	1156
Possibility Thinking with Undergraduate Distance Learning Mathematics Education Students: How It is Experienced <i>Els De Geest</i>	1166
Typologies of Mathematical Problems: From Classroom Experience to Pedagogical Conceptions <i>Oleg Ivanov, Tatiana Ivanova & Konstantin Stolbov</i>	1175
Mathematical Problems for the Gifted: The Structure of Problem Sets <i>Alexander Karp</i>	1185
Learning with Pleasure – To Be or Not To Be? <i>Romualdas Kasuba</i>	1195
The Connection between Mathematical Creativity and High Ability in Mathematics <i>Miriam Lev & Roza Leikin</i>	1204
Mathematical Creative Solution Processes of Children with Different Attachment Patterns <i>Melanie Münz</i>	1214
Twice-Exceptional Children - Mathematically Gifted Children in Primary Schools with Special Needs <i>Marianne Nolte</i>	1225

Teaching Highly Able Students in a Common Class: Challenges and Limits of a Case-Study 1235
Ildiko Pelczer, Florence Mihaela Singer & Christian Voica

Mathematical Creativity and Highly Able Students: What Can Teachers Do? 1245
Bernard Sarrazy & Jarmila Novotná

Brain Potentials during Solving Area-Related Problems: Effects of Giftedness and Excellence in Mathematics 1254
Ilana Waisman, Mark Leikin, Shelley Shaul & Roza Leikin

Posters

Mathematically Able but Yet Underachieving in School Mathematics 1264
Elisabeth Mellroth

Can We Just Add Like That? 1266
Alv Birkeland

Proposing a Theoretical Framework for Studying Mathematical Excellence 1268
Sérgio Carlos

Creativity and Critical Thinking in Solving Non-Routine Problems among Talented Students 1270
Einav Aizikovitsh-Udi

Working Group 8 - Affect and Mathematical Thinking

Introduction to the Papers and Posters of WG8 1272

Research Papers

The Effect of the Origami Course on Preservice Teachers' Beliefs and Perceived Self-Efficacy Beliefs towards Using Origami in Mathematics Education 1279
Okan Arslan & Mine Işıksal

Young Students Solving Challenging Mathematical Problems in an Inclusive Competition: Enjoyment Vis-À-Vis Help-Seeking <i>Susana Carreira, Rosa A. Tomás Ferreira, & Nélia Amado</i>	1289
Mathematics Security and the Individual <i>Eleni Charalampous & Tim Rowland</i>	1299
Where Does Fear of Maths Come from? Beyond the Purely Emotional <i>Pietro Di Martino & Rosetta Zan</i>	1309
Classroom Groupings for Mathematics Learning: The Impact of Friendships on Motivation <i>Julie-Ann Edwards & Debra Deacon</i>	1319
Reconstructing Teachers' Beliefs on Calculus <i>Ralf Erens & Andreas Eichler</i>	1329
Analyzing Focused Discussions Based on MKT Items to Learn about Teachers' Beliefs <i>Janne Fauskanger & Reidar Mosvold</i>	1339
Attitudes towards Mathematics of Teachers in Service of Telesecundaria: An Exploratory Study <i>Maricela Fuentes Rivera & Inés María Gómez-Chacón</i>	1349
Ethiopian Preparatory Students' Perceptions of the Relevance of Mathematics to Learning Goals <i>Andualem Tamiru Gebremichael</i>	1359
Mathematics Confidence: Reflections on Problem-Solving Experiences <i>Divan Jagals & Marthie van der Walt</i>	1369
What Teachers Want out of Professional Learning Opportunities: A Taxonomy <i>Peter Liljedahl</i>	1379
Using Content Analysis to Investigate Student Teachers' Beliefs about Pupils <i>Reidar Mosvold, Janne Fauskanger, Raymond Bjuland & Arne Jakobsen</i>	1389

Teachers' Beliefs and Knowledge Related to the Cyprus Mathematics Curriculum Reform	1399
<i>Marilena Pantziara, Marianna Karamanou & George Philippou</i>	
Factors Motivating the Choice of Mathematics as a Career among Mexican Female Students	1409
<i>Mario Sánchez Aguilar, Avenilde Romo Vázquez, Alejandro Rosas Mendoza, Juan Gabriel Molina Zavaleta & Apolo Castañeda Alonso</i>	
Investigating Teachers' Trigonometry Teaching Efficacy	1419
<i>Ayşe Saraç & Fatma Aslan-Tutak</i>	
Uncertainty Orientation, Preference for Solving Task with Multiple Solutions and Modelling	1429
<i>Stanislaw Schukajlow & André Krug</i>	
Students' Motivation and Teachers' Practices in the Mathematics Classroom	1439
<i>Kjersti Wæge & Marilena Pantziara</i>	
Posters	
Handling Negative Emotions in Learning Mathematics	1449
<i>Engin Ader & Emine Erktin</i>	
 Working Group 9 - Mathematics and Language	
Introduction to the Papers and Posters of WG9	1451
Research Papers	
Seeing - Acting - Speaking in Geometry: A Case Study	1458
<i>Thomas Barrier, Christophe Hache, & Anne-Cecile Mathé</i>	
A Linguistic Analysis of the Didactical Environment in Support of the Scaffolding Concept	1468
<i>Thierry Dias & Chantal Tieche Christinat</i>	
Meanings of the Concept of Finite Limit of a Function at a Point: Background and Advances	1477
<i>José Antonio Fernández-Plaza, Luis Rico, & Juan Francisco Ruiz-Hidalgo</i>	

The Influence of How Teachers Interactionally Manage Mathematical Mistakes on the Mathematics that Students Experience	1487
<i>Jenni Ingram, Fay Baldry, & Andrea Pitt</i>	
Writer Identity as an Analytical Tool to Explore Students' Mathematical Writing	1496
<i>Steffen M. Iversen</i>	
Design and Validation of a Tool for the Analysis of Whole Group Discussions in the Mathematics Classroom	1506
<i>Laura Morera, Núria Planas, & Josep M. Fortuny</i>	
Reading Stories to Work on Problem Solving Skills	1516
<i>Marianne Moulin & Virginie Deloustal-Jorrand, Eric Triquet</i>	
Choice of Notation in the Process of Abstraction	1526
<i>Mona Nosrati</i>	
An Investigation into the Tension Arising between Natural Language and Mathematical Language Experienced by Mechanical Engineering Students	1536
<i>Michael D. Peters & Ted Graham</i>	
The Productive Role of Interaction: Students' Algebraic Thinking in Large Group Work	1546
<i>Núria Planas & Judit Chico</i>	
Place of the Conversion of Semiotic Representations in the Didactic Framework R ² C ²	1556
<i>Maryvonne Priolet</i>	
The Use of ICT to Support Children's Reflective Language	1566
<i>Eva Riesbeck</i>	
A Comparison of Irish and English Language Features and the Potential Impact on Mathematical Processing	1576
<i>Máire Ní Ríordáin</i>	
Making Sense of Fractions Given with Different Semiotic Representations	1586
<i>Frode Rønning</i>	

Primapodcasts – Vocal Representation in Mathematics <i>Christof Schreiber</i>	1596
Linguistic Intercourse with Spatial Perception. Comparative Analysis in Primary School, Infant School and the Family <i>Marcus Schütte</i>	1606
Perceiving Calculus Ideas in a Dynamic and Multi-Semiotic Environment - The Case of the Antiderivative <i>Osama Swidan</i>	1616
Factors Affecting the Establishment of Social and Sociomathematical Norms <i>Konstantinos Tatsis</i>	1626
Posters	
Studying the Discourse of School Mathematics over Time: Some Methodological Issues and Results <i>Candia Morgan, Sarah Tang, & Anna Sfard</i>	1636
Analyzing Teachers' Follow Ups and Feed Forwards, Seen as a Way to Enable Students' Participation in Mathematical Reasoning <i>Anna-Karin Nordin</i>	1638
Texbooks and Logbooks in Mathematics <i>Cecilia Segerby</i>	1640
Working Group 10 – Cultural Diversity and Mathematics Education	
Introduction to the Papers and Posters of WG10	1642
Research Papers	
Understanding Immigrant Students' Transitions as Mathematical Learners from a Dialogical Self Perspective <i>Guida de Abreu, Sarah Crafter, Nuria Gorgori, & Montserrat Prat</i>	1648

Reflections on Recontextualising Bernstein's Sociology in Teachers' Instructional Strategies	1656
<i>Nina Bohlmann, Johannes Hinkelammert, Felix A. Rhein, & Hauke Straehler-Pohl</i>	
Deaf Students and Mathematics Learning: Promoting Inclusion and Participation	1666
<i>Ines Borges & Margarida César</i>	
Social-Political Interfaces in Teaching Statistics	1676
<i>Celso Ribeiro Campos; Otavio Roberto Jacobini; Maria Lucia Lorenzetti Wodewotzki; & Denis Helena Lombardo Ferreira</i>	
School and Family Interplays: Some Challenges Regarding Mathematics Education	1686
<i>Margarida César, Ricardo Machado, & Ines Borges</i>	
The Gap between Mathematics Education & Low-Income Students' Real Life: A Case from Turkey	1697
<i>Oğuzhan Doğan & Çiğdem Haser</i>	
Ethnomathematics and Teacher Education: Reasoning Over the Meaning of Students' Prerequisite and the Teacher's Listening	1705
<i>Maria do Carmo S. Domite</i>	
Mathematics For Life or Mathematics Of Your Life: A Study of the RVCC Process Of Portugal	1715
<i>Maria Cecilia Fantinato</i>	
The Emergence of Agency in a Mathematics Class with Robots	1725
<i>Elsa Fernandes</i>	
Multimathemacy	1735
<i>Karen François & Rik Pinxten</i>	
It is a Matter of Blueness or Redness: Adults' Mathematics Containing Competences in Work	1744
<i>Maria C. Johansson & Lisa Björklund Boistrup</i>	
Logic, Society and School Mathematics	1754
<i>David Kollosche</i>	

Diversity, Dialogism and Mathematics Learning: Social Representations in Action	1764
<i>Ricardo Machado & Margarida César</i>	
‘Regime of Competence’ in a School Practice with Robots	1774
<i>Sonia Martins</i>	
The Dialogical Mathematical ‘Self’	1784
<i>Richard Newton & Guida de Abreu</i>	
To Participate or Not to Participate? That is Not The Question!	1794
<i>Hauke Straehler-Pohl & Alexandre Pais</i>	
Mathematics for All and the Promise of a Bright Future	1804
<i>Paola Valero</i>	
Posters	
Single-Sex Mathematics Classrooms in Public Schools: A Critical Analysis of Discursive Actions	1814
<i>S. Megan Che & William Bridges</i>	
Socio-Political Issues in the Context of Different Conceptualizations of Subjects	1816
<i>Reinhard Hochmuth</i>	
It Does Make You Feel a Bit Hopeless’’: Parents’ Experiences of Supporting their Children’s School Mathematical Learning at Home	1818
<i>Richard Newton & Guida de Abreu</i>	
Working Group 11 - Comparative Studies in Mathematics Education	
Introduction to the Papers and Posters of WG11	1820
Research Papers	
A Cross-National Standards Analysis: Quadratic Equations And Functions	1825
<i>Tuyin An, Alexia Mintos, & Melike Yigit</i>	

The Development of Foundational Number Sense in England and Hungary: A Case Study Comparison <i>Jenni Back, Judy Sayers & Paul Andrews</i>	1835
Modelling in French and Spanish Syllabus of Secondary Education <i>Richard Cabassut & Irene Ferrando</i>	1845
The Validity-Comparability Compromise In Crosscultural Studies in Mathematics Education <i>David Clarke</i>	1855
Mathematics Teachers' Beliefs In Estonia, Latvia and Finland <i>Markku S. Hannula, Madis Lepik, Anita Pipere, and Laura Tuohilampi</i>	1865
Analyzing Mathematics Curriculum Materials in Sweden and Finland: Developing an Analytical Tool <i>Kirsti Hemmi, Tuula Koljonen, Lena Hoelgaard, Linda Ahl & Andreas Ryoe</i>	1875
Boredom In Mathematics Classrooms from Germany, Hong Kong and the United States <i>Eva Jablonka</i>	1885
The Problem of Detecting Genuine Phenomena Amid a Sea of Noisy Data <i>Christine Knipping & Eva Muller-Hill</i>	1895
School-Based Mathematics Teacher Education in Sweden and Finland: Characterizing Mentor-Pro prospective Teacher Discourse <i>Malin Knutsson, Kirsti Hemmi, Andreas Bergwall & Andreas Ryoe</i>	1905
Comparing Mathematical Work at Lower and Upper Secondary School from the Students' Perspective <i>Niclas Larson & Christer Bergsten</i>	1915
Re-Examining the Language Supports for Children's Mathematical Understanding: A Comparative Study between French and Vietnamese Language <i>Hien Thi Thu Nguyen & Jacques Gregoire</i>	1925

Comparing the Structures of 3rd Graders' Mathematics-Related Affect in Chile and Finland 1935
Laura Tuohilampi, Markku Hannula, Valentina Giaconi, Anu Laine, & Liisa Näveri

Working Group 12 – History in Mathematics Education

Introduction to the Papers and Posters of WG12 1945

Research Papers

Teaching Modules in History of Mathematics to Enhance Young Children's Number Sense 1951
Mustafa Alpaslan & Zişan Güner

Students' Views about Activities for History of Mathematics Included in Mathematics Curriculum 1961
Semiha Betül Bayam

Arithmetic Textbooks and 19th Century Values 1970
Kristin Bjarnadóttir

"I was Amazed at How Many Refused to Give Up": Describing One Teacher's First Experience with Including History 1980
Kathleen Clark & Lisa G. Philips

The Use of Original Sources and its Possible Relation to the Recruitment Problem 1990
Uffe Thomas Jankvist

History of Mathematics as an Inspiration for Educational Design 2000
Rainer Kaenders, Ladislav Kvasz & Ysette Weiss-Pidstrygach

The History of 5th Postulate: Linking Mathematics with Other Disciplines Through Drama Techniques 2010
Panagiota Kotarinou & Charoula Stathopoulou

PROCEEDINGS OF THE EIGHTH CONGRESS OF THE EUROPEAN SOCIETY FOR RESEARCH IN MATHEMATICS EDUCATION: GENERAL INTRODUCTION

Maria Alessandra Mariotti
University of Siena

Ferdinando Arzarello
University of Turin

We are glad to present the Proceedings of the Eighth Congress of the European Society for Research in Mathematics Education (ERME), which took place 6-10 February 2013, at Manavgat-Side/Antalya in Turkey.

The story of ERME begins at its first congress in Osnabrueck, Germany, in 1998 and develops all along the CERME congresses that have taken place every two years since CERME2 in 2001. The vision shared by the first group of founders was that of establishing a community to promote communication, cooperation and collaboration in mathematics education research in Europe. At the very beginning of the ERME story, considerable time was spent talking about the nature of our conferences. Especially we wondered how were we going to achieve the communicative, cooperative and collaborative spirit we envisaged. It was clear that the conference should offer more than just a platform for presenting and listening to papers, as many other conferences do. We wanted that CERME could allow groups of researchers in a particular scientific area really to *work* together on their area of research, with sufficient time to get to know each other, to share and discuss their research and to engage in deep scholarly debate. At the same time we wanted to support the scientific development of young researchers fostering their active participation to our research community.

Therefore it was decided that CERME should abandoned the common format of parallel research report presentations and adopt a new format based on Working Group activities where participation by all who attend the congress could be promoted. Such a format has been developed stating a clear policy for the organization and the management of thematic Working Groups. At CERME participants spent most of the time in discussion and debate within the thematic Working Groups (WGs), during 6 or 7 *working* sessions of 90-120. Each CERME participant selects the membership of just one such Group, on the base of her/his personal scientific interests. For each WG, a team of leaders is nominated by the Scientific Program Committee, the leaders have in charge the complex organization of the WGs, preparing and managing what will happen at the Conference. Though participation to the conference is completely free, prospective participants are encouraged to contribute with submitting a paper or a poster. The leaders' team organizes the peer review process among the member of the Group according significantly devolved and distributed responsibility in criticising but also supporting the elaboration of the single contributions. This process aims not only at rising the quality of the papers but also at developing a sense of belonging to a community, for

all participants. At the end of this first phase all the accepted paper will be posted on the website of the conference and participants are expected to read all the papers related to their own WGs, before attending the conference. This corpus of papers will constitute the first working material for the WGs activities, and a great deal of time and intellectual efforts are spent by the leaders to outline the structure of the working sessions where the different contributions will be fully discussed and related to the other contributions.

At CERME 8, different ways of organizing the working group sessions were set up by the different leaders teams. The main objective was always that of fostering the discussion exploiting the richness of the contributions. In some cases the discussion was structured according to subthemes focussing on specific clusters that emerged from the variety of the papers. Other times the leaders proposed the participants specific questions that were sent in advance to the authors of the papers who were requested to focus a short contribution on this question. The variety in the organization structure witnesses of the complexity of the task that the leaders team are asked to face but also of their passion and commitment in accomplishing their work, for which the ERME community is highly grateful to them. In the introduction to the collection of papers of each WG, the reader will find a description of the different organizations that were adopted.

The particular format of the conference gives the participants the opportunity of getting fruitful feedbacks that can enlarge and enrich their own perspectives; thus, after the conference the authors have the possibility to further revise their papers, integrating significant elements emerged from their WG's discussion: this will be the latest form in which papers will pass the final review process and when accepted will appear in the proceedings. The double review process that is used at CERME congresses - papers are firstly accepted for discussion in the WGs and than their final version has to be accepted for being published in the proceedings - not only aims at raising the quality of the papers but also at assuring a fair balance between quality and inclusion, two goals that seem to pull in different directions, and may create tension, sometimes frustration. However, the attainment of a good balance between *quality* and *inclusion* constitutes the main challenge of our community according to our main objective: to ensure the ERME spirit' of communication, cooperation and collaboration.

The number of WGs increased in the years and since CERME7 we have 17 WGs, and excepting of the WG 15 and WG 17, the number of participants in each is around 25-30 on average, including about 4 WG leaders.

The themes of the WGs are as follows:

WG1: Argumentation and proof

WG2: Arithmetic and number systems

WG3: Algebraic thinking

WG4: Geometrical thinking

WG5: Stochastic thinking

WG6: Applications and modelling

WG7: Mathematical potential, creativity and talent

WG8: Affect and mathematical thinking

WG9: Mathematics and language

WG10: Cultural diversity and Mathematics Education

WG11: Comparative studies in Mathematics Education

WG12: History in Mathematics Education

WG13: Early Years Mathematics

WG14: University mathematics education

WG15: Technologies and resources in mathematics education

WG16: Different theoretical perspectives / approaches in research in mathematics education

WG17: From a study of teaching practices to issues in teacher education

The success of the ERME Conferences is witnessed by the constant increasing number of participants and presentations. In Manavgat 520 participants attended the congress, from 45 countries within and beyond Europe.

In addition to the WG activities, the congress was enriched by in a number of plenary scientific activities, and a varied social and cultural program.

The opening session included a plenary address by Paolo Boero who proposed a deep reflection on how to deal, as researchers, with the unavoidable complexity of big problems concerning the teaching and learning of mathematics in our societies. On the base of a long personal elaboration, strictly and functionally interwoven with the evolution of the experimental activity in the school carried out with the Genoa research group since the seventies, Boero offered us some answers to those big questions emerging from complex phenomena, particularly those concerning societal needs and values and related educational choices.

As at previous CERME congresses, two other plenary talks were given by former WGs leaders, Alain Kuzniak and Candia Morgan.

Kuzniak presented a vivid account of what are today the core items and the contributions of researches in the didactics of geometry, and he did it in the light of the rich discussions which have been occurring in the CERME Working Group on geometry from its beginning in 1999. Candia Morgan delineated a superb survey of the complex field of study of language in mathematics education. As she said, she offered *her* map, her personal and critical account, on previous studies in this field, and especially a theoretical elaboration as it emerged from the active discussion

taking place at the CERME Working Group on Language and Mathematics over the years.

Three papers corresponding to these three plenary addresses are included in these proceedings.

Though these proceeding do not contain any document related to it, let me mention another fundamental event that took place one day before the opening of the Congress: the YERME (Young European Researchers in Mathematics Education) day. This is now a constant appointment where young researchers – doctoral students or post-doctoral researchers - meet expert scholars in thematic discussion groups. This event, together with the YERME Summer School (YESS), is based on the volunteering of some members of the society. At CERME 8 the organization of the YERME day was coordinated by João Pedro da Ponte, Ferdinando Arzarello and Behiye Ubuz; the activities were led by professors Paolo Boero, Uffe Thomas Jankvist, Barbara Jaworski, Ester Levenson, Maria Alessandra Mariotti, João Pedro da Ponte, Susanne Prediger, Mario Sánchez, Susanne Schnell, Behiye Ubuz. (<http://cerme8.metu.edu.tr/yerme.html>)

As said, our Conference has a very particular format, it promotes the active involvement of all the participants and its success highly depends on their contributions; however, success also depends on the commitment of those who made this involvement possible, to them we want to express our gratitude in behalf of the ERME community: to the members of the Scientific Program Committee, for the inspiration and support that they offered in the scientific planning of the conference, to the Leaders of the WGs, for the competence, the energy and the engagement that they invested in their responsibility, and last but not least to the President, Behiye Ubuz, and the members of the Local Organizing Committee, for the incredible work done in preparing and supervising the organization of the conference, they allowed all the participant enjoy the conference days of intensive intellectual work in a efficient, comfortable and delightful place. Their attentive support did not finished with the end of the conference but continued in the patient and competent work of editing these proceedings.

We are certain that the reader will appreciate the richness of the contributions collected in this text that we hope will offer the opportunity to share with us something of the exciting experience of our congress, and encourage interested researchers to meet us at the next CERMEs.

Maria Alessandra Mariotti

EDITORIAL INTRODUCTION FOR THE EIGHT CONGRESS OF THE EUROPEAN SOCIETY FOR RESEARCH IN MATHEMATICS EDUCATION

<http://www.cerme8.metu.edu.tr/>

Behiye Ubuz and Çiğdem Haser
Middle East Technical University, Turkey

Maria Alessandra Mariotti
University of Siena, Italy

The Eight Congress of the European Society for Research in Mathematics Education (CERME8) was held at the Starlight Convention Center, Thalasso & Spa Hotel in Manavgat-Side, Antalya, Turkey from 6th to 10th February, 2013, chaired by Prof. Dr. Behiye Ubuz (Local Organizer Chair) and Prof. Dr. Maria Alessandra Mariotti (International Program Committee Chair). It aimed to promote the development of mathematics education through intellectual communication and cooperation by attending thematic working groups, plenary talks, poster sessions, and so forth. At CERME8 there were 3 invited plenary talks given by Paolo Boero, Alain Kuzniak, and Candia Morgan together with 17 thematic working groups (WGs). The main work of the congress took place in these Thematic Working Groups, facilitated by some 73 Working Group leaders. The congress was preceded by a meeting of Young European Researchers in Mathematics Education (YERME) on 5th and 6th February 2013. A total of 375 Research Papers and 90 poster proposal were submitted for the congress. Following peer review, 310 Research Papers and 57 poster proposals were accepted for publication in the proceeding.

A view from Starlight Convention Center, Thalasso & Spa Hotel

Around 520 participants attended the congress, from 45 countries within and beyond Europe. Many participants from European countries were there: UK (31), Portugal (29), Germany (98), Italy (22), Greece (10), Finland (6), Spain (30), Netherlands (8), Sweden (54), Cyprus (2), Denmark (16), Norway (24), Austria (1), Czech Republic (5), France (41), Ireland (5), Romania (1), Russia (4), Belgium (4), Iceland (4), Estonia (2), Latvia (1), Poland (2), and

Switzerland (4). Moreover, there were 34 researchers from Turkey, 12 from Israel, 20 from the US and 16 from Canada, and 1 from Australia, 1 from the Far East (Japan), 27 from Latin America (Brazil, Chile, Colombia, Mexico) and several others from non-affluent countries, such as Iran (2), South Africa (1), Saudi Arabia (3), Algeria (1), Kuwait (1), Tunisian (2), Lebanon (1), and Zaire (1).

In the first section of this proceeding, the plenary talks by Paolo Boero, Alain Kuzniak, and Candia Morgan are presented. They kindly accepted the invitation of the scientific program committee and provided a written account of the ideas they presented in their plenary talks. The second section documents the research papers and poster communications accepted for publication in the proceeding. The papers and the posters are presented under each WG following the introduction written by each WG's leaders. Introductions summarize the scope of the WGs' works and the value of the studies presented.

A view from Side-Antalya (Taken from <http://www.resim11.com/Antalya.html>)

CERME8 must surely be regarded as a great opportunity for teachers, mathematics educators, teacher educators, and policy makers around the world and in Turkey who are interested in mathematics education and its development. It also provided a valuable development opportunity for the young researchers through YERME.

The proceeding for CERME8 is produced electronically both in CD format and in the website <http://www.mathematik.uni-dortmund.de/~erme/doc/cerme8/CERME8.pdf>. You can access the individual research papers and poster contributions via the hyperlinks provided on the contents page. We hope that every participant enjoyed the conference and their stay in Turkey!

PLENARY LECTURES

MATHEMATICS EDUCATION TODAY: SCIENTIFIC ADVANCEMENTS AND SOCIETAL NEEDS

Paolo Boero

Università di Genova

How to deal, as researchers in mathematics education, with big, complex problems related to societal needs? Through a chronological presentation of some steps of my personal and group research trajectory, I will try to show the potential inherent in establishing a dynamic relationship between: the design, experimentation and analysis of broad, long term classroom activities, planned according to wide scope theoretical constructs; and research activities performed in that context according to well established research methodologies. The research generative power of such an approach will be demonstrated, together with the necessity of further elaboration concerning local integration of different theoretical perspectives. As an example, a problem related to the PISA definition of mathematical literacy will be dealt with.

INTRODUCTION

Thanks to the organizers of CERME-8, this is an occasion for me to reflect on how to deal, as researchers, with the unavoidable complexity of big problems concerning the teaching and learning of mathematics in our societies. I will try to get some answers by considering my personal forty years experience and that of the Genoa research group in mathematics education.

Focusing on a few variables and low levels of complexity allowed mathematics education researchers to perform rigorous, reproducible experiments and, thus, get partial insights into many phenomena. In several cases, methodology was borrowed from other disciplines - particularly experimental psychology - through adaptations to classroom teaching and learning situations: see many Research Reports in the first two decades of PME conferences; see also the volume on the first thirty years of PME research, Gutierrez & Boero (2006). In most cases results were used to try to improve teacher education and teaching practices within the current perspective of schooling in western societies, without putting into question that perspective.

The difficulty met when we want to move towards more complex phenomena, particularly those concerning societal needs and values and related educational choices, depends on the usual scientific methods. Such methods seem to be too limited to deal with non-reproducible phenomena involving a long time span, a lot of inter-related variables, a lot of agents and cultural influences (be they on the scene of the classroom, or outside). As a result of the limit of usual research methods, researchers often tend to refuse the constraints of rigorous research methodology when they want to deal with those complex phenomena. Hence, we have a shift from ordinary scientific papers in the field of mathematics education to political or ideological or philosophical essays.

As an example of the difficulty to deal with complex, big problems, let us consider the following PISA definition of Mathematical Literacy (retrieved from page 4: <http://www.oecd.org/pisa/pisaproducts/46961598.pdf>):

Mathematical literacy is an individual's capacity to formulate, employ, and interpret mathematics in a variety of contexts. It includes reasoning mathematically and using mathematical concepts, procedures, facts, and tools to describe, explain, and predict phenomena. It assists individuals to recognize the role that mathematics plays in the world and to make the well-founded judgments and decisions needed by constructive, engaged and reflective citizens.

In many countries, given the importance attributed to mathematical literacy, the feeling of inadequacy of the educational system to face the challenges of the so-called globalization puts into question the traditional content to be taught (usually, a set of notions and techniques) and the traditional methods of teaching mathematics. In those countries (and in others too), PISA comparative studies and PISA - related elaborations, like the above definition, are going to be very influential on long-term educational choices, teaching methods, and also cultural values and the answer to societal needs. The above definition is not neutral: it implies a specific personal relationship to mathematics, specific ways of dealing with "phenomena", a specific role of mathematics in making "well-founded judgments and decisions", and also a specific status of mathematics as an universal cultural entity. As such, the definition may result in specific curricula, teaching strategies, teacher preparation.

A big, complex problem inherent in the PISA definition of mathematical literacy is the identification of its specific epistemological and cultural features, of the consequences that it may have (if coherently adopted) on teachers, students, culture, and of possible alternatives to it (if it is the case of).

In this paper I will try to motivate and present the idea that the interplay between wide-scope theoretical framing and practices (rooted in philosophical, epistemological, anthropological, psychological elaborations), resulting in activity and reflection on activity in school, and related "local" scientific studies, may contribute: to a scientific approach to big, complex problems (like the one related to PISA definition of mathematical literacy) in mathematics education; and also to the generation of research hypotheses, further constructs, and new actions (planning and experimentation of innovative teaching sequences).

The above idea is the conclusion that I am able to derive now from a long personal and group elaboration, strictly and functionally interwoven with the evolution of our experimental, extensive activity in the school since the seventies. Therefore, I think that the best way to present the above idea is to follow a chronological thread, in order to put into evidence the origin and the "why" of it, and "how" it may contribute to develop research and to tackle big educational problems.

Forty years ago we tried to build an alternative, in primary and lower secondary school, to the "New Mathematics" movement, a big challenge at that time! At the end

of the eighties, after more than fifteen years of work in hundreds of classrooms, as well as our involvement in the international community of mathematics educators (ICME, PME and CIEAEM conferences; French Summer Schools of Didactics of Mathematics), and our readings in anthropology, history and epistemology of mathematics, the need for theoretical clarification and framing emerged. This need resulted in the wide-scope construct of Field of Experience (FoE). We will present the FoE construct as a tool to frame the teaching of mathematics as a component of a broader enculturation process, according to the need of that time (and present time too!) to overcome the fragmentation of the cultural offer of school and provide opportunities to tackle some important educational problems in mathematics education, like that of the approach to proof.

Afterwards, we will show how the extensive experience of classroom work and related analyses in the perspective of the FoE construct suggested to revisit, fifteen years later, the Vygotskian *everyday concepts/scientific concepts* dialectics. In particular we will see how some "local" studies put into evidence the potential variety of ways of dealing with concepts in a *scientific* way (inside and outside mathematics), related to their roots in cultural practices and personal experiences, and to different cultural horizons. Our answer to the needs emerging from such work was the adaptation of Habermas' elaboration on rationality to educational purposes; we will present it, with some examples of its use in research.

In the perspective of the adapted construct of rationality, the teacher must act, in particular, as an interpreter, mediator and promoter of rationalities. Specific implications for teacher education derive from it; we will see how the competence of Cultural Analysis of the Content to be taught is needed for such a teacher.

As an example of the use of our present theoretical toolkit, we will show how it allows to tackle the problem related to the PISA definition of Mathematical literacy; the elaboration on that problem will result in some elements for an alternative, possible definition of Mathematical literacy.

The paper will end with some general "method" conclusions and research directions, particularly those related to the networking and, possibly, integration with other theoretical constructs.

THE FIELD OF EXPERIENCE DIDACTICS

For me (and for the research group that I lead at the Genoa University) one of the main research aims was since the beginning, and still is, to widen the borders of scientific investigation in mathematics education in order to encompass big problems raising from the reality of ordinary classrooms: they are situated in a socially and culturally more and more fragmented and diverse society, in spite of the pressures towards globalization exercised through media and political and economic decisions.

In the seventies, the initial challenge for our group was to react in a constructive way against the strong political and cultural pressures in OCSE countries aimed at

reforming school teaching of mathematics according to the New Mathematics perspective. During the sixties New Mathematics had been advocated as a universal means to promote an effective teaching of mathematics, overcome social differences and cultural discriminations in mathematics education, and convey the real flavour of mathematics. But in those countries (like France) where New Mathematics had been adopted in national programs, by the half of the seventies it was already clear that all those aims were very far from being achieved, and the quality and extension of learning results were rather scarce. Available epistemological and didactical analyses, like those by Freudenthal, helped us to take distance from the theoretical background of New Mathematics and better understand its consequences. Our alternative was initially inspired by the fascinating work of Emma Castelnuovo ("Mathematics in the reality"- see Castelnuovo & Barra, 1980) and by what would have become, following Freudenthal's seminal work, the Realistic Mathematics Education movement. Since 1976, one project for the integrated teaching of mathematics and sciences in grades 5-8 and one project for teaching mathematics and other main disciplines in elementary school (grades 1-5) were elaborated and implemented in school, with the help of specialists in experimental sciences, linguistics, economy, history and psychology. In the period 1976-1985, more than one hundred teachers were involved in the design and experimentation of the teaching units.

During the eighties, problems arising from the design and experimentation of the teaching units (see Boero, 2011) brought us to refer to Vergnaud's elaboration on concepts (with the key role of reference situations as depositary of their "sense": Vergnaud, 1990), to Vygotsky's everyday concepts/scientific concepts dialectics, and to Bishop's perspective of "mathematical enculturation": a thoughtful analysis of how, in the history of mankind, basic mathematical knowledge is rooted in everyday practices (Bishop, 1988). The resulting action-oriented construct of "Field of experience" (FoE) was presented in my plenary lecture at PME-XIII in 1989 (see Boero, 1989) and further elaborated on the educational and epistemological sides (see Boero, 1992; Boero & al, 1995; Dapueto & Parenti, 1999).

The FoE construct was proposed as a means to frame the teaching and learning of mathematics according to the aim of providing students with the opportunity of both accessing mathematical knowledge, and developing the knowledge of natural and social reality. We may note that, at the moment of its elaboration, the FoE perspective did not escape a pretension of universal objectivity, since it aimed at promoting students' access to "the" knowledge.

A FoE is made up of three evolutionary components: the student's inner context (specific experiences, mental representations, schemes, ways of reasoning, and so on); the teacher's inner context; and the external context (artefacts, material and social constraints, social practices, etc.). The FoE didactics consists of suitable actions performed by the teacher in order to promote the evolution of the students' inner context according to the teacher's aims and expectations. At the core of FoE didactics

are argumentative activities that make reference to specific features and opportunities offered by the external context.

FoEs are cultural domains characterized by specific practices, constraints, ways of behaving and knowing. In our Project for grades 1-5, non-mathematical FoEs deal with subjects like Money and purchases, Time and calendar, Seasonal changes, Sun shadows, Machines. As concerns mathematical FoE, arithmetic and geometry gradually become FoEs: they develop in classroom, thanks to the mediating role of the teacher, around those mathematical tools of knowledge that are needed to deal with non-mathematical problem situations.

The FoE didactics is based on the fundamental didactic cycle (Douek, 1999; Boero & Douek, 2008), which consists of three phases: an initial task requiring written individual productions (possibly supported by the teacher, when needed); the subsequent classroom comparison and discussion, orchestrated by the teacher (Bartolini Bussi, 1996), of some individual texts selected by the teacher, which allows the teacher to play a direct or indirect (i. e. based on students' productions) mediating role; the collective production, under the guide of the teacher, of a provisional synthesis, which may open a new cycle of activity. Such phases allow an equilibrium between the students' constructive involvement in the activity, and the mediating role of the teacher. While practicing FoE didactics, the fundamental didactic cycle is sometimes integrated with other activities according to the specificity of the subject to be dealt with: a preliminary classroom discussion may prepare the initial individual task; small group discussions on individual productions may precede the classroom discussion mediated by the teacher.

In the perspective of the FoE didactics, mathematics is a "culture" (Hatano & Wertsch, 1991), consisting of activities, artefacts, transmissible practices: an alternative to mathematics as a tool of knowledge, or as an ontologically established domain of knowledge, or as a cultural construction reflecting minds' structures.

Non-mathematical FoEs are cultural domains with their own criteria of validity and problem solving strategies; at the beginning of the ninetieths we engaged in studies aimed at ascertaining their potential for mathematics education as sources of mathematical concepts and ways of reasoning (rooted in their typical practices). The first one was a longitudinal study in primary school, reported in Boero (1990), concerning, in particular, the emergence of conditional reasoning in written texts in non-mathematical and mathematical FoE contexts. The implications of those studies for solving important mathematics education problems as well as their research developments are exemplified in the next sub-section.

A research contribution in the context of the FoEs didactics: The Cognitive Unity of Theorems

As a first example of the research generative power of the FoE construct, I report here what happened in our group during a study aimed at identifying the mechanisms of production and argumentative validation of hypotheses in the FoE didactics. The

analysis of the relationships between those processes in space problem situations in the FoE of Sun shadows suggested the idea of a Cognitive Unity of theorems: the continuity that for some theorems may be established by students between arguments used for generation and plausibility of the conjecture, and arguments used for proving. Such continuity may work as a facilitator of proving, thus leading students to a smooth access to mathematical proof (Boero, Garuti, Lemut & Mariotti, 1996) - a very demanding aim for teaching in secondary school. Our perspective was in contrast with current ideas in those years about the unavoidable cognitive and epistemological gap between argumentation and mathematical proof (cf Duval, 1991).

At the beginning, the idea of Cognitive Unity arose when analyzing VIII-grade students' written productions during their work related to the following task:

In the past years we observed that the shadows of two vertical sticks on the horizontal ground are always parallel. What can be said of the parallelism of shadows in the case of a vertical stick and an oblique stick? Can shadows be parallel? At times? When? Always? Never? Formulate your conjecture as a general statement.

More than one half of the students were able to produce a "conjecture" and, according to the didactical contract, some reasons for its plausibility. After the comparison and discussion of the conjectures, two shared statements, corresponding to two ways of reasoning in students' productions, were formulated under the guide of the teacher:

If sun rays belong to the vertical plane of the oblique stick, shadows are parallel.
Shadows are parallel only if sun rays belong to the vertical plane of the oblique stick.

If the oblique stick is on a vertical plane containing sun rays, shadows are parallel.
Shadows are parallel only if the oblique stick is on a vertical plane containing sun rays.

Then the individual task: "What do you think about the possibility of testing our hypotheses by experiment?" and the 2-hours discussion of the students' answers brought students to realize that "an experimental testing is very difficult, because one should check what happens in all the infinite positions of the sun and in all the infinite positions of the sticks". These activities prepared students to engage in the individual production of a general justification of the statements.

By comparing the production of the "conjectures" with the production of the "proofs", we found several couples of texts like those reported below, in which the arguments developed to find the "conjecture" and justify its plausibility were re-invested in the production of the "proof".

Formulation of the conjecture with the shifting of the stick (Beatrice):

I tried to put one stick straight and the other in many positions (right, left, back, front) and with a ruler I tried to create the parallel rays. I sketched the shadows on a sheet of paper and I saw that: if the stick moves right or left shadows are not parallel; if the stick is moved forward and back shadows are parallel. Shifting the stick along the vertical plane, forward and back, the two sticks are always on the same direction, that is to say

they meet the rays in the same way, therefore shadows are parallel. Whereas shifting the stick right and left the two sticks are not on the same direction anymore and therefore do not meet the Sun rays in the same way and shadows in this case are not parallel. Shadows are parallel if the oblique stick is moved forward and back in the direction of sunrays.

Proof:

Shadows are parallel because, as we already said, Sun rays belong to the vertical plane of the oblique stick. But all this does not explain to us why this is true. First of all, though the sticks stand one in an oblique and the other in a vertical position, they are aligned in the same way and if the oblique stick is moved along its vertical plane and is left in the point in which it becomes vertical itself we see that they are parallel and, as a consequence, their shadows must naturally be also parallel, and also parallel with the shadow of the oblique stick, which has the same direction of that produced by the imaginary, vertical stick.

In this case the justification produced during the conjecturing phase ("meet the Sun rays in the same way") is reworked in the subsequent proof, where Beatrice imagines the oblique stick moving along the vertical plane containing Sun rays.

Formulation of the conjecture with the movement of the Sun (Sara):

They could be parallel if I imagine being the Sun that sees and I must place myself in the position so as to see two parallel sticks. In this way the sun sends its parallel rays to enlighten the sticks. But if the Sun changes its position it will not see the parallel sticks and, therefore, their shadows will not be parallel either. Shadows can be parallel if the oblique stick is on the same vertical plane as the Sun rays.

Proof:

If the Sun sees the straight stick and the oblique stick parallel it is as if there were another vertical stick at the base of the oblique stick. If this stick is in front of the oblique stick its shadow covers the shadow of the oblique stick. These shadows are on the same line, therefore, the oblique and vertical sticks shadows are parallel.

In this case the initial idea "I imagine being the Sun" seems to suggest the main argument of the proof (the shadow of the imaginary, vertical stick covers the shadow of the oblique stick).

The construct of Cognitive Unity of theorems (further elaborated through other teaching experiments - see Garuti, Boero & Lemut, 1998) contributed to clarify the nature of the conjecturing and proving processes, to put into evidence the necessary tension between the direction of the proving process and the features of the product to be achieved, and to open the way to further studies. In particular Pedemonte (2007, 2008) introduced the distinction between the continuity that in the case of the Cognitive Unity of theorems exists between the content of the arguments used in the conjecturing and in the proof construction phases, and the structural break that may happen (particularly in the case of synthetic geometry theorems) between the

abductive or inductive nature of argumentation in the conjecturing and early proving phases, and the deductive nature of the proof to be achieved.

The teaching experiment reported in Boero & al. (1996) not only suggested the possibility of the Cognitive Unity of theorems as a facilitator of the proving process, but offered also an example of how in non-mathematical FoEs students can develop ways of reasoning, which are consistent with those that are fundamental in mathematics. Indeed we can see how in the case of the "two sticks problem" the FoE of Sun shadows offers a physical counterpart for a space geometry problem situation of conjecturing and proving: if we replace sticks, parallel Sun rays, Sun shadows with segments, parallel straight lines, parallel projections on a plane surface we get a conjecture and a semantically-based proof in space geometry. In this case we can say that the logical-linguistic organization of mathematical proof develops in a non-mathematical context suitable for an immediate transfer to a mathematical setting. FoE didactics offers several opportunities for such kind of transfer, significant for solving important *educational problems arising within mathematics education*, like that just considered, of a smooth access to mathematical proof. Some evidence will be provided also through the first examples of the next section, which at the same time aims at introducing the discourse concerning further theoretical developments related to *more general educational problems*.

FROM STUDIES IN THE EDUCATIONAL CONTEXT OF FoE DIDACTICS TO THE NEED OF FURTHER THEORETICAL DEVELOPMENTS

The following episodes and excerpts are derived from past or ongoing studies performed in the educational context of the FoE didactics since the end of the ninetieths. This section is aimed at showing the necessity of re-interpreting the Vygotskian everyday concepts - scientific concepts dialectics, in order to deal (in the *specific* field of mathematics education) with *general*, important and complex educational problems such as:

How to cope with the necessity that students acquire cultural tools deriving from the present dominating scientific culture, at the same time avoiding students' alienation from their cultural roots?

How to exploit the potential richness of students' personal contributions and social cultural background, in order to develop a culture related to personal dispositions and societal needs?

Examples in the FoEs of Money and purchases, and Calendar

The first two examples refer to grade 1 and grade 3 students engaged in reflective activities on the writing of numbers in the decimal - position system. In the first case the teacher helps the students to deal with some semiotic aspects of the FoE of arithmetic. In the second case she wants to develop students' knowledge and awareness of the decimal-position system.

The first example was collected at the beginning of December, in grade 1: after two months of work in the FoEs of "Money and purchases" and "Calendar", the teacher exploited one child's mistake (Anna had written *tredici* - thirteen - as 31) to ask students: "Explain Anna why her writing is a mistake". Four types of individual productions (oral sentences dictated to the teacher) were collected:

It is a mistake because...

...three and one are exchanged;

...in a month, the day thirteen comes much before the day thirty one;

...with thirteen cents I can buy less than with thirty one cents;

...thirteen cannot be written as we write thirty one, otherwise we could not understand which number it is.

The second example was collected in another class, at the beginning of grade 3.

Mario wrote *centodieci* (one hundred and ten) as 1010. The teacher asked the students to produce an individual text: "Explain to Mario why his writing is a mistake". Five types of individual productions were collected.

It is a mistake because there are four digits instead of three, you should delete the second digit;

1010 means that the number is one thousand and ten, it cannot mean another number at the same time;

1010 means a big quantity of money, you can buy a bike, while with 110 you can buy only a roller;

Mario, you have made a mistake because you have thought: one hundred and one, 101, one hundred and two, 102,..., one hundred and 9, 109, then one hundred and ten, 1010; you had to move 1 to the left, in the place of tenths;

1010 means one thousand, zero hundreds, one tenth, zero units, differently from *centodieci*, while 110 is composed by one hundred, one tenth and zero units, exactly like *centodieci*.

According to the didactical contract (see below), both tasks engaged students in explanations. In both cases, the explanations given by the students are of different kinds: in particular some of them refer to the shape of signs (morphologic aspect: like in the first texts of both cases), others to pragmatic reasons (the third texts in both cases), others to the meaning of digits according to the decimal-position system of written representation of numbers (like in the last text of the second case). Different epistemic criteria and related ways of thinking emerge as indicators of different potential directions for the development of conceptualisation towards consciousness and explicitness.

Where these productions come from? The didactical contract plays a crucial role: in the FoE didactics, since the very beginning of Grade 1 children are used to engage in

supporting positions (or explaining the why of mistakes) of their schoolmates, and to move from the individual effort to the discovery of different positions and search for consensus, or the identification of unbridgeable differences. The fact that in Italy usually the same teacher teaches the same group of students over a period of five years (in the case of primary school, grades 1-5) or of three years (in the case of lower secondary school, grades 6-8) amplifies the effects of the didactical contract on students' intellectual maturation.

What to do with this kind of productions? In the perspective of a straightforward approach to structural knowledge of the decimal-position system of writing numbers, the teacher might drive the attention on those contributions that are oriented towards it. But pragmatic arguments (and even morphological arguments!) are important to enter a reflective, conscious, intentional attitude towards knowledge; thus, after comparison and discussion of the different arguments (i.e. an exposure to the others' reasoning) the conclusion should be that different reasons (conveniently reported) can be advocated to explain the mistake. While valuing different personal contributions, this might represent a first step in the direction of becoming aware that different ways of reasoning can offer different (possibly, complementary) keys to ascertain the truth (or fallacy) of a statement.

Example in the field of experience of Sun shadows

In a study reported in Boero (2002), two sets of grade 3 students' written productions concerning Sun shadows are compared and analysed.

After observations and games with Sun shadows in the courtyard in some subsequent days, students write a report about what they have discovered. The percentage of those who juxtapose "low Sun" - "long shadows" (with sentences such as "In the early morning, the Sun is low and its shadows are long") is higher than 70%. Then the teacher gradually introduces, on the basis of students' drawings and observations, the elementary geometric model of Sun shadows and its use in some problem solving activities: e.g. to establish whether the lengths of the shadows of two equal vertical sticks in two near courtyards are equal or not at the same moment.

After those activities the wording of the phenomenon dramatically changes: more than 70% produce a causal or conditional description, with sentences such as "In the early morning the shadows are long because the Sun is low", but also: "If the Sun is low, the shadows are long".

This example shows how suitable activities led by the teacher in a given FoE, resulting, in this case, in the appropriation by students of a new sign, may allow students to move to a higher level of understanding of the same phenomenon; and it shows also how the choice of suitable non-mathematical fields of experience may allow students to access high level mental activities in a "natural" way.

Anyway, in a grade 7 classroom in Eritrea some completely different productions were collected:

The shadows are long in the early morning because the strength of the Sun is not yet sufficient to win the darkness, while the shadows will become shorter and shorter till midday because the light has gradually taken strength, and then again darkness will prevail, and it will happen everyday.

This conception allowed students to solve several problems (e.g. the problem of the shadows of the sticks in two near courtyards) in a straightforward way; afterwards they used the geometrical model introduced by the mathematics teacher to accomplish their duty as "mathematics students".

Here we see how FoE didactics may put into evidence significant aspects of students' background culture. Taking background culture into account and developing the classroom debate on it could help students becoming aware of the differences with the culture brought by the teacher and, finally, appreciating the richness of cultural diversity. Indeed we may observe that for Eritrean students the phenomenon was framed within a broader system of knowledge, based on a cyclic, dynamic equilibrium: something that traditional farmers currently use; that was already conceived in pre-socratic Greek philosophy, particularly in Heraclitus' notion of dynamic dualism (Graham, 2008); that we find in the history of Chinese culture (again as a dynamic version of dualism, see Cheng, 1997); that Western mathematics succeeded to model in the second decade of the XX Century in the case of Lotka-Volterra predator-prey differential model. At that time the idea of a cyclic, dynamic equilibrium gained full scientific legitimacy in western culture by relying on the role of mathematics. This point reminds me of my experience as a mathematics teacher in university courses for natural sciences students. Usually those students experienced many difficulties in entering the cyclic dynamic equilibrium perspective, before my introduction of the Lotka-Volterra model and the related graphical representations. The cyclic dynamic equilibrium perspective seemed completely alien for them.

Example in the FoE of arithmetic in primary school

In Boero, Douek & Garuti (2003) the following excerpt is reported; it comes from a 5 grade classroom dealing (within the FoE of arithmetic) with the problem of "how many numbers exist between 1 and 2"; students are discussing the hypothesis of "infinite numbers" proposed by a schoolmate:

- | | |
|-----------|---|
| Valentina | What does it mean to say that infinite numbers exist, if we cannot count them because we must die? |
| Stefano | I do agree, man is not everlasting but life is everlasting. |
| Valeria | The woman's body ends, but she creates another woman, and so life goes on to infinity. |
| Emanuele | Numbers create other numbers, to infinity, by multiplying. Each number is finite, but an infinite list is produced. |

Valeria's metaphor, conceived outside mathematics, works as a grounding metaphor (Nunez, 2000) for Emanuele, who exploits it to produce a strong argument in favour

of the infinity of numbers. This is an interesting example of contamination between different domains. In the educational context of the FoE didactics such kinds of phenomena frequently occur in our classes. Still as concerns contamination between mathematical and non mathematical domains, we may consider grounding metaphors derived from concrete physical situations (like the balance) to support the solution of quadratic inequalities in grade 8 (see Boero, Bazzini & Garuti, 2001).

Example in the FoE of arithmetic in lower secondary school

As an example of different, potential evolutions of spontaneous students' productions, which could be driven by the teacher towards different scientific outcomes, we may consider the case of the "Think a number" game in Grade 7 (see Morselli & Boero, 2011). Students try to understand why the teacher is able to discover the result of a sequence of operations performed by students on a number chosen by them; the sequence is aimed at introducing algebra as thinking tool. Under the guide of the teacher, students move from verbal productions describing the game, towards the representation of the sequence of calculations performed on a given number and then to the representation of the sequence of calculation on a letter, that is to say "any number". In some classes two kinds of mathematical representations emerged: a procedural one, consisting of a more or less complete sequence of instructions like $N=N+3$; and a relational one, consisting of one more or less correct algebraic expression. Starting from their own productions, students may arrive, under the guide of the teacher, to two different and correct models of the game, which exemplify two different ways (procedural and relational) of representing a sequence of calculations in general. Further activities could bring to an early approach to two different mathematical domains (computational mathematics and algebra).

REVISITING THE EVERYDAY CONCEPTS / SCIENTIFIC CONCEPTS DIALECTICS

Several studies in the perspective of the Field of Experience didactics brought us, through episodes and reflections such as those reported in the previous section, to reconsider the everyday concepts /scientific concepts dialectics hypothesized by Vygotsky as the key component of the enculturation process. With reference to Vergnaud' definition of concepts (Vergnaud, 1990), Nadia Douek's in-depth work on conceptualization (Douek, 1989; 2003; 2006) suggested that:

- "scientific" is not an ontological quality of concepts; it consists of specific (intentional, conscious, systemic, explicit) relationships that the subject develops with concepts. In the classroom those relationships depend on the cultural and didactical choices of the teacher, as we put into evidence in the discussion of previous cases. We may add that scientific relationships to a concept frequently evolve in the long term towards an everyday use of it;
- everyday concepts may evolve towards different, even conflicting "scientific" horizons under the influence of different agents (the teacher, but also the cultural environment) - see in the previous case of Sun shadows: the evolution of students'

ways of thinking the phenomenon after the introduction of the model by the teacher; and an alternative, non geometric consistent conception, rooted in students' culture;

- the evolution of everyday concepts in a mathematical FoE may depend on non-mathematical arguments elaborated in different FoEs as grounding metaphors (Nunez, 2000) for their systemic links and inferences - see the example on the infinity of numbers;

- moreover, "pragmatic" (but still intentional, conscious and explicit) relationships to a concept (cf Verillon, 2011; Verillon & Rabardel, 1995) pose the research problem of the relationships between two possible kinds of evolution of conceptualization: the pragmatic one and the scientific one - see the cases of the writing of numbers.

All the above points concern the relationships between the potential inherent in students' dispositions and their cultural background, on the one hand, and the educational aims to be achieved in school, on the other; thus they seem to be relevant in order to deal *in mathematics education* with the enculturation problems evoked at the beginning of the third section. But even our enlarged interpretation of Vygotsky's everyday concepts - scientific concepts dialectics seems insufficient to analyze, and take decisions in those situations where students' cultural diversity and their personal contributions pose problems like: how to identify and characterize students' resources, in the perspective of possible, different evolutions of their everyday concepts? How to frame the educational choices and plan the classroom activities aimed at promoting: the evolution of students' everyday concepts towards scientific concepts; and their awareness of the potential and limitations inherent in different cultural perspectives and tools, inside and outside mathematics?

A COMPREHENSIVE FRAMEWORK FOR DIVERSITY OF "SCIENTIFIC" CONCEPTS AND WAYS OF ACCESSING THEM

Cultural contaminations and different, possible "scientific" horizons for the evolution of students' everyday concepts towards scientific concepts required a new toolkit in order to deal with such a diversity in an educational perspective. The key idea to get it derived from the observation that diversity concerns strategies to achieve the aim of the activity, ways of communicating with other people, and criteria of validation of statements, as three inter-related components of the same process. For instance, in the case of the writing of numbers in the decimal-position system some students refer to an extra-mathematical experience and to social constraints in order to invalidate Anna's and Mario's written representations, while other students' reasoning remains within arithmetic and refers to structural properties of the writing system. In the case of the debate on the infinity of numbers it is remarkable the shift from ordinary language to natural language in the mathematical register (cf Halliday, as quoted in Boero, Douek & Ferrari, 2008, p. 265), and from the everyday experience with its well known true facts to arithmetic properties and related inferences.

These reflections brought us to consider Habermas' elaboration on rational behaviour as a possible analytical tool to identify and compare different ways of solving

problems, validating statements and communicating in mathematical FoEs, in mathematical modelling and when dealing with non-mathematical subjects. Indeed, Habermas (1999; 2001, Ch. 2, pp. 100-107) proposed a definition of rational behavior in discursive practices based on three inter-related criteria:

- ***epistemic rationality***: it concerns accounting for validation of statements according to shared principles and rules of inference ("shared" in a given cultural context);
- ***teleological rationality***: it concerns accounting for the choice of tools and strategies to achieve the aims of the activity;
- ***communicational rationality***: it concerns the intentional choice of means to communicate with others in a given social context.

Initially, we adapted Habermas' idea of rational behaviour in order to encompass the complexity of mathematical activities, which develop effectively when the adopted strategies keep into account the epistemic constraints of the product to be achieved (e.g.: the case of *proving* and *proof*). Then we extended its use to plan and analyze classroom activities aimed at promoting students' rational behaviours in mathematics and in mathematical modelling. At present, we use (or foresee the use of) Habermas' construct in order to deal with different speculative and operational aims, in mathematics education and in general education.

As regards mathematics education the construct can be used:

- to characterize and compare different kinds of rational behaviours within mathematical activities (e.g. rational behaviours in analytic geometry and in Euclidean geometry are very different - cf Boero, Guala & Morselli, 2013, in press);
- to put into evidence the different levels and kinds of awareness needed to behave rationally in mathematics, which concern the three components of rational behaviour; for instance, on the epistemic side of proving, awareness concerns particularly the rules of inference and the nature of definitions, axioms and theorems in a theory, and also the role of examples;
- to promote and analyze the evolution of students' behaviour towards the intended mathematical behaviour, according to the components of rational behaviour;
- to compare the student's actual behaviour with the expected one; and to realize how, in some cases, the student behaves in a rational way, but according to a rationality that is different from the expected one.

As regards general education (thus, with a different level of zooming) the construct can be used:

- to characterize and compare rational models of behaviour of different disciplines, or even informal cultural domains (like traditional agriculture), and establish relationships between them;

- to help teachers and students to cross the borders between different domains of knowledge in the perspective of a wide-scope enculturation, thanks to the possibility of identifying common requirements of rationality and differences.

We may note that the problems quoted at the beginning of the third section can be reformulated in terms of rationalities: how to combine the possibility of keeping the contact with the rationalities rooted in the students' cultural background, with the necessity of accessing rationalities developed within the global system of cultural production (including present mathematicians' mathematics); and how to promote the development of rationalities by exploiting the potential inherent in the diversity of individual dispositions and cultural backgrounds.

The elaboration concerning the adapted construct of rational behaviour was exploited to perform studies involving students at different age levels. The construct was initially used to plan and analyze specific classroom mathematical activities, particularly those intended to approach conjecturing and proving with/without the use of algebraic language; afterwards, it was used also for planning and promoting a reflection on different rationalities within mathematics.

As regards the first line of research, concerning rationality in conjecturing and proving, I mention the following studies:

- in Morselli & Boero (2011), the authors adapt Habermas' construct of rational behaviour to deal with the case of the use of algebraic language in conjecturing and proving, and describe teaching experiments planned, performed and analyzed according to that construct. In particular, epistemic constraints concern two different aspects of those mathematical activities: checking for correctness of algebraic manipulations according to syntactic rules of algebraic language; and checking for validity of algebraic formalization and interpretations (i.e. for the passage from a non-algebraic situation to its linguistic representation through the algebraic language; and for the interpretation of the algebraic expressions deriving from suitable transformations);

- in Boero, Douek, Morselli & Pedemonte (2010), the authors show how rational behaviour in conjecturing and proving may work as an useful theoretical construct to design, manage and analyze suitable classroom activities aimed at the students' approach to the culture of theorems (i.e. to the knowledge of some crucial features of a theorems as a statement and its proof within a theory - see Mariotti, Bartolini Bussi, Boero, Ferri & Garuti, 1997).

As regards different rationalities within mathematics and their relevance in mathematics education, Boero & al (2013, in press) considered the following problem, belonging to a selective test for candidates (having a MD in Mathematics) to become high school mathematics teachers:

To characterize analytically the set \mathbf{P} of (non degenerated) parabolas with symmetry axis parallel to the ordinate axis, and tangent to the straight line $y=x+1$ in the point $(1,2)$.

To establish for which points of the plane does it exist one and only one parabola belonging to the set \mathcal{P} .

To find straight lines that are parallel to the ordinate axis and are not symmetry axes of parabolas belonging to the set \mathcal{P} .

Candidates met big difficulties in solving the problem; most of them were not able to choose and exploit well known tools from synthetic geometry, analytic geometry, algebra, which would have allowed them to get straightforward answers to the three questions or to identify their mistakes in an easy way. Even discussing "how to solve it" in a-posteriori interviews was difficult for them. In Boero & al (2013, in press) difficulties are interpreted in terms of different rationalities inherent in those mathematical domains, which contribute to a rigid, unilateral approach to the problem, and of lack of awareness about the potential and limitations (on the teleological and epistemic sides) of the tools at disposal in the different domains.

In general, in the already performed studies the development of students' awareness about what they would like to do, or might do, or should do seems to be an educational aim difficult to achieve; but awareness (so important in both Habermas' elaboration on the idea of rationality, and Vygotsky's characterization of "scientific concepts") is a crucial requirement for a mature relationship with the scientific enculturation promoted by the teacher.

The early development of awareness is a key educational aim in an ongoing teaching experiment, which concerns another use of the construct of rationality. It consists in the approach to, and promotion of, different kinds of rational behaviour to deal with the same extra-mathematical subject. In the case of the FoE of Sun shadows we are developing, in two classes (grades 3 and 4), a multi-disciplinary approach (involving mathematics, physics, natural sciences, visual arts, literature) to the study and representation of the phenomenon. Students experience different ways of validating statements, of posing and solving problems, of communicating; they reflect on the differences under the guide of their teachers. This experiment is intended to explore the possibility of making students aware of what distinguishes a discipline from the others in terms of rationality, just at the beginning, in Italy, of the systematic study of different disciplines.

Concerning the relationships between different cultural domains, we are also engaged in the analysis of analogies and differences between the rationalities inherent in different FoEs, in order to search for new, more "natural" connections for students between mathematics and other domains of knowledge. Two FoEs emerge as candidates from already performed activities in primary school. The first is the FoE of Grammar rules; students' activities consist of reflective work on texts, aimed at searching for regularities, rules and exceptions. The second is the FoE of Rules concerning students' behaviours in the school; rules are motivated, negotiated and written in the classroom under the guide of the teacher. Inevitably the consideration of these fields of experience recalls one of the possible "externalist" interpretations of

the raising of mathematical rationality in Greece, around the V-th Century B.C., as rooted in the philosophical debate on truth and language (Sophists) and the formulation and interpretation of laws (see Szabo, 1978). In early grades, when argumentative activities in the fields of arithmetic and geometry are limited to easy questions, the domain of rules seems particularly promising, because it allows to develop rather complex argumentation, as it is shown in the following episode.

After an incident, grade 2 students are debating about a rule that concerns how the class should go from the second floor to the ground floor at the end of the school time. Barbara had proposed the following text:

Children must be in couples, from the exit of the classroom to the exit of the school; on the staircase each child keeps a schoolmate with his hand.

Danilo reacts in this way:

I do not agree with Barbara's rule for two reasons: first, if one child falls down also his schoolmate falls down; second, which schoolmate? Because 'a schoolmate' means any schoolmate, not 'the' schoolmate of the couple!

While Danilo's first criticism comes from figuring out possible dangerous consequences of the rule given by Barbara, the second one refers to a grammatical rule with a high sensitivity to the logical features of natural language. Both criticisms by Danilo offer evidence for the emergence of skills that are important for the development of mathematical argumentation: to find the scope and consequences of a given rule; and to identify the logical meaning of articles and conjunctions in a text.

The educational context of the FoE didactics allows to perform such kind of studies under appropriate conditions, due to its specific didactical contract and the fact that teaching involves different FoEs and disciplines.

According to our intentions, these studies should prepare us to deal in the future with two much more demanding and complex problems, strictly related to the big educational problems quoted at the beginning of the third section: how to deal with different rationalities brought in the classroom by students belonging to different cultures; how to develop mathematical rationalities, in pure mathematics as well as in the application of mathematics to other subjects, taking into account different cultural environments.

Evoking such past, present and (possibly) future uses of the construct of rational behaviour outlines a broad research perspective, to be necessarily shared by experts of different disciplines. In such a perspective the richness of everyday concepts carried by learners, with their different sources (ethnic, familial, personal), should be exploited to develop knowledge and awareness of the variety and potential of human cultures, and to prevent breaking the roots with students' native cultures. Today this educational aim looks like one of the necessary conditions for exercising the informed freedom of choice, advocated by Habermas in his introduction to the elaboration on rationality, and a culturally-based tolerance as well.

THE ROLE AND THE COMPETENCES OF THE TEACHER

Dealing with the everyday concepts/scientific concepts dialectics in the perspective of different rationalities needs a "competent" mathematics teacher (as an interpreter, promoter and mediator of rationalities) with additional competencies, if compared with those usually considered in teacher education literature.

Shulman's Pedagogical Content Knowledge, as well as Mathematical Knowledge for Teaching (Ball & Bass, 2003), are defined in terms of knowledge the teachers should be provided with in teacher education programs. In our perspective of multiple rationalities within mathematics and in comparison with other cultural domains, the teacher must have the competence of Cultural (=epistemological, anthropological, historical) Analysis of the Content to be taught (CAC: see Boero & Guala, 2008). Such a competence should enable the teacher to recognize the cultural potential inherent in students' productions and make short term and long term conscious choices concerning: in which direction, and in which way, to drive students' attention; when and how to mediate pieces of established mathematical knowledge, criteria for validating statements, strategies, ways of communicating knowledge, etc..

In our elaboration CAC is a competence to be developed by practicing it through suitable tasks in a suitable mathematics teacher education context, and not a set of pieces of knowledge. In the CAC perspective, the teacher must be able to bring the cultural dimension of mathematics into the classroom. Under the guide of the competent teacher, who has experienced such kind of reflections and practices at an adult level, students may become aware of the potential and limitations of mathematical tools to deal with "real" problems, of the different rationalities inherent in mathematical activities, and of their connections/ conflicts with other rationalities.

Concerning the issue of the different rationalities inherent in mathematical activities, we are working on the design of tasks for teacher education, suitable for promoting prospective teachers' awareness about the deep differences, in terms of rationality, between activities in different mathematical domains (see Boero & al., 2013, in press). The already quoted task concerning the set of parabolas that are tangent in $(1,2)$ to the straight line $y=x+1$ is exploited by us in teacher education; it seems suitable to drive pre-service teachers' attention towards different rationalities and the necessity of avoiding to teach mathematics as a set of closed domains.

WHAT ABOUT MATHEMATICAL LITERACY?

By employing the theoretical toolkit developed during our research trajectory, what can we say now about the PISA definition of mathematical literacy?

First of all, that definition does not take in charge what may be derived from the cultural context the teachers and students belong to. Potential and obstacles inherent in the teacher's and students' inner contexts and in the external context are not explicitly considered. Indeed, culture may be a source of mathematical experiences

for students (D'Ambrosio, 1999), and a source of problem situations that can be considered for a treatment with mathematical tools in the classroom (Brenner, 1998).

Second, the differences between the rationalities in different mathematical domains are not considered, as concerns both their inner epistemic and teleological characters, and their descriptive, interpretative and predictive potential and limitations.

Third, the definition conveys the idea of mathematics as a universal, privileged toolkit "to make the well-founded judgments and decisions needed".

Consequences of such a perspective on teachers and students (future citizens) may be: cutting the links with people's cultural background (a well known premise to alienation); and not supporting, or even preventing, the evolution of people's cultural background, which may result in a loss of potential richness in a historical moment in which some important aspects of dominating western culture are put into question. Furthermore, this definition may convey an image of mathematics as an absolute, homogeneous body of knowledge and tools to solve every kind of problem; this image, in turn, may be an obstacle in the choice of the appropriate tools to deal with extra-mathematical problems.

Keeping the above critical considerations and the adapted Habermas' construct into account, I have tried to write down a provisional, alternative definition of Mathematical Literacy (trying to keep it near to the length and the scope of the PISA definition, in order to make comparisons easier). The resulting, "draft" definition is:

ML consists in the capacity of consciously moving from the subject's perception of a problem, rooted in his/her socio-cultural background and experience, to possible mathematical treatments; and at the same time it consists in the awareness of the epistemic and teleological constraints and limitations inherent in the different mathematical rationalities and of the consequences that they impose on the solving process and the related solutions, in comparison with non-mathematical rationalities.

The proposed draft definition is different from the PISA definition as concerns the conception of mathematics, the students' and adults' relationships with mathematical knowledge, the use of mathematical knowledge to deal with questions related to societal needs, and the attempt to keep into account the issues evoked at the beginning of the third section.

In our tentative definition the cultural, mathematical and non mathematical, background is brought to the fore and related to possible mathematical horizons; moreover different mathematical treatments might be compared, integrated, or even rejected. In particular our definition leaves the possibility, in the case of non-mathematical problems, of identifying non-mathematical ways of reasoning as more effective on the teleological side and even more secure on the epistemic side, in comparison with a standard mathematical treatment with mathematical tools. Concerning this issue, it is interesting to observe how today, and differently from fifty years ago, the degree of mathematization is no more considered as a measure of

the quality of an investigation in some domains - not only biology, but also economics (a subject of lively debate today!) and ecology.

CONCLUSION AND FURTHER DIRECTIONS OF RESEARCH

Keeping the research trajectory described in this paper into account, I will try to offer some elements to answer the question posed at the beginning of this paper: "How to deal, as researchers in mathematics education, with big, complex problems related to societal needs?" I will also outline some further directions of research concerning questions that are emerging in our research activities.

It is evident that our research trajectory cannot be replicated: it depended non only on specific historical circumstances (e.g., at the very beginning, the failure of the New Mathematics reform and even the post-'68 climate) but also on the personalities of the protagonists, including researchers in history, economics, linguistics, psychology who plaid an important role in the initial phase of our work. However I think that from our experience some indications can be derived, in order to create the conditions that may allow to tackle "big and complex problems" in an effective way.

First of all, I think that it is important to create a research team (including school teachers as researchers) to plan and perform long term experimental activities in order to meet societal needs of the time, related to the big problems that one wants to tackle. The elaboration of a consistent, wide scope theoretical framework, with the collaboration of experts from different disciplines, is necessary to plan and analyse the experimental activities. Indeed, mathematics is not an isolated fragment of contemporary culture, but an important component of the historical development of cultures, strictly related with practical and speculative issues. As a consequence, if we want to tackle in an effective way big and complex problems in mathematics education (like those evoked at the beginning of section 3) it is very useful to experience on the field, and analyse with suitable theoretical lenses, the complexity of the school teaching of mathematics, of its relationships with other subjects and extra-school cultures, and of the cultural role of the mathematics teacher in the classroom. As concerns the role of the teachers in the research team (cf Malara & Zan, 2008), their research commitment offers the opportunity of a "research eye" on what happens in the classrooms, on students engaged in the planned activities, on their cultures, on the difficulties that they meet to achieve the intended educational aims and on their potential for intellectual development.

In such an educational and research environment, "local" studies should be performed, according to appropriate and well established methodologies, in order to answer specific research questions. Such questions may come from the long term experimental activities or from current research on related issues, in mathematics education or in other fields. In turn, such local studies might put into evidence the need (or the opportunity) for further developments of the general theoretical framework, provide the research team with results useful to tackle the big problems,

and also offer opportunities to improve the effectiveness of the experimental activities for students.

As concerns our work in such a perspective, further investigation is needed in order to progressively develop a suitable theoretical toolkit to deal with the problems that are emerging now in our research trajectory. Some directions are outlined in the subsequent part of this section. What follows is partly influenced by the important work developed in the European community of mathematics educators, and particularly in the CERME context, under the name of "networking of theories". Indeed, our adaptation of Habermas' construct of rationality to the case of mathematics education does not exclude the use of other frameworks aimed at dealing with the complexity of mathematics education phenomena from different viewpoints; on the contrary, we think that complementary constructs are needed, and that some work in that direction should be made. The articulation between the FoE perspective and the construct of rational behaviour is per se an example of possible complementarity, and even integration, between different theoretical perspectives: the FoE construct offers a way of conceiving a cultural context in terms of its educational potential, the FoE didactics offers criteria for exploiting that potential. The adapted Habermas' construct works as an analytical tool to describe and compare different rationalities within a given FoE and between different FoEs, and to plan and analyse the transition from one rationality to another.

As an example of further development in a "networking perspective", we may consider the fact that both the original Habermas' construct and our adaptation do not encompass the institutional dimension, so relevant when we consider (for instance) the mechanisms that determine the kind of epistemic rationality that teachers should promote at a given school level. Here we acknowledge the necessity of taking into account the work done within the frame of Chevallard's Anthropological Theory of Didactics (ATD) (see Wozniak, Bosch & Artaud, 2012). A contact point concerns the possibility of analyzing mathematical activities according to semiotic and epistemic criteria (cf Chevallard's model of mathematical praxeologies). However, some components of rational behaviour have a marginal weight in the ATD: in particular, the teleological rationality, as concerns both intentionality and consciousness of problem solving strategies.

Another development concerns the situated cognition perspective, in particular the construct of Legitimate peripheral participation (Lave & Wenger, 1991): some aspects of the practical implementation of the FoE didactics, particularly those related to the development of specific forms of rational behaviour, can be seen as an enculturation process that develops according to a Legitimate peripheral participation model. Furthermore, that model accounts for the specific social contexts, for instance the school setting, in which rational behaviours are passed over to young generation, an issue that is not dealt with in Habermas' elaboration. For these reasons, we feel the situated cognition perspective could enrich our elaboration. On the other hand, the situated cognition perspective lacks a specific discourse concerning the

epistemological side of the enculturation process, whilst this aspect would be so important to qualify, in the school setting, the mediation exercised by the teacher and the output of the enculturation process in terms of rationalities.

Another possible development is the integration with H. Simon's construct of bounded rationality (Simon, 1991), which takes into account the complexity of factors that intervene in decision making in economics and in other fields of decisions at risk. In term of Habermas' construct, Simon's construct concerns teleological rationality. In an ongoing research on the use of Habermas' construct in mathematics education, carried out between the Genoa team and the Turin team lead by F. Arzarello, we are engaged in comparing and, possibly, integrating Habermas' and Simon's constructs in order to deal with the approach to game theory in school (the Turin team is performing teaching experiments on it at different school levels).

Particularly due to the challenges deriving from ongoing experiences of teacher education and innovative teaching in different cultural contexts, which some members of our group are involved in (in Africa, Latin America, and multicultural Italian classes as well), further needs and elements for developing our theoretical framework will probably emerge. In particular power relationships and identity issues in the relationships with different cultures will be likely to oblige us to take into account related relevant theoretical elaborations (see Engeström & Sannino, 2010).

All the above examples, even if just sketched here, suggest that a single theoretical perspective is not sufficient to encompass the complexity of mathematics education phenomena and related big problems, and that a modesty attitude seems to be the most appropriate to develop a productive dialogue and, possibly, local integrations and complementarities between different theoretical perspectives.

Acknowledgements: I am particularly indebted to Nadia Douek for her important contributions to the elaboration of the present theoretical toolkit in the last 15 years, and for her critical, constructive reading of subsequent versions of this paper; and to Francesca Morselli for her collaborative, thoughtful work on the adaptation of the Habermas' construct and the final refinement of this paper. But I must also acknowledge the enormous contribution of so many colleagues and school teachers who have taken part in the research itinerary summarized in this paper.

TEACHING AND LEARNING GEOMETRY AND BEYOND...

Alain Kuzniak

Laboratory of Didactics André Revuz

University Paris Diderot, Paris, France

Geometry and its teaching have always been a problematic and exemplar issue regardless of the period. Torn between utilitarian and idealistic visions, the very nature of geometry has moved within very wide margins from regarding it as sacred to aiming at its disappearance. Regarding mathematics education, researches on geometry have raised the attention of many prominent researchers in the domain such as for instance Freudenthal and Brousseau. What are today the core items and the contributions of researches in the didactics of geometry, a domain in which the current development of specific software has caused quick changes? We address this question in the light of the results of recent researches and also the rich discussions which have been occurring in the CERME Working Group on geometry from its beginning in 1999. We also develop some ideas about the perspective of geometric paradigms and spaces for geometric work (SGW) and show how it allows describe and change the nature of geometric activity in various educational contexts.

First of all, I would like to thank the organizers and the members of the scientific Committee for their invitation to give this plenary on geometry teaching and learning.

During this talk, I present some possible orientations for researches within the field of geometry didactics. The main point is, to me, that we should take advantage to focus on what I call Geometric work to advance and to develop new views on geometry education. And I develop, with some details, this idea and the framework related to it during the presentation. Another point is that we would get some benefits by linking geometry to other maths areas and to technological tools. That explains partially the meaning of Beyond in the title.

WHY TEACH AND LEARN GEOMETRY TODAY?

For a long time mathematics has been synonymous with geometry and questioning the usefulness of mathematics was equivalent to questioning geometry. Today, it is somehow different but we can learn from the past in order to think on the question but keeping in mind how the current situation is specific.

In *An essay on the usefulness of mathematical learning* written in 1701, Arbuthnot, an English physician, tried to persuade the rich people of his time to learn and practice mathematics. He based his argumentation on three points which are always interesting to consider:

1. Develop Mind and Reasoning. “Truth is the same thing to the Understanding as Music to the Ear and Beauty to the Eye”, he wrote in the flourishing style of his time. This argument is classic and will be used and summarized later with the famous “For the honour of human spirit” of Jacobi (1830) quoted by Dieudonné (1987).

2. For their applications in a wide variety of fields. Arbuthnot favoured Trade, Navigation, Art of War...
3. To learn how to get to the results and not only the results. This means that the path is as important as the result. Arbuthnot praised mathematics and geometry as a method of freeing the mind from superstition.

The third argument keeps its value today in a world with a lot of technologies meaningless for common people and at the same time an increasing strength of superstitions.

Nearer from to-day and into the field of maths education, the “modern maths” revolution and the subsequent counter-reform have questioned geometry through the name of Euclid. “A bas Euclide” was Dieudonné’s provoking motto against traditional geometry based on an amount of triangle properties disconnected from the evolution of contemporary science. In a same way but for different reasons, teachers and researchers involved in the counter-reform rejected Euclid because he did not give any efficient method to apply it in the real world problems. Another marginal and provoking view was Brousseau's idea of considering Euclid as the first didactician. Indeed, Euclid wrote a text organizing knowledge and used, with some adaptations, as a base for textbooks during centuries and up to the beginning of the XXth century.

To view the variety of points of view, eventually conflicting, it is interesting to quote this remark by Fletcher, a well-known math educator, in an ESM special issue on geometry published in 1971

The cry "Euclid must go!" has gained a certain notoriety in recent years. Our reaction to this in England was merely mild surprise since as far as we were concerned Euclid had already been gone for a long time. (Fletcher, ESM. 3-3, 1971).

This remark shows how the teaching traditions and the relationships with geometry are different among countries which may be geographically very close.

Nowadays, all these questions and conflicting viewpoints coexist and the teaching and learning of geometry have been to be developed in a changing context characterized by the tension between utilitarian and idealist visions on mathematics with an advantage to the utilitarian approaches. At the same time the use and potentialities of Dynamic Geometry Software (DGS) have deeply changed the way of discovering and proving in the domain and created a new relationship with Truth and Proof within maths education.

To progress in the direction of making our knowledge grow on how and what to teach and learn in Geometry, researchers in the domain can use the great amount of texts elaborated for the group on geometry which was existing in the Conferences of ERME since the first Conference. Among the numerous papers presented in the working group on Geometry, we can distinguish some recurrent and relevant points:

1. Development of spatial abilities and geometrical thinking through consecutive educational levels.
2. Geometry education and the "real world": geometrisation and applications
3. Instrumentation: artefacts such as, computers and the way they are used
4. Explanation, argumentation and proof in geometry education.

To this four classic topics in the domain we can add some theoretical aspects which in a certain sense are local and specific to the domain: Van Hiele's levels; Duval's registers of semiotic representation; Houdement and Kuzniak's geometrical paradigms.

The need for a common framework related to Geometry education appeared necessary in the working group in order to facilitate exchanges among members and to allow a capitalisation of knowledge in the domain. Due to collaborations initiated during Cerme meetings with colleagues from Cyprus, Spain and Canada or other from Mexico and Chile, it has been made possible to develop a theoretical framework that I will introduce. In our mind, the framework should be dedicated to study the teaching and learning of elementary geometry on the whole educational system that means during compulsory education and also teacher training. It should be neutral in the sense that it can be used to compare the teaching of geometry in different countries and institutions without any a priori on "best" directions. For that it appeared very soon, that it could be interesting to focus on the nature and form of the effective geometric work made by students and teachers in Geometry.

MATHEMATICAL WORK CONSIDERED A CRUCIAL POINT

As it has been underlined above, the notion of geometric work is central in the approach and we start by detailing what is geometric work for us. First we need to precise, more generally, our view, oriented by educational perspectives, on mathematical work.

In the special issue of ESM already quoted, Freudenthal (1971) found it useful to answer to the question "What is mathematics" before presenting his ideas on geometry education. Addressed to teachers and researchers considered as mathematicians, he put the stress on two aspects of the work in the domain: the activity of solving problems and the activity of organizing.

Of course you know that mathematics is an activity because you are active mathematicians. It is an activity of solving problems, of looking for problems, but it is also an activity of organizing a subject matter. ESM 3-3 – 1971

In a same vein but a step further, the well-known conception of Thurston (1995), Fields medal in 1982, give a shared view on mathematics considered a human activity.

Mathematics includes integers numbers and geometry plane and solids

Mathematics is what Mathematicians study

Mathematicians are those human beings who make advance human understanding of mathematics.

At a first glance, the definition looks circular, but it is not. Initiated on numbers and geometry plane and solids, it creates a dynamic between mathematics knowledge and people who make mathematics. Both aspects are important in this work which relates intimately epistemological and cognitive aspects through the image of a mathematician that we can consider a cognitive subject in charge of the “human understanding of mathematics”.

Once mathematics is clearly defined as a human activity, it is easy to turn to the idea of mathematical work including and orienting these activities, but it remains to characterise the specificity of such work and for that, Habermas’s (1985) consideration on work defined as a rational activity oriented toward an end will be useful.

By work or rational activity relative to an end, I hear or an instrumental activity, or a rational choice, or else a combination of both.

Boero developed during his conference some aspects of what rationality is for Habermas, and I will not insist on this point but only retain, for our framework related to education, the necessity of thinking mathematical work as a rational human activity oriented toward a better understanding of specific topics.

How can we interpret and use this in Geometry education? Again, Freudenthal in his paper warns again the taste of mathematicians and educators to restrain mathematics work to organizing.

A great part of mathematical activity today is organizing. We like to offer the results of our mathematical activity in a well organized form where no traces betray the activity by which they were created. This objectivation is a habit of mathematicians from the oldest times. It is a good habit, and it is a bad one. We freeze up the result of our activity into a rigid system, because this is objective, because it is rational, and because it is beautiful, and this we teach.

To avoid the risk of freezing up the results of mathematic work, it will be necessary to introduce the idea that several work context exist. Two of them are classically identified: a context of discovery where new results and solutions of problems are sought; a context of justification where discoveries are proved and presented to a larger community with its proper rules and style of work. We can add a context of use where the results become familiar to the user, are applied to solve problems which are not necessary mathematical. This variety of contexts need to be kept in mind when developing activities within an educational system and it implies various forms and phases of student's work: researching, presenting, practising...

GEOMETRIC WORK AND ITS SPACE

To study specifically the geometric work within the scope of education, we have introduced the idea of a space, named Space for Geometric Work (SGW), organized to ensure the work of people solving geometrical problems. The subject may be an ideal expert (the mathematician) or a student or senior student in mathematics. Problems are no part of the space but they justify it and speed up its construction.

Initially, this idea was suggested by architects' definition of work spaces as places to be built to ensure the best practice of a specific work (Lautier, 1999).

To ground SGW, we will think of it through epistemological and cognitive dimensions which structure the whole work. As we noted before, the former is in charge of the coherence of the mathematics content and the latter refers to the cognitive subject supposed to solve geometric problems.

According to the epistemological dimension, we introduced three characteristic components of the geometrical activity in its purely mathematical dimension. These three interacting components are the following ones:

- A real and local space as material support with a set of concrete and tangible objects.

- A set of artefacts such as drawing instruments or software.

- A theoretical reference frame based on definitions and properties.

These components are not simply juxtaposed, they must be organized with a precise goal depending on the mathematical domain in its epistemological dimension. This justifies the name of epistemological plane given to this level. From the point of view of geometry considered as a mathematical theory, the theoretical frame of reference is crucial, even if for the users it is sometimes implicit or hidden.

From Duval (1995), we have adapted the idea of three cognitive processes involved in geometrical activity and structuring the cognitive level.

- A visualization process connected to the representation of space and material support;

- A construction process determined by instruments (ruler, compasses, etc.) and geometrical configurations;

- A discursive process conveying argumentation and proofs.

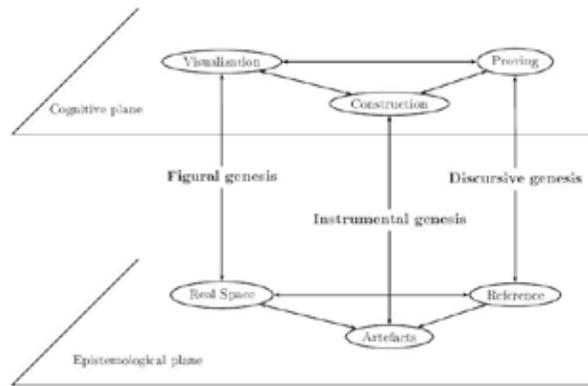

In our approach, both levels, cognitive and epistemological, need to be articulated in order to ensure a coherent and complete geometric work. This process supposes some transformations which can be pinpointed through different ways. It is possible to refer to general notion like intuition, experiment and deduction as Gonseth (1952) did in his major book on geometry. But here, in order to insist on the developmental process involved in the constitution of SGW, the notion of genesis has been used. For us, a genesis involves the development and not only the origin of a process. Strictly related to our ternary conception of each level, three genesis need to be considered:

An instrumental genesis which transforms artefacts in tools within the construction process.

A figural and semiotic genesis which provides the tangible objects their status of operating mathematical objects.

A discursive genesis of proof which gives a meaning to the properties used within mathematical reasoning.

This can be summarized and illustrated by a diagram which will play at the time a metaphoric role and be a prospective tool to think about SGW.

Space for Geometric Work and its geneses

The representation of each level by a plane does not mean that these levels are strictly plane and parallel, and the distance between the poles – the length of the processes necessary to articulate the two levels – depends on and differs from one pole to the other regarding the problem and the tools used. On the other hand, as arrows appear in the diagram, it will be necessary to see what could be the meaning of each way when we want to describe the effective work made when solving a problem.

WHAT GUIDES THE WORK? IN SEARCH OF GEOMETRIC PARADIGMS

We will start to answer the question on what guides the geometric work by giving a first example (Kuzniak and Rauscher, 2011) which among numerous others of the same kind shows that a single viewpoint on geometry would miss the complexity of the geometric work, due to different meanings that depend both on the evolution of mathematics and school institutions.

Let ABC be a triangle with a right angle in B , with $AB=4$ cm and $BC=2$ cm. The ray (Ax) is perpendicular to the line (AB) . And M is a point on the ray (Ax) . The purpose of this problem is to obtain particular configurations of the triangle AMC .

Question: Does a point M exist such that the triangle ACM is equilateral? Justify your answer.

This problem was given to a lot of students at different grades but especially to pre-service teachers. In this case, students have a high general and university level and no problem with reasoning and formulating an answer.

A common answer which appeared was the following:

The correct answer is “no” and it can be shown, using compasses, that there is no third vertex on the ray (Ax) for an equilateral triangle constructed on the side (AC) .

Such a response is emblematic of what we named Geometry I. The student carries out an experiment in the real, perceptible world by constructing a triangle with drawing instruments and then s/he realises that no crossing points lie on the line where they should be for the triangle to be equilateral. The argument is supported by diagrams, objects that are typical and central to Geometry I.

This response, however, does not match what is expected in French traditional education at this level. A solution without any measurement and information supported by the drawing is ruled out. And for a student, it is better to propose this kind of solutions:

If ACM is an equilateral triangle with M on Ax , the angle MAC will measure 60° and the angle CAB 30° (sum of the three angles of a triangle) and by symmetry $\angle CAC'$ will be 60° (C' is the symmetric of C through the line (AB)).

As the triangle CAC' is isosceles in A (by symmetry), it should be equilateral. This is not true because the length of $C'C$ is 4, which is unequal to CA and $C'A$ ($2\sqrt{5}$) by Pythagoras' theorem).

This solution is illustrative of Geometry II. A reasoned deductive argument is constructed on the basis of initial data and geometric theorems.

From this example, it cannot be induced that deduction does not exist in Geometry I as we can see it with the following solution:

We can explain this by the fact that in an equilateral triangle all the angles are equals and the sum of the angles is 180° . The value of each is 60° . In this case, when we measure with a protractor, we observe that CAM is more than 60° , indeed $CAM = 64^\circ$.

This student deduced some properties belonging necessarily to the figure and then he checked directly on the drawing that the property is not true.

The notion of geometrical paradigm is useful for understanding, clarifying and organising the various and conflicting points of view observed in education. In our framework, we use the notion of paradigm according to Kuhn's definition. In his fundamental book about scientific revolution, Kuhn (1966) uses this term many times and after some approximations, he defines it by putting the stress on two aspects.

In its most global use, the term paradigm stands for the entire constellation of beliefs, values, techniques, practices etc. shared by the members of a given community.

On the other, it denotes one sort of element in that constellation, the concrete problem-solutions which, employed as models or examples, can replace explicit rules as basis for the solution of the remaining problems of normal science.

The concept of paradigm broadens the notion of theory and relates it to the existence of a community of individuals who share a common theory.

A paradigm is what the members of a scientific community share, and, a scientific community consists of men who share a paradigm (Kuhn, 1966).

Interpreted in the education world, it gives sense to the question about students' and teachers' different work in problem solving. We can argue that they are working in distinct paradigms and this epistemological difference can explain some didactic misunderstandings.

THREE ELEMENTARY GEOMETRIES

Geometrical paradigms were introduced into the field of didactics of geometry to take into account the diversity of points of view (Kuzniak and Houdement, 1999, 2003) and we summarize our findings by quoting former papers and especially (Kuzniak and Rauscher 2011, Kuzniak 2011).

To bring out geometrical paradigms, we used three viewpoints: epistemological, historical and didactical. That led us to consider the three following paradigms described below.

Geometry I: Natural Geometry

Natural Geometry has the real and sensible world as a source of validation. In this Geometry, an assertion is supported using arguments based upon experiment and deduction. Little distinction is made between model and reality and any arguments are allowed to justify an assertion and convince others of its correctness. Assertions are proven by moving back and forth between the model and the real: The most important thing is to develop convincing arguments. Proofs could lean on drawings or observations made with common measurement and drawing tools such as rulers, compasses and protractors. Folding or cutting the drawing to obtain visual proofs is also allowed. The development of this geometry was historically motivated by practical problems.

The perspective of Geometry I is of a technological nature.

Geometry II: Natural Axiomatic Geometry

Geometry II, whose archetype is the classic Euclidean Geometry, is built on a model that approaches reality. Once the axioms are set up, proofs have to be developed within the system of axioms to be valid. The system of axioms could be incomplete and partial: The axiomatic process is a work in progress with modelling as its perspective. In this geometry, objects such as figures exist only by their definition even if this definition is often based on some characteristics of real and existing objects.

Both Geometries are closely linked to real world even if it is in various ways.

Geometry III: Formal Axiomatic Geometry

To these first two approaches, it is necessary to add a third Geometry (Formal Axiomatic Geometry) which is little present in compulsory schooling but which is the implicit reference of teachers' trainers when they have studied mathematics in university, which is very influenced by this formal and logical approach. In Geometry III, the system of axioms itself, disconnected from reality, is central. The system of axioms is complete and unconcerned with any possible applications to the world. It is more concerned with logical problems and tends to complete "intuitive" axioms without any "call in" to perceptive evidence such as convexity or betweenness. Moreover, axioms are organized in families which structure geometrical properties: affine, euclidean, projective, etc.

These three approaches (and this is one original aspect of our viewpoint) are not ranked: Their perspectives are different and so the nature and the handling of problems change from one to another. More than the name, what is important here is the idea of three different approaches of geometry: Geometry I, II and III. It must also be clear that Geometry I is not a poor and small geometry for young students even if it is the first that they encounter. Abstract and complex forms of this geometry exist as it can be found in Lemoine's work on geometrography or Klein's students researches on approximation made by industrial drawing makers and using probabilistic theory to estimate the effects of errors.

Various SGW

A SGW exists only through its users, current or potential. Its constitution depends on the way users combine the two planes and their components for solving geometric problems. It also depends on the cognitive abilities of a particular user, expert or beginner. The make-up of a GWS will vary with the education system (the reference GWS), the school circumstances (the implemented or suitable GWS) and on the practitioners (students' and teachers' personal GWS). In practice, the constitution of a GWS does not rely on a single paradigm, but rather on the interplay among different paradigms and a specific study of each level is necessary. Before giving some examples we will detail these various GWS involved in Geometry education and relate them to different kinds of vigilance: epistemological, didactic and cognitive.

The reference SGW or the expected reorganization This space is normally defined and based on mathematical criteria. But it also depends on social, economical and political criteria. Studies of treatises written by mathematicians or maths educators and of the intended curriculum will allow describe this level in which an epistemological vigilance is at stake. This means that the rules of functioning of this SGW do allow knowledge to be organized in a well-defined and coherent domain.

At this point of the curriculum, the good functioning of the personal SGW is the ultimate goal of geometry teaching and learning and this point needs a cognitive vigilance. Here, the cognitive plane is concerned by a specific individual and not an epistemic or institutional subject, and to know more about its contents, conceptions,

knowledge of students have to be studied through problem solving and questionnaires.

Between the two planes, and fundamental in the make-up of a coherent and global geometric work, it remains to focus on the implemented SGW concerned by the didactic vigilance which will assure that the personal student's work corresponds to what the reference SGW proposes. Indeed, when a general paradigm is accepted and the reference SGW built, it remains to teach geometry to students and for that it's necessary to organize a suitable SGW to convey the kind of geometry expected by the educational institution. The geometrical working space turns to be suitable only if it allows the user link and master the three components defining the working space. Curriculum, textbooks, observation of real class implementation and preparation will support the study.

AN EXAMPLE OF COHERENT AND QUASI ASSUMED GEOMETRY I

To show what a suitable and implemented SGW fitted to Geometry I could be, an example will be given, taken from a comparative study of the teaching of geometry in France and Chile (Guzman and Kuzniak 2006).

Following a standard model in Hispanic world, education in Chile is divided into elementary school (Básica) till Grade 8 and secondary school (Media) till Grade 12. From 1998 on, the teaching of mathematics has left aside the very abstract teaching which was in place before and turned into a more concrete and empirical way. And today, the reference SGW is underlined by Geometry I. To illustrate this and point out some differences between France and Chile, let us observe the following exercise taken from the textbook *Marenostrum* (Grade 10).

The problem is given to students starting the chapter on similarity and the solution will be given later in the same chapter:

Alfonso is just coming from a journey in the precordillera where he saw a field with a quadrilateral shape which interested his family. We want to estimate its area. For that, during his journey, he measured, successively, the four sides of the field and he found approximately : 300 m, 900 m, 610 m, 440 m. Yet, he does not come to find the area.

Working with your classmates, could you help Alfonso to determine the area of the field?

The exercise is then completed by the following hint:

We can tell you that, when you were working, Alfonso explained its problem to his friend Rayen and she asked him to take another length of the field: a diagonal.

Alfonso has come back with the datum: 630 m.

Has it done right? Could we help him now, though we could not do it before?

The proof suggested in the book begins with a classical decomposition of the figure in triangles based on the indications given by the authors. But the more surprising for a French reader is to come: the authors ask to measure the missing height directly on

the drawing . We recall that this way of doing is strictly forbidden at the same level of education in France.

How can we compute the area now?

Well, we determine the scale of the drawing, we measure the indicated height and we obtain the area of each triangle (by multiplying each length of a base by the half of the corresponding height).

In this case, the geometrical work is clearly within Geometry I and goes back and forth between the real world and a drawing which is a schema of the reality. Measuring on the drawing gives the missing data. The activity is logically ended by a work on the approximation closely related to a Geometry based on the possibility of measuring.

THE IMPACT OF THE SOFTWARE ON THE IMPLEMENTED FRENCH SPACES FOR GEOMETRIC WORK

In her master dissertation, Boclé (2008) described the typical situation given in French textbooks to introduce a new notion in geometry at the end of junior high school. In textbooks conceived just after 1996, the typical structure [SP1] was the following:

1. Construction of some particular figures with drawing instruments.
2. Measurement on these figures by using instruments (marked ruler or protractor).
3. Conjecture of a property.
4. Institutionalization of the property, either accepted without proof or formally proved later.

In the textbooks printed after 2005, a new tendency appears. A new notion is introduced using dynamic geometry software (DGS). The typical situation [SP2] is then the following one:

1. Construct a figure with DGS..
2. Get measures from the software.
3. Drag points to notice that the property remains true.
4. Institutionalize the property, either accepted or accepted without proof or formally proved later.

In both cases, to introduce the property, students have to construct several figures satisfying some criteria. Thanks to the measures made on the figures, it is possible to notice an invariant then to make a conjecture. In the textbooks following the 2005 syllabus, the activities of construction and measuring imply the use of DGS. At its beginning, every activity is clearly in SGW directed by Geometry I and favouring perception and instrumentation. In both approaches, with and without software, the point 4 is crucial for determining the type of geometry really used and the appropriate

SGW. If the property is only proved in a deductive way without any use of measuring, it is possible to enter Geometry II. But what happens if the property is not demonstrated? It seems that students remain in Geometry I.

These typical situations fulfil well the curricular instructions recommending the implementation of activities leading to conjecture properties. The recent emphasis on the use of DGS is taken into account in textbooks but the real contribution of the software in the transition from Geometry I to Geometry II deserves to be questioned. Indeed, the use of a DGS is justified in the textbooks by improving the measuring accuracy and the possibility of multiplying the examples. But a measure remains an approximation and therefore is not exact.

This vagueness can create a contradiction in the classroom and lead some students to become convinced by another way and then been led to prove without any measurement. By contrast, insisting on the precision of the software and its advantage with regard to ruler-and-compasses constructions risks to turn away students from the necessity of proving, which was one of the stakes expected within the reference SGW.

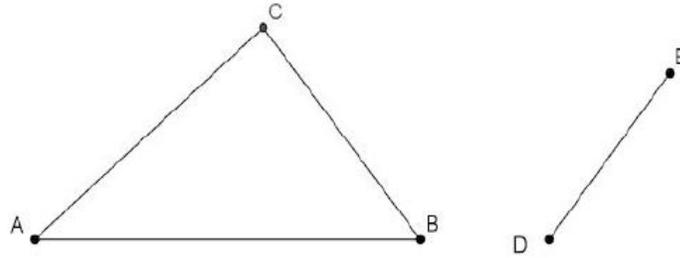

In her work, Boclé tried to see if the use of software in these typical situations favoured the transition to Geometry II or either if on the contrary it created a blocking element. She noticed that the strength of the proof by experiment overcame the classic work on demonstration with a purely deductive proof. In that case, it seems that the use of the software in standard situation stabilizes rather a SGW of Geometry I type and not a transition toward GII.

THE BREAK ACHIEVED IN GRADE 10 OR WHEN OSTENSION BECOMES DEMONSTRATION.

This contradiction is to be found again between the work expected by the institution and the work effectively set up in the teaching of similar triangles in an ordinary class at Grade 10. Similar triangles were reintroduced in French compulsory education in 2000. The notion has been removed from the syllabus since the modern maths reform and it reappeared in a quite different context in 2000 at Grade 10. Similar triangles are not considered by the programs as a new notion but as an opportunity to stabilize the geometric work at the end of compulsory education. We shall consider here only the result of a session managed by a teacher who first follows the typical way [SP1] but who changes on phase 4 (institutionalization) and then follows the process [SP2] by using the software by himself.

The activity is the first one about similar triangles. A sheet of paper is given to the students with a drawing on and the first task is to create a triangle DEF such that $\angle BAC = \angle EDF$, $\angle ABC = \angle DEF$.

Partie I : Créer un triangle DEF tel que $\widehat{BAC} = \widehat{EDF}$, $\widehat{ABC} = \widehat{DEF}$.

Below the figure, the following questions appear on the sheet given to the students:

What can we say about $\angle ACB$ and $\angle DFE$?

Compare the sides of the triangles with your ruler. What can be noticed?

Complete the sentence : We can guess that if two triangles have then their sides are

For the teacher the construction is not a problem. He anticipated two possible configurations, which seems an interesting difficulty to him. He wants to motivate in Geometry I the origin of a property which will belong completely to Geometry II when it will have been proved in the following lesson. For him, the figure is a generic example and he has not really thought about the measures given on the sheet.

The great majority of students, but not all, undertake completely the activity of construction which turns out to be long and complex. Students have difficulties with the use of their drawing instruments: the task « to make an equal angle » does not fit a well-known technique. Furthermore, the two possibilities for the final figure cause problems in the class since students are working on particular and not on general figures.

Other students understood that the construction is not important for the teacher and they quietly wait that the course goes on. They give, by abduction, purely linguistic conjectures by trying to adapt their mathematical knowledge to the situation. At the same time, students engaged in the construction task produce very different and contradictory results but actually these results and the work of these students will be left aside by the teacher who will favour the solution with DGS (Geogebra) and present it by video-projection in the class. The teacher follows the SP2 structure but without making any devolution to the students. He is the unique user of the software and he makes an institutionalization denying all the previous work of the students.

On the computer, the figure is the starting point and measures are given with five digits, even for angles. The proportion ratio calculated by the computer was 1.875 and was exactly the same for the three ratios.

The accuracy of the measures given by the computer shows to students the imperfection of their work with instruments on a very violent way. Strictly speaking,

the students' work is rather useless because it is left aside by the teacher. Moreover, the accuracy of the software turns it into a tool for proof and a source of truth and, this, without the teacher knowing, as it can be seen in the following dialogue, which closes the class after the statement of the conjecture.

Teacher: Did we demonstrate the property?

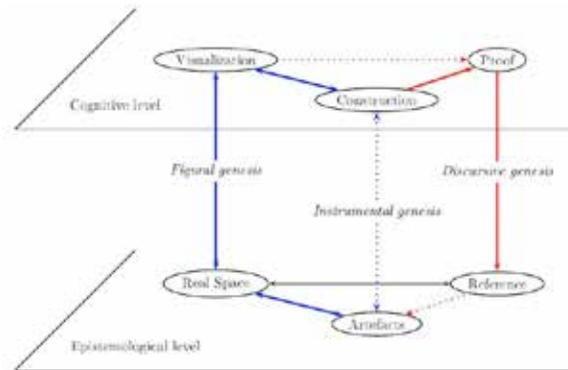

Almost all the students: Yes! We have done a demonstration.

Teacher (taken aback): Hum... No, it is too imprecise!

So after more than three years of progressive entrance in Geometry II and despite the programs which insist on the necessary awareness of the status of the statements, accepted or demonstrated, the gap between the expected work and the effective work is deep. It largely results from the appropriate SGW proposed to the students being itself very ambiguous and probably fundamentally a surreptitious Geometry I.

Within the SGW framework, it is possible to follow the break between two approaches of Geometry through various diagrams

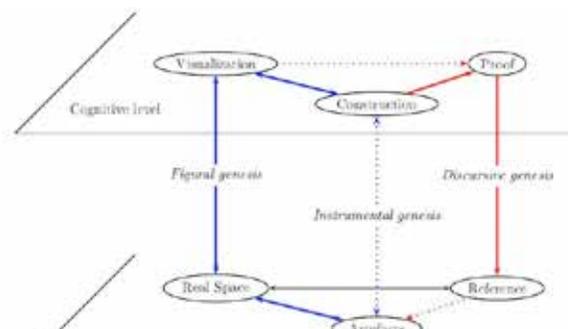

For the teacher, the construction is simple and will not cause trouble. His idea is to motivate the entrance in Geometry II by a preliminary work in Geometry I (in blue) and then to introduce a formal proof based on properties to justify the construction (in

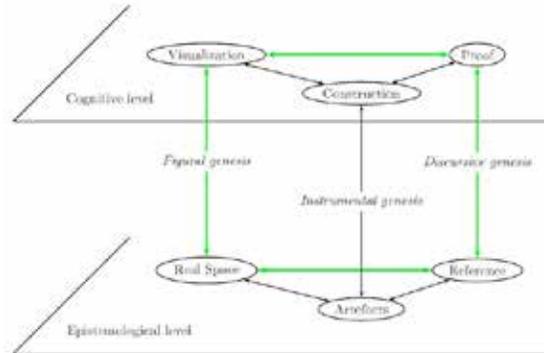

red).

Teacher's expectations

Students with low level in geometry try to construct with drawing tools. This is complex and requires a long time because the expected construction is not based on a standard technique at this grade. Moreover, due to a diversity of measurement results, a great diversity of properties are drawn by the students who consider the drawing as a particular figure without any general nature.

The construction work made by students is ignored by the teacher who gives the solution using a software, he is the only user of this tool which is really different from classical drawing tools, both in its uses and the precision of measurements. So after the “monstration” on a screen, students immediately conclude from results based on construction (in red) and the software appears as a source of Truth, but grounded on

experiment and no more on pure reasoning as in Arbuthnot's approach.

Students' geometric work without instruments

The last group of students give the conclusion without any construction work and can be summarized with the green diagram which shows an incomplete geometric work. They understand that the construction with drawing tools will be of no use for the conclusion and they complete the questions by abduction.

Even if the reference SGW always insists on a transition to GII based on GI, the implemented SGW is unstable and depends on the level of the students. For most of them, a real shift to Geometry I is favoured by the software which gives the “proof”. Due to a lack of a theoretic system to ground the teaching, the reorganisation of the SGW is led only by the teacher who attempts to adapt his teaching to the supposed low level of his students. In short, a lack of epistemological vigilance conducts to a lost of cognitive vigilance.

CONCLUSION

The forms for teaching geometry and its need have always been questioned and discussed. But today, the traditional view of a geometry education useful for training logical reasoning is reconsidered by our society increasingly technological and consumerist.

With geometrical paradigms, it is possible to make explicit different stakes involved in the teaching of geometry. Each paradigm stresses a different view of “mathematical culture” considered, on the one hand, essentially practical with applications to real world or, on the other hand, more theoretical and guided by internal mathematical requirements. From this, it results that geometric work depends on various factors which can be described by the concept of SGW.

But again, the reference SGW remains difficult to determine in some countries. In France, today, the debate between the two lines is not over, even if the utilitarian line is strengthened by international institutions and evaluations like PISA which promote an empirical and utilitarian view on mathematics. So, the emergence of the suitable SGW looks very confuse and that explains partly the fickleness of personal SGWs which do not seem to reach a stable point and depend a lot on the didactical contract.

In other countries the choice of Geometry I is clearly assumed during the major part of education with a sudden change at the end of the syllabus toward a traditional SGW of type (GII/gI) with ancient forms of teaching based on Euclidean tradition.

Whatever is the chosen paradigm, a consistent geometric work has to be implemented into the classroom in order that students can solve interesting problems and are aware of the authorized tools to justify their results. So, from a Geometry I perspective, a work on approximation is essential to fix the degree of confidence to be given to the results. Similarly, in Geometry II, students and teachers need to have clear ideas on the role and use of properties. One route to be explored could be to make explicit the existence of two geometries and to seek solutions based on GI or GII for some specific problems especially in the case of modelling. Another approach is needed to overcome the conflicting viewpoints on proof and it would be interesting to relate geometric activity to other mathematical areas. Changes of areas, changes of semiotic representations have always been at the centre of mathematical work. In the case of geometry, solutions of problems are based on different sets of numbers, use of functions and all this is reinforced by new software with great semiotic potentialities. By focussing on three main geneses, semiotic – instrumental – discursive, SGW provides a framework suitable to take into account the main key points of individual mathematical work which must be linked one with another to develop a global and effective work.

LANGUAGE AND MATHEMATICS: A FIELD WITHOUT BOUNDARIES

Candia Morgan

Institute of Education, University of London, UK

It is widely acknowledged within the field of mathematics education that language plays an important (or even essential) role in the learning, teaching and doing of mathematics. However, general acceptance of the importance of language is not matched by agreement about what this role (or these roles) might be or even about what the term language itself encompasses. I propose to construct a map of the field, identifying the range of ways of conceiving of language and its relevance to mathematics education, the theoretical resources drawn upon to systematise these conceptions and the methodological approaches employed by researchers.

INTRODUCTION

In this paper I propose to offer a map of the field of study of language in mathematics education – a way of conceptualising the various sub-fields, the connections between them and their connections to other domains of study both within mathematics education and beyond. This map is inevitably idiosyncratic and partial. It is *my* map, though its components, construction and conceptualisation owe much to the work of others (not all of whom can be explicitly acknowledged), but especially all those who have shared the task of organising the CERME Working Group on Language and Mathematics over the years – a task that I think it is important to acknowledge is not merely organisational but also has demanded scientific work in planning to enable coherent discussion, bringing researchers with widely disparate foci and theoretical orientations into productive conversations.

Language has been a topic of research in mathematics education for a long time. An early review article by Austin and Howson published in *Educational Studies in Mathematics* in 1979 drew on research from the previous two decades to provide a “state of the art” picture of the field at that time (Austin & Howson, 1979). I hope to show some of the directions in which our thinking and knowledge have developed since then, though my intention is to attempt a schematic rather than a comprehensive review.

In more recent years there has been a massive increase in the attention paid to language in mathematics education. I see this as a consequence of three trends within the field as a whole.

1. The development of mathematics education as a mature field of study has seen serious attention to theorisation and problematisation of the components, concepts and methods of the field, including language.
2. More specifically, the development of attention to language reflects the “social turn” (Lerman, 2000) in mathematics education as a whole. An orientation to

the importance of the social environment within which mathematics education takes place has inevitably been accompanied by raised awareness of the significant roles of language and other forms of communication within that social environment. This awareness has in its turn been accompanied by changing views of and more sophisticated attention to the relationships between language, mathematics and learning.

3. As well as these trends in the theoretical orientation of the field, developments in classroom practice, professional discourse and policy have increasingly included an important role for language-rich activity in the classroom, especially talking or “discussion”. While curriculum and policy developments may be informed by research and theoretical ideas about learning and language, their recontextualisation into classroom practice is often simplistic. Nevertheless, the widespread and influential notion that “discussion”, “interaction”, “discourse” in classrooms is a good thing, in itself strengthens the need for research that interrogates the nature and functioning of such discussion.

CHARACTERISING MATHEMATICAL LANGUAGE

First it is necessary to establish the scope of what I mean by language – and more specifically *mathematical language*. Looking at dictionary definitions we find, for example:

- the method of human communication, either spoken or written, consisting of the use of words in a structured and conventional way
- a non-verbal method of expression or communication e.g. body language
- system of communication used by a particular country or community (<http://oxforddictionaries.com/definition/english/language>)

Within mathematics education literature we find language used in each of these ways: dealing solely to words (referred to variously as natural language, verbal language, etc.) or including non-verbal modes of communication, especially (or indeed sometimes exclusively) mathematical symbolism, but also diagrams, graphs and other specialised mathematical modes as well as gestures and other modes of communication used in a variety of settings. There is also concern with the third sense of language both in the context of working with multilingual learners and in considering doing and learning mathematics in different national languages.

I would suggest an addition to this list in which language is used to refer to what Halliday calls register:

- the specialised method of communication used in a particular social practice

This includes mathematical language, of course, (the forms of communication used when doing mathematics) but also everyday language, scientific language, academic language, even classroom language.

While communication within the practice or practices of mathematics education and of doing mathematics is of central interest, it is also relevant to consider how this relates to other practices. On the one hand, considering how the practices of mathematicians are similar to those of other scientific or academic fields allows us to make use of knowledge about language and communication developed in those fields. On the other hand, recognising that our students are participants in a range of extra-mathematical practices may enable us to understand better their experience of communication in mathematics classrooms.

In recent years, thinking about language in mathematics education has broadened from considering primarily either words or mathematical symbolism towards a more comprehensive concern with a range of other means of communication. Again, I would suggest that this development has arisen at least in part from increasing recognition in the field as a whole of the importance of taking the social environment of learning and doing mathematics into account within research. By focusing on the social environment, the face-to-face communication that takes place in classrooms has come more into focus, moving attention away from written texts to the spoken word. This has also led to greater use of naturalistic data arising in classrooms and elsewhere together with qualitative methodologies that recognise and attempt to deal with the complexity of social situations. When observing in a classroom it is hard to miss the fact that words and mathematical symbols form only part of the communication that is going on. Whereas there are well established means of describing language, drawing on the field of linguistics, as well as attention to the syntax of mathematical symbolism (e.g., Ervinck, 1992), recognition of the multimodal nature of mathematical communication demands the development of means of describing and studying other modalities.

Of course, new technologies are changing our ways of communicating, not only introducing new semiotic resources, notably dynamic, manipulable and multiple linked representations, but also new forms of human interaction, both asynchronous (as is generally the case through email, discussion boards, blogs, podcasts etc.), and potentially synchronous (as in chat rooms, instant messaging, video conferencing). The potentialities of these new forms disrupt our established understandings of, for example, differences between spoken and written language. Developments in the general fields of communication and media studies offer some ways of theorising and analysing this wider range of resources, adding to what may be taken from linguistics, semiotics and theories of discourse. However, at the heart of any research in mathematics education we must find mathematics itself. Our conceptions of mathematics inform how we choose, use, interpret and adapt the theoretical and methodological tools offered by other fields.

We need not only to describe the language used in mathematical and mathematics education settings but also to be able to address questions such as:

- What is distinctly mathematical (or not) about the way language is being used?

- What role does the language play in the processes of doing mathematics and producing mathematical knowledge?
- How does the language function to establish what is and what is not to count as mathematics in this setting?
- How does this person's use of language position them in relation to mathematics?

and many other questions that focus on relationships between language and the activity of doing mathematics.

TRENDS IN RESEARCH

As ideas about what mathematical language encompasses have developed, I identify three related trends that have emerged (and which I will return to in the course of this presentation):

1. attention to forms and patterns of interaction in the classroom (and here I include studies of interaction mediated by new technologies).

Much of this research looks primarily at verbal language, especially the spoken word but there is also increasing interest in how gesture features in interaction and development of interactionist approaches that draw on semiotic theory to incorporate attention to a wider range of signs.

2. attention to a wider range of mathematical means of communication and the relationships between them.

There is a long tradition of study of mathematical graphs, diagrams, etc. from a cognitive perspective concerned with individual representation of mathematical concepts. This tradition has been moved on by research looking at the role of multiple representations and the cognitive demands and benefits of moving between them. As a more holistic view of language and mathematics within a social environment has come into focus, recognition of the multimodal nature of communication, including use of new technologies, has led to the development of more comprehensive and rigorous means of describing the complexities of mathematical communication and to research that seeks to describe and understand how teachers and students make use of them as mathematics is done in the classroom.

3. attention to what is achieved by using language.

A functional view of language is increasingly widespread, though sometimes alongside a representational view rather than displacing it. In other words, studying language has moved from focusing simply on what is said about mathematics to what the language achieves within a mathematical practice. This may be studied at several levels. We might characterise as micro-level a study addressing the functioning of particular words or other signs in relation to a single mathematical construct, for example, Rønning's (Rønning, 2009, 2013) work with children on fraction tasks

looking at how the use of different types of semiotic resource affected the course of their problem solving.

At a meso-level, we find studies, which, while maintaining a focus on a single mathematical topic area or issue, looked at a range of data sources over several lessons to gain a wider view of how the various semiotic resources function separately and together to shape students' experiences in this area, for example, Chapman's (1995) study of lessons on function in which she showed how the teacher's and students' use of the various forms of representation of function made connections and developed over the course of a sequence of lessons. Such studies not only provide us with detailed insight into the specific topic area but also point to more general issues about the significance of the selection and coordination of representational forms.

At macro-level, there are a small number of studies looking more generally at how language use contributes to mathematical practices. Misfeld's (2007) study of how research mathematicians make use of various forms of writing during their creative work is an interesting example of this type of study, drawing on resources from the field of writing research that theorise the process of writing as problem solving or as discovery of knowledge rather than only "telling" what is already known.

The interest in how language functions thus does not focus solely on texts arising in classroom interactions but can extend to address a much wider range of texts that play a role in shaping mathematical and educational practices. In a current project in collaboration with Anna Sfard, we are addressing mathematics education at the level of the curriculum, analysing the language of high stakes examinations in the UK in order to characterise how these examinations function to construct the forms of mathematical activity expected of school students (Tang, Morgan, & Sfard, 2012).

WHAT IS THE RELATIONSHIP BETWEEN MATHEMATICS AND LANGUAGE?

Before moving on, I want to comment briefly on a major theoretical issue that informs and divides research in this field. It is claimed that language has a special role in relation to mathematics because the entities of mathematics are not accessible materially. This entails particular importance for the study of language and language use in mathematics as in some sense mathematics is done in or through using language (in the broad sense of means of communication I have discussed). However, I say "in some sense" because there are radically different theoretical conceptualisations of what the entities of mathematics actually are and how they are related to language. On the one hand, some take the position that mathematical objects have an independent existence, even though they are only experienced through language:

We do not have any perceptual or instrumental access to mathematical objects ... The only way of gaining access to them is using signs, words or symbols, expressions or

drawings. But, at the same time, mathematical objects must not be confused with the used semiotic representations. This conflicting requirement makes the specific core of mathematical knowledge. (Duval, 2000, p.61)

On the other hand, those working with Sfard's (2008) theory of cognition and communication reject any dualist separation of mathematical object and language, arguing that mathematics is an entirely discursive activity and that mathematical objects are no more than the total of the ways of communicating about them.

These very different theorisations of language and mathematics have consequences for how researchers may think about the development of mathematical knowledge – as a process mediated by language or as the development of mathematical ways of using language – and about the place of language itself in researching mathematical thinking. Is language taken to be the means by which we get limited and partial access to learners' mathematical thinking or is the communication itself the object of study?

So far I have tried to outline some of the ways in which the field of study of language and mathematics has developed its conceptualisation of language. One recurring theme in attempting this task is the growing recognition of the complexity of the field both empirically and theoretically. I now turn to a very simple statement that still forms a starting point for much research.

“MATHEMATICAL LANGUAGE IS DIFFICULT”

The perception that language is a source of difficulty in mathematics learning has framed and continues to frame much research. This perception rests upon a dualist conceptualisation of language and mathematics as separate domains, though conceptualisations of the relationship between the domains vary from a naïve view of language as a barrier to learning that must be overcome to more sophisticated theorisation of language use embedded within particular social practices.

Early research in the field identified a number of features of mathematical language that students at all stages of education had difficulties understanding and using correctly. These included difficulties with vocabulary, with algebraic notation, with handling logical connectives but also difficulties at the level of more extended texts. Analysis of reasons for these difficulties were, however, less evident. The issue of confusions with everyday language was recognised, especially in relation to young children, for example, Durkin and Shire's (1991) analysis of ambiguities in elementary mathematics, identifying words that have different meanings in mathematical and in everyday contexts. I suggest that this relatively untheorised notion of confusion between different meanings of words may be associated with what I have called a naïve view of language as a barrier to learning. As thinking about relationships between language and learning change, ways of interpreting “confusion” between everyday and mathematical meanings also develop. We thus see more complex analyses of difficulties and attempts to theorise what happens as

students encounter mathematical forms of language. While difficulty and failure to communicate effectively is still a relevant area for research, the focus now is not so much on what children cannot do or what they fail to understand as on seeking to understand what is actually happening in classroom interactions, on the nature of communication among students and teachers and on the sources and functioning of apparent miscommunication

Relationships between mathematical and everyday language continue to be a focus of research but we now see more theoretical subtlety in attempts to understand why difficulties arise. There are several notable theoretical ideas that contribute to this understanding. The first is the widespread influence of the idea of “situatedness” – the idea that people make sense and behave differently when situated in different practices. Using a word in its everyday sense may thus be seen as the result of failure to recognise the situation as mathematical rather than failure to distinguish the correct mathematical sense of the word. Moving away from dualist separation of language from mathematics, discourse theoretical developments suggest that we think of mathematics as a discursive practice: doing mathematics essentially entails speaking mathematically (or writing or using other communicational modes).

The influence of discourse theoretical approaches, provides alternative ways of thinking about miscommunication in particular as non-arbitrary combination of resources drawn from different discourses Thus, for example, in a study conducted as part of the ReMath¹ project of students’ and teachers’ use of gestures while working with three dimensional figures, we found we could understand some apparent student difficulties in terms of the mismatches between the ways systems of directional vocabulary, Logo formalism and systems of gestures functioned in mathematical and everyday discourses (Morgan & Alshwaikh, 2012).

The teacher-researchers, drawing on specialised mathematical discourses that include expectations of formal definitions of terms, initially assumed that there was a consistent relationship between each term in the system and the type of movement or direction referred to. However, closer analysis suggested that, while students adopted some aspects of the formal systems introduced by teacher-researchers, for some, local characteristics of their activity seemed to call up other types of (everyday) discursive resources (see Table 1).

	Specialised discourse	Everyday discourse
Linguistic/ Logo formalism	<p><i>Turn Left/Right</i></p> <p><i>Pitch Up/Down</i></p> <p>Each instruction has a single defined function</p> <p><i>Right/Left</i> and <i>Up/Down</i> are always relative to current orientation</p>	<p><i>Turn up/right/ clockwise</i></p> <p><i>Go right/down</i></p> <p><i>Roll over/ around</i></p> <p>Terms are multivalent and their use is context-specific, depending on the type of object that is moving and its starting orientation</p>

		<i>Right/left</i> is usually relative while <i>up/down</i> is usually absolute
Gesture	Iconic, mimicking trajectory One-to-one relationship to Logo instructions	Deictic, pointing in direction of movement or iconic or hybrid Substitutable, especially to overcome physical difficulties

Table 1: Specialised and everyday language for movement in three dimensional space

For example, the student in Figure 1 was attempting to “play turtle” with her hand, a method of using gestures to support Logo programming that had been used during the introduction to the sequence of work. However, as she encountered physical difficulty in turning her right hand through more than 180°, she showed no hesitation in switching hands and changing the relationship between her gesture and the desired motion of the turtle suggesting an “everyday” type focus on direction of movement (using a discourse that allows ambiguity and substitutability) rather than the anticipated “Logo” type focus on type of turn (a discourse that demands precision and unique definition of terms).

Figure 1: Switching hands - shifting discourses

While difficulty in learning and using mathematical forms of language is still evidently an issue in classrooms and for research, efforts to understand the sources of difficulty have thus led researchers to orient towards analysing what students do communicate as well as what they do not.

Related research arising from increasing interest in the multi-semiotic nature of mathematical communication and the recognition that moving from one semiotic system to another is not a straightforward matter of translation (even if we believe that translation can be straightforward) explores how students choose from and make use of available semiotic resources to do mathematics. I have indicated here some of the theoretical approaches that address this issue. An important aspect of this is the recognition that different semiotic systems offer different possibilities for engaging with mathematical constructs. For example, a function represented by an algebraic expression lends itself:

- to analysis of its parts – does it have factors? is it a function of a function? does it contain a quadratic term? –
- to categorisation as a polynomial, a trigonometric function –
- to manipulation – can it be expressed more simply? what is its value when $x=$
...

while the same function represented by a graph is more likely to lend itself to consideration of global and local characteristics:

- is the function odd or even?
- is it periodic?
- is it continuous?
- does it have maximum or minimum values?
- how does y change as x increases

Again, in our ReMath project work, observing students working on an open problem solving task in a technology rich environment, we saw how their choices of communicational modes affected the ways students defined their problem and the trajectory of the problem-solving process (Morgan & Alshwaikh, 2009). This and other work shows that sensitivity to a wider range of modes of communication, including gesture and the richly multi-semiotic environments offered by new technologies, both highlights the complexity of students' encounter with mathematical discourse and offers us conceptual and analytical tools to address this complexity.

WHAT DOES LANGUAGE ENABLE US TO STUDY?

My own thinking about language and mathematics education is strongly influenced by the social semiotics of Michael Halliday (Halliday, 1978, 2003; Halliday & Hasan,

1989). An important insight offered by this theory is the recognition that the language we use not only construes the nature of our experience of the world but also our identities, relationships and attitudes. Study of language use thus offers opportunities to address many of the problems of mathematics education. I shall briefly consider three of these here:

- analysis of the development of mathematical knowledge
- tools to describe engagement in mathematical activity
- understanding processes of teaching and learning in social interactions

Analysis of the development of mathematical knowledge

Many areas of research within mathematics education have used data consisting of what students say (or other signs they produce) as evidence of their mathematical understanding. Development of thinking about language challenges some of the assumptions that lie behind such research and has also brought theoretical and methodological tools that contribute to understanding development of mathematical thinking and enable a more grounded analysis of linguistic data.

Naïve conceptions of language as a transparent means of transmission of ideas from speaker to listener have been seriously challenged by current thinking about communication. Moreover, a number of influential theoretical frameworks, including Peircean semiotics, Wittgenstein's notion of language games, and post-structuralist theories reject any fixed relationship between word and referent. These have been taken up and developed within mathematics education to address the specific problems of mathematical learning.

Work in semiotics has offered sophisticated means of conceptualising and investigating relationships between signs and mathematical meaning making. In particular, we have seen the notion of epistemological triangle, introduced by Steinbring (2005), used as a means of describing the nature and development of mathematical knowledge in classroom situations, focusing on the role of the symbols, words, material objects and other forms of representing mathematical concepts. This notion emphasises that relationships between representations and concepts are mediated by the "reference context", including the previous knowledge and experiences of the students.

Another approach to the issue of the development of mathematical knowledge makes use of the Vygotskian notion of tool mediation (Vygotsky, 1986). From this perspective, verbal language and other semiotic systems are conceived of as psychological tools that shape the nature of human activity. This framework has been used to analyse the effects of particular tools (whether specific words or other forms of representation or more extensive semiotic systems) on the development of mathematical activity (see e.g. Bartolini Bussi & Mariotti, 2008).

Tools to describe engagement in mathematical activity

From a different tradition, current theories of language use and discourse tend to focus on what utterances achieve rather than treating them as a means of accessing inner thought or objective reality. Within mathematics education, this perspective has been developed by Anna Sfard in her communicational theory (Sfard, 2008). Here no distinction is made between speaking/writing/communicating in mathematical forms and doing mathematics/thinking mathematically. Detailed characterisation of the nature of mathematical language thus provides a means of describing the ways in which learners are engaging in mathematical activity.

Understanding processes of teaching and learning in social interactions

Developments in the study of language in mathematics education are closely related to developments in the wider field. The move to focus on practices rather than on individuals, to consider learning as a social or socially organised activity and the move from ideas of individual construction of meaning to considering meaning as something formed by individuals within social environments have opened up a space within which language oriented studies contribute to the overall project of understanding teaching, learning and doing mathematics. Many of the theoretical and methodological resources that researchers into classroom interaction draw on originate outside the field – in ethnomethodology, linguistics, pragmatics, sociology etc. – and have been developed to deal with general interactions. These ways of thinking recognise that there are patterns in any social interaction that are distinctive to particular practices and functional in shaping what gets done in the interaction. Recognising these patterns and what they achieve provides tools for analysing classroom processes and can also inform development of teaching practice. For example, the patterns of funnelling and focussing identified and discussed by Bauersfeld (1988) and Wood (1998) have proved a useful tool for working with teachers as well as a foundation for further work on identifying patterns of interaction and establishing their functions.

It is important, however, to ask what are the specifically mathematical issues that arise in studying interaction in mathematics classrooms. Why should mathematics educators be concerned? Indeed, some studies located in mathematics classrooms analyse interactions in ways that do not seem to address the teaching and learning of mathematics directly. Such studies certainly illuminate important issues, for example, how knowledge is produced in interaction or how students may be positioned differently by classroom discourse. These issues are of concern both theoretically and in practice but as a researcher in mathematics education it is not enough for me to say simply that these studies are located in mathematics classrooms. I want to know what they have to say about mathematics and about the teaching and learning of mathematics.

Studies of interaction that engage in significant ways with mathematical aspects of interaction include those using the notion of socio-mathematical norms (Cobb &

Yackel, 1996) as well as studies of specifically mathematical forms of interaction such as argumentation (Krummheuer, 1998; Planas & Morera, 2011) or group problem solving (Edwards, 2005).

In a world in which new communication technologies provide new opportunities for interaction, it seems important to develop our understanding of how technologies may affect pedagogic and mathematical communication. This is especially pertinent as funding bodies encourage the development of internet-based tools and on-line collaboration. The CERME working group has seen some interesting analyses of on-line mathematical interactions, ranging from analysis of the pedagogic and mathematical practices of participants in an on-line discussion board (Back & Pratt, 2007) to analysis of semiotic activity during paired problem solving undertaken in an internet chat-room (Schreiber, 2005). At this time, these studies of technologically mediated communication are still relatively isolated, focusing on the features of specific special contexts. This is an area that offers many opportunities for both empirical research and theoretical development as the use of communication technologies becomes more widespread in mathematics education. Again, research in mathematics education needs to be informed by the developing field of research in on-line and mobile communication while maintaining a distinct focus on mathematics.

BILINGUAL LEARNERS

The final substantive issue I shall address is that of learners studying mathematics using a language different from their mother tongue/first language. This has been of concern for many years. Indeed, current understanding of the nature of mathematical language as a whole owes much to a paper by the linguist Michael Halliday that was originally presented in 1974 as part of a UNESCO symposium addressing the issue of education in post-colonial countries (Halliday, 1974). In many of these countries the colonial language was still used as the language of instruction but there was increasing interest and political desire to make use of local languages. In many cases a mathematical register did not exist in the local languages, raising many questions for the development of mathematics education. We are still grappling with problems arising from colonialism; problems which are not only linguistic but also political.

On the one hand, questions about which language should be used for teaching and learning mathematics and about the effects on learning of using one language rather than another have been addressed by studying the affordances of a language and the issues that arise for learners. For example, Kazima (2007) has identified issues in the learning of probability concepts in Malawi due to structural differences between the local language Chichewa and English, the language of instruction in secondary schools, while Ní Riordáin (2013) offers a psycholinguistic analysis of the potential differences in cognitive processing involved in using English or Irish. Bill Barton (Barton, 2008) has provided a fascinating discussion of relationships between the characteristics of a language and the kinds of mathematical thinking that may develop

through using it. His theorisation of the relationships between mathematics and languages opens up a rich field of study.

However, the practical questions about which language to use in the classroom cannot be answered fully without addressing the wider socio-political role of language. Setati's work in the context of multilingual South Africa raises an important distinction between what she calls the epistemological access to mathematical ideas that may be enabled by teaching and learning in a student's home language and the access to social, economic and political advancement enabled by developing higher levels of fluency in a world language such as English (Setati, 2005). The learners in South African classrooms and elsewhere in the world are not only learners of mathematics but are also becoming citizens of their own countries and of the world. The significant roles of language in both these domains cannot be ignored or resolved easily. In the context of this conference I am very aware of the privilege accorded to me as a native speaker of English, of the struggles that speakers of other languages go through to make themselves heard and of the complexity of the choices that have to be made by all those working in multilingual settings.

Increasingly in many European countries as well as elsewhere in the world, educators are faced with multilingual classrooms as global mobility of populations increases. This is reflected in an expanding area of research considering learning in a variety of multilingual and multicultural contexts. Within CERME this has led to certain overlap between the Working Group on "Language and Mathematics" and that on "Cultural diversity and mathematics education". As a field of study, multilingual/multicultural teaching and learning is challenging in its complexity. The contexts considered vary enormously – culturally, linguistically and economically. Alongside issues of language, many of these contexts also involve complex issues of social deprivation, social and political exclusion and cultural differences and diversity. As might be expected in a maturing field, considerable work is being done to map out the scope and develop a coherent understanding of the theoretical diversity brought to work in this area, yet there is room for further intercommunication.

A BROADLY RELEVANT METHODOLOGICAL ISSUE

Moving on to consider how work on Language and Mathematics relates outside the narrow sub-field brings me to a methodological issue that I believe should be of concern to all those using language-based forms of data, not only those for whom language itself is a major focus. I have already referred to the privileged position of English speakers. This is not just a social and political issue but also a methodological concern. Where international conferences and journals use English as the primary language for communicating scientific studies, many researchers experience the pressure of expectations to present their work, including the data and its analysis, entirely in English. However, many of the theoretical positions regarding relationships between language, mathematics, epistemology, thought, etc. that are adopted by those whose work I have touched upon in this paper make claims about

the constitutive nature of language. If the words we use and the ways in which they are combined grammatically play a constitutive role in the construction of mathematical thinking then we need to be aware of how this role may be different depending on the specific (national) language that is being used. However, there are few examples in the international English language literature that present data or analysis in other languages except in studies whose main focus is on the distinct characteristics of the (national) language of the learners.

A rare example that illustrates the importance of using the original language was given by Boero & Consogno (2007). They presented an extract of data (translated from Italian into English) to illustrate a mechanism by which individual students' contributions combine to allow joint conceptual construction and reasoning:

Maria: In the case of two as divisor, we need to move from one even number to the following one, two steps far.

Barbara: While in the case of three as divisor, we need to move from a divisible number to the next number divisible by three... three steps far

Francesco: And in the case of four, four steps far!

Lorena: The distance is growing more and more, when the divisor increases... the distance is the divisor! ... (long silence)

Roberto: So if the distance is one, the only divisor is 1.

But, in order for this extract to form an effective illustration of the mechanism, the authors' analysis needed to incorporate information about the original Italian.

The expression "... steps far" ("...passi distante" in Italian) allows students to move from one example to another, then the idea of "distance" ("distanza" in Italian) allows to embrace all the examples in a general statement that Roberto can particularise in the case of interest for the problem situation. Note that in the Italian language students can move easily from the adjective "distante" to the noun "distance". (p. 1155)

By publishing only translated versions of interactional data, subtle yet important aspects of the functioning of language may be lost. Equally, readers of translated data are likely to form their own interpretations based on the translated words – interpretations that may have no basis in the words of the original data. I would suggest that this is an issue for research in general, not just that which focuses on language.

Clearly authors, editors, readers, conference organisers and attendees have a common interest in making forms of communication as inclusive as possible while simultaneously ensuring that the research itself is reported accurately, rigorously and meaningfully. This interest might suggest that there should be more parallel presentation of original and translated versions of data and analyses. However, we know that pressures of time, space and labour costs militate against this suggestion.

There is room for innovative solutions here – perhaps making more use of the possibilities offered by new technologies.

OUTSTANDING SUBSTANTIVE ISSUES

In spite of the widespread recognition of the difficulty that many learners have with mathematical language and the importance of language in learning mathematics, much less attention has been paid to the question of how children learn to speak or write mathematically. Detailed studies of classroom interactions sometimes demonstrate student acquisition of particular signs or ways of communicating about specific mathematical constructs but the focus here tends to be on how language use contributes to learning the mathematics rather than on acquisition of mathematical ways of speaking or writing that may be more generally applicable and acceptable in a wide range of areas of mathematics. Of course, those who adopt Sfard's rejection of the dualist separation of language from mathematics would argue that learning mathematics is identical to learning to speak in mathematical ways; even studies within this framework, however, tend to focus on particular instances of mathematical contexts rather than on the general question of the acquisition of mathematical discourse.

I suggest three areas of concern in which, while some work has been started there is a need for more substantial and coordinated research effort.

- What are the linguistic competences and knowledge required for participation in mathematical practices?
- How do students develop linguistic competence and knowledge?
- What knowledge and skills might teachers need and use in order to support the development of students' linguistic competence?

FINALLY ...

As suggested in my title, in preparing this paper one challenge I have had to face is defining the scope of the field of Language and Mathematics. This is a challenge that has been implicit in the work of the CERME Working Group. The membership of the group has been very fluid as many colleagues whose main research focus may lie elsewhere have found language issues relevant to some aspect of their work and so have joined us for one year but gone to a different group in other years. This fluidity has on the one hand hampered efforts to develop greater coherence and continuity. On the other hand, it has, I believe, also enriched our work. It has provided opportunities to test out theoretical and methodological questions about language in a wide range of contexts and to disseminate them widely.

In some sense almost all studies involving language and communication in mathematics education also address other significant issues – learning, teaching, affect, identity, curriculum, assessment, etc. At the same time, it could be argued that, as most studies that locate themselves in other fields also make use of some form of

textual data and communication between researchers and the participants in the research, the findings and theoretical developments related to language and communication are likely to have very broad implications. Hence my title: “A Field without Boundaries” and an open invitation to relate your own research to Language and Mathematics.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG1: ARGUMENTATION AND PROOF

Viviane DURAND-GUERRIER, University Montpellier 2, France

Samuele ANTONINI, University of Pavia, Italy

Kirsten PFEIFFER, NUI Galway, Ireland

Gabriel STYLIANIDES, University of Oxford, UK

Keywords: Argumentation; proof and proving; reasoning; logic and language; formalisation; didactics; epistemology; mathematics education from primary school to university; teacher training; activities fostering argumentation and proof skills

INTRODUCTION

This chapter collects the contributions discussed during the working sessions by the twenty-six participantsⁱ from fourteen countries of the WG1 «Argumentation and proof» at CERME 8 in Antalya (Turkey). Nineteen papersⁱⁱ and a posterⁱⁱⁱ from nine countries were presented and discussed. The papers were presented in seven sessions under four themes: *Epistemological and didactical issues and their relationships in proof and proving in mathematics education (one session)*, *The role of logic and language in teaching, learning and analysing proof and proving process (two sessions)*, *Designing activities fostering argumentation and proof skills (two sessions)*, *Theoretical perspectives on reasoning, proof and proving (two sessions)*.

In each session, we collectively discussed a main question that had been sent in advance to the presenters who were requested to focus their short presentation on this question. We present in this introduction a summary of these discussions.

EPISTEMOLOGICAL AND DIDACTICAL ISSUES

According to Lakatos, in the construction of a mathematical theory, proving and defining are intertwined processes. The presenters were asked to take in consideration the question of epistemological and cognitive aspects involved in the relations between proving, defining, truth and validity, relying on prior research and on their experience. Renaud Chorlay proposed an epistemological and didactical perspective on the making of a proof-chain, while the paper from Judith Njomgang and Viviane Durand-Guerrier presented a classical example in calculus to discuss the distinction between truth and validity, and their relationships. The main points that were raised in the discussion were the importance of considering mathematical theories as both products and processes, and to take into account the interplay between proving and defining: within a deductive chain, definitions come first, although they are usually developed last (Proving may lead to discover/identify unexpected properties of mathematical objects). Considering the relationship between proving and conceptualisation (formation and development of mathematical

concepts), the connection with intuition, the role of argumentation and the possibility for students to have access to the key ideas of a theory have been pointed. Concerning truth and validity, there are different uses of these terms in classrooms; there are differences in considering truth for physical objects or for abstract objects; some students do not understand the link between proof and truth (they can accept a proof and reject the statement that has been proved); moreover validity is not necessarily connected to proof by students. So, it seems important to give opportunity to students to discuss about validity, truth, defining and proving in a theory. Some suggestions are provided in the third theme.

THE ROLE OF LOGIC AND LANGUAGE

Two sessions were devoted to this theme. In the first session we examined issues at the secondary level. The discussion focused on identification of aspects of logic and language likely to be an obstacle for developing proof and proving skills, and aspects that are likely to favour it. In the interest of teaching logic for fostering proof and proving competencies, Jenny Cramer discussed the possibility of *language barriers as an obstacle in the process of mathematical reasoning*. Considering that logic and language are closely related, Zoe Mesnil supported the interest, for teachers, of *logical analysis in mathematical discourse*. A crucial question is “how to do this?”. In her paper, she presents elements that are proposed for teacher training in France, where logic has been reintroduced in the high school curriculum. Pro and contra arguments were provided. Concerning the respective role of logic and language in conceptualization, there is a balance between the necessity of mathematical language, and the importance of remaining close to the natural language. But where should we draw the line? In multilingual contexts, logical analysis could have negative effects of excluding or discriminating students. On the positive side, logical argumentation may provide a bridge between natural and mathematical languages. Should we consider logical competencies and/or logic as a body of knowledge; logic as a theory modelling human reasoning and/or as a theory aiming to control validity of proof; should logical proof be considered both in terms of a final product and as a process in action? We neither reached a consensus on these questions, nor on the relevance of teaching or not teaching logic at secondary school.

In addition, in this first session, Christavgi Triantafillou presented an on-going research on *the nature of argumentation in school texts in different contexts*, pointing the role of nomo-logical, logical-mathematical, logical-empirical and empirical inferences, mediated through linguistic and non-linguistic tools.

The second session on this theme was devoted to issues for advanced mathematical thinking. According to Quine, formalisation in predicate calculus contributes to conceptual clarification. However, it appears that for many students, formalisation is an insuperable obstacle. The discussion raised the relationship between logic and formalisation. Formalisation is essential for mathematical work, in particular to control correctness. In this respect, there are both mathematical and logical

formalisations. Formalisation serves the choice of aspects of a concept that fit in a theoretical way when defining it (for example perpendicularity and continuity). Such choices could have a cognitive effect on students' understandings. Educational research is concerned with the relationship between students' difficulties and formalisation. For example, Nadia Azrou analysed *students' difficulties in a proof in Algebra* in group theory. Another issue in mathematics education is the variability of formalisation in text books as presented by Faiza Chellougui *on the case of continuity at higher education*. Eva Müller-Hill discussed the *epistemic status of formalised proof and formalisability as a meta-discursive rule from a philosophical perspective*. In mathematics education understanding formalisation as a process is essential. An important aspect is the dialectic between syntax and semantics. There is a semantic context to syntactic work (how does a machine know what to do next when presenting a proof?). We can wonder how students could understand what a mathematical object is (i.e. group) without being able to rely on examples.

DESIGNING ACTIVITIES

In CERME 7, a crucial issue that was pointed was the necessity of sharing relevant activities fostering argumentation and proof skills across the curriculum, from kindergarten to university and in teacher education.

In CERME 8, five papers and a poster focused on this theme. Two papers and the poster proposed research situations aiming to develop proof and proving competencies. Patrick Gibel *analysed a mathematical lesson in primary school* including a situation of validation. The sequence aims to teach the rules of the 'game' in the proving process. Specifically, the sequence focuses on true and false statements but also on the way of establishing truth/falsity, in line with the relationship between truth and validity discussed in the first session. Denise Grenier of the team Math-à-Modeler presented *Research situations to learn logic and various types of mathematical reasonings and proofs*. Simon Modeste, also member of the team MathsàModeler presented a poster on the fundamental role of problem in modelling algorithmic thinking. Before the session, Denise Grenier and Simon Modeste had invited the participants to experiment a mathematical SiRC (*Research Situation for Classroom*), in line with the importance in the model they propose of experiencing the situations in order to understand what competencies they are likely to develop. The discussion was initiated by the question addressed to the presenters: in what respect the models they have elaborated were sound supports for developing new research situations oriented to the development of proof and proving skill? For researchers, models are useful for: developing situations, predicting or describing students' activities and analysing students' reasoning and their evolutions. The models are also beneficial for communication with teachers and educators and for trying to promote students' engagement in proving. They also provide criteria to identify relevant mathematical problems (e.g. optimisation – number theory – discrete mathematics) and to organise situations. The dialectics between action, formulation and validation, in line with the function of reasoning, are taken into account: to make

decisions; to open possibilities; to express and discuss methods. An important issue refers to the possibility of learning both new concepts and proving techniques at the same time. On the one hand, proof is constitutive of a concept; it is partly content dependent. However, there is a difference between mathematicians and students, and we could consider that if the priority is to focus on proof and proving, it could be relevant to choose problems where the involved knowledge will not raise content difficulties for students. Finally, it appears that both aspects need to be developed in the classroom. Another important point is that in such a situation, the teacher's role is crucial: favouring the engagement of students in the problem, giving the possibility to students to modify the problem, organizing exchanges among students, introducing relevant elements (new question- new games – variants, etc.), allowing the evolution of the methods and favouring the production of proofs, including counter examples. A recurrent question addressed to developers of such situation is how to evaluate the development of proof and proving skills. Some paths: along a dedicate course, evaluation should be done on such problems; one could try to evaluate if students recognize that they have produced a correct proof or not (It may occur that for teachers something is a proof but not for students, and vice versa). Many participants that were both researchers and educators reported that students aiming to become mathematics teachers express negative beliefs and attitudes toward proof. So, a crucial issue, once one considers that it is important to develop situations aiming to foster proof and proving competencies, is to identify what in-service and pre-service teachers' experiences should be in order to be able to face the educational challenge of allowing students to develop proof and proving skills. The three papers of the second session of this theme contributed to this issue. A first path is to allow them to experience the relevance and the fecundity of such situations; however, there is often a gap between knowledge and experience in teacher training and in teaching practice. This raises the question of how to make the teacher become a cultural agent in school (self-reflection is important but something more is necessary). Margo Kondratieva proposed to a group of *in-service primary and secondary teachers* to work together on the same problem and to discuss *the multiple proofs* that were provided. Ruthmae Sears presented *a case study on the enactment of proof tasks in high school geometry*. Rolf Biehler and Leander Kempen advocated the importance for teachers of recognizing generic proofs. The main question is how you know that something is generic; what is it about it that makes it generic, is complicated. Different people see different things in examples. Students face two main difficulties: seeing the generality in the specific examples and communicating this generality. A challenge for the teacher is to decide if the students recognize the generality (even if students are writing the correct algebraic formula we cannot be sure that they are aware of the generality).

THEORETICAL PERSPECTIVES

In CERME 8, six papers were discussed in this section. Theoretical perspectives have been presented in the working group on proof for a long time. In CERME 7, we

discussed the use, evolution, elaboration or integration of theoretical constructs introduced at the previous CERME (e.g., cognitive unity; Toulmin's model, transparency background) and of new theoretical frames (e.g., Habermas' model for rational behaviour in proving).

Francesca Morselli's paper is in line with this perspective, crossing the theoretical framework developed by the Genova team around Paolo Boero with the cycle of Algebra in order to *approach algebraic proof at lower secondary school level through developing and testing an analytical toolkit*. The author enlightens the necessity for students of a goal-oriented approach for algebraic transformation, in reference to Habermas' rationality.

Following a long tradition in mathematics education consisting to question what we can learn from (brilliant) mathematicians, Gila Hanna introduced a new concept developed by Timothy Gowers: *the width of proof*; this is also the case with Annie and John Selden's paper which introduced the concepts of *persistence and self-efficacy in proof construction*, contrasting their availability between students and mathematicians and their role in the success in proving. The discussion during the two sessions of this theme focused on the following question addressed to the six presenters: *what are the more prominent aspects of your theoretical approach that should interest the research community involved in proof and proving in an educational perspective?*

The following points emerged from the discussion: the importance of conceptual (non formal) proof; the importance of what is memorized: concepts, mathematical knowledge and methods (mathematicians draw on a repertoire of tools when they proof and to get a repertoire, one needs to collect different proofs); the importance of long term research for solving a problem. Some potentially useful actions for the problem-solving part were identified: exploring – reworking – validating; in this respect proof control occurs at a meta level, and as it has been already pointed since a long time, communication and intrinsic properties of a proof are different things.

David Reid stated that proving is done by human beings and claimed that understanding the origins of the human ability to prove helps us to identify important research questions related to proof and proving. He also considered that necessity is not a property of deduction, but a feeling people have when reasoning deductively; he hypothesized that experience and education can change this feeling. Some participants argued that deduction is inherent to our cultural construction. Markus Ruppert focused on *analogical reasoning*, while the paper from Andreas Lorange and Reinert Rinvold focused on multimodal proof in arithmetic, assuming that other modalities than the written symbolic modality can be used in proofs, allowing visualization of generality. During the discussion, many questions emerged and were not fully addressed: What is the basic nature of human thinking? When and why do people think deductively? How people use analogical reasoning? Which are the relationships between deduction and causality? Some questions concern the connection between language and deductive reasoning, while others refer to the

relationship between language and level of abstraction.

CONCLUSION AND PERSPECTIVES

Regarding conclusions, we tried to shape what emerged from the discussion all along the sessions by focusing on some striking features.

First of all, epistemology, as well historical as contemporaneous one, appeared to play an important role all along the sessions, closely related with didactical issues: to understand proof and proving process; to consider the role of logic and language; to choose suitable problems when designing situations aiming to foster proof and proving competencies, and finally in elaboration of theoretical perspectives. Making more explicit these intertwined relationships between epistemology and didactics for research on proof and proving in mathematics education would be helpful for nurturing discussion and collaboration.

A second point that appeared in the discussion in the session devoted to *the role of logic and language in teaching, learning and analysing proof and proving process* is a kind of discrepancy between the strong interest for this question of the participants as teachers and educators, and some interrogation concerning the interest of conducting research program on this topic. This can constitute a challenge for future CERMEs to provide findings supporting the interest of developing such program through European collaboration.

The third point concerns the interest of going on sharing successful designs aiming to foster proof and proving competencies.

This opens paths for next up-coming meeting in CERME 9.

PROOF IN ALGEBRA AT THE UNIVERSITY LEVEL: ANALYSIS OF STUDENTS DIFFICULTIES

Nadia Azrou

University Yahia Farès of Médéa, Médéa. Algeria

The reported research aims to investigate the difficulties encountered by university mathematics-major students when dealing with proof in Algebra. An exercise dealing with an equivalence relation and a subgroup, with an a-priori difficulty level compatible with the students' preparation in Algebra, assessed the students' abilities to use their definitions in some new situations and to construct simple proof steps based on mastery of concepts and their symbolic representations. According to performed analyses, students' difficulties depend on conceptual, logical and meta-mathematical factors. Some pedagogical implications are derived.

Keywords: proof, university, formalisation, logic, algebra.

I- INTRODUCTION

In the Algerian mathematical curricula, proofs become a regular activity only at the university level. After the last university reform, the time for courses and exercises sessions has been shortened for the same subjects in comparison with the past years. This change resulted in difficulties for teachers on how to teach the same material in a shorter time. In mathematical courses for engineer students, many teachers eliminated proofs from both courses and exercises to devote the 'short' time left only to definitions and statements of main theorems and results. For mathematics-major students, this was considered to be not convenient by many teachers, so they kept dealing with proofs during the exercise activities.

The teaching of logic subjects has been for years a subject of disagreement among teachers, educators and researchers (for a survey, see Durand-Guerrier & al, 2012); it comes back to discussion in Algeria these past few years, after eliminating logic and even the conscious treatment of mathematical symbols from high school programs. At present, at the university, elements of logic are taught only by some teachers. The question comes over and over again, how can we teach elements of logic so that they can help understanding formal statements from a syntactic point of view but also, and mainly and basically, from a semantic point of view. Anyway, even if this is not taught in logic lessons, it must be dealt with somewhere. The activity of proving seems to me good means for this. When students deal with proof, they must use definitions and results, construct formal steps with arguments and link all this in the final product of the proof. Weaknesses and pitfalls in doing so may be an effect of how mathematical concepts and mathematics proof are taught.

This study is intended to investigate mathematics-major students' difficulties in proving in Algebra and what are they related to in the teaching of mathematics, logic and proof. In order to perform this investigation a theoretical toolkit was derived from different sources and an exam exercise (at the end of the second Algebra

course) was arranged and used, whose contents were an equivalence relation and a subgroup.

II- BACKGROUND AND THEORETICAL TOOLKIT

Mathematics education literature offers a wide spectrum of positions concerning: the relationships between the proving process, including the exploration phases, and proof as a product (as examples, see Hanna, 2000 and Pedemonte, 2007), and between argumentation and proof (with several different positions: as examples, see Duval, 1991 and Boero, Douek, Ferrari, 2008); what is relevant in the teaching and learning of proof and proving, in particular the role of logic and logical skills in proving (see Durand Guerrier, 2008 and Tanguay, 2007); classifications of students behaviours (Harel & Sowder, 1998) and interpretations of difficulties met by them in proving (as examples, see Dreyfus, 1999, Weber, 2001 and Selden&Selden, 2003). Some contributions on the above issues, in particular on those concerning formal and semantic aspects of proof, come also from mathematicians reflecting on their activities (see Thurston, 1994).

According to the aim of my study, I have considered some theoretical tools and positions that can provide different, sometimes alternative lenses to deal with data collected in my investigation. I have chosen:

- Vergnaud's theory of conceptual fields (Vergnaud, 1991), to account for Algebra as a conceptual field and to deal with the problem of meaning in Algebra. We may recall that according to Vergnaud the mastery of concepts and conceptual fields depends on the mastery of reference situations, operational invariants and linguistic representations. In particular, Vergnaud points out the deep difference between: knowing definitions of concepts, on one side; and dealing with problem situations that need to use properties ("operational invariants") and representations of concepts, and to make reference to previously experienced "reference situations" (a crucial component of transfer), on the other.
- The importance of the conceptual (in Vergnaud's sense) mastery of (meta-mathematical) knowledge about what a theorem and a proof are, as a component of that "culture of theorems", which should be passed on to students in order to promote their awareness of the "rules of the game" in proving activities (see Boero, Douek, Morselli, Pedemonte, 2010).
- Duval's epistemological and cognitive distinction between argumentation and proof as formal derivation (Duval, 1991), and the (partly) opposite positions presented in some more recent papers (see for instance Boero, Douek & Ferrari, 2008), which make also reference to Thurston's position (Thurston, 1994) on the crucial role of semantic aspects in the proving process and in the checking and communication of proofs.
- The crucial role of logic and logical skills in proving (Durand-Guerrier, 2008; Tanguay, 2007). In our educational perspective, we follow Durand-Guerrier & al. (2012, p. 370) concerning what we mean here by Logic:

(...) logic as the discipline that deals with both the semantic and syntactic aspects of the organization of mathematical discourse with the aim of deducing results that follow necessarily from a set of premises. When we refer to logic as a subject, we mainly restrict ourselves to the mathematical uses of the words *and*, *or*, *not*, and *if-then* (the basis for “propositional logic”), especially in statements that involve variables, as well as *for-all*, and *there-exists* (the extension to “predicate logic”)

The resulting theoretical toolkit is not homogeneous; this choice depends on the exploratory character of this study and on the need of testing different lenses to interpret students' behaviours and difficulties.

III-METHODOLOGY

A-priori Analysis

The experiment is about an exercise (presented below) that has been chosen by me as a teacher of twenty math-major students at the second year university level. It was an exercise of an exam of the first semester (2011). The course (Algebra II) is about algebraic structures, it is taught during two sessions per week, one course session and one exercise session; each session lasts one hour and a half. The students were supposed to have been provided with the principal prerequisites in the previous year, in the Algebra I course (set theory, applications: surjections, injections; group theory and a part of linear algebra). However, according to them, many of those concepts were not well mastered because of the little time devoted for each chapter; moreover dealing with proof was not among their regular tasks within the exercises proposed to them in Algebra I. I wanted, by choosing to assess students' preparation during an exam, to get the best possible results from them (students usually do prepare well to the exams) and I believe that working individually might reveal some errors that cannot appear when working in groups. I also wanted to know where (content, skills, ways of thinking) the difficulties with proof were situated - the answer was not clear for me during my semester teaching, especially when dealing with proofs (most exercises were about proofs). And the answer is crucial if we want to improve our teaching in order to help students overcome proof difficulties. Another issue to be dealt with was about the obstacle inherent in the mastery of formalisms and the relation with the teaching of logic. In mathematics courses, students show more and more difficulties in dealing with symbols (as concerns both syntax and semantics). Many teachers argue in favour of the elimination of teaching logic (in its technical aspects) because it is useless; many others insist on it as an initiation to mathematical language in such a way that students may interiorize some rules that can help them in understanding concepts, definitions, theorems, that intervene in proof production. The toolkit arranged for this study and presented in the previous section was expected to help tackling the above problems.

I have chosen questions with high formal-symbolic features to get the students writing formally (which is normal at the university level and even the objective of some chapters of the courses for mathematics-major students) but also to check what reasoning resulted in correct formal proofs and what kinds of difficulties were met by

students. Productive reasoning, I assume, is strongly based on concept understanding and argumentation skills. My aim was to investigate the movement, made during the proving process, between the concepts, the formal transcription and the argumentation. Within such a wide exploratory study I have chosen to present in this paper only data and analyses concerning students' difficulties in proving.

Let G be a non commutative multiplicative group.

Let R be a relation defined in G by: $x R y \Leftrightarrow \exists g \in G$ such that $y=gx$.

1-Prove that R is an equivalence relation.

Let $x \in G$, we define G_x by: $G_x = \{g \text{ such that } gx=x\}$, prove that :

2- G_x is a subgroup of G .

3-The application defined in G by $f_g(x)=gxg^{-1}$ transforms a subgroup into a subgroup.

According to what students were supposed to have learned in their past algebra courses and exercises, the proofs should be as follows.

1- Let's prove that R is reflexive, symmetric and transitive.

Let $x \in G$, let's prove that xRx . Let's find a g in G that verifies $gx=x$, for $g=I$, we have $x=Ix$. Hence $\forall x \in G, xRx$. That is R is a reflexive relation.

Let be $x, y \in G$ such that xRy , let's prove that yRx . We have xRy i.e $\exists g \in G$ such that $y=gx$, as G is a group, then $x=g^{-1}y$ i.e yRx . Hence R is a symmetric relation.

Let be $x, y, z \in G$ such that xRy et yRz , let's prove that xRz . We have xRy and yRz i.e $\exists g \in G, y=gx$ and $\exists g' \in G, z=g'y$, by replacing y , we get $z=g'gx=g''x$ and $g'' \in G$ i.e xRz . Hence R is a transitive relation.

2-Let's prove that G_x is a subgroup of G .

Let's prove that $e \in G_x$, we have $x=ex$, i.e $e \in G_x$ which means that G_x is not empty.

Let's prove that if $g \in G_x$ then its inverse $g^{-1} \in G_x$. Let $g \in G_x$ i.e $gx=x$, multiplying by g^{-1} we get $x=g^{-1}x$ that is $g^{-1} \in G_x$.

Let's prove that G_x is close under multiplication of G . Let $g_1, g_2 \in G_x$, let's prove that $g_1 g_2 \in G_x$.

We have $g_1 x=x$ and $g_2 x=x$, by replacing x in the first equality (or the second), we get $g_1 g_2 x=x$ which means that $g_1 g_2 \in G_x$. Hence G_x is a subgroup of G .

When a-priori evaluating the task, according to the exercises given to the students in both Algebra I and Algebra II courses, we arrived at the following conclusions (partly put into question by the analysis of students' performances - see Global Analysis):

- It is an easy exercise as the questions are classical and most exercises of equivalence relations and groups given to the students had the same questions.
- The mathematical content engaged in the proof is supposed to have been taught in the previous course (algebra I): groups, applications, direct image of a set by an application.
- The proofs of the statements are a direct application of definitions; there are no tricks or unusual techniques that may cause students to be stuck.
- The students are expected to show that they are able: to understand and use the symbolic language (quantifiers, implication); to make the difference between a variable and a parameter; but especially to be able to use a definition in a new situation, which (according to Vergnaud) needs to master the concept beyond its definition and may allow to build the proof steps through its properties.

IV- ANALYSIS OF STUDENTS' DIFFICULTIES

I have chosen three individual productions, which will represent the situation of the great majority of students and the most common difficulties met by them.

Production 1

2/ soient $x, y \in G_x$. Alors $xy \in G_x$.
 $m y = (g x)(g y) = g m y \in G_x$

3/ Orna $x = 1 \in G_x$ alors G_x est un sous groupe de G .

This production deals with question 2 of the exercise.

The student satisfies only two conditions among three for a subgroup, failing to prove that G_x contains the inverses of its elements. Despite of this, he finishes his proof by deducing the required result that is G_x is a subgroup; this might indicate how his conceptual (meta-) knowledge about proof is weak.

He starts by showing that G_x is closed for multiplication; he writes the definition as it is given in courses and mathematics books (with x and y) without adapting it to the exercise notations where the elements of G are denoted by g . Designing by x the elements of G is not convenient at all as x has already been used for the definition of G_x . The student shows a lack at the operatory level of transfer, probably related to an insufficient mastery of the concept of group (in the sense of Vergnaud).

In the second line, when trying to prove that the product of any two elements of G_x lies in it, the student replaces x by gx and y by gy ; this shows that the elements of G_x are not clear for the student, and he is not able to identify the role of g . Here, the lack concerning the mastery of the conceptual content of the definition is clear. The last step (in line 2) is not justified by the student. I think that, being in an impasse, he wrote the last result just to finish, without being able to derive it from the previous steps. Again the lack of knowledge, of what a proof is, seems evident here.

In the third line, the lack at the operatory level of transfer is shown again by using l for x .

Production 2

① Mq R est une relation d'équivalence

② Reflexive
soient $x \in G$ Mq $x R x$
ora: $x R x \Leftrightarrow \exists g \in G, x = gx$

③ Symétriques
soient $x, y \in G$ Mq $x R y \Rightarrow y R x$
ora: $x R y \Leftrightarrow \exists g \in G, y = gx$
④ $y R x \Leftrightarrow \exists g \in G, x = gy$
① $y = gx$ pour ④ $x = gy$
donc $y = g(gy) = g^2y$ contradiction
 R n'est pas symétrique

④ transitive
soient $x, y, z \in G$ Mq $x R y$ et $y R z \Rightarrow x R z$
et $\begin{cases} x R y \\ y R z \end{cases} \Leftrightarrow \begin{cases} \exists g \in G, y = gx & \text{①} \\ \exists g \in G, z = gy & \text{②} \end{cases}$
le produit ① ②
 $\exists g \in G, yz = g \cdot xg = g^2x$ (G non commutative)
 $yz = gx$ R n'est pas transitive

In this production, we deal with question 1 of the exercise.

We can see how the student proves the opposite of the required result.

At the first step (reflexivity), the student writes correctly the definition of reflexivity and what is to be shown, but then adding nothing, shows that he is not able to adapt it to the definition given in the exercise. Lack at the operatory level of transfer, which probably depends on insufficient mastery of the concept (in Vergnaud's sense), is clear here. At the second step (symmetry), the definitions and what is to be proved are also written correctly. The student starts proving by developing both the hypothesis (xRy) and the result (yRx) of the implication according to the given definition. Then what is supposed to be proved is used as means to make the proof. Even though, the student uses the same notation for g for both definitions, this doesn't show whether it is the same or not. When arriving to an impasse ($y=gy$), the student declares that it is a contradiction and deduces the opposite result. It seems to him the 'legal' way to get away. An important question arises here. Why he does not put into question his proof instead of questioning the required result? Why does he trust his reasoning more than the text of the exercise? I think that the student is not able to see other possibilities in his proof than what he could write; if this

interpretation is correct, available data show how the student's logic abilities of understanding (semantic sense) and dealing with formal statements are very limited.

At the third step, the student begins as before, by showing that his definitions are very well memorised. Then the product of the two equations is given in order to prove xRz .

One cannot say for sure if g is considered to be the same or not. The existential quantifier, at the last line, indicates that g is the same, but in what is crossed out (g'), we can tell that it is not the same. So, the student is lost again (on the logical ground, in the sense of Durand-Guerrier & al, 2012, p. 670) and gets away as before.

We can also see that this student is far from having conceptual (meta-) knowledge about what a mathematical proof is from a semantic point of view.

Production 3

1) montrons R est une relation d'équivalence
 a) R réflexive
 $x R x \Leftrightarrow \exists g \in G, x = gx$
 pour $g = 1, x = x$
 donc R réflexive

b) R symétrique
 on a : $x R y \Leftrightarrow \exists g \in G, y = gx$
 $y R x \Leftrightarrow \exists g \in G, x = gy$
 pour $x = y = \begin{cases} y = gx \\ x = gy \end{cases}$
 donc R symétrique

c) R Transitive :
 $x R y$ et $(y R z) \Rightarrow x R z$
 $x R y \Leftrightarrow \exists g \in G, y = gx$
 $y R z \Leftrightarrow \exists g' \in G, z = g'y$
 $\Rightarrow z = g'gx \Leftrightarrow x R z$
 donc R est transitive

donc R est une relation d'équivalence

This production deals with the question 1 (equivalence relation).

The student tries to prove that the three conditions are satisfied. He starts good, at the reflexivity step, by replacing g by 1 to prove that xRx . But then he fails later, by considering the same g . This leads necessarily to an absurd situation (from $y=gx$ we want to get $x=gy$); to get away from this situation, a small and simple trick seems to be the key: putting $x=y$, without realising that this is in contradiction with the symmetry definition that holds for all elements. We can interpret this as due to a lack of logical-semantic mastery of the symbolic language.

At the third and last step, the student considers g to be the same as he gets ($z=g^2x$) when doing the product. But this is still a trap, because as g is the same, g^2 wouldn't work to deduce the last result, but despite of this, the student concludes by (xRz) .

This behaviour on one side recalls the ritual proof scheme of Harel & Sowder (1998), on the other puts into question again the logical-semantic mastery of the symbolic language of the exercise.

Global analysis

The tasks proposed in the exercise supposed to be easy (as they belong to past courses activities) turned out to be complicated and some of them even impossible to deal with by many students, regarding to the level of their competencies revealed by the analysis (see below). Among twenty students, no one could completely solve the first part of the exercise (equivalence relation), only two could give a correct proof of some properties of the subgroup (question 2) and no one dealt with the third question (the direct image of a subgroup). Three main problems are evident in the productions: lack of transfer at the operatory level (depending on lack of mastery of the concept at state, in Vergnaud's sense), lack of logical mastery of symbolically- stated definitions and inference steps (see Durand-Guerrier et al, 2012, p. 670), and lack of (meta-) knowledge about what a proof is in mathematics. The definitions are memorized only in a formal and very superficial way which is far from sufficient when adapting them to any other new situation and even logical mastery of their symbolic presentation is lacking. Moreover, available data confirm that students face strong difficulties in proofs involving multiple quantifiers (e. g. Chellougui, F., 2009). Still concerning proof, there is evidence that several students do not know what they are expected to do in a mathematical proof, how to use definitions that they are provided with, and what are the meaning of the hypothesis and the thesis as elements related to the proving process. Most of them do nothing or meaningless operations and then deduce the final result. And some students seem not to know what "doing mathematics" means in general!

The undergraduate students tested are in their second university year and first year in mathematics as a discipline (math-majors). For these future teachers, it's clear that dealing with a proof seems to be new and strange. The formal-symbolic language is considered as a meaningless copying of definitions. Making proofs shows well how it is difficult, even impossible, to deal with a concept by considering only the formal transcription without mastering the meaning. The semantic side of a proof seems also nonexistent; it is thought that a proof should be a sequence of formal steps done by any technique, provided that it looks at the end, somehow, like the final result (cf. "ritual proof scheme" in Harel & Sowder, 1998). The students show difficulty with proof dealing with one single concept, even if they manage the beginning and some of the steps of the proof; but they are not able to start a proof that deals with many concepts (question 3: sets, direct image of a set by an application and subgroups).

V- CONCLUSION

The analysis shows a disconnection between formal transcription and conceptual mastering of the content of definitions. Nowadays the teaching of mathematics is more focused on formal-symbolic level rather than on the semantic level of mathematics content; but I believe it is necessary to teach definitions associated with all their conceptual content (in Vergnaud's sense: reference situations, operational invariants, linguistic representations) as well as their role and their usage in proving. The productions show that the students are not used to continually switching back and forth the meaning of the definitions and the meaning of the formal symbols. This activity is crucial in proving and without it; the students cannot be able to learn how to make proofs. This might be taught partially in logic (in the sense of Durand-Guerrier & al., 2012, p. 370) and this can help in the future mathematics activity.

We have also seen that the absence of meta-knowledge about the proof in mathematics prevents constructing arguments that result in a proof. This may be a consequence of a teaching process that uses proofs as means to establish theorems and results and not as an object of an activity (as is done with multiplication, continuity, integration etc) to be taught, used and mastered by students. Even when teachers make a proof at the board, most of them write formally the main steps and fail 'to write' the arguments justifying the inference steps, in order to show all that lies behind. I think as far as this is not revealed and shown clearly, the students cannot be aware of how the proving process works, which is mainly based on argumentation sustained by a deductive chain of propositions and inference steps related to their full meaning (cf. Thurston, 1994).

STUDENTS' USE OF VARIABLES AND EXAMPLES IN THEIR TRANSITION FROM GENERIC PROOF TO FORMAL PROOF

Rolf Biehler and Leander Kempen

University of Paderborn (Germany)

First-year students are supposed to be able to handle the deductive, axiomatic system of mathematics, to learn the formal symbolic language and to master different methods of proving. In this paper, we report on our findings from a redesigned bridging course lecture for preservice teachers, in which the students were asked to construct generic proofs to complete their transition to formal proof, using their mathematical knowledge from school. The students' first assignment was collected and their handling and use of examples, generic proofs, formal proofs and variables were analysed.

Keywords Generic proof, example, variable, formal proof

INTRODUCTION

The University of Paderborn offers a lecture specifically designed to help students to deal with higher mathematics. This course, "Introduction to the culture of mathematics", serves as a bridging course and was held for the first time in 2011/2012 as a requirement for the first year secondary (non grammar schools) preservice teachers, who had passed their German "Abitur" before. The course contents comprise logic, proof method, principle of induction, functions and sequences. Since the problems of the students with higher mathematics, especially proofs, are well known, the lecture's main focus was on argumentation, refutation and proving. Yet, the mathematic was not presented in an axiomatic deductive system. On the contrary, the mathematics of the university were connected with the mathematics learned at school. In the context of proving, generic proofs were presented as a valid argumentation method for lower school grades, as a special tool for grasping the main idea of a proof and as a point of departure for formal proofs. So the generic proof was thought of as a didactic tool for enabling students to find the general argument and to fulfill a transition to formal proof by keeping the main idea and in addition using variables. However, after the correction of the first assignment, the students' work showed problems in their understanding of generic proofs and their use of variables.

Our goal in the current study is twofold: to investigate the students' problems with generic proofs and their use of examples in the proving process of statements and to document the obstacles in their use of variables as placeholders for concrete numbers in the field of elementary number theory.

THEORETICAL FRAMEWORK AND RELATED RESEARCH

Since Balacheff (1988) identified the generic proof as one of four main types in the cognitive development of proof, research on generic proofs (or generic examples) as a didactic tool for learning to prove has increased throughout the years (e.g. Leron & Zaslavsky, 2009; Mason & Pimm, 1984; Rowland, 1998 and 2002). But still Rowland is right, when he states: *[...] I am saying that the potential of the generic example as a didactic tool is virtually unrecognized and unexploited in the teaching of number theory, and I am urging a change in this state of affairs* (2002, 157). Also, the potential for teaching and learning to prove has not been exhausted yet: Firstly, generic proofs are said to be useful in order to convince students of the truth of a statement and *they enable students to engage with the main ideas of the complete proof in an intuitive and familiar context, temporarily suspending the formidable issues of full generality, formalism and symbolism* (Leron & Zaslavsky, 2009, 2-56). So secondly, they might pave the way for the transition to formal proof and help the students to handle variables and the structure of proof (e.g. Padberg, 1997). But in the transition from generic proof to formal proof two problematic areas arise: students' difficulty to generalize from the particular, to recognize and to take into account the generic quality of a generic example (Mason & Pimm, 1984; Nardi, 2008; Selden, 2012) and to adhere successfully to the mathematical language.

In this context the use of variables plays a subordinate role as they are a formal tool in the service of generalization. The research on students' use of variables has shown their difficulties with the concept of variables (e.g. Akgün & Özdemir, 2006; Cooper, Williams & Baturo, 1999; Ely & Adams, 2012; Philipp, 1992; Trigueros & Ursini, 2003). Although variables play various different roles in mathematics which cause various difficulties (Epp, 2011; Schoenfeld & Arcavi, 1988), their concept is rarely discussed in courses at university level. As Akgün and Özdemir (2006) explored in their case study, most students consider a variable in the context of equation as one specific number, even if it is used as a general number. In addition Trigueros and Ursini (2003) argued, that first-year undergraduates cannot distinguish between a variable as a specific unknown and a variable as a general number and that they have serious difficulties when variables are related to each other. They conclude: *Students' understanding of the concept of variable lacks the flexibility that is expected at this educational level* (2003, 18).

RESEARCH QUESTIONS

Our central research questions concern students' use of examples and variables in their transition from generic proof to formal proof:

1. How do first-year students argue when they are asked to construct “generic proofs”?
2. Do they also use the general argument found in the generic case in their formal proof?

3. What characterizes students' use of variables when formulating a formal statement and a formal proof?

THE LEARNING SEQUENCE

Before the students had to submit their first assignment, two lectures and one tutorial were given. In the first lecture, the aims of the first section (“Discovery and Proof in Arithmetic”) were named: Getting to know the process of discovering and proving and distinguishing between verifications of a statement with concrete examples, with generic proofs and with formal proofs including variables. A research process was initiated by the question: “Someone claims: The sum of three consecutive natural numbers is always odd. Is this correct?”. The statement was tested with some examples which led to the conjecture that the sum is always three times the mean number. As verification and explanation, a generic proof was presented (see table 1) and discussed by the students until the following statement was arrived at: “In this example, we are performing operations with concrete numbers, which are also possible with all (natural) numbers. Thus, this argumentation differs from our previous examples. It is a “generic proof”, which includes a general argument. So here we have got a verification for the statement and an explanation, why the sum is always three times the mean number.” Thus, “generic proof” was introduced by the lecturer and not invented by the students themselves.

Then, the general argument was used in the following formal proof (see table 2).

Handwritten calculations showing the sum of three consecutive numbers. The first example uses the numbers 1, 2, and 3, and the second uses 10, 11, and 12. In both cases, the middle number is used as a reference point, and the sum is shown to be three times that number.

$$\begin{aligned}
 1 + 2 + 3 &= (2-1) + 2 + (2+1) \\
 &= 2 + 2 + 2 \\
 &= 3 \cdot 2 \\
 10 + 11 + 12 &= (11-1) + 11 + (11+1) \\
 &= 11 + 11 + 11 \\
 &= 3 \cdot 11
 \end{aligned}$$

TABLE 1: The generic example

Handwritten formal proof showing the sum of k consecutive numbers starting from (k-1). The sum is calculated as (k-1) + k + (k+1), which simplifies to 3k.

$$\begin{aligned}
 k \in \mathbb{N}: (k-1) + k + (k+1) &= k + k + k \\
 &= 3 \cdot k
 \end{aligned}$$

TABLE 2: The following formal proof

After this, the “research process” in the lecture continued until the following surprising conjecture was found: „The sum of k consecutive natural numbers is divisible by k, if and only if k is an odd number“. The sum of k consecutive numbers with initial number n was defined as $S_{n,k}$ and finally the statement was formally proven.

In the tutorial groups, most of the time was needed to practice the representation of odd and even numbers by variables ($2n$ and $2n-1$, $n \in \mathbb{N}$), because it was needed in the first assignment, and the difference between an implication and a biconditional. In the following task in the tutorial group, the students had to use the representation of odd numbers as $2n-1$ to prove that a certain product is even. In the second task a proof by contradiction was needed, which one could obtain by using the formal representation of an even number.

TASK

The participants in the course were supposed to solve problems as a weekly assignment in order to get the permission to participate in the final test. The assignments of 64 students from four tutorial groups were scanned and their solutions for the following task were analyzed in an exploratory way to investigate the acceptance of the generic proof in a proof-oriented course and the students' use of variables. The task was as follows:

*Prove the following statement with a generic proof and a formal proof. Before starting the formal proof, formulate the statement mathematically:
The sum of an odd natural number and its double is always odd.*

TASK ANALYSIS AND EXPECTED SOLUTIONS

The generic proof

First, a generic proof consists of operations within concrete examples that can be generalized. Moreover, one has to find a generic argumentation, why the assumption is true in these specific examples. Afterwards one has to explain why this argumentation also fits all possible cases.

The generic proof (1):

$$1 + 2 \cdot 1 = 3 \cdot 1 = 3 \quad 3 + 2 \cdot 3 = 3 \cdot 3 = 9 \quad 5 + 2 \cdot 5 = 3 \cdot 5 = 15$$

Comparing the equations, one can recognize that the result must always be three times the initial number. Since three times an odd number is always odd, the result is an odd number.

The generic proof (2):

$$1 + 2 \cdot 1 = 1 + 2 = 3 \quad 3 + 2 \cdot 3 = 3 + 6 = 9 \quad 5 + 2 \cdot 5 = 5 + 10 = 15$$

Comparing the equations one can recognize that the second sum will always contain an odd and an even addend, because two times an odd number is always even. Since the sum of an odd and an even number is always odd, the result must be an odd number.

Formulating the statement mathematically

Formulate the statement mathematically: version (1):

Let $a \in \mathbb{N}$ be an odd number. Then the sum $a + 2a$ is also an odd number.

Here the representation of an odd and an even number is not used, however, the use of one variable is necessary. This solution is in line with the expected level of knowledge of the students and the socio-mathematical norms created in the lecture.

Formulate the statement mathematically: version (2):

For all $n \in N$ there exists an $m \in N$ with:

$$(2n - 1) + 2 \cdot (2n - 1) = 2m - 1.$$

This is a more advanced solution, in which the use of two variables is necessary. Since n represents the first odd number, a second variable m is required. This statement also explicitly contains a universal statement and an existential quantifier.

The formal proof

Formal proof (1) - following the generic proof (1) and the statement (1):

Let a be an odd number. Then $a + 2a = 3a$.

Since three times an odd number is always odd () the statement is proven.*

In this proof one can transfer the argumentation of the generic proof directly to the formal proof. The letter is used as a generalized number, as a generic element of a set of values. For the implication (*) we have to consider two possibilities: Either one can argue that the statement (*) is well-known in the sense of self-evident and true, which would be in line with the provided norms of the lecture, or one has to prove it, since it has not been proven before. In order to do this, one can argue: “ $3a = (a + a) + a$ ”, “The sum of two odd numbers, $a + a$, is always even” and “The sum of an even and an odd number is always odd”.

Formal proof (2) - following the statement (2):

$$\text{For all } n \in N: (2n - 1) + 2(2n - 1) = 6n - 3 = 2(3n - 1) - 1 = 2m - 1;$$

where $m := 3n - 1 \in N$.

Here the existential statement has to be shown for all $n \in N$.

RESULTS

The students' use of variables and their solutions for the generic proof, the formal proof and the formulation of the statement were categorized. But due to the size of this paper, we will just describe the categories for the generic proof and the formal proof in detail.

1. Types of students' proofs given as generic proofs

Students' proofs were classified into four different categories:

E0 The “generic proof” contains examples, which do not fit to the statement.

$n=2$:	$(3 \cdot 2) - 3 = 3$	✓
$n=4$:	$(3 \cdot 4) - 3 = 9$	✓
$n=6$:	$(3 \cdot 6) - 3 = 15$	✓
$n=12$:	$(3 \cdot 12) - 3 = 33$	✓

TABLE 3: a student proof, which belongs to the category E0

E1 The “generic proof” is just a verification by several examples without presenting the examples as generic. (These purely concrete examples are lacking explanations, further ideas or conclusions.)

$n=7$	\rightarrow	$7 + (2 \cdot 7) = 21$	\rightarrow odd
$n=11$	\rightarrow	$11 + (2 \cdot 11) = 33$	\rightarrow odd
$n=3$	\rightarrow	$3 + (2 \cdot 3) = 9$	\rightarrow odd
$n=9$	\rightarrow	$9 + (2 \cdot 9) = 27$	\rightarrow odd

TABLE 4: a student proof, which belongs to the category E1

G1 The examples are presented as generic, but no further explanation is given.

1)	$7 + 14 = 21$ (true)
	$7 + (2 \cdot 7) = 7 + 7 + 7 = 3 \cdot 7 = 21$
2)	$3 + 6 = 9$ (true)
	$3 + (2 \cdot 3) = 3 + 3 + 3 = 3 \cdot 3 = 9$
3)	$5 + 10 = 15$ (true)
	$5 + (2 \cdot 5) = 5 + 5 + 5 = 3 \cdot 5 = 15$

TABLE 5: a student proof, which belongs to the category G1

G2 The generic proof contains operations and ideas, which are named and generalized. (Here, the students identify different findings from operations, generalize them and use their findings in their argumentation process.)

Examples	
a)	$3 + (2 \cdot 2) = 7$ ✓
b)	$3 + (2 \cdot 2) = 7$ ✓
c)	$7 + (2 \cdot 2) = 11$ ✓
\rightarrow The statement is true, because two times an odd number is an even number. And the sum of an odd and an even number is odd.	

TABLE 6: a student proof, which belongs to the category G2

The frequencies of the categories are: E0: 3 (5.6 %), E1: 36 (67.9 %), G1: 8 (15.1 %) and G2: 6 (11.3 %).

So 39 Students (73.5 %) only presented examples in their “generic proofs” without connecting them with any argumentation to verify the statement generally (E0 + E1). Obviously, they have not understood the fundamental difference between a generic proof and verification by some examples. Out of the 14 students, who presented their examples as generic (G2 + G1), only six built an argumentation upon these in order to prove the statement in the generic proof (G1). In these six solutions, where the students succeeded in constructing the generic proof, the generic proof (1) was used two times and the generic proof (2) four times (see section “task analysis and expected solutions”). Four of these students did not use algebraic operations, but they argued verbally with the correct arguments.

2. Generic proof and formal proof

When the formal proof was successfully constructed, 18 students used formal proof (1), whereas none of the students used formal proof (2) (see section “task analysis and expected solutions”).

Eleven students, out of the 14 belonging to category G1 and G2, tried to construct the formal proof and eight of these were using the same argumentation in the formal proof and in their previous generic proof.

3. Formulating the statement mathematically

34 out of the 64 students tried to formulate the statement mathematically including variables. Here the version (1) was used 21 times and the version (2) 6 times. 7 students used a mixed form of these. All of the students' statements included formal mistakes.

Moreover in version (2), the hidden existential statement was not made explicit at all and only one student explicitly mentioned the universal statement in the conjecture.

4. Types of formal proofs and formal mistakes with variables

Students' solutions of the formal proof were classified into four different categories:

- P1: The reasoning in the formal proof is logical and correct.
- P2: The reasoning process contains gaps and/ or statements are used that are not true in general.
- P3: The reasoning does not contain any argumentation.
- P4: Miscellaneous

(One student tried to prove a wrong statement. His solution is placed into the fourth category “Miscellaneous”.)

In most of the solutions belonging to category P2, the students did not give an explicit argument, why the term $3a$ or $3(2n - 1)$ represents an odd number. We were expecting at least the argument “ $3a$ (or $3(2n - 1)$) is odd because both factors are odd”.

The quantitative results are shown in table 7:

Type of solution	Frequency	formally correct	with formal mistakes
P1	29 (51.8 %)	7 (12.5 %)	22 (39.3 %)
P2	18 (32.1 %)	1 (1.8 %)	17 (30.4 %)
P3	8 (14.3 %)	1 (1.8 %)	7 (12.5 %)
P4	1 (1.8 %)	0	1 (1.8 %)
Sum	56 (100 %)	9 (16.1 %)	47 (83.9 %)

TABLE 7: Frequencies of answer types

29 students (51.8 %) succeeded in constructing the formal proof (P1), of which only seven students accomplished this without formal mistakes concerning variables. 18 (32.1 %) students struggled with a correct logical argumentation (P2). In the formal proofs of another 8 students, no argumentation does occur (P3). In total, there are nine formal proofs (16.1 %) constructed formally correct and 47 (83.9 %) containing formal mistakes concerning variables.

In the process of proving, many students also struggle with the distinction between conditions, conjecture and proof. Sometimes the formulation of the statement is immediately followed by algebraic manipulations. Some students use different variables in the conditions and in the following proof.

The most common mistake in using variables is not clarifying to which domain the variable belongs. However this is essential in number theory. Usually numbers have to be whole numbers and not just rational numbers. Also, many students use $2n + 1$ $n \in N$ as representation for an odd number, not considering that 1 cannot be represented hereby.

When dealing with variables the students use a mixed form of everyday language and of the symbolic language of mathematics. Many students enrich the formal mathematical language with everyday language, when they seem to struggle with the formalism of the symbolic language. Letters and word symbols are used simultaneously, often without defining a correct domain. Moreover, one can recognize an inconsistent use of the symbolic language of mathematics. In addition, mathematical symbols like “=” or “ ϵ ” are often used in wrong ways.

FINAL REMARKS

The results of this case study are not representative, but they shed a new light on the current discussion about the role of generic proofs in the learning process of proving. In our study, only a few students understood the idea of a generic example. This finding corresponds with the literature. It is well-known that preservice elementary teachers have difficulties in distinguishing proof and verification by examples (e.g. Martin & Harel, 1989; Recio & Godino, 2001). Furthermore, they have problems in understanding the explanatory power of generic proofs and in identifying the general idea in the particular case (Rowland, 2002). Yet, those students that recognized a common ground in the concrete examples were able to transfer it to the formal proof.

In this transition to formal proof the students struggled with the formal language of mathematics, the use of the symbols and the meaning and definition of the variables.

Formulating the statement mathematically is another important part in the process of proving. At this point it becomes clear that this process requires more than just a correct argumentation in the formal proof. To prove a statement correctly, the initial statement must be understood with all its hidden universal and/or existential statements. This is a valid starting point of a proper proof strategy.

One can consider different reasons, why the students in this study had such problems dealing with generic proofs. First of all, more time is needed to teach the idea of a generic proof in contrast to examples and formal proofs. Nevertheless, it was surprising that one lecture plus one tutorial devoted to the topic had such limited success. Also, tutors familiar with this example-oriented proof are needed to support the (didactical) ideas. Generic proofs had not been a topic in their previous mathematical lectures they had attended. Since it is well known that first-year students struggle with formal proofs and mathematical language in general, one has to be careful in using both examples and proofs in an argumentation process and one still has to consider the barrier that the formal mathematical language presents.

For the subsequent version of the lecture – held in the winter term 2012/13 - , we redesigned the content including known misconceptions on generic proving and discussions about the generic power of the four categories named above. Further, we trained tutors in handling and explaining generic proofs and integrated new tasks for the students. In this run we obtained much better results concerning generic proofs (E0: 4%, E1: 28%, G1: 26 % und G2: 42%). These results will be discussed in detail in another paper.

USE OF FORMALISM IN MATHEMATICAL ACTIVITY

CASE STUDY: THE CONCEPT OF CONTINUITY IN HIGHER EDUCATION

Faïza Chellougui

FS of Bizerte, University of Carthage – Tunisia

Rahim Kouki

IPEI of el-Manar, University of Tunis el-Manar – Tunisia

In this paper, we consider logical-mathematical formalism in mathematical statements. We examine formalism regarding the notion of continuity in higher education. The choice of this concept is based on the fact that this concept involves a large number of related variables and that its logical structure nevertheless not too complex because all quantifiers are at the top of the form (Chellougui, 2009).

First we present the didactic transposition of the continuity from knowledge learned to knowledge taught. In a second step, we consider the definition of continuity as presented in various mathematics textbooks for first year university science students.

INTRODUCTION

In Tunisian secondary mathematics education, according to official instructions, logical symbols (logical connectors: \Rightarrow , \Leftrightarrow , ..., and quantifiers: \forall , \exists) are not introduced, and mathematical statements (theorems, definitions) are generally expressed in natural language (Chellougui, 2003). However, from the beginning of the first year of university, scientific formalized statements are used without a specific introduction to symbolism or to the relationships between statements in natural language and formalized statements. This widespread use of formalized language at university is motivated by the supposed superiority in terms of operating statements fully or partially formalized. However, for many students, formalism seems to be an obstacle to mathematical work and therefore to conceptualization (Quine 1970). Thus, in mathematical activity in the first year of university, we identify problems of interpretation of logical-mathematical vocabulary or gap of operating order to students, specifically difficulties in manipulation of complex statements with multiple quantifications. Generally, these issues are not addressed in common textbooks. We adopt the assumption that they reflect ordinary mathematical practice of mathematics teachers (Durand-Guerrier, 2003).

To illustrate this, we chose the concept of continuity of functions which is studied in high school and again in college. For this concept, an understanding of how a definition in natural language can be expressed in form of a formal definition is required. Consider, for example, the definition of continuity of a function at any point proposed by Schwartz (1991):

(For all $a \in \mathbb{R}$) (for all $\varepsilon > 0$) (there exist $\eta > 0$ such that) (for all $x \in \mathbb{R}$ such that $|x - a| \leq \eta$), we have: $|f(x) - f(a)| \leq \varepsilon$. This sentence can be written formally. [...]:
 $(\forall a \in \mathbb{R}) (\forall \varepsilon > 0) (\exists \eta > 0) (\forall x \in \mathbb{R}) [(|x - a| \leq \eta) \Rightarrow |f(x) - f(a)| \leq \varepsilon]$. (p.20)

Here, there are three universal quantifiers and an existential quantifier in third position. The scope of these quantifiers on implication is between parentheses. This study is concerned with the definition of the term as found in several mathematical textbooks of first year scientific university. Prior to this study, we present some elements of didactic transposition of the concept of continuity from expert knowledge to knowledge to be taught.

SOME ELEMENTS OF DIDACTIC TRANSPOSITION

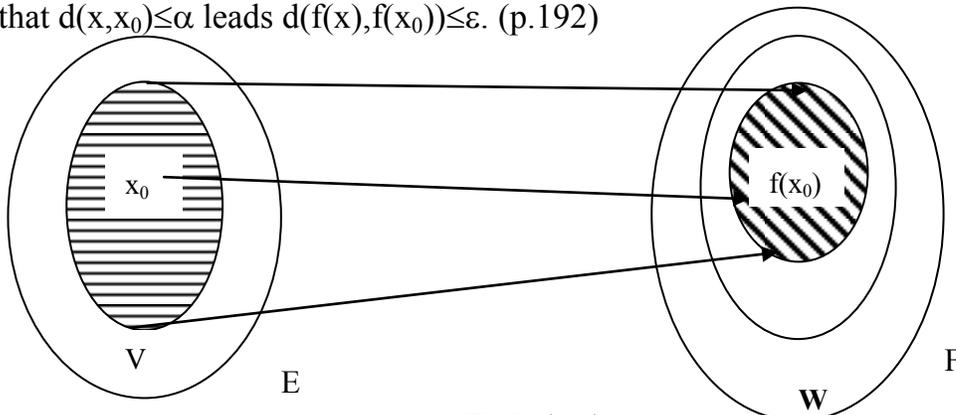

The first comprehensive outline of the Didactic Transposition Theory was developed in Chevallard (1991). This theory aims to produce a scientific analysis of didactic systems and is based on the assumption that the mathematical knowledge set up as a teaching object ('savoir enseigné'), in an institutionalized educational system, normally has a preexistence, which is called "expert knowledge" ('savoir savant').

Some objects of mathematical expert knowledge are defined as direct teaching objects and constructed in the didactic system (by definition or construction), i.e. mathematical notions, such as for example addition, the circle, or second order differential equations with constant coefficients. However, there are other knowledge objects, termed para-mathematical notions, useful in mathematical activities but often not set up as teaching objects per se but pre-constructed, such as the notions of parameter, equation, or proof (Klisinska, 2009).

We try to analyze the question of the use of para-mathematical logical symbolism in mathematical activity.

We start with the general definition of continuity of a function at a point made in a Dictionary of Mathematics (Bouvier and al., 1979):

Application continuous at a point. – An application f of a topological space E into a topological space F is continuous at $x_0 \in E$ if for all neighbourhoods W of $f(x_0)$ in F , there exists neighbourhood V of x_0 in E whose image $f(V)$ is contained in W . This is the mathematical expression of the sentence " $f(x)$ tends to $f(x_0)$ as x tends to x_0 ". In the case where E and F are metric spaces, f is continuous at $x_0 \in E$ if any $\varepsilon > 0$, there exists $\alpha > 0$ such that $d(x, x_0) \leq \alpha$ leads $d(f(x), f(x_0)) \leq \varepsilon$. (p.192)

(p.192)

This definition is given in topological spaces and neighbourhoods; it is then translated into metric spaces. It is formulated in a mixed language, an association of natural language and mathematical symbols. The authors do not use any logical symbol but illustrate this definition by charts. They were inspired by the approach of Bourbaki (1971), which itself offers the following definition:

Definition 1. - We say that f of a topological space X into a topological space X' is continuous at a point $x_0 \in X$ if any neighbourhood V' of $f(x_0)$ in X' , there exists a neighbourhood V of x_0 in X such that $x \in V$ implies $f(x) \in V'$. (P.I.8)

In comparison, Durand-Guerrier and Arsac (2003) use logical symbolism and even suggest a fully formal definition to define a uniformly continuous application:

Application uniformly continuous. – An application f of a metric space E with values in a metric space F is uniformly continuous if for all $\varepsilon > 0$, there exists $\eta(\varepsilon) > 0$ such that $d(x, y) \leq \eta(\varepsilon)$ implies $d(f(x), f(y)) \leq \varepsilon$. This can be symbolized by:

$$(\forall \varepsilon > 0) (\exists \eta(\varepsilon) > 0) (\forall (x, y) \in E^2) (d(x, y) \leq \eta(\varepsilon) \Rightarrow d(f(x), f(y)) \leq \varepsilon). \text{ (p.193)}$$

In this definition the quantification is complete and dependency relationship between η and ε appears.

To give a definition of continuity in \mathbb{R} , it is possible to get a definition equivalent with intervals since the intervals form a basis of neighbourhood in set \mathbb{R} .

Haug (2000) suggests the following definition:

Definition 6.a Let E be a set of real numbers. Let f be an application of E into \mathbb{R} , a and b are real numbers.

We say that b is a *limit* of f if: any open interval J centred on b , there exists an open interval I centred on a such that $f(E \cap I) \subset J$. (p.107)

He then notes:

Show that if we replace the above equation by the following equation we obtain an equivalent definition.

$$\forall_{\mathbb{R}^*} \varepsilon, \exists_{\mathbb{R}^*} \eta, \forall_E t, |a - t| \leq \eta \Rightarrow |b - f(t)| \leq \varepsilon. \text{ (p.107)}$$

Here, we note that there are no parentheses to express the scope of quantifiers on implication, which is a fairly common practice among authors of textbooks and mathematicians. Some students may not be aware of the difficulties related scope of quantifiers and use of parentheses. It is indeed important to understand the effects on the meaning of a statement and interpret in a mathematical theory, when changing the order of quantifiers (Dubinsky & Yiparaki, 2000).

Further, we read:

Definition 6.b– Let E be a set of real, let a be an element of E , let f an application from E to \mathbb{R} .

We say that f is *continuous* at a if f has a limit at a . (p.111)

The definition of a limit of a function is followed by a geometric representation based primarily on intervals of \mathbb{R} , which can enlighten the definition; there is also an explanation of the passage from the “neighbourhood” point of view to the “distance” point of view, which is not very common in other textbooks studied. Use of intervals favours the didactic transposition of the definition with neighbourhoods; it reduces the number of quantifiers and may in some cases be easier to handle (Chellougui, 2009).

STUDY OF SOME TEXTBOOKS: CONCEPT OF CONTINUITY IN THE KNOWLEDGE TO BE TAUGHT

Below we present a study of certain textbooks for students in their first year of university. We chose these textbooks because they were used by students and teachers of the Faculty of Sciences of Bizerte. The textbooks we have examined are: Chambadal and Ovaert, *Mathematics*, 1966; Arnaudies and Fraysse, 1988; Schwartz, 1991; Guégand and Gavini, 1995.

Our focus is on the different types of language used. Three phenomena emerged from this study which will be analyzed below.

Implication versus bounded quantification

In a mathematics textbook (Chambadal & Ovaert, 1966), we find the definition of a limit of a function at a point followed by that of continuity.

Definition 19. - Limit of a function at a point. - Let f be a function defined on a part A of $\overline{\mathbb{R}}$ and x_0 an accumulation point of A . We say that f has a limit at x_0 if it has a limit when x tends to x_0 remaining in $P=A-\{x_0\}$. We also say more briefly that f has a limit when x tends to x_0 . (pp.394-395)¹

This definition, first given in natural language, is then made more explicit and formalized:

-If x_0 is finite, so that f tends towards l when x tends to x_0 , it is necessary and sufficient that:

$$\forall \varepsilon \in \mathbb{R}_+^*, \exists \eta \in \mathbb{R}_+^* : \forall x \in A \cap ([x_0 - \eta, x_0 + \eta] - \{x_0\}), |f(x) - l| \leq \varepsilon \quad (1)^2$$

what writes:

$$\forall \varepsilon \in \mathbb{R}_+^*, \exists \eta \in \mathbb{R}_+^* : \forall x \in A, |x - x_0| \leq \eta \text{ and } x \neq x_0 \Rightarrow |f(x) - l| \leq \varepsilon. \quad (2) \text{ (pp.395-396)}$$

A beginning reader might ask where the implication that appears in (2) comes.

In another analysis textbook of first year science (Guégand & Gavini, 1995), we can learn:

2.1 Definition: Let I be an interval of \mathbb{R} , $a \in I$ and $f : I \rightarrow \mathbb{R}$

¹ Our translation

² To facilitate the study of different official statements, we have numbered (1) to (12) in the illustrations taken from different books or in our own analysis

We say that f is **continuous at a** if and only if f admits a limit in a equal to $f(a)$.

Otherwise we say that f is discontinuous at a .

Let us clarify this definition:

f is continuous at a

$$\Leftrightarrow \forall \varepsilon > 0, \exists \alpha > 0, \forall x \in I, |x-a| < \alpha \Rightarrow |f(x)-f(a)| < \varepsilon \quad (3)$$

$$\Leftrightarrow \forall \varepsilon > 0, \exists \alpha > 0, \forall x \in I, |x-a| \leq \alpha \Rightarrow |f(x)-f(a)| \leq \varepsilon \quad (4)$$

$$\Leftrightarrow \forall \varepsilon > 0, \exists \alpha > 0, \forall x \in I \cap [a-\alpha, a+\alpha], |f(x)-f(a)| \leq \varepsilon. \quad (5) \text{ (p.108)}^3$$

Here the beginning reader might wonder why the implication has disappeared in (5). This game appearance/disappearance of implication is related to mathematical practice of bounded quantification. This type of quantification is present in mathematics, but absent in the predicate calculus. For example, the mathematical writing:

$\forall x \in A F(x)$ is reflected in the predicate calculus by: $\forall x(x \in A \Rightarrow F(x))$.

In fact bounded quantification hides the implication the domain of quantification is limited to the elements that satisfy the antecedent of the conditional statement, which removes the implication. The practice of bounded quantification is present in textbooks, several authors provide a formulation of the definition of continuity without the conditional, often without providing explanations allowing students to be able to restore the conditional by changing the domain of quantification (e.g. Chambadal & Ovaert 1966, Guégand and Gavini 1995). Durand-Guerrier (2003) considers that being able to restore or remove correctly the conditional according with the domain of quantification in such cases contribute to the understanding of implication.

Implication versus conjunction

In another textbook of mathematics (Arnaudies & Fraysse, 1988), the authors begin defining continuity at a point with the neighbourhoods in a metric space:

Definition III.4.1 - Let A be a part of \mathbb{R} and $f: A \rightarrow \mathbb{R}$ a function. We say that f is continuous at $a \in A$ if and only if for every neighbourhood W of $f(a)$ there exists a neighbourhood V of a such that $f(V \cap A) \subset W$.

We say that f is discontinuous at point $a \in A$ if and only if it is not continuous at that point.

The function f is continuous if and only if it is continuous at every point of A . (p.108)⁴

After they present the classic definition using a mixed language:

[...] we obtain in particular the following definitions of continuity of f at a equivalent to the definition III.4.1:

(I) For all real $\varepsilon > 0$, there exists a real $\eta > 0$ such that

$$(x \in A \text{ and } |x-a| \leq \eta) \Rightarrow (|f(x)-f(a)| \leq \varepsilon)$$

(II) For all real $\varepsilon > 0$, there exists a real $\eta > 0$ such that

$$(x \in A \text{ and } |x-a| < \eta) \Rightarrow (|f(x)-f(a)| < \varepsilon). \text{ (p.108)}^5$$

³ Our translation

⁴ Our translation

We can ask: why is there "and" in the antecedent of the implication?

We rather expect the following entry:

For all real $\varepsilon > 0$ there exists a real $\eta > 0$ such that for all $x \in A$ ($|x-a| < \eta \Rightarrow |f(x)-f(a)| < \varepsilon$)
or:

$$\forall \varepsilon > 0 \exists \eta > 0 \forall x \in A (|x-a| < \eta \Rightarrow (|f(x)-f(a)| < \varepsilon)) \quad (6)$$

Another formulation of the statement (II) presented in the textbook, using logical symbols for the quantification of each variable ε and η gives:

$$\forall \varepsilon > 0 \exists \eta > 0 (x \in A \text{ and } |x-a| < \eta \Rightarrow (|f(x)-f(a)| < \varepsilon)) \quad (7)$$

Are statements (6) and (7) equivalent?

As noted above, removing the bounded quantification on the variable x to the statement (6), we obtain:

$$\forall \varepsilon > 0 \exists \eta > 0 \forall x [x \in A \Rightarrow (|x-a| < \eta \Rightarrow |f(x)-f(a)| < \varepsilon)].$$

Our question refers back to logical equivalence between:

$$(x \in A \wedge |x-a| < \eta \Rightarrow (|f(x)-f(a)| < \varepsilon)) \quad (8)$$

$$\text{and } [x \in A \Rightarrow (|x-a| < \eta \Rightarrow |f(x)-f(a)| < \varepsilon)] \quad (9)$$

Considering only variable x , statements (8) and (9) are respectively of the form:

$$(p(x) \wedge q(x)) \Rightarrow r(x) \quad \text{and} \quad [p(x) \Rightarrow (q(x) \Rightarrow r(x))].$$

It is known that in the propositional calculus, the following equivalence:

$$[p \Rightarrow (q \Rightarrow r)] \Leftrightarrow [(p \wedge q) \Rightarrow r] \quad \text{is a tautology.}$$

By extension, in predicate calculus, the two following equivalences are universally valid:

$$[p(x) \Rightarrow (q(x) \Rightarrow r(x))] \Leftrightarrow [(p(x) \wedge q(x)) \Rightarrow r(x)]$$

$$\forall x [p(x) \Rightarrow (q(x) \Rightarrow r(x))] \Leftrightarrow [(p(x) \wedge q(x)) \Rightarrow r(x)].$$

So using logical arguments, we prove the equivalence between the two statements: (6) and (7). We summarize this equivalence in the following table with a justification in logical syntax by translating writing mathematics into predicate calculus (Kouki, 2008):

Writing mathematical	Predicates calculus
$\forall x \in A (F(x) \Rightarrow G(x))$	\rightarrow
	$\forall x [x \in A \Rightarrow (F(x) \Rightarrow G(x))] \equiv$
	$\forall x [(x \in A \wedge F(x)) \Rightarrow G(x)]$
$\forall x [(x \in A \text{ and } F(x)) \Rightarrow G(x)]$	\leftarrow

Negation of formalized statements

a- It is generally recognized that formal logic is to facilitate the transition to negation (e.g. Guégand and Gavini 1995).

Those quantified expressions can be easily denied. So to formulate that f does not tend to L (real) at a (real), we have (negation of the definition)

$$\exists \varepsilon > 0, \forall \eta > 0, \exists x \in U, |x-a| < \eta \mid |f(x)-L| \geq \varepsilon \quad (10) \text{ (p.108)}^6$$

In the textbook *those quantified expressions* mean:

$$(1') \quad \forall \varepsilon > 0, \exists \eta > 0, \forall x \in U, |x-a| < \eta \Rightarrow |f(x)-L| < \varepsilon$$

$$(2') \quad \forall \varepsilon > 0, \exists \eta > 0, \forall x \in U, |x-a| \leq \eta \Rightarrow |f(x)-L| \leq \varepsilon$$

$$(3') \quad \forall \varepsilon > 0, \exists \alpha > 0, \forall x \in U \cap [a-\alpha, a+\alpha], |f(x)-L| \leq \varepsilon. \text{ (p.107)}$$

In statement (10), we find a blank between the two inequalities:

$(|x-a| < \eta)$ and $(|f(x)-L| \geq \varepsilon)$. How to fill this blank? Is it the negation of (1'), (2') or (3')?

The negation of (1') is: $\exists \varepsilon > 0, \forall \eta > 0, \exists x \in U, |x-a| < \eta \wedge |f(x)-L| \geq \varepsilon$

The negation of (2') is: $\exists \varepsilon > 0, \forall \eta > 0, \exists x \in U, |x-a| \leq \eta \wedge |f(x)-L| > \varepsilon$

The negation of (3') is: $\exists \varepsilon > 0, \forall \eta > 0, \exists x \in U \cap [a-\alpha, a+\alpha] \mid |f(x)-L| > \varepsilon$

Expression (10) doesn't correspond to any of the previous negations. We hypothesize that the authors aimed to negate statement (1) and did not want to use logical symbolism for the conjunction "and". If they did not put the word "and" in this blank to keep all words in formal language and to avoid using a mixed language. This is based on the fact that in mathematics we very rarely use the logical symbol " \wedge " which represents conjunction. This is reflected in the textbooks studied. Indeed, the logical symbol of the conjunction is identified just once among these textbooks: in the first paragraph of the part entitled: *Set Theory*, of Laurent Schwartz (1991). The author, in this section, uses the definition of continuity of a real function to illustrate the rules for handling negation: inversion of two types of quantification, negation of implication. For example:

For express now that the function is continuous at every point, we write:

[...]

$$"(\forall a \in \mathbb{R}) (\forall \varepsilon > 0) (\exists \eta > 0) (\forall x \in \mathbb{R}) [(|x-a| \leq \eta) \Rightarrow |f(x)-f(a)| \leq \varepsilon] \text{ (p.20)}$$

Further, we read:

For example, the property for a function f of a real variable not is everywhere continuous, that is to say to be discontinuous at least one point is expressed by the single line:

$$(\exists a \in \mathbb{R}) (\exists \varepsilon > 0) (\forall \eta > 0) (\exists x \in \mathbb{R}) [(|x-a| \leq \eta) \wedge (|f(x)-f(a)| > \varepsilon)] \text{ (p.21)}$$

This second statement is obtained by recursively applying transformation rules:

$$\neg(\forall x Fx) \equiv \exists x \neg Fx \quad (11)$$

$$\neg(\exists x Fx) \equiv \forall x \neg Fx \quad (12)$$

⁶ Our translation

These rules allow change progressively the quantifiers and finally to focus on the negation of the open sentence into brackets. The application of the general rule: $\neg(p(x)\Rightarrow q(x)) \equiv p(x)\wedge\neg q(x)$ to this open sentence provides the conjunction of an atomic formula and of the negation of another atomic formula. So, finally we need to focus only on the negation of the atomic formula: $|f(x)-f(a)|\leq\varepsilon$. Then, the logical negation symbol disappears by the equivalence between the relation ">" and the negation of the relation " \leq ".

Note that these transformation process of quantifiers only apply if they are heading the formula. Indeed, a quantifier in the antecedent of an implication is not modified by the negation:

$$\neg[(\forall x Fx) \Rightarrow G] \equiv (\forall x Fx) \wedge (\neg G)$$

b-In another textbook (Arnaudies and Fraysse (1988) mentioned above), following the definition of continuity, the authors define the discontinuity noting:

The discontinuity of f at a point $a\in A$ means:

(III) There exist $\varepsilon>0$ such that for all $\eta>0$, $(x\in A \text{ and } |x-a|\leq\eta) \not\Rightarrow (|f(x)-f(a)|\leq\varepsilon)$

i.e

(IV) There exists $\varepsilon>0$ such that for all $\eta>0$ we can find at least one x in A such that $|x-a|\leq\eta$ and $|f(x)-f(a)|>\varepsilon$. (p.109)⁷

In statement (III), the authors use the symbol $\not\Rightarrow$ that does not conform to the syntax of logic. It leads to the question: what is negated? Especially since the universal quantification remains implicit: $[(x\in A \text{ and } |x-a|\leq\eta) \not\Rightarrow (|f(x)-f(a)|\leq\varepsilon)]$

The authors answer in statement (IV) using a given vocabulary in a language of action, where we would expect more usage of the logic symbol of the existential quantifier. This shows that what is negated is of course the implicitly universally quantified statement. This point could not be obvious for some students; indeed, some beginners could consider the following statement: $\forall x (x\in A \text{ and } |x-a|\leq\eta) \not\Rightarrow (|f(x)-f(a)|\leq\varepsilon)$ which is interpreted by: "None x satisfies the implication", which is not the negation of the definition.

The following negation: $\neg [(x\in A \wedge |x-a|\leq\eta) \Rightarrow (|f(x)-f(a)|\leq\varepsilon)]$ does not give rise to the appearance of an existential quantifier.

The negation is obviously on the universal $\neg[\forall x (x\in A \wedge |x-a|\leq\eta) \Rightarrow (|f(x)-f(a)|\leq\varepsilon)]$

CONCLUSION

Logical-mathematical formalizations in definitions of continuity, limits and discontinuity are different from one textbook to another. One might think that they reflect the everyday practices of mathematicians. Anyway, the authors of the textbooks

⁷ Our translation

we have studied do not provide to students means to overcome the linguistic difficulties raised by the use of formalism, in particular concerning its relationships with natural language, so that it seems that there is an “illusion of transparency of mathematical language”.

In some expressions, the presence of bounded quantification is indicated; practice creates a phenomenon of appearance/disappearance of involvement and quantification product entries do not conform to the syntax and logic that generates ambiguity, then the transition formalism is supposed ambiguities of ordinary language (Kouki, 2006). In addition, the use of automatic syntactic rules, not problematized, to construct recursively the negation of a sentence obscures many fundamental questions for operative use of formalism (Durand-Guerrier and al., 2012).

The introduction of logical-mathematical formalism in the learned knowledge aims to introduce a certain level of mathematical rigor in mathematical discourse in order to get rid of ambiguities, implicit assumptions and call to evidence. In the knowledge to be taught, the study showed a wide variety of formulations as well in formal language as in natural or mixed language, for which we have identified and analyzed syntactic difficulties, which are likely to affect student work.

THE MAKING OF A PROOF-CHAIN: EPISTEMOLOGICAL AND DIDACTICAL PERSPECTIVES

Renaud CHORLAY

IREM de Paris & IUFM de Paris

We will present an epistemological narrative based on a corpus of historical texts pertaining to the theorem: the sign of the derivative of f determines the variations of f . From a didactical perspective, the main points are: (1) the texts illustrate the role of “local” counter-examples (to use Lakatosian terminology); (2) the various proof-attempts are based on at least two pretty different proof-ideas; (3) even a proper (meaning, both intuitive and formal) understanding of the concepts involved in the statement of the theorem may lead to a faulty proof scheme; (4) it helps understand how long deductive chains emerge and stabilise. On the basis of this narrative, we eventually underline connections with current research works on proof in mathematical analysis, and mention teaching and teacher-training perspectives.

Key words: epistemology, proof analysis, mathematical analysis, AMT.

RATIONALE

In the twentieth century, most tertiary-level textbooks of mathematical analysis prove the following theorem: let f be a differentiable real-valued function defined on an interval, if its derivative f' is positive, then f increases over this interval. Its standard proof is a rather straightforward application of the “mean value theorem”¹ (“*égalité des accroissements finis*” in French, “*Mittelwertsatz*” in German); the proof of which is a rather straightforward application of the “Rolle theorem”², which, in turn, depends on the fact that a continuous real-valued function defined on a closed and bounded (i.e. compact) interval has a maximum or a minimum. The latter fact, although quite intuitive, depends on not-so-trivial properties of the set of real numbers (completeness of the metric space, local compactness). Historically speaking, this *deductive chain* can be found in the textbook (Jordan, 1893, p.65-67).

With this example, we can see that the proof of a rather intuitive qualitative fact (namely: if all the tangents point upward, the curve has to move up) requires several layers of sophisticated concepts (differentiability, continuity, properties of the numerical continuum), and a few standard tricks (affine changes of variable). In this paper, we will present some of the proofs given, over the 19th century, either of this

¹ Let f be a differentiable real-valued function, defined over some interval $[a,b]$, there exists a value c between a and b such that $f'(c) = \frac{f(b)-f(a)}{b-a}$. Geometrically speaking: on the arc of curve joining the points $(a,f(a))$ and $(b,f(b))$, there is a point where the tangent is parallel to the chord joining the two endpoints.

² Let f be a differentiable real-valued function, defined over some interval $[a,b]$, such that $f(a) = f(b)$. There is a value c between a and b for which the derivative vanishes.

mathematical fact, or of some key points in its proof; and some instances of critical proof-analysis.

We must stress the fact that this paper is not a work in the history of mathematics, but a work of an *epistemological* nature based on a historical corpus. The corpus consists of documents that we selected and translated into English (from the French or German languages). For lack of space, only part of the corpus can be presented here (for a more comprehensive presentation, see (Chorlay, 2012)). Quite a few works in maths education research have focused on similar issues (for recent examples: (Arsac & Durand-Guerrier, 2005), (Barrier, 2009)): our goals are (1) to make this new corpus available to this community of researchers; (2) to compare what this corpus helps document with current research perspectives on proof in mathematical analysis; and (3) to point to potential uses in a teaching or teacher-training context.

LAGRANGE'S PROOF (1806)

Let us quote the beginning of Lagrange's proof

A function which vanishes when the variable vanishes, will, as the variable increases positively, have finite values of the same sign as that of its derived function; or of the opposite sign if the variable increases negatively, as long as the values of the derived function keep the same sign and do not become infinite.

(...) Let us consider the function $f(x + i)$, whose general development is

$$f(x) + if'(x) + \frac{i^2}{2!}f''(x) + \dots .$$

As we saw in the former lesson, the form of the development may be different for some specific values of x ; but we saw that, as long as $f'(x)$ is not infinite, the first two terms of the expansion are exact; and that the other terms will, consequently, contain powers of i greater than the first, so that we shall have

$$f(x + i) = f(x) + i[f'(x) + V],$$

V being a function of x and i , which vanishes when $i = 0$.

So, since V vanishes when i vanishes, it is clear that, should i be made to increase from zero through imperceptible degrees, the value of V would also increase from zero by imperceptible degrees, either positively or negatively, up to a certain point, after which it may decrease; consequently, one will always be able to assign to i a value such that the corresponding value of V – regardless of the sign – is less than any given quantity, and that for lesser values of i , the values of V are also lesser.

Let D be a given quantity, which may be chosen as small as one pleases; one can always assign to i a value so small that the values of V are bounded by the limits D and $-D$; so, since we have

$$f(x + i) = f(x) + i[f'(x) + V],$$

It follows that the quantity $f(x + i) - f(x)$ will be bound by these two

$$i[f'(x) \pm D].$$

(Lagrange, 1884, p.86-89)

In this passage, we can see that Lagrange also had a proper numerical understanding what the value of the derivative at a given point represents, and that he did interpret limits as relationships of dependence between inequalities. For instance, he rephrased “V being a function of x and i , which vanishes when $i = 0$ ” as “one will always be able to assign to i a value such that the corresponding value of V – regardless of the sign – is less than any given quantity (...)”.

In the part of the proof which we omitted (see (Chorlay, 2012) for a more comprehensive translation), Lagrange applied the above inequalities for x -values of type $x+i, x+2i, \dots, x+(n-1)i$, determined an upper bound for the sum, then passed to the limit. In spite of the fact that the theorem Lagrange set out to prove is correct, and that the proof relied on a correct numerical understanding of the derivative construed as a limit, something does not sound right in the proof: a critical reader may spot hidden uniformity assumptions (namely: uniform derivability), and circular chains of dependent quantities (see (Barrier, 2009) for a detailed analysis of very similar cases, and (Ferraro & Panza, 2012) for recent historical work on Lagrange).

CAUCHY’S PROOF (1823)

Problem. Assuming that the function $y = f(x)$ is continuous relative to x in the neighborhood of specific value $x = x_0$, one asks whether the function increases or decreases as from this value, as the variable itself is made to increase or decrease.

Solution. Let $\Delta x, \Delta y$ denote the infinitely small and simultaneous increments of variables x and y . The $\Delta y/\Delta x$ ratio has limit $dy/dx = y'$. It has to be inferred that, for very small numerical values of Δx and for a specific value x_0 of variable x , ratio $\Delta y/\Delta x$ is positive if the corresponding value of y' is positive and finite. (...)

This being settled, let’s assume function $y = f(x)$ remains continuous between two given limits $x = x_0$ and $x = X$. If variable x is made to increase by imperceptible degrees from the first limit to the second one, function y shall increase every time its derivative, while being finite, has a positive value. (Cauchy, 1823, p.37)

Unlike Lagrange, Cauchy defined the derivative as a limit; just like Lagrange, he was able to derive proper numerical conclusions from this numerical conception of the derivative. So what makes his argument so different from Lagrange’s? Actually, they do not have the exact same understanding of what the *conclusion* to be reached is; both have implicit definitions³ of what it is for a function to be increasing, but their definitions do not match exactly. Lagrange’s definition is closer to the one we find in today’s textbook: a real valued function defined over some interval I is an increasing function if, a and b being any elements of I, $a < b$ implies $f(a) < f(b)$. Lagrange’s

³ We could use the notion of “in-action definitions” (Ouvrier-Bufferet, 2011). For a more detailed analysis of Cauchy’s proof, see (Chorlay, 2007).

(implicit) definition reads slightly differently, since he compared the values of f at 0 and at any other *given* value.

Cauchy's implicit definition of an increasing function can be rephrased as follows: a real-valued function f defined over some interval I is an increasing function if, a being any element of I , there is a neighbourhood N_a of a such that, for any x in N_a , the order between $f(a)$ and $f(x)$ is the same as that between a and x . Lagrange's definition is global, point-wise, and refers to two (arbitrarily, independently) given points; Cauchy's definition is one in which some local property holds in the neighbourhood of every (arbitrarily) given point. It can be shown – but it takes a little work – that both definitions are actually equivalent from a mathematical viewpoint⁴. However, they differ significantly, both from an epistemological viewpoint (in which, for instance, the difference between local and global properties are put to the fore), and from a cognitive viewpoint (Chorlay, 2007).

The fact that both definitions coincide from a mathematical viewpoint does not imply that proving that the first holds involves the same kind (and amount) of work than proving that the second holds. The information we start with (sign of the derivative) being of the everywhere-local-type, a mere rephrasing of the hypotheses leads to Cauchy's definition of increasing functions, hence to the conclusion. Reaching Lagrange's conclusion involves patching up local pieces of information to reach global conclusions, an endeavour which the modern reader knows to be usually tricky.

BONNET'S PROOF (IN J.-A. SERRET'S TEXTBOOK, 1868)

Theorem I.- *Let $f(x)$ be a function of x which remains continuous for values of x between two given limits, and which, for these values, has a well-determined derivative $f'(x)$. If x_0 and X denote two values of x between these same limits, the following $\frac{f(X)-f(x_0)}{X-x_0} = f'(x_1)$, will hold, with x_1 a value between x_0 and X .*

Indeed, the ratio $\frac{f(X)-f(x_0)}{X-x_0}$ has, by hypothesis, a finite value; and, if A denotes this value, we will have (1) $[f(X) - AX] - [f(x_0) - Ax_0] = 0$.

Let $\varphi(x)$ denote the function of x defined by the formula

$$(2) \quad \varphi(x) = [f(x) - Ax] - [f(x_0) - Ax_0],$$

then, from equality (1), $\varphi(x_0) = 0$, $\varphi(X) = 0$,

so that $\varphi(x)$ vanishes for $x = x_0$ and for $x = X$. Let us assume, for instance, that $X > x_0$, and let x increase from x_0 to X ; at first, the value of $\varphi(x)$ is zero. If we assume that

⁴ One must nevertheless stress the fact that if the Cauchy property holds at one given point $x = a$, it does not imply that the function is increasing in any neighbourhood of a . Consider $x + 10x^2 \sin 1/x$ in the neighbourhood of 0.

this function is not everywhere zero, for values of x between x_0 and X , it will have to either begin to increase, thus taking on positive values, or begin to decrease, thus taking on negative values; be it from $x = x_0$, or from some other value of x between x_0 and X . If these values are positive, since $\varphi(x)$ is continuous and vanishes for $x = X$, it is obvious that there will be a value x_1 between x_0 and X such that $\varphi(x_1)$ is greater than or equal to the neighbouring values $\varphi(x_1 - h)$, $\varphi(x_1 + h)$, h being an arbitrarily small quantity.

[Serret then proved that $\varphi'(x_1) = 0$, by a well-known argument; and stressed that this proof idea is Ossian Bonnet's]

(...) Theorem III.- *If the derivative $f'(x)$ of function $f(x)$ remains finite for all the values of x between the limits x_0 , if $X > x_0$, and if x is made to increase from x_0 to X , the function $f(x)$ will increase as long as the derivative $f'(x)$ will not be negative, and it will decrease as long as $f'(x)$ will not be positive.*

Indeed, since x lies between x_0 and X , the ratio $\frac{f(x+h)-f(x)}{\pm h}$ has limit $f'(x)$, which is a finite quantity; so it will be of the same sign as that of the limit, for values of h between zero and some sufficiently small positive quantity ε . Consequently, for these values of h , the following will hold

$$f(x-h) < f(x) < f(x+h) \quad \text{if } f'(x) \text{ is } > 0,$$

$$\text{and } f(x-h) > f(x) > f(x+h) \quad \text{if } f'(x) \text{ is } < 0.$$

Thus, the function $f(x)$ will increase, as from any value of x for which $f'(x)$ is > 0 ; and decrease, as from any value of x for which $f'(x)$ is < 0 . (Serret, 1900, p.17-22)

In this passage, Serret introduced Bonnet's proof of the mean value theorem, a proof idea which relied on an affine change of variable and the vanishing of the derivative at a local extremum. The existence of the extremum is not proved (at least when one compares with later rewritings of this proof), but made obvious in the *narrative* style which is so typical of the first half of the 19th century.

Strikingly, Serret did not use the mean value theorem to establish the relationship between the sign of f' and the variations of f ; he relied on Cauchy's argument, hence on Cauchy's notion of functional variation.

PROOF-ANALYSIS AND REGRESSIVE ANALYSIS

Proof-analysis: the role of uniform convergence

We identified in Lagrange's proof a flaw which can be described in several ways: implicit assumption of uniform differentiability; failure to notice that some variable is dependent on some other, while trying to consider the limit of second while leaving the first fixed; exchange, without due caution, of two limiting processes. The same flaws were common to most proofs in analysis which dealt with the numerical aspect of functions (as opposed to formal aspects) (Dugac 2003) (Chorlay 2012).

At this point, one could choose to focus on texts where the new concepts of uniform convergence/continuity were first expressed with full clarity (Dugac 2003). Instead, we would like to stress the interest of texts which criticized faulty proofs, or spotted hidden lemmas. For now, let us quote just one excerpt from the correspondence between Hoüel and Darboux⁵. In this passage (dated Jan. 1875), Darboux comments on the standard argument he read in the drafts of Hoüel's textbook:

Here is where I find fault with your reasoning, which no one deems rigorous any more. When setting

$$\frac{f(x+h)-f(x)}{h} - f'(x) = \varepsilon,$$

ε is a function of the two variables x and h which tends to zero when, leaving x fixed, h vanishes. But if x and h vary, as in your proof; even more, if every new subdivision $x_1 - x_0$ generates new ε quantities, I cannot see anything clearly any more, and your proof becomes only seemingly rigorous. (...) You could get out of this predicament in one of two ways, 1. By changing proofs altogether, which I advise you to do. 2. By proving that if a function always admits a derivative between x_0 and x_i , one can find a quantity h such that for all values of x between x_0 and x_i , and all values x_0 and h_1 of h less than some limit value, one has

$$\frac{f(x+h)-f(x)}{h} - f'(x) < \varepsilon,$$

where ε has a value which is fixed but chosen as small as one wishes; which is difficult⁶. (Gispert, 1983, p.99-100)

Regressive analysis: the role of the existence theorem for extrema

A critical mind might object to Bonnet's proof of the mean value theorem that it depends on the existence of a maximum or a minimum, an existence which is implicitly taken for granted. It seems clear that if the function is piece-wise monotonous (as seems to be assumed in the text), it will indeed admit either a local maximum or a local minimum; but a differentiable function needs not be piece-wise monotonous, as the ever useful example $f(x) = x^2 \sin \frac{1}{x}$ shows.

In fact, the existence of a maximum can be grounded without piece-wise monotony, or continuous differentiability, as Weierstrass established, for instance in his 1878 lectures on the theory of functions. The following passage has nothing to do *a priori* with calculus. It comes after the construction of the set of real numbers \mathbf{R} (or, more precisely, $\bar{\mathbf{R}} = [-\infty, +\infty]$) starting from rational numbers. Weierstrass derived the

⁵ This correspondence was published in (Gispert, 1983). It was discussed in (Balacheff, 1987).

⁶ The fact that, if the derivative is continuous, then $\frac{f(x+h)-f(x)}{h}$ does tend to $f'(x)$ uniformly on every closed and bounded interval was proved, for instance, in the second edition of Jordan's textbook (Jordan, 1893, p.68).

existence theorem for extrema as a consequence of a very general and abstract theorem, proved using nested intervals (we quote the theorem but skip the proof):

Let a value y correspond to every point (x_1, \dots, x_n) of some domain; then y is also a variable quantity, hence has a lower and an upper bound; let g denote it. Then, there exists at least one point in the x -domain (that point needs not belong to the defined domain), with the following property: if we consider however small a neighbourhood of that point, and consider the values of y corresponding to that x -domain, then these values of y also have an upper bound, this upper bound being exactly g . Similarly for the lower bound.

(...) One is commonly faced with the question: among the values taken on by some magnitude, is there a maximum or a minimum (maximum or minimum in the absolute sense). Let y be a continuous function of x , $y = f(x)$. Here, x must remain between two given limits a and b . In which circumstances is there a maximum and a minimum for y ? There is an upper bound for y . According to our proposition, there must be some point x_0 in the x -domain such that the upper-bound of the values of y for x between $x_0 - \delta$ and $x_0 + \delta$ is also g . Point x_0 either lies inside $a \dots b$, or on its border ($x_0 = a$, or $x_0 = b$).

In the first case, $f(x_0)$ is a maximum. Indeed, $f(x_0)$ must be equal to g : for $f(x) - f(x_0)$ can be made as small as we wish, by choosing an adequately small $|x - x_0|$; on the other hand, since x lies between $x_0 - \delta$ and $x_0 + \delta$, $f(x)$ can be chosen arbitrarily close to g ; hence $f(x_0) = g$. (If we had $f(x_0) = g + h$, we would have $f(x) - f(x_0) = f(x) - g - h$, and $f(x)$ could not come arbitrarily close to g if h was not 0).

If x_0 coincided with either a or b , then we could only claim that $f(a)$ (resp. $f(b)$) is a maximum if $f(x)$ was continuously at a (resp. b) as well. (Weierstrass, 1988, p.91-92)

DIDACTICAL PERSPECTIVES

Epistemological summary

First, let us attempt to summarize the pretty intricate network of definitions, proof-ideas (or proof-germs (Downs & Mamona-Downs, 2010)), proof-techniques, and proof-analyses displayed in this sample of texts. What follows constitutes an *epistemological narrative*.

At least two *definitions* of what it means for a real-valued function to “increase” can be found in the 19th-century: a point-wise and global definition which can be found in Lagrange; a definition that relies on an everywhere-valid local property, which can be found in Cauchy. If we stick to Cauchy’s definition, then the proof of the theorem about the relationship between the sign of f' and the variations of f is pretty trivial. If we want to reach the Lagrange-style conclusion, then much more work is needed, since one has to start from an everywhere-valid local property (sign of f') and reach a global conclusion.

To reach that conclusion, we saw two very different *proof-ideas*, namely Lagrange's and Bonnet's. In the proof we studied, and in quite a few other parts of his work, Lagrange distanced himself from the formal manipulation of formulae (finite or infinite), and engaged in numerical proof: he relied on the correct numerical understanding of the notion of limit; on this basis, he cautiously built networks of inequalities; he finally endeavoured to ground his reasoning on the determination of upper bounds for the errors in a process of affine approximation. In the first half of the 19th century, many proofs of the most important theorems in function theory were written along this line. Distrust of this proof-scheme spread as mathematicians grew aware of the distinction between point-wise and uniform (continuity, convergence). They spread all the more slowly since the theorems were correct, the building blocks of the proofs showed a proper understanding of the notions at stake, and local counterexamples⁷ were hard to find. As Darboux insightfully (but to no avail, as far as Hoüel was concerned) stressed, there were only two ways out of this predicament: either to change proof-germs, or to establish uniformity.

For the theorem on which we chose to focus, an alternative proof became available in the 1860s, which relied on a completely different proof-idea; unlike Lagrange's proof, it did not rely on what the derivative of a function at a point *is* (a limit, which provides some local affine approximation), but on a *property* of the derivative (stated in the mean value theorem). Some elements of Bonnet's proof were later seen as insufficiently grounded, in particular the existence of a minimum or a maximum; in the 1890s, mathematicians such as Jordan used Weierstrass' analysis of the set-theoretic properties of the real line to back up that weaker step in Bonnet's proof.

Didactical issues, and topics to be discussed

As to connections with current work on mathematical proof from a maths education research perspective, we would like to stress several features; we hope this will trigger discussion, possibly collaboration:

* Instead of focusing on *one* proof, the (abridged) corpus we presented and the epistemological narrative we based upon it deal with a *chain of proofs* (or *deductive chain*) which has remained stable since the beginning of the 20th century. The strong deductive nature of the final chain, with it seemingly necessary conceptual connections, makes it difficult to even imagine how it could have emerged progressively. The corpus shows how this emergence is (1) a collective phenomenon (a point emphasized in (Balacheff, 1987, p.148)), (2) gradual. As to the second point, it turns out that the various stages do not make up a linear chain of rigorization steps, in which each tentative proof would be more sea-worthy than the previous one. Indeed, the stages are of a much more varied epistemological nature, and do not make up one single line: really *different* proof ideas were at play; *several* forms of rigorization can be encountered, such as regressive analysis (finding conceptual

⁷ Meaning: a counterexample to a step in a proof, not to the theorem itself.

grounds from which to derive something that was previously taken to be obvious or improvable), or conceptual distinction (between point-wise and uniform). From a teaching perspective, we feel the use of such corpuses in teacher-training could help change their *image* of maths (i.e. their view of the *nature* of mathematics). We should also discuss whether or not *meta*-level, epistemological, descriptive terms such as those we used⁸ should/could be used in teacher-training.

* Here, the emphasis lies on the *reading* of proofs rather on the writing of proofs. Hence, this corpus and this narrative do not directly address central issues such as the distinction between argumentation and proof, or the question of what it takes to write a formal proof-text on the basis of a well-grounded conjecture or even a proof-idea. We focused on the analysis of proof-texts, in terms of rigour and conceptual content (i.e. concepts at play); an analysis carried out by mathematicians; an analysis which students could be asked to carry out⁹.

* In the corpus we presented, we did not lay the emphasis on the use (or misuse, or lack of use) of quantifiers. It would have been possible; it would have been relevant. We focused on conceptual content rather than on deductive rigour, and claim it leads to fruitful questions. For instance, we would like to know to what extent students are able to recognize/identify fundamental theorems or concepts, when they are stated in a slightly unusual form (think of Lagrange's wording of the theorem, or his and Cauchy's use of the notion of derivative-as-a-limit); we would like them to explore whether or not, and in what respect, Lagrange's and Cauchy's views on what "increasing function" means are equivalent.

POSSIBLE LANGUAGE BARRIERS IN PROCESSES OF MATHEMATICAL REASONING

Jenny Christine Cramer

University of Bremen

The fostering of deductive reasoning within mathematical argumentation processes is a demanding task for teachers. Deductive reasoning requires not only awareness of the epistemic value of statements but also of the structural components of mathematical knowledge. The relations between different statements become visible within mathematical arguments, and the truth of propositions is established independent from their current context. The aim of this paper is to show that this requires a certain language register, characterized by context-independency and precision, to which learners in school have different levels of access.

Mathematical reasoning, academic language, migration background

INTRODUCTION

The introduction of reasoning and proof into the NCTM standards 2000 triggered a focus on argumentation and proving in the curriculum in many countries. As mathematical reasoning is closely connected to the exploration of connections between new statements and existing mathematical knowledge, it seems to be a promising way of promoting learning. More reasoning in school thus appears to be a welcome development. Research on problem solving (Lubienski 2000, 2004) and modelling (Leufer and Sertl 2010) has however shown disadvantages for children with a lower socioeconomic background and linked these findings to Bernstein's theory of different access to the language register required in education. Knipping (2012b) points out that so far, there has not been any research on the question whether similar effects can be observed for argumentation.

Limited access to the language register required in school contexts can be seen as a possible explanation of the PISA 2000 results in Germany, which showed huge deficiencies in the performances both of students with a lower socioeconomic background and of children with migration background. In this paper I will first explore the nature of deductive reasoning and its possibilities for the learning of mathematics. Secondly, I will focus on the language required in educational contexts and the possible obstacles it holds for students from a lower socioeconomic background and learners for whom the language of education is not the mother tongue. After that, I will establish a connection between the characteristics of mathematical reasoning and the features of academic language. Finally, I will present my research approach that aims at facilitating the integrated learning of mathematical reasoning and the academic language register.

ARGUMENTATION, PROOF AND DEDUCTIVE REASONING

Much has been said about the “complex, productive and unavoidable” (Boero, 1999) relationship between argumentation and proof. Following Toulmin (1958), proof can be considered as a special form of argument. Toulmin sees arguments as steps from a datum or a set of data to a conclusion, justified by a warrant for which backing may be produced if necessary. Mathematical proofs follow the same structure, ideally relying on axioms or established mathematical knowledge as data, and using rules of logical deduction in order to arrive at a conclusion. In mathematical practice however, Hanna and de Villiers (2012, p.3) state that “a proof is often a series of ideas and insights rather than a sequence of formal steps”. In academic mathematics, the scientific community has been negotiating the rules for proving for a long time, and mathematicians generally have an idea about which steps in a proof they may omit (Knipping 2012b).

For school mathematics however, Knipping (2012b, p.4) points out that “there are no previously negotiated criteria for argumentation”. These criteria need to be agreed upon by the community in which argumentation takes place. School mathematics cannot take an axiomatic approach to proving, or assume that the students know which types of deduction are acceptable. The role of the social community is crucial for argumentation processes. I follow Knipping’s definition, which takes the social community into account and defines argumentation as “a sequence of utterances in which a claim is put forward and reasons are brought forth with the aim to rationally support this claim” (Knipping 2003, p.34, my translation). This definition encompasses proof and deductive reasoning.

As pointed out before, mathematical argumentation can be seen as a continuum, reaching from very informal arguments and inferences based solely on the authority of the speaker to strictly logical proof. These kinds of arguments differ significantly in the way in which they use deductive inferences. Not every argumentation in mathematics contains deductive reasoning. Aberdein (2012) sees mathematical argumentation as consisting of two parts. It is characterised by an underlying inferential structure, which follows strictly logical criteria, and an argumentation, which is the visible part of the argument. The argumentational part seeks to convince others that logical criteria have been obeyed and that the given inferences are valid. In order to account for this two-layered view on mathematical argumentation, Aberdein has suggested a categorization of arguments into different schemes. Arguments in which every step is a deductive transmission from the premises to a conclusion are characterized as A-scheme arguments because of the direct connection between argumentational and inferential structure. Mathematical proof falls into this category, as justifications based on logical deduction are given for each step of the argument. If the connection to the inference structure is less clear, but could theoretically be made explicit in a limited number of deductive steps, Aberdein classifies the argument as B-scheme. This type of argument is based on deductive reasoning; however, intermediate steps may be omitted or references to statements

proven elsewhere may be included. In academic mathematics this is often the case in proofs presented in mathematics journals, where some steps are omitted and left for the qualified reader to complete. Deductive reasoning is a prerequisite for A- and B-scheme arguments as it ties the logic of the inferential structure to the visible argumentation. The last category for arguments proposed by Aberdein is the C-scheme. All arguments without direct or indirect reference to the inferential structure are contained in this category. Typical for this category are visual arguments and other informal argumentation techniques which make no use of deductive reasoning.

Mathematical reasoning and learning mathematics

As all of the presented argument types occur in academic mathematics, school mathematics needs to face the question, which kinds of argumentation it wants the students to engage in. C-scheme arguments can be very helpful in conjecturing processes, as they lead to assumptions about possible hypotheses. In order to systematize new mathematical knowledge however, some connection to an inferential structure needs to be established. Arguments that are solely based on informal practice or intuition cannot show what the truth of statements and their relationships depend on. They do not explain why a statement is true. However, Hanna (2000), de Villiers (1990) and others have pointed out the importance of the explanatory potential offered by a proof based on deductive reasoning. The direct link to the inferential structure also simplifies the systematization of new knowledge into the existing internal mathematical knowledge structure.

In recent years, there have been many attempts to make proving more accessible to students. As deductive reasoning is necessary for proving, much about its fostering can be learned from these approaches. Boero, Garuti, Lemut and Mariotti (1996) introduced the concept of cognitive unity between conjecturing and proving. This concept states that proving becomes easier if during the conjecturing phase, students discover arguments that they can later use in the proof. Suitable tasks must be chosen in order to enable the discovery of important arguments. Knipping (2012b) compares the restructuring of arguments found in the conjecturing phase into a deductive chain to a transition from Aberdein's C-scheme to B- or A-scheme arguments.

Another approach for dealing with proofs in school was developed by Hanna and Jahnke (2002). In this approach, the importance of hypotheses for proving is emphasized, and Freudenthal's concept of local organisation plays a major role (Hanna and Jahnke 2002, p.3). At the beginning of a new exercise, the learners are engaged in measuring and experimentation, which leads to a speculation about possible hypotheses. When several hypotheses have been collected, the students are asked to create connections between them and put them into a structure, thereby establishing a local order. Jahnke (2009) emphasizes the importance of inferences for mathematics. With Aberdein's scheme, the established structure between the hypotheses based on the newly created local order can be characterized as B-scheme or A-scheme arguments. Emphasis is not put on the validity of the hypotheses but on

the certainty of the inferences. The learners work out a deductive chain that is valid as long as the hypotheses are true.

The specification of starting conditions and the insight that statements are dependent on other statements are characteristics of mathematical reasoning, and especially of deductive reasoning. Reasoning which has its origins in an inferential structure requires awareness of the mathematical background of theorems. Having established the connection of a new statement to existing mathematical structures, further exploration becomes possible. Bikner-Ahsbabs et al. (2011) have pointed out the potential of mathematical reasoning for learning mathematics. Reid (2001) has described how deductive reasoning plays a role in the acceptance of explanations. Connections and links between new knowledge and existing knowledge are forged, and bridges between previously independent islands of knowledge are established by mathematical reasoning. Schoenfeld (1994, p.68) claims that “looking to perceive structure, seeing connections, capturing patterns symbolically, conjecturing and proving, and abstracting and generalizing” are fundamental to mathematics. All of the processes mentioned in the quote are also important in mathematical reasoning. Thus, promoting the ability to reason deductively seems to be a promising path in order to enable students to learn mathematics.

Possible obstacles in the teaching of mathematical reasoning

However, more deductive reasoning in schools may also trigger some unwelcome effects. Lubienski (2000) has pointed out that not all students benefitted equally from the greater emphasis that was put on problem solving in recent years. Her findings showed that while learning was fostered for both students from lower and students from higher socio-economic backgrounds, the open and context-embedded material increased the gap between the two groups. The group of students from a lower socioeconomic background was much slower in its progress, and these students often felt insecure about the acceptability of their arguments. Many of the students uttered the wish for more support by the teacher. Furthermore, the arguments brought forth by these students were often directly linked to the context given in the task, without focussing on the intended mathematical background.

For mathematical modelling, similar problems were observed by Leufer and Sertl (2010). The application of mathematics on realistic problem situations was supposed to increase motivation and bridge the gap between school and real life, especially for students from lower social classes. However, especially these students had problems in solving the given tasks.

A possible explanation for these differences in achievement between students with higher and lower socioeconomic status given by Lubienski and by Leufer and Sertl is based on Bernstein’s sociology of education. According to Bernstein (2003), the social class of the speaker influences the language register he or she is capable of, and likely to be, using. Bernstein distinguishes between restricted and elaborated codes. The different codes are characterized by specific discourse forms and different

conversation modes. Language of a restricted code takes place in situations of temporal and spatial proximity. The discourse can be classified as horizontal (Bernstein 1999), is dependent on the immediate context in which it is spoken and can, while coherent in one given context, be illogical across different contexts. Elaborated code, on the other hand, is characterized by its reference to objects that are not necessarily tangible. It makes use of vertical discourse, which is marked by context-independency, coherence, and the ability to abstract from concrete objects. Bernstein (2003, p.109) describes that, while restricted code appears in all social classes, children from a working class background are often limited to this type of language. In contrast to this, children from the middle and higher classes experience the usage of both restricted and elaborated code at home.

The considerations of Bernstein explain general deficiencies of children from a lower socioeconomic background in school, as elaborated code usually is the required language register in the educational context. In order to see which kind of language is demanded in a certain situation, Knipping (2012a) describes Bernstein's approach of necessary recognition and realisation rules. The usage of real-world contexts in mathematical tasks impedes the recognition of the expected vertical discourse. These problems of children from a lower socioeconomic background have not been analysed with a focus on argumentation yet. Mathematical reasoning requires many processes of abstraction and generalization. It can be expected that children with limited access to vertical discourse encounter problems.

ELABORATED CODE AND SECOND LANGUAGE LEARNING

Bernstein's theory of linguistic codes is concerned with children from different socioeconomic backgrounds. Social class, however, is not the only factor for language learning and achievement in school.

The results of PISA 2000 forced the German educational system into becoming aware of the fact that a successful participation in school is closely connected to the personal background of students. Both immigrant children and children with lower socioeconomic status turned out to achieve lower overall results. Heinze et al. (2011) present results from a follow-up investigation of children with migration background using the DEMAT testing material; it was shown that language proficiency in the German language has a higher influence on achievement in mathematics and cognitive performance in general than on reading skills.

If the language used in the educational system is not the speaker's mother tongue, special problems are encountered. In order to account for the specific challenges for second language learners, Cummins (2008) introduced the notions of BICS and CALP in order to distinguish between different levels of language. BICS stands for basic interpersonal communication skills, CALP means cognitive academic language proficiency. Duarte (2011, p.60) pointed to different results showing that the acquisition of BICS can be achieved within two years of being exposed to the new language, CALP abilities usually require at least five years.

In general, academic language shows the characteristics Bernstein pointed out for vertical discourse, whereas everyday speech can be compared to horizontal discourse. Duarte (2011) has given a concise overview on the characteristics of academic language compared to those of everyday speech. The features of the different language levels are listed in Table 1.

Academic language	Everyday speech
Orientation towards written language	Oriented towards spoken language
Abstract, symbolic	Concrete, factual
Context-disembedded	Context-embedded
Generalizing	Specific
Can be technical and domain-specific	Unscientific, general
Linguistically concise	Linguistically diffuse
Precise	Imprecise
Impersonal (uses personal pronouns)	Personal (usually agents are explicit)
High degree of cohesion	Partially unstructured and loose
High lexical density	Low lexical density

Table 1: Main differences between academic language and everyday speech (Duarte, 2011, p. 71, adapted and shortened)

In addition to the obstacles shown in table 1, which are true for the academic register in all languages, Duarte (2011, p.71) lists some features of German academic language. Among these are the use of sophisticated verbs instead of simple verbs with prefixes, adjectival and adverbial attributes, and nominalisations. Gogolin (2009) has introduced the term “Bildungssprache” to account for these special characteristics of German academic language. Referring to Habermas, she defines Bildungssprache as “the language register which enables to gain orientational knowledge using the means of school education” (Gogolin 2011, p.108, my translation).

Children with a migration background in Germany often come from families with a low socioeconomic status and little education (Gogolin 2009, p.267). As shown before, this leads to further disadvantages in the familiarity with elaborated code before entering school. These obstacles are important in all subjects and must be taken into account by teachers.

Language requirements for deductive reasoning

A bigger emphasis on reasoning in the mathematics classroom must take into consideration possible language barriers. Children from all backgrounds are likely to

understand language based on basic interpersonal communication skills. On the other hand it is visible in the definition of Bildungssprache by Gogolin given above that academic language abilities are needed in order to gain orientational knowledge in a new context. Thus, fostering CALP should be one aim of education in all subjects, also in mathematics. In addition to this demand, mathematical reasoning has some characteristic features that make academic language not only desirable but also necessary.

Mathematical reasoning takes place *abstracted from concrete situations*. Processes of reasoning in mathematics establish a link between new knowledge and existing knowledge structures. These knowledge structures are internal and show hardly any connection to tangible objects. Furthermore, mathematical reasoning frequently makes use of *generalizing* techniques, especially in the inference rules used in deductions. Another feature of mathematical reasoning is the *precise, coherent and concise form* desired as the outcome of the reasoning process.

All of the named features are also characteristics of the academic language register. From this I conclude that academic language can hardly be avoided in the teaching and learning of reasoning. The required language register can quickly become an obstacle. I am convinced, however, that the close relationship between mathematical reasoning and academic language also offers many learning opportunities.

FIRST INSIGHTS INTO MY RESEARCH WORK

In my research, I am working as a teacher-researcher in a project for children with a migration background whose mother tongue is not German. They come to university once a week to receive support in different subjects in groups of 4-6 learners at no charge. The students come into the project from different schools. From September 2012 until July 2013 I am teaching and researching in two groups of students, one group is in their 9th year in school and the other in their 11th year.

I am collecting data from three different sources. Videotaped interviews at the start of the project, before Christmas and towards the end, combined with a reasoning task, are used as control points for the students' views on and abilities in deductive reasoning. In the first interview I found that in the mathematics classes in the schools of most of the students, hardly any reasoning takes place. For material creation and in order to have a second opinion on developments in the groups, there are weekly consultations with David Reid as an expert on reasoning, which are audiotaped. The third data source is the videotaped material from the lessons. In addition to all that, I keep a research diary in which I keep track of my experiences. The videotaped material will be evaluated at the end of the project, in order to retrace the individual development of mathematical reasoning.

Material development within the project takes place on a weekly basis, constantly taking into consideration the consultations with David Reid and the immediate impressions from the previous lessons. I am developing language sensitive material that creates opportunities for mathematical reasoning. In task creation, I am inspired

by the cognitive unity approach developed by Boero et al. (1996) as well as by the approach concerning the local organisation of hypotheses by Hanna and Jahnke (2002). In both groups I detected large gaps in the knowledge from previous school years. This led to the decision of not only focussing on topics from their current grade but also including topics that the children are supposed to have dealt with in the past.

In the following, I will present some material on linear functions from my grade 9 group. In the previous lesson the children had been working with laptops, developing some hypotheses on the influences of the chosen parameters on the slope and y-intercept of linear through a game in Geogebra. In the next lesson I tried to deepen the understanding in this area in a paper task on which the students worked together. Once again, they were given two tasks with points on a coordinate grid; this time, however, the points in each grid belonged to just one function. (Fig. 1 and Fig. 2).

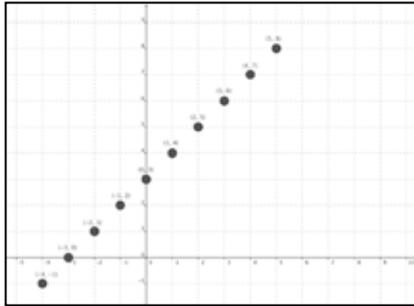

Fig. 1 First task

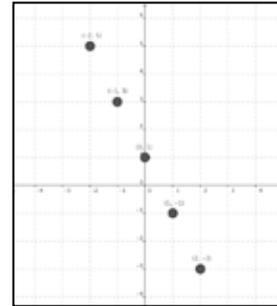

Fig. 2 Second task

Additionally, a table of values for each of the two functions was given. The students had to complete several sentences such as: “If the value for x increases by 1, ...”, “The intersection point of graph and y -axis is...”, “If you put a 0 for x into the equation $y=m \cdot x+b$, the equation simplifies into...”. These sentences make use of language from the academic register. When the students had come up with a suggestion for an equation on which they all agreed, they were allowed to check its correctness on Geogebra.

After having discussed about the influence of the chosen parameters in linear functions, a third task was given, “Find a linear function which goes through the point $(0|2)$ and is parallel to the function from task two”. The students engaged in a vivid discussion on the solution to this task. There was no agreement on a solution until one girl came up with the argument that m defines the steepness of the graph, and therefore it has to be the same in the two functions.

After six months, generalization and abstraction have turned out to be major problem areas, especially in the grade 9 group. The main difficulty seems to lie in the transition from example-based observations to the creation of general hypotheses. Further tasks will be examined in order to assess obstacles for deductive reasoning more clearly.

PRESENTATION AND SETTING UP OF A MODEL OF ANALYSIS OF REASONING PROCESSES IN MATHEMATICS LESSONS IN PRIMARY SCHOOL

Patrick GIBEL, Laboratoire LACES, Université de Bordeaux

***Abstract:** The purpose of this paper is to consider reasoning processes elaborated by the pupils during a lesson “The biggest number”, proposed in a class of fifth graders at primary school. We would like to describe our model of analysis, in order to highlight the main elements which structure the analysis. This research, made mainly within the framework of the theory of didactical situations in mathematics, aims at analysing on one hand pupils reasoning processes, specifying their functions, on the other hand, the conditions in which the reasoning processes are produced.*

Key words: reasoning, arithmetic, proof, situation of validation, semiotics.

INTRODUCTION

The first part of this paper aims at describing briefly the model of analysis for reasoning processes elaborated by Bloch & Gibel (2011) and establishing its relevance to analyse a mathematics lesson involving a research dimension. In the second part, we will present the lesson “The biggest number” proposed in a class of fifth graders at primary school (pupils age 10 to 11). We will make interest aspects and propose an a priori analysis of this lesson. In the third part, we will present the specificities of this lesson, explaining the different didactical situations (situation of action, situation of formulation, situation of validation) in order to identify and characterize the different shapes and functions of reasoning processes.

1. PRESENTATION OF THE MODEL OF ANALYSIS FOR REASONING PROCESSES

1.1 The theoretical tools used in the elaboration of the model

The subtle analysis of the reasoning processes produced, in a situation of validation, cannot be limited to an analysis in terms of propositional calculus based on Lorenzen’s dialogical logics, as Durand-Guerrier points out (2007).

The need to take into account the semantic dimension, when analysing the reasoning processes, has contributed to sustain and justify our decision to choose the Theory of Didactical Situations (TSD), elaborated by Brousseau (1998), as foundation of our model. This theoretical framework must, however, be completed with tools of local analysis, and with an analysis of functions of the reasoning processes (Gibel, 2004) and of the signs, both formal and linguistic, which back it up. We will present the

theoretical framework used to perform the semiotic analysis in the following paragraph.

1.2 The semiotic dimension of the analysis

During our previous research (Bloch & Gibel, *ibid.*) we underlined the fact that reasoning processes elaborated by the pupils and the teacher during a lesson, can take diverse forms: linguistic, calculative, scriptural, and graphic elements. Consequently the semiotic analysis constitutes one of the dimensions of our model, completing those previously presented: on the one hand the function of the reasoning processes and on the other hand the corresponding level of the didactical milieu.

Pierce's semiotics seems particularly appropriate for our research and will indeed enable us to study more precisely the evolution and the transformations in the signs used by different actors of the lesson.

In our application of Pierce's semiotics we will use the three designations: icon, index sign and argument-symbol. An iconic interpretation is based on intuition, sometimes based on a diagram, or using a programme of calculations; an index sign is to do with a proposition, for example, in the sequence studied, "the biggest number is obtained by multiplying the five (whole) numbers given", considered as an argument-symbol related to a mathematical proof.

1.3 The didactical repertoire and the repertoire of representations

All semiotic means used by a teacher and those he expects from his pupils, through his teaching, form the didactical repertoire of the class as defined by Gibel (2004).

The didactical repertoire of the class can be identified as being part of the mathematical knowledge that the teacher has chosen to explain, namely for validation and during institutionalization.

The repertoire of representations is a constituent part of the didactical repertoire. It is made up of signs, diagrams, symbols and shapes and also linguistic elements (oral and/or written sentences), which make it possible to name the objects encountered and to formulate properties and results.

1.4 Methodology. The model of analysis for reasoning processes

The model of structuration of the didactical milieu used in this model is that of Bloch (2006). The chart below (Table 1) sums up the levels of milieu – from M1 to M-3 – corresponding to the *experimental* situation.

The negative levels are of particular interest in the sequence studied i.e. the appearance of a proof process in the setting up of a situation involving a research dimension.

It is in terms of the articulation between the objective milieu and the reference milieu that we hope to see the expected reasoning processes appear and develop.

M1 Didactical milieu	E1: E-The universal subject	P1: P-planner	S1: Project situation
M0 Learning milieu : Institutionalization	E0: The generic student	P0: The teacher teaching	S0: Didactical situation
M-1 Reference milieu : Situation of formulation Situation of validation	E-1: E-The subject as learner	P-1: P Regulator	S-1: Learning situation
M-2 Objective milieu : Situation of action	E-2: E-The subject as an actor	P-2: P The teacher devolves and observes	S-2: Situation of reference
M-3 Material milieu	E-3: E-The epistemological subject		S-3: Objective situation

Table 1 – Structuration of the didactical milieu

In the previous research (Bloch & Gibel, 2011), we decided to focus on didactical analysis on three main “axes” of study used to guide our analysis of the reasoning processes.

The first axis of study is linked to the nature of the situation: in a situation involving a research dimension, the pupils produce reasoning processes which depend to a great extent on the nature of the situation (situation of action, situation of formulation or situation of validation) in relation to the level of the corresponding milieu (Table 1).

The second axis of study is the analysis of the functions of reasoning.

We will try to bring together the previous two axes of study by showing how the reasoning functions are linked to the situation specifically to the levels of milieu and how these functions also *manifest* these levels of milieu.

The third axis of study is that of observable signs and representations. These things can be observed in different forms which affect the way the situation unfolds.

The application of the model to the situation will be followed by an analysis of the milieu and semiotic analysis of the students’ and teachers’ productions.

In conclusion, we classify reasoning, calculations, formulas, depending on the characteristics of the situation and knowledge(s) expressed by students in the

previous phase, which reflect the situation in which they are located, and the nature of signs produced. Our project consists in using our model to analyse reasoning processes in a situation of validation involving a research dimension, proposed in primary school.

2. PRESENTATION AND A PRIORI ANALYSIS OF THE DIDACTICAL SITUATION “THE BIGGEST NUMBER”

2.1 Origin of this problem

The mathematics problem below was originally proposed by G. Glaeser (1999):

Take any five natural numbers a, b, c, d, e . What is the biggest number that can be obtained using the four elementary operations $\{+, -, \times, \div\}$ applied to these numbers which can only be used once in the calculation; the same operation can, however, be used several times.

The setting up of this sequence at the C.O.R.E.M. is linked to the encounter of Brousseau and Glaeser, which was at the origin of this didactical project. The problem proposed is an open problem; G. Brousseau’s idea is to get the pupils to discuss mathematical statements following rules which lead them to produce proof, and, more precisely, to search for counter-examples.

The analysis of this sequence, using our model, should enable us to provide some answers to the following questions:

What are the different forms of reasoning processes which come into play in the different phases of this sequence? What functions do they cover? What level(s) of milieu do they refer to?

2.2. Elements of a priori analysis of the sequence

2.2.1. Analysis of the nature of the expected answer to the problem proposed

To determine the nature of the answer expected answer by the teacher it is necessary to distinguish the conditions in which the answer must be given:

- If the sequence of numbers is given by the teacher, the answer expected is a number together with the programme of calculations enabling it to be obtained.
- If the five numbers are not given, that is to say if one is presented with a general case, then the proper answer will be a method of calculation. However, it must be emphasized that writing an algebraic expression will not be appropriate because it is necessary to distinguish different cases according to the sequence of numbers under consideration.

In the second case we are led to consider the algebraic expression

$$a \times b \times c \times d \times e$$

where a, b, c, d and e designate any five whole natural numbers.

Yet this algebraic expression is only valid, to obtain the biggest number, from a given 5-uplet, if none of the five numbers is 0 or 1.

The field of validity of this natural algorithm is not immediately obvious, it should lead the pupils to ask themselves questions about the status of the numbers 0 and 1.

It must be pointed out that, to obtain the biggest number, it is necessary in the presence of one or several 0's to determine the biggest number of the sequence of whole numbers excluding the zero(s), and to add the zero whole number(s) afterwards, which means distinguishing special cases when formulating the method.

2.2.2. Didactical analysis of the lesson

One of the objectives of this lesson is to make it possible for pupils to move progressively from arithmetic to general statements of methods enabling them to win. The lesson also aims to teach the rules of the game of proof: it is a lesson on right and wrong but also on the way of establishing it. The main objective of the lesson is therefore to put the pupils in a situation where they are led to discuss the validity of methods for obtaining the biggest number, whatever the sequence of numbers proposed.

In this situation, it is anticipated that the rejection of a method will go together with the production of a counter-example, more precisely to the production of a sequence of five numbers and of a new method leading to the production of a new number – higher than the one obtained by the method proposed originally.

3. ANALYSIS OF THE DIDACTICAL SITUATIONS

In order to carry out an analysis of the reasoning processes produced, we use, first of all, the structure of the didactical milieu chart to distinguish the « embedded » situations corresponding to the different milieu (Brousseau et Gibel, 2005). The different didactical situations which appear in the conduct of this lesson are successively: situation of action, situation of formulation and situation of validation.

Concerning the lesson “The biggest number”, our model should enable us to analyse a posteriori, the transformations occurring during the reasoning processes produced by the pupils as regards their formulation, taking into account their functions in the didactical relation.

3.1 The situation of action

In the analysis of the sequence « The biggest number », the teacher's objectives are, on the one hand to present the rules of the game, and, on the other hand, to lead the pupils to formulate the number obtained and the justification of the programme of calculation.

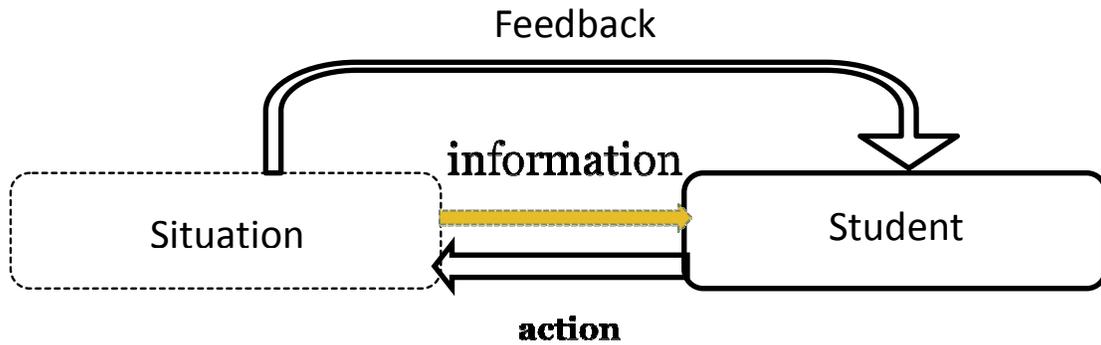

Figure 1-Situation of action

“When the teacher devolves the objective situation to the students, they are faced to the situation of action. They take information from the objective situation, act on the situation and get feedback.”(Brousseau,1998)

The situation of action (Figure 1) constitutes the process by which the students form strategies.

The dialectic of action leads pupil to produce reasoning processes corresponding to different functions: taking a decision and justifying the validity of the number obtained.

After the two games proposed to the pupils (Appendix), the teacher presents to the pupils the *situation of formulation*, which we explain in the next section.

3.2 The situation of formulation

The objective of the situation of formulation is that pupils write down a *general* method, that is to say one that can be used to obtain the biggest number whatever the sequence of five numbers proposed.

So the objective is to get the pupils to produce a method whose field of validity is the largest possible. The situation of validation aims at giving pupils the possibility to take a clear position concerning the action, and therefore to become fully aware of the decisions on which their actions are based, so that they can produce procedures whose validity can be discussed.

Each group must write a method, a *general* method, enabling them to obtain the biggest number whatever the sequence of five integers proposed.

It must be pointed out that, to obtain the biggest number, it is necessary in the presence of one or several 0's to determine the biggest number of the sequence of whole numbers excluding the zero(s), and to add the zero whole number(s) afterwards, which means distinguishing special cases when formulating the method. Moreover it is necessary to distinguish different cases, according to the numbers of 1's included in the sequence of numbers.

Denoting N , as the biggest number and distinguishing the different cases, we obtain

Case n°1 If the sequence includes one 1, 1-b-c-d-e with $1 < b \leq c \leq d \leq e$ then

$$N = (b+1)cde$$

Case n°2 If the sequence includes two 1's, 1-1-c-d-e with $1 < c \leq d \leq e$

If $c=d=2$ then $N = (c+1)(d+1)e$

else $N = (1+1)cde$

Case n°3 If the sequence includes three 1's, 1-1-1-d-e with $1 < d \leq e$ then

$$N = (1+1+1)de$$

Case n°4 If the sequence includes four 1's, 1-1-1-1-e with $1 < e$

If $e=2$ then $N = (1+1+1)(e+1)$

else $N = (1+1+1+1)e$

Case n°5 If the sequence includes five 1's, 1-1-1-1-1 then $N = (1+1+1)(1+1)$

During the situation of formulation, the pupils use reasoning processes to formulate a general method. They produce reasoning processes which allow them to consider special cases similar to those described previously.

3.3 The situation of validation

During the situation of validation there are discussions between the groups about the validity of the methods. The didactical scheme of validation (Figure 2) motivates the student to discuss a situation and favours the formulation of their implicit validations, but their reasoning is often insufficient, incorrect, and clumsy.

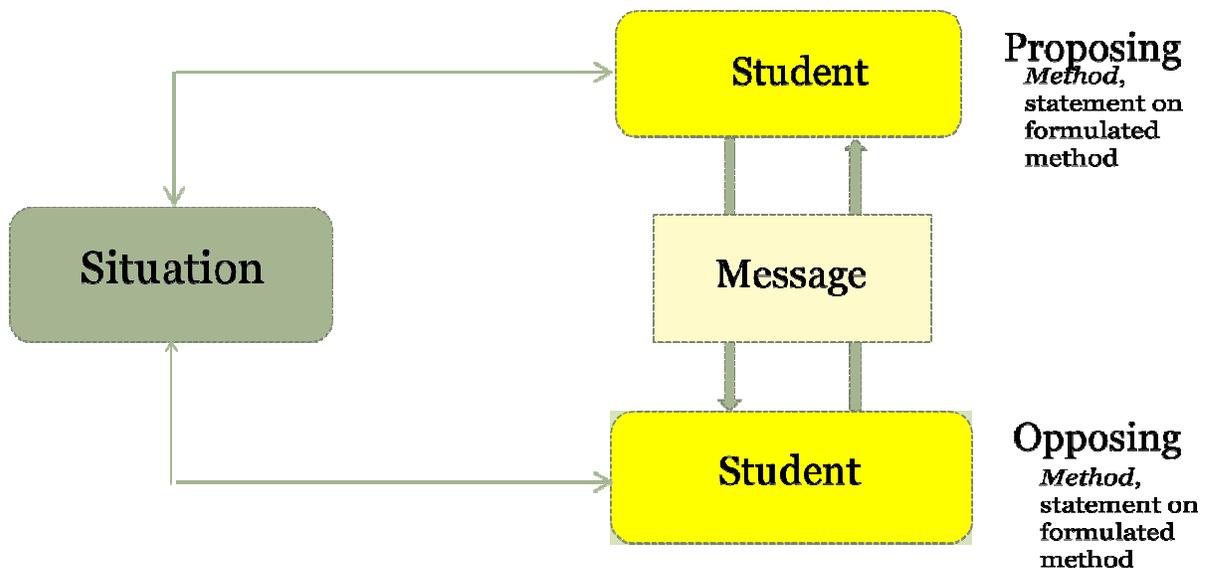

Figure 2-Situation of validation

The level (M-1), detailed in Table 1, is that of assertions. At the previous level, (M-2), we were at the level of mathematical relations, the truth was obvious, the relation was right or wrong but there was no judgment made. Whereas at level (M-1) the pupil, having the status of opponent in a situation of validation, arrives with a certain culture, and knowledge linked to the didactical repertoire he/she has at his/her disposal.

3.4 The didactical situation: the pupil and the learning situation

The didactical situation, for example a new game, based on a sequence of numbers proposed by the teacher, leads pupils to evolve or to revise their opinions. Thus the teacher can choose a sequence of numbers that leads them to develop a new method of calculations which includes specific cases that they had not previously considered.

Moreover if students cannot find a counter-example to invalidate a method, the teacher may decide to submit a new game that highlights the shortcomings of a method to get the largest number. Thus students become aware of the shortcomings of the program calculations and encouraged to write another one.

CONCLUSION

The analysis of the didactical situations allows us to highlight the different shapes of reasoning processes which appear all along the lesson. The model offers us the possibility to analyse the different functions of the reasoning processes in different didactical situations (situation of action, situation of formulation and situation of validation).

The model underlines the reasoning processes produced and links them up to previous knowledge and awareness of didactical repertoire concerning elementary operations and properties of multiplication. Concerning formulations, the model shows their evolution in relation to the different situations: one goes from giving sequences of arithmetic calculations to the formulation of general methods, of an almost algebraic nature, to end up with the production of semantic and syntactic arguments during the situation of validation. The semiotic analysis also shows the gap between the formalism introduced by the teacher and the repertoire of signs mobilised by the pupils throughout the lesson.

RESEARCH SITUATIONS TO LEARN LOGIC AND VARIOUS TYPES OF MATHEMATICAL REASONINGS AND PROOFS

Denise GRENIER

Institut Fourier (Department of Mathematics)

Resarch Federation Maths-à-Modeler – Université de Grenoble I (France)

Abstract – *We present an analysis of the role of research processes and experimental activities in our “Research Situations”, allowing students to learn fundamental knowhow in mathematics : experimentation, studying particular cases, reasoning, formulation of conjectures, examples and counterexamples, generalizing, proving, etc, as described in curricula and related documents of French junior high schools and high schools. The reasoning and proving processes are a full part of our SiRC. This will be illustrated here with examples.*

Key-words – *Research Situation, mathematics investigation, logic, reasoning, proof.*

INTRODUCTION

Routine researcher activities comprise elementary tasks such as : choosing a question, experimenting, studying special cases, choosing a solution framework, modelling, reasoning, stating conjectures, proving, defining, eventually changing the initial question, etc. *Knowledge and tools* to tackle these tasks are intrinsically part of a scientific approach, they are necessary to do mathematics and cannot be brought down to mere technics or methods.

In many countries, these basic tools are not available to a majority of scientific students. What they do and say when confronted with an « open problem » shows that their relation to mathematics is very far from the mathematician standpoint :

- « I don't know how to solve this problem, because it's new for me »
- « I don't know what to do, because I don't know the technique »
- « This problem is badly formulated, hypotheses are missing »
- « To which chapter is related this problem ? »

French mathematical curricula insist on experimentation, discovery and quality of scientific classroom activity for learning different types of reasoning and proofs, and involve some elements of mathematical logic. However, in schoolbooks and teaching practices, these objectives are not really treated, and the experimental approach and research activities are scarce. The objections raised by teachers to avoid the research situations in class are the institutional constraints and a lack of training to grasp and manage such situations. The idea that, in mathematics, one can experiment, model, study specific cases, infer conjectures from examples, is not present in the standard didactical procedures. Mathematics are seen as a service discipline, that offers a set of techniques and computation algorithms, although these can sometimes be

sophisticated. Theoretical and fascinating aspects are kept inaccessible and reserved to experts.

The consequences of such positions and choices include attitudes and practices that seem to go against those which would precisely enable a significant research activity :

- Students are not allowed to change the hypotheses, nor to choose their own solution framework.
- Two strong « rules » become implicit, when students have to write or validate their proof :
 - « **Only** the problem data and the properties taught in class should be used in the proof »
 - « To complete a proof, one has to verify that **all** the hypotheses given are used »
- The mathematical activity is reduced to the technique of writing the proof, thus shrinking the research and arguing initial process.

HYPOTHESES TOWARDS GUARANTEEING A GENUINE MATHEMATICS ACTIVITY

H1. There is no real possibility of an investigation if a « toolbox » (theorems, properties, algorithms) is available and designated for the resolution of an obvious question. There is no real mathematical activity without a truth issue that can be taken and tested by students, while being non obvious to prove.

H2. It is neither necessary nor sufficient to arrange « real life » contexts (Coulange 1998) to perform a research or an experimental investigation : such contexts do not guarantee the relevance of the problem, and can even make noise that impede the investigation and the understanding of the underlying logic.

H3. It is not reasonable to propose research situations that bring into play mathematical concepts in construction. As a further advantage of avoiding such lapses, the problems will be accessible to many levels of knowledge (sometimes from primary school to university).

Our research work consists in conceiving appropriate specific situations – e.g. problems and didactical staging (in the sense of scenic design) – available in different institutional contexts, in experimenting them and analyzing their effects on the learning of mathematical reasoning, proofs, and the underlying logic.

CHARACTERIZATION OF THE MODEL “SIRC”¹

This didactical model was already in gestation in Arsac & al. 1995 and Grenier & Payan 1998. Recall here the characterization of the SIRC model, as it has been described in Grenier & Payan 2003 & 2007. As any model, it is a reference (both epistemological and practical) for situations that we build, which can somewhat differ from the model.

¹ SiRC : “Situation de Recherche pour la classe” , ie. “Research Situation for Classroom”

- A SiRC is similar to an *actual question* in mathematical research or in a non « didactified » one. This condition, very restrictive a priori, aims to avoid the question or the answer may seem obvious or familiar. The objective is to give relevance to the research activity. This condition can be artificially recreated by the « staging » of the problem.
- The initial question is easy to understand at various levels of knowledge. Our intention is to break with the usual didactic practice that tends to attribute any problem to a specific grade level. To fulfill this requirement, the statements must in general be not as heavily mathematized. However, we try to avoid random real life « noises », which complicate the task of students in non-mathematical « concrete » problems, and sometimes prevent them from entering into actual mathematics.
- Strategies to start with are available, but they won't solve the problem completely – usual techniques or properties are not sufficient. In other words, one must ensure the devolution of the problem, by leaving space to some uncertainty that cannot be reduced just by applying known techniques or usual properties (i.e., what Brousseau described in his theory as a « good » situation). The theoretical framework of resolution is neither given nor obvious.
- One can use several strategies, such as « trials and errors », study particular cases, etc ; relevant conjectures are not obviously true, counter-examples are attainable. These points are meant to encourage the construction of conjectures by students, based on an exploration of the question investigated. These conjectures can be examined by the students, through accessible examples and counterexamples.
- Hypotheses, or the initial question, can be changed. One can change the assumptions or the original question, and grab a new problem. The initial question can lead to related questions : closing a problem through the choice of certain parameter values, or starting a new research activity.

A SiRC is characterized by some *research variables* : problem's parameters which could be didactical variables (i.e. at teacher's disposal), but that are left at the student's disposal. The *social organization* is constitutive of a SiRC : working in small groups, material to play and search, time sufficient to search and discuss. Teachers dealing with a SiRC is a specific activity : training teachers is necessary.

Methodology and experimental results

The SiRC didactical model (Research Situations for Classroom) has been studied in the “Maths-à-Modeler” team for 15 years, using classical didactical theories and methodologies : construction of situations, experiments with numerous students at many different levels of knowledge (several hundreds of students) and analyses of the results. Some of these SiRC have been integrated in certain courses at university and in secondary schools. Results have been published in articles (Grenier 2002, 2003, 2008a, 2008b, Tanguay & Grenier 2009 & 2010) and in Theses (Ouvrier-Bufferet 2003, Deloustal-Jorrand 2004, Godot 2005, Cartier 2008, Giroud 2011). We give in annex 1

a list of Research Situations for Classroom which have been studied for more than ten years.

Example of different types of reasonings and proofs worked in a SiRC

In the SiRC given in annex 2, « Tiling polyminoes with dominoes », in the case where the polymino is a square and $n = 3$, at every level of knowledge, properties and *conjectures* emerge from experimentations and research (Grenier 2008b):

A necessary condition to tile a square, that is *not sufficient* – this result can be proved by a very easy *counter-example*; Then, a *necessary and sufficient condition* to tiling emerges, according to the position of the hole. The proof consists in two steps: first, a *proof of impossibility* – by a « forced solution » tiling (*reductio ad absurdum*) – and a *proof of possibility* – by exhibiting an *example* of tiling (*existence property*).

Inductive and deductive reasonings and proofs in mathematics

Leading students to these admittedly different types of reasoning - inductive and deductive reasoning – is a declared goal of French college and high school programs. Generally, inductive reasoning aims to generalize to other objects a property known for certain objects, or to build new objects. Mathematical induction differs from induction in other sciences, especially in physics, by its intrinsic validity. Here is a well known excerpt from H. Poincaré :

The induction applied to the physical sciences, is still uncertain, because it is based on the belief in a general order of the universe, an order which is always outside ourselves. Mathematical induction, namely, proof by induction, is required instead of necessity, because it is the assertion of a property of the mind itself. (H. Poincaré, Science and Hypothesis. Flammarion).

The activity of experimenting and studying special cases plays an important role, and is almost necessary in learning inductive reasoning, because it helps to establish and justify the formulation of conjectures – rather than raising them randomly, and helps to study these conjectures by going back and forth between the experimental data and the setting up of their evidence.

Reasoning by induction has the particular characteristic of being at the junction point of the inductive and deductive procedures. In my study of students and teachers conceptions on induction (Grenier 2002 and 2003), it appears that the understanding of the concept is severely lacking in depth. Induction is reduced to one or two techniques, and is perceived as a non-constructive tool of proof, which sometimes raises doubt for its justification. Accordingly, the scope of problems that can be solved by this tool remains extremely limited. Problems of various types designed to lead to a better appraisal of induction were introduced and studied (Grenier 2012).

A RESEARCH SITUATION INVOLVING OPTIMIZATION : HUNTING BUGS

The assigned task is to protect a grid field against “bugs”, by forbidding them to land on the grid. In order to do this, traps – uniminos – are available, each covering a box.

The bugs are small polyminoes (dominoes, triminoes, etc.), and they can “land” by covering exactly some boxes of the grid. The question is to find a minimal configuration of traps that protect the field. We consider in the sequel a 5 x 5 grid field.

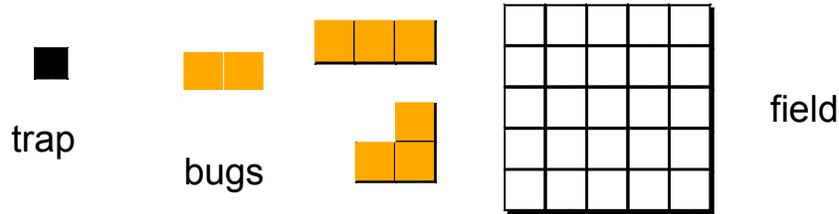

Figure 1

To solve the problem, students are equipped with appropriate material (wood, cardboard, etc.) that allows them to try and modify easily configurations without practical constraints. We are going to distinguish:

A « solution » : a set of boxes such that if one puts a trap on each of these boxes, then the field is protected. Putting a trap on each of the 25 squares is a trivial solution, but clearly a non optimal one.

An « optimal solution » : a configuration of minimum cardinality.

There may be several optimal solutions, namely sets of the same cardinality corresponding to different configurations.

The question is : for each of the three types of bugs represented above, what is the smallest number of traps that protects the area ?

Hunting Domino bugs

In that case, an optimal solution satisfies the following necessary condition : there are no two adjacent boxes without a trap. This condition is also sufficient : if there are not two adjacent boxes without a trap, then no bug can land on the field, because no domino can be put on the grid. Two « spontaneous » solutions satisfy this condition : one with 13 traps (figure 1a) and the other with 12 traps (figure 1b) – this property proves that the 13 traps solution is not optimal, but does not prove (yet) that the 12 traps configuration is optimal.

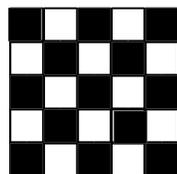

figure 2a

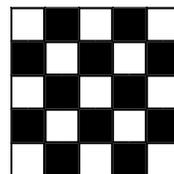

figure 2b

The following question is : Is it possible to protect the field with only 11 traps ? The answer is no. To prove this, we can study the « dual » problem, that is : what is the largest number of dominoes that can be placed on the grid area without overlap. Indeed, for a given pavement, it takes at least a trap by a domino-bug. We find easily that you can put down 12 dominoes without overlap, so at least 12 traps are necessary

to protect the field. If the optimal number is denoted by N_{opt} it has been therefore established that :

12 traps are sufficient, that is, $N_{opt} \leq 12$

and 12 traps are necessary, that is, $N_{opt} \geq 12$.

So, we have proved that $N_{opt}=12$.

Numerous experiments of this problem, with students at different levels, show that a false property-in-act appears frequently, when the 13 traps solution is discovered first : « Any solution that is no longer a solution when an arbitrary trap is removed, is optimal ». figure 2b is of course a nice counter-example.

Hunting Long trimino bugs

Some of the reasonings and results that were established with dominoes can be reinvested here.

A solution satisfies the following necessary condition : there are no three adjacent boxes without a trap.

This condition is also sufficient : if there are no three adjacent boxes without a trap, then no bug can land on the field, because no long trimino can be put on the grid.

This second problem is more difficult than the first one : at every level, the experiments lead students to solutions that are far from the optimal one, such as the configuration given for the dominoes (figure 1b) – in a first step, a lot of students think that this is the optimal solution, because they cannot find any other. After performing new attempts, students frequently consider the one given by figure 3a below, with 9 traps. However, this configuration turns out not to be optimal. If no better solution is found, the teacher has to resume the situation, because otherwise students feel no clear incentive to continue the research.

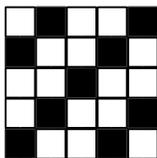

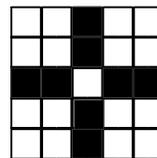

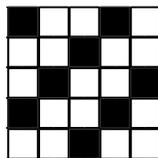

figure 3a. a 9-trap solution

figures 3b and 3c. two 8-trap solutions

Finally, there is almost always a group that finds one of the two 8-trap solutions (figure 3b and 3c). It remains to prove that these two solutions are indeed optimal. If one reinvests the « dual » proof already encountered in the domino problem, the majority of students finds that it is possible to put down 7 long triminos without overlap (figure 4a), so at least 7 traps are necessary to protect the field. So, we have proved that $7 \leq N_{opt} \leq 8$. Finding a pavement with 8 triminos would allow them to close the question. However, this pavement seems in practice very difficult to find by students. The pavement in figure 4b proves that 8 traps are necessary to protect the field, that is $N_{opt} \geq 8$ (hence $N_{opt}=8$).

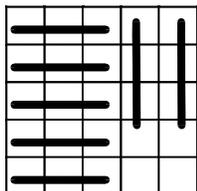

figure 4a

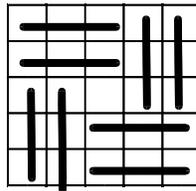

figure 4b

Hunting L-trimino bugs

Reasonings and proofs to conduct in this third problem are more complex, essentially because of the less tractable shape of the triminos : it is not easy to give a necessary condition for a solution (that protects the field). It can be a good strategy to begin by finding a pavement of the grid by a maximal number of L-triminoes (dual problem). One can easily find that there exists a pavement with 8 L-triminoes (figure 5). This pavement proves that $N_{opt} \geq 8$.

A recurrent false reasoning frequently follows this discovery : a claim that $N_{opt} \leq 8$, justified by the fact that it is impossible to put down more than 8 L-triminoes on the grid, as the equality $3 \times 8 = 24$ leads to 8 being the obvious maximum.

After a substantial time for experimentation and research, in general, many students find 12-traps solution (figure 6a), then 10-traps solution (figure 6b).

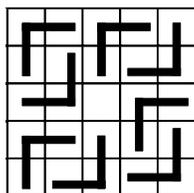

figure 5

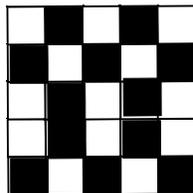

figure 6a

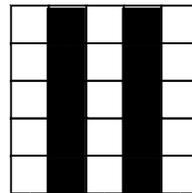

figure 6b

CONCLUSION

Learning argumentation, logical reasoning and different types of mathematical proofs requires work on appropriate specific problems, the resolution of which can be attained not just by applying techniques or formal results from the main course. We have built and experimented a number of "research situations" that should allow such acquisitions by students of various levels. We analyze especially a situation of "bug hunting" that enables students to construct conjectures and later to reformulate them in terms of implications, necessary and sufficient conditions (along with the methods of exhaustivity of cases, contraposition, reasoning by contradiction, counterexamples, etc). Our "SiRC" therefore contain all necessary ingredients to enter into genuine mathematical activities.

ANNEX 1. SIRC EXAMPLES (MATHS À MODELER, IREM, UQAM)

Some examples of Research Situations for classroom, with the main concepts or tools that they bring into play.

Polyminos tilings / *algorithms, existence theorems* / graph theory

Hunting the bug / *optimization* / number theory, lower and upper bounds

Discrete geometrical objects / *representation, definition* / euclidian an non euclidian geometries

Moving on the discrete plane / *definition* / generating or minimal systems, linear algebra

Geometry at the mountain / *space representation* / non euclidian geometry, euclidian axioms

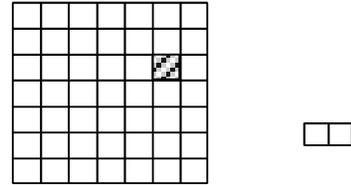

Regular 3D polyhedra / *defining, handling and proving* / 3D geometry

Regular polygons with integer vertices / *induction, ad absurdum* / combinatorial geometry

Disks in triangles or squares / *optimization* / combinatorial geometry, graph theory

ANNEX 2. TILING POLYMINOES

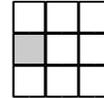

Problem P1. Rectangle with a hole in any position to tile with dominoes

Some elements of the mathematical activity in the resolution of Problem 1

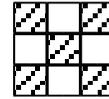

Properties and conjectures that emerge from experimentations and research

Property 1. A *necessary condition* to tile a square having a hole with dominoes, is that the area is even.

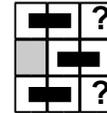

This condition is not sufficient. counter-example :

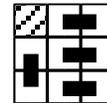

Property 2. For $n = 3$, a necessary and sufficient condition to tile with dominoes is that the hole is situated on any of the streaked position below.

proof of *impossibility* : by a « forced » tiling (ad absurdum)

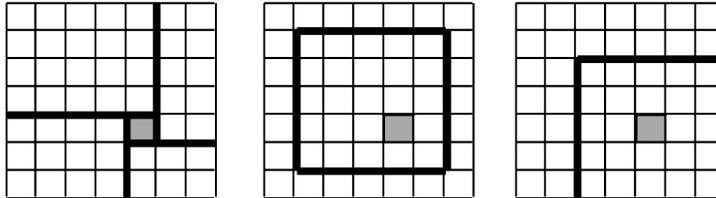

proof of *possibility* : by exhibiting a tiling (existence property)

These proofs are not transferable to any n .

Proof for every n , when tiling is possible : by structuration in rectangles with even area (without any hole), or by induction. This result is also true for rectangles

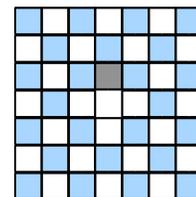

Proofs of impossibility for n arbitrary

Property. A necessary condition to tile is that, in a checkered coloration, the polymino is *balanced*

Proof by coloration, proof ad absurdum or by contradiction (if non balanced, then non tiling)

This condition is necessary for any type of polymino, but generally not sufficient.

THE WIDTH OF A PROOF

Gila Hanna

Ontario Institute for Studies in Education, University of Toronto, Canada

The paper's aim is to discuss the concept of "width of a proof" put forward by Timothy Gowers. It explains what this concept means and attempts to show how it relates to other concepts discussed in the existing literature on proof and proving. It also explores how the concept of "width of a proof" might be used productively in the mathematics curriculum and how it might fit with the various perspectives on learning to prove.

Keywords: argumentation, explanation, memorability, proof

INTRODUCTION

The paper addresses parts of themes one and four of the call for papers, namely "The importance of *explanation*, *justification*, *argumentation* and *proof* and their relationships in mathematics and in mathematics education" and "The use, evolution, elaboration or integration of theoretical frames relevant for research argumentation and proof in an educational perspective". Its aim is to discuss the concept of "width of a proof" put forward by Timothy Gowers (2007).

Both mathematicians and mathematics teachers are well aware that "mathematical explanation" and "mathematical understanding" are elusive terms. Indeed, these concepts are recurring topics in both mathematics and mathematics education. Even though the term "understanding" is not precisely defined, it is often invoked in the context of proof and proving. Most mathematicians and educators do share the view that a proof is most valuable when it leads to understanding (Balacheff, 2010; de Villiers, 2010; Hanna, 2000; Manin, 1998; Mejia-Ramos et al, 2012; Mariotti, 2006; Knipping, 2008; Thurston, 1994). For this reason, mathematicians see proofs less as correct syntactical derivations and more as conceptual entities, consisting of a logical sequence of related mathematical ideas, in which the specific technical derivation approach is secondary.

But when the focus on proof is primarily conceptual, there arises a need for well-defined criteria, apart from the well-known syntactical ones, by which the quality of a proof can be evaluated. In the absence of such well-defined criteria, value judgements are often made on the basis of properties with an aesthetic flavour that have no precise meaning, such as "comprehensible", "ingenious", "explanatory", "elegant", "deep", "beautiful", and "insightful". Clearly, such properties go well beyond the logical correctness necessary to prove a theorem. But in both mathematical practice and mathematics education these quasi-aesthetic properties of proof, ill-defined as they may be, are extremely important, because they speak to the

recognition by mathematicians and educators that proofs are “far more than certificates of truth” (Gowers, 2007, p. 37).

Aesthetically pleasing proofs enjoy a privileged position for that reason alone, of course, but Gowers notes that: “...it is remarkable how important a well-developed aesthetic sensibility can be, for purely pragmatic reasons, in mathematical research” (p. 37). The pragmatic reasons include enhanced ease of communication among mathematicians, increased interest, and the very important feature of being memorable. Memorability takes us to the concept of “the width of a proof”.

WHAT IS MEANT BY THE WIDTH OF A PROOF?

In approaching this concept, it is helpful to consider first what drove the mathematician Timothy Gowers to define the quality of mathematical proof for which he coined the term “width”, and the weight he gives to the associated notion of “memorability”. Deploring the fact that there is no well-defined language for expressing value judgments about the desirable “quasi-aesthetic” properties of proof, such as the ones mentioned above, Gowers (2007) set out by trying to clarify what is really meant by the words already in use to describe the quality of a proof. His attempt to come up with “a good theory of informal mathematical evaluation” (p. 39) led him to suggest paying more attention to memory. More specifically, he found it valuable, in formulating a good “theory of mathematical evaluation”, to consider the way mathematicians employ memory in creating and in understanding proofs.

Memorability

In the field of education the terms “memory” and “memorizing” are unfortunately associated with the undesirable notion of rote learning, which by definition eschews both explanation and understanding. But for Gowers memory has an entirely different meaning; in his discourse the term is very strongly associated with explanation and understanding, and he sees it as a crucial tool for mathematical thinking. Gowers notes, first of all, that a memorable proof is “greatly preferable to an unmemorable one” (p. 39), and adds that “memorability does seem to be intimately related to other desirable properties of proof, such as elegance or explanatory power” (p. 40). This raises the interesting question of why some proofs are easier to remember than others, and what role is played in memorability by various other non-syntactical properties such as elegance and ingenuity.

Unlike other properties so often cited, Gowers argues that the concept of “memory” is sufficiently precise to be easily investigated and eventually quantified. First, it is easy to determine whether one remembers how to prove a theorem or doesn’t. Second, it would be feasible for educators or psychologists to find out what features of proofs make them more memorable. Third, memory is clearly related to the background knowledge of the learner (or the mathematician).

Gowers may have gone too far in stating that there is a “very close connection between memorizing a proof and understanding it” (p.40), as if that were firmly established. He states:

The fact that memory and understanding are closely linked provides some encouragement for the idea that a study of memory could lie at the heart of an explication of the looser kind described earlier. It is not easy to say precisely what it means to understand a proof (as opposed, say, to being able to follow it line-by-line and see that every step is valid), but easier to say what it means to remember one. Although understanding a proof is not the same as being able to remember it easily, it may be that if we have a good theory of what makes a proof memorable, then this will shed enough light on what it is to understand it that the difference between the two will be relatively unimportant. (Gowers, 2007, p.41.)

The concept of memorability leads Gowers to suggest looking at *width*, a term borrowed from theoretical computer science, where it refers to the amount of storage space needed to run an algorithm. (Gowers draws a parallel between “keeping in mind” and “computer storage space”, in the belief that storage in computers is analogous to memory in humans.) Thus the “width of a proof” would be a measure of how many distinct pieces of information or “ideas” one has to keep in mind (to hold in your memory) in order to be able to construct or follow a proof, to understand it, and to remember it.

Width

It is important to make the distinction between the width of a proof and its length. Whereas the length of a proof refers to how many lines of argument are needed to prove a theorem, the width refers to the number of distinct ideas one has to keep in mind (or memorize) in achieving that goal. As mentioned above, for Gowers (2007) the term “memorable” is intimately connected with understanding and means “easy to memorize”. Thus it becomes important to try to determine which features of a proof might contribute to making it memorable, and in his opinion:

Some proofs need quite a lot of direct memorization, while others generate themselves ...if we think about what it is that makes memorable proofs memorable, then we may find precise properties that some proofs have and others lack. ... if mathematicians come to understand better what makes proofs memorable, then they may be more inclined to write out memorable proofs, to the great benefit of mathematics (p. 43).

Gowers suggests paying close attention to how mathematicians might memorize a piece of mathematics in general and a proof in particular. For this reason he goes on to expand on his notion of “memorability” by placing it in the context of mental arithmetic, discussing how one remembers sequences of numbers and how one might go about adding large numbers without writing anything down.

It is sufficient here to mention familiar arithmetic operations in which the “width” of the calculation (that is, the number of pieces of information one must keep in one’s

memory in order to perform a calculation) can be reduced by appropriate simplifications. For example, the mental multiplication of 47 by 52 could be greatly reduced in “width”, according to Gowers, as soon as it is perceived as the difference of two squares. One could represent the product 47×52 as the product of $(50-3)$ by $(50+3)$, minus 47, which yields $(2500 - 9) - 47$. The reduction in “width” occurs because this way of handling the operation means that one has to keep fewer digits in mind than when mentally performing the multiplication 47×52 using the customary algorithm. One has eliminated the need to remember multiple digits, at the cost of introducing a single new insightful idea, the concept of the difference of two squares. In Gowers’s terms, this new idea has transformed the original large-width operation into a lower-width one.

Examples

Gowers also illustrates his ideas by citing two examples that are more complex and go beyond the realm of numerical calculation, one being the proof of the existence of a prime factorization (a fundamental theorem of arithmetic) and the other being the proof that the square root of 2 is irrational. The latter is shown here.

Proof that the square root of 2 is irrational

There are several proofs of this theorem using different methods, such as proof by infinite descent, by contradiction, by unique factorization, and by the use of geometry. The proof by contradiction is appropriate for mathematics education, and in fact has often been discussed by mathematics educators in the context of the overall notion of proof by contradiction. The following is one version of the proof by contradiction.

Assume that $\sqrt{2}$ is a rational number. This would mean that there are positive integers p and q with $q \neq 0$ such that $p/q = \sqrt{2}$. We may assume that the fraction p/q is in its lowest terms; it can be written $\sqrt{2} = (2 - \sqrt{2}) / (\sqrt{2} - 1)$.

Then, substituting $p/q = \sqrt{2}$; $p/q = (2 - p/q) / (p/q - 1) = (2q - p) / (p - q)$

Because $p/q = \sqrt{2}$, it lies between 1 and 2, we have $q < p < 2q$,

It follows that: $0 < 2q - p < p$ and $0 < p - q < q$

We found a fraction equal to p/q but with smaller numerator and denominator. This is a contradiction, so the assumption that p/q is in lowest term ($\sqrt{2}$ is rational) must be false. ■

Gowers’ point is that this version of the proof contains a step (step 2) that seems to “spring from nowhere”, namely the choice to write $p/q = \sqrt{2}$ as the expression “ $p/q = (2 - \sqrt{2}) / (\sqrt{2} - 1)$ ”. Clearly this expression is useful, but where does it come from? Clearly it would come from the memory of the trained mathematician. This is a case in which one has to have used one’s memory to store an idea for later application. But this proof is nevertheless of lower width than it would have been without this one ingenious idea, because of the greater number of calculations that would have

been needed to complete it otherwise. Of course, another low width proof is the one by contradiction: Assuming $p/q = \sqrt{2}$ is rational, then $p^2 = 2q^2$ means that p is even. Assuming p and q mutually prime, q must be odd. However, the square of an even number is divisible by 4, which implies that q is even, hence a contradiction.

Of course it would help the reader of the proof to clarify why someone thought of this idea, because a step in a proof should not appear as a *deus ex machina*. Leaving that aside, however, Gowers points out that this particular step is no more than “what mathematicians normally mean by an idea” (p. 48). Ideas, according to Gowers, are in fact an intrinsic property of proofs, side by side with the property of correct logical derivation.

An example from geometry: Proof of Viviani's Theorem

Viviani's Theorem: For a point P inside an equilateral triangle ΔABC , the sum of the perpendiculars p_a , p_b , and p_c from P to the sides of the triangle is equal to the altitude h .

Proof: The idea is to recall that the area of a triangle is half its base times its height. This result is then simply proved as follows:

$$\Delta ABC = \Delta PBC + \Delta PCA + \Delta PAB$$

With s the side length, we have:

$$\frac{1}{2} sh = \frac{1}{2} sp_a + \frac{1}{2} sp_b + \frac{1}{2} sp_c$$

$$h = p_a + p_b + p_c \blacksquare$$

This proof of Viviani's theorem is also of low width, because it can be generated by using just one powerful idea (the area of a triangle).

Back to width

What then is the width of a proof? Gowers' first try at a definition is:

It is tempting to define the width of a proof ... as the number of steps, or step-generating thoughts, that one has to hold in one's head at any one time. ... suppose that I want to convince somebody else ... that a proof is valid, without writing anything down. It is sometimes possible to do this, but by no means always. What makes it possible when it is? Width is certainly important here. For example, some mathematics problems have the interesting property of being very hard, until one is given a hint that suddenly makes them very easy. The solution to such a problem, when fully written out, may be quite long, but if all one actually needs to remember, or to communicate to another person, is the hint, then one can have the sensation of grasping it all at once (p.55).

This restates the idea that the factor that determines the “width of a proof” is the number of distinct pieces of information, or ideas, needed to complete it. In Gowers' view, the fewer such pieces, the easier it should be to follow a proof or to actively devise one. A proof of low width, with few pieces of information to carry in one's head, would be superior to one of high width. Often it is a case of introducing a

single new but very productive idea that makes it unnecessary to deal with a larger number of less interesting ones.

That does not mean that a proof must be short, because the length of a proof is not identical with its width, as pointed out earlier. Whereas the length of a proof usually refers to the number of deductive steps required to complete it, the width of a proof refers to the number of distinct items, or distinct ideas, that must be kept in memory in order to read, learn and understand the proof.

Reflections on Gowers' notion of width

Gowers's notion of "width" does not seem to capture in a single measure the many non-syntactical properties of proof, such as "comprehensible", "ingenious", "explanatory", "elegant", "deep", "beautiful", and "insightful". Discussion of this point is difficult because none of these terms are well defined, as Gowers points out. The main difficulty, however, seems to be that these terms are far from being synonyms or even overlapping. One could even argue that some of these properties of proof, if not opposites, are at least orthogonal to one another. Very concise proofs are often considered elegant or beautiful, for example, but they are also less likely to be comprehensible or explanatory.

Thus, even if width does prove to be a useful and potentially measurable property of proof, it would not appear to be one that could serve in place of the less measurable non-syntactical properties that mathematicians have always found meaningful and useful. To which of these properties width is most correlated remains an interesting question. An elegant proof, for example, would presumably be considered of low width (and that would be seen as a positive thing). One can imagine, however, a proof designed expressly to be highly explanatory, in which the multiplicity of ideas brought to bear would make it of high width.

The concept of width would also appear to suffer from a lack of clarity as to how different kinds of memorized information – digits, concepts, rules – are to be counted. In the above example of arithmetic multiplication, the point is made that mental use of the normal algorithm requires that many interim digits be kept in mind, implying that the procedure has a large width. The width can be reduced, as Gowers states, by using an ingenious procedure employing the difference of two squares. Now, it is true that in the ingenious procedure there are fewer digits to memorize, but on the other hand one has to have had in mind the notion of the difference of two squares. One could argue that the mental capacity to store such a relatively sophisticated mathematical notion is greater than that needed to store a few digits. Perhaps there is an opening to refine the idea of width by considering whether or not different types of information might be assigned different weights.

Another consideration might be how long a piece of information has to be kept in mind. To take the example of the calculation just discussed, the concept of the difference of two squares must be kept in mind always, so it can be called upon

whenever needed, in this calculation or others, while the memory devoted to interim digits can be released as soon as the calculation is finished. The management of computer storage has a strong focus on how long a piece of storage is required. The inspiration for the term “width” came from computer storage, so it might be refined by taking into account the dimension of time.

In considering the concept of width, one is tempted by some examples to say that lower width is good, while others show the value of a richness of ideas, in which case a greater width is better. Be that as it may, mathematics educators already know that it is not enough for students, when they engage in proving, to have mastered the concepts and techniques required to construct valid sequences of logical steps. It is important for them to have a broad grasp of mathematics, so that they can draw upon a reservoir of important mathematical ideas, stored in their memory, and see how to apply them to the mathematical argument they are engaged in constructing.

Because it is a psychological concept, it is not surprising that width is difficult to define. Gowers says as much when he states that a “... precise discussion of width as a *psychological* concept is quite difficult” (p. 51, italics in the source).

An even more basic question that might be raised, however, is whether it is necessary to have quantifiable measures of non-syntactical properties. Mathematicians know an elegant proof or an ingenious proof when they see one, just as mathematics educators are quite capable of deciding which proofs are going to be more useful in conveying to their students important mathematical ideas and their connections.

In commenting on the concept of width, one must keep in mind that Gowers sees his investigation as a work in progress. While conceding that the notion of “width of a proof” is not precise and certainly still lacks a formal definition, Gowers hopes that more work will lead him to come up with a definition “more precise than subjective-sounding concepts such as ‘transparent’, or even ‘easily memorable’” (p. 57).

ASSOCIATED MATHEMATICS EDUCATION RESEARCH

A review of the current literature on proof and proving in mathematics education shows that the concept of the width of a proof is not discussed (understandably so since it is a novel one), but several research papers have dealt, as Gowers does, with the non-syntactical properties of proofs and their importance.

Mejia-Ramos et al (2012), recognizing that different proofs of the same theorem improve mathematical comprehension to different degrees, sought to devise an assessment model that could be used to measure the impact of the proof judged more promising from the point of view of comprehension.

They first reviewed the mathematics education research on the purposes of proof; and then the existing recommendations for proof that encourage comprehension, at various educational levels. Finally they interviewed nine university mathematics professors to determine what types of proof comprehension were most valued in

university mathematics. Judging by their abstract, these researchers saw the importance to comprehension of the non-syntactical aspects of proof that impelled Gowers to look into the idea of the “width of a proof”.

[...]in undergraduate mathematics a proof is not only understood in terms of the meaning, logical status, and logical chaining of its statements but also in terms of the proof’s high-level ideas, its main components or modules, the methods it employs, and how it relates to specific examples. We illustrate how each of these types of understanding can be assessed in the context of a proof in number theory. (Mejia-Ramos et al, 2012, p. 3).

Hanna and Barbeau (2009) investigated the properties intrinsic to certain proofs that allow them to convey to students methods and strategies for problem solving. They also looked at the extent to which certain types of proof might yield new insights that are somewhat easier to keep in memory.

Closely related to the concept of width is that of a memorable idea in a proof, which Leron (1983) looked at from a unique perspective in his work on structured proofs. Structured proofs are those that are organized into components in such a way that students can see how each component supports the main thrust of the proof. As Leron saw it, the memorable idea was the entire proof structure, not a step within the proof.

Leron and Zaslavski (2009) discuss the strengths and weaknesses of generic proofs. One of the strengths of generic proofs is that they “enable students to engage with the main ideas of the complete proof in an intuitive and familiar context, temporarily suspending the formidable issues of full generality, formalism and symbolism.” (p. 56). Generic proofs contain identifiable (and thus potentially memorisable) main ideas. The discussion in Hemmi (2008) is also closely related to pedagogical properties of proofs and to the way in which students encounter transparency and benefit from it.

In her paper “Key ideas: what are they and how can they help us understand how people view proof?” Raman (2003) characterizes people’s views of proof by bringing together two ideas about the production and evaluation of mathematical proof, making a distinction between an essentially *public* and an essentially *private* aspect of proof, and the notion of a *key idea* related to explanatory proofs. She concurs with Gowers that for mathematicians proof is essentially about *key ideas*.

The vast research literature on proof and argumentation also contains many references to the valuable properties of proof that Gowers sought to capture with his idea of width. See the extensive surveys by Mariotti, (2006) and Durand-Guerrier et al., (2012); see also Pedemonte (2007). For example, Douek (2007) discusses the “reference corpus” that is used to back up an argument. This reference corpus might include visual arguments and experimental evidence, and might even depend on a given social context. Douek argues for non-linearity as a model of the mathematical thinking that takes place in the process of proving. This is where one sees a parallel

between Douek's view of argumentation and Gowers' description of the quality of a proof, recalling that Gowers pointed out that proofs admit of "artificial" steps that look as if they "spring from nowhere" but turn out to be useful.

Jahnke (2009) argues that it is possible to bridge between argumentation and mathematical proof through explicit discussions of the role of mathematical proof in the empirical sciences, and by allowing students to bring in factual arguments. He says that "giving reasons in everyday situations means frequently to mention only the fact from which some event depends without an explicit deduction" (p. 141).

Knipping (2008) speaks of a method for revealing structures of argumentation in the classroom and invokes the concepts of local and global arguments to analyze a proof, believing that mathematical logic alone cannot capture all the processes of proving. Local arguments can certainly qualify as "proof ideas" in Gowers's sense.

In sum, Gowers' focus on memorability as a desirable property of a mathematical proof, and his introduction of the concept of width, bring a new dimension to the teaching of proof. There remains a need to investigate the relationship between "width of a proof" and memorability on the one hand, and on the other hand the many other important dimensions of proof and proving, such as mastery of mathematical concepts and techniques, grasp of proof structure, and knowledge of methods of proving. A deeper investigation of the concepts of "width of a proof" and memorability may lead to new ways of presenting and teaching proofs.

MULTIPLE PROOFS AND IN-SERVICE TEACHERS' TRAINING

Margo Kondratieva

Memorial University, Canada

This paper discusses a possibility to use interconnecting 'proof' problems that allow multiple solutions for teachers' professional development. Groups of teachers, which consisted of practitioners from various K-12 grade levels, were asked to produce several proofs of a given statement. I present a sampling of these proofs, which includes approaches and ways of reasoning specific for each grade level. Moments of teachers' collaboration and mutual influence are highlighted. This training method gives the participants an opportunity to make deeper mathematical connections as well as to understand better the culture of proof as a developing process along the entire mathematics curriculum across all grades.

Keywords: interconnecting task, proof development, geometry, teacher collaboration.

INTRODUCTION

Proofs and logical explanations of mathematical ideas appear in various forms at all levels of mathematics education. Many mathematical facts can be observed and hypothesized at an early stage of a child development, perhaps in the primary or elementary school. They are introduced and explained by means appropriate for that level. However, the same facts may be proved later in the secondary school using more sophisticated vocabulary and advanced methodology, and illustrated at the university level using even more rigorous and abstract ideas. A mathematical problem, in particular, one that asks to prove a given statement, is called *interconnecting* if it obeys the following conditions: (1) allows a simple formulation; (2) allows various solutions at both elementary and advanced levels; (3) may be solved by various mathematical tools from different mathematical branches, which leads to finding multiple solutions, and (4) is used in different grades and courses and can be understood in various contexts (Kondratieva, 2011a, 2011b).

The role of multiple proof tasks as a crucial pedagogical tool was highlighted in (Leikin, 2010; see also refs there). As well, Sun&Chan (2009) found these tasks to be powerful "for guiding teaching and learning" within a "spiral variation curriculum". Inspired by these works and my own practices I proposed (Kondratieva, 2011a) that a study of a succession of mathematical ideas that revolves around one *interconnecting problem* is useful for developing learners' perception of mathematics as a consistent subject. Students familiar with the problem from their prior hands-on experience will use their intuition to support more elaborate techniques taught in the upper grades.

What is lacking about this approach, while it has a theoretical basis, is empirical evidence concerning teachers' practical reliance on it in their own classrooms. A related question is how to help teachers to adopt the interconnecting problem approach through their professional development. In this paper I discuss in-service

teachers' experience with a problem that allows multiple proofs. A group of 25 mathematics teachers participated in this study in 2010 and another group of 20 teachers in 2012. Both groups took a graduate course on solving mathematical problems (I was the instructor) and this activity was one of the assignments in the course. Altogether nine subgroups of 5 students were formed, each of which included at least one primary/elementary, one junior high, and one senior high teacher. They were given one week to work on a problem stated below. Within each subgroup, the teachers were contributing solutions and explanations appropriate to the level they teach, reflecting on and checking each other's solutions. Each subgroup was required to submit at least three distinct proofs. According to their responses, this activity allowed the teachers to view the statement from various perspectives and to see how it might be used within different grade levels and mathematical topics. In the next section I discuss a theoretical background of this research project. Then I analyse mathematical ideas that emerged from the teachers' collective work. In conclusion I comment on the possibility for teachers' development offered by this study.

THEORETICAL CONSIDERATIONS

Teachers' abilities to model proofs are very important for their students' progress in understanding of mathematics. Poor or confusing instruction produces a little learning (see e.g. Hsieh, 2005 as cited in Fou-Lai Lin et al, 2012). Thus, teachers' professional development in the area of proofs and argumentation is desirable (Stylianides & Stylianides, 2009). Teacher education should involve such classroom practices as spontaneous engagement in the processes of justification and evaluation of mathematical ideas and arguments (Simon & Blume, 1996). Solving proving tasks individually or sharing and criticizing each other ideas in small groups are recommended practices helping teachers developing their understanding of proof (Zaslavsky, 2005; Stylianides & Stylianides, 2009). In the process of proof construction, both self-convincing and persuasion of others are important (Harel and Sowder, 2007; Mason et al 1982). Teachers need to have an appropriate experience of proving processes in order to successfully implement them in their classrooms, which often would require a dramatic change in existing classroom practices (Douek, 2009). Such experiences include making conjectures, moving from experimental verification to general argumentation (Kunimune et al, 2009), becoming aware of limitations of current 'justification schemas' (Harel & Sowder, 1998), and developing more sophisticated or more efficient proofs. It is also desirable that teachers were familiar with the culture of argumentation, made rational choices of mathematical tools and means of communication (Boero, 2011) and were explicit regarding transparency of proofs' presents in their classrooms discussions (Hemmi, 2008).

It had been observed that primary and secondary teachers might have distinct views on the appropriate ways and means of mathematical argumentation. This is generally consistent with cognitive stages of maturation of proof structures (Tall et al, 2012) as the learner grows from a child to adult. However, some elements of

teachers' practices may cause an obstacle in their students' proper mathematical development. Teachers dealing with very young students use little symbolism and operate with 'quasi-real' mathematical objects (Wittman, 2009) and may be reluctant to accept other modes of argumentation. Elementary teachers also tend to rely on textbooks or more capable peers' information while constructing their own arguments (Simon & Blume, 1996). In contrast, secondary teachers often reject verbal and visual proofs as being invalid (Biza et al, 2009) as they believe that all proofs must be formal algebraic (Dreyfus, 2000) and follow specific steps (Herbst, 2002). Consequently these teachers may focus on steps and algebraic details ignoring the overall logic of argumentation (Knuth, 2002). The idea that all proofs must be formal and rigorous leads some teachers to believe that proofs are inaccessible for grade school students, and thus excludes proofs from their pedagogical repertoire.

In this study, I was looking at a possibility to address several concerns and to adopt teachers' training recommendations found in the literature through teachers' engagement with interconnecting problems. When forming working subgroup of in-service teachers I specifically combined primary and secondary teachers in order to achieve the following outcomes: (1) expose elementary teachers to techniques and approaches employed in the secondary school; (2) expose secondary teachers to 'common logic' and intuition based explanations available at the elementary level; (3) let teachers to collaborate in solving an interconnecting proving problem, and thus let them to see and evaluate each other's concept of proof. Such collaboration could allow teachers to perceive proof as a developing and continuing process present in various forms at all stages of schooling. I was interested to collect an evidence of these processes as well as to find out what kind of assistance the teachers might need in order to benefit from solving interconnecting problems in mixed groups.

A PROBLEM AND COLLECTIVE POOL OF IDEAS

The problem for this study was chosen from (Totten, 2007) based on the criteria (1)-(4) for the interconnectivity listed in the Introduction.

Problem: Given a square ABCD with E the mid-point of the side CD, join B to E and drop a perpendicular from A to BE at F. Prove that the length of the segment DF is equal to the length of the side of the square.

In this section I present all ideas generated by nine groups of five teachers. Some parts of original (given in italic) students' solution are summarized to save the space.

Approach 1. Direct measurement and comparison using various materials including a ruler, string, Popsicle sticks, compass, or dynamic geometry software.

I used point D as the center of a circle and placed my compass on point C which I knew was 6 units from point D, as seen in the diagram provided. I wondered if point F would be a point on the circle's circumference. I tried it, and sure enough point F was on the circumference of the circle. Point D was the center of the circle and both points C and A were on the circumference of the circle.

Therefore, segment DF is the same length as line AD and line DC which are 6 units in length. As well it is the same length as line AB and line BC , since all four sides of a square are equal. Below (see Figure 1, left) is the graph with part of the circle described above drawn to show how I showed that segment DF was equal to the length of the side of the square $ABCD$:

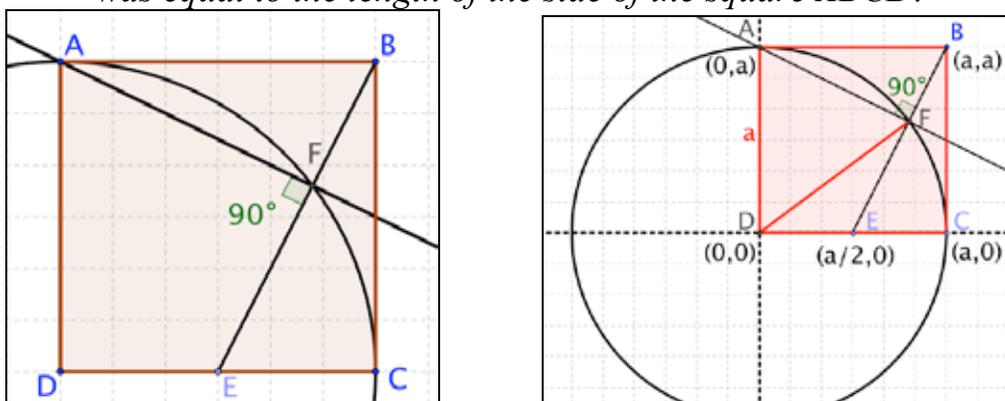

Figure 1: Approach 1 (use of compass) gives rise to Approach 2 (use of coordinates).

This approach generated an algebraic method produced by another group member.

I really liked the idea that was suggested in Method 1 of drawing a circle through the points using D as the Center, but I am not sure how to generalize that. STUCK! Then I thought that if I could find the point F , I could sub it into the equation for my circle using a side length of “ a ”. I know how to find F by using the equation for the line that intersects to make F . I can find the slopes using “ a ” as my side length, but how can I find the y intercept to finish my linear equations? STUCK! If I incorporate my previous idea of using points into this it will work! AHA!

Approach 2. Use of Cartesian coordinates of the points (see Figure 1, right). Let’s assume that D is located at the origin. Denoting the side length of the square as a we have the points $D(0,0)$; $A(0, a)$; $B(a, a)$; $C(a,0)$. To determine the coordinates of point F we must first find the equations of the lines BE and AF . We have two points $B(a, a)$ and $E(a/2,0)$ from which we may determine slope of the line BE and ultimately the y -intercept: $y=2x-a$; Since BE is perpendicular to AF , the slope of line AF is -0.5 and the y -intercept is a . Thus AF has equation $y=-0.5x+a$. The intersection point F is found by solving the equation $2x-a=-0.5x+a$, which implies $x=0.8a$ and $y=0.6a$. The distance DF between F and the origin D is the square root from the sum of squares of the coordinates of F , which after simplifications gives a , the side length of the square. This completes the proof. In students’ version of the proof it reads:

So point F is $(4a/5,3a/5)$. Then to see if it fell on the circle, we just need to plug it into the equation for our circle. The circle has a radius of “ a ” so we have our equation: $x^2 + y^2 = a^2$. Now we just substitute our point F and see if it works: $(4a/5)^2 + (3a/5)^2 = (16a^2 + 9a^2)/25 = a^2$. Thus, our point F must be on the circle. Therefore, segment DF must be the exact same length as AD and DC which are also radii of the same circle and are also the sides of the square $ABCD$!

Approach 3. Recognition of similar and congruent triangles (see Figure 2, left).

I had to find yet another proof. I liked Method 2 but needed to show that $\triangle AFD$ is an isosceles triangle by some other method... I used the properties of similar triangles and congruent triangles to show that $\overline{DF} = \overline{DA} = 6$ units. Draw a line from point D to the midpoint of AB . Call this midpoint X . DX is parallel to EB because they have the same slope, so DX must intersect AF at a 90° angle. Call this intersection point Y . Consider $\triangle AFB$ and $\triangle AYX$. $\angle FAB = \angle YAX$ (common angle); $\angle AFB = \angle AYX = 90^\circ$ angles. Therefore, $\triangle AYX \cong \triangle AFB$. This means that $\frac{\overline{AF}}{\overline{AY}} = \frac{\overline{BF}}{\overline{YX}} = \frac{\overline{AB}}{\overline{AX}}$. Since: $\overline{AX} = \overline{XB} = 3$ units, $\overline{AB} = \overline{AX} + \overline{XB} = 6$ units, and the ratio $\frac{\overline{AF}}{\overline{AY}} = \frac{\overline{AB}}{\overline{AX}} = \frac{6}{3} = 2$ units. We know that \overline{AB} is twice as long as \overline{AX} , so \overline{AF} must be twice as long as \overline{AY} . Therefore, $\overline{AY} = \overline{YF}$. Consider $\triangle DAY$ and $\triangle DFY$. We know: $\overline{AY} = \overline{YF}$ and $\angle AYD = \angle FYD$ are 90° angles, and $\overline{DY} = \overline{DY}$ (common side). Therefore, $\triangle DAY \cong \triangle DFY$ because of the Side-Angle-Side congruence property. So $\overline{DF} = \overline{DA} = 6$ units. QED

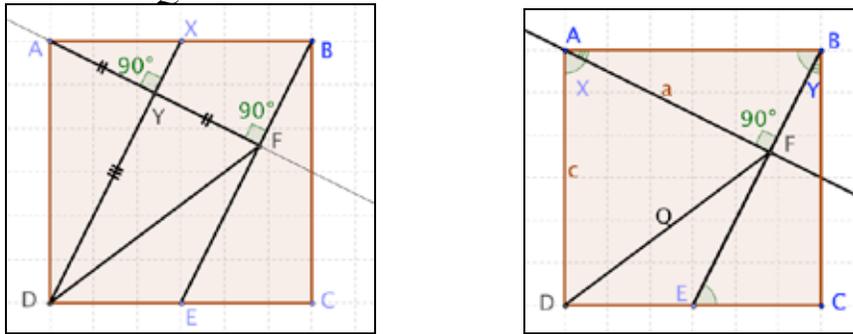

Figure 2: Approaches 3 and 4 look at triangle $\triangle AFD$ in two different ways.

Approach 4. Use of trigonometry and the Cosine Theorem (refer to Figure 2, right).

I was looking at triangle $\triangle AFD$ and thought that I could possibly apply the Cosine theorem to find the side of interest. Note that angles $\angle CEB$, $\angle EBA$ and $\angle DAF$ are equal, call it X . Angles $\angle CBE$ and $\angle BAF$ are equal Y , and $X + Y = 90$ degrees. Let the square has side c , $\overline{AF} = a$ and $\overline{DF} = Q$. Then we obtain the following.

From right triangle $\triangle ABF$ we have $c = a / \sin(X)$. From right triangle $\triangle BCE$ we find $\cot(X) = 0.5$. From triangle $\triangle AFD$ we conclude by Cosine Theorem that $Q^2 = c^2 + a^2 - 2ac \cos(X) = c^2 + a^2 - 2a^2 \cot(X) = c^2 + a^2 - a^2 = c^2$. So, $Q = c$, or $\overline{AD} = \overline{DF}$.

Reflection: Will this work for any size square? Yes because the ratio of the sides used in $\triangle BEC$ will always be 0.5 because E is the midpoint of side DC .

Approach 5. Based on the recognition that $\triangle AFED$ is cyclic (Figure 3, left).

Aha! $\triangle ADEF$ forms a quadrilateral and opposite angles $\angle ADE$ and $\angle AFE$ are both 90° so they add up to 180° . (We know $\angle AFE$ is a right angle because it's supplementary to $\angle AFB$) This means the other two opposite angles ($\angle DAF$ and

$\angle DEF$) must also add up to 180° since all angles in any quadrilateral add up to 360° . Therefore, a circle can be constructed around the quadrilateral $ADEF$ where each vertex, A , D , E , and F lie on the circle. Now it's likely I can prove it using arc measures.

Now, note that angles CBE , BAF and DAE are equal, call this value y . Then $\angle DAF = 90^\circ - \angle BAF = 90^\circ - y$. From the relation for inscribed angles and arc measures we have $2\angle AFD = \text{arc}(ADE) - \text{arc}(DE) = 180 - 2y$. Thus $\angle AFD = 90^\circ - y$.

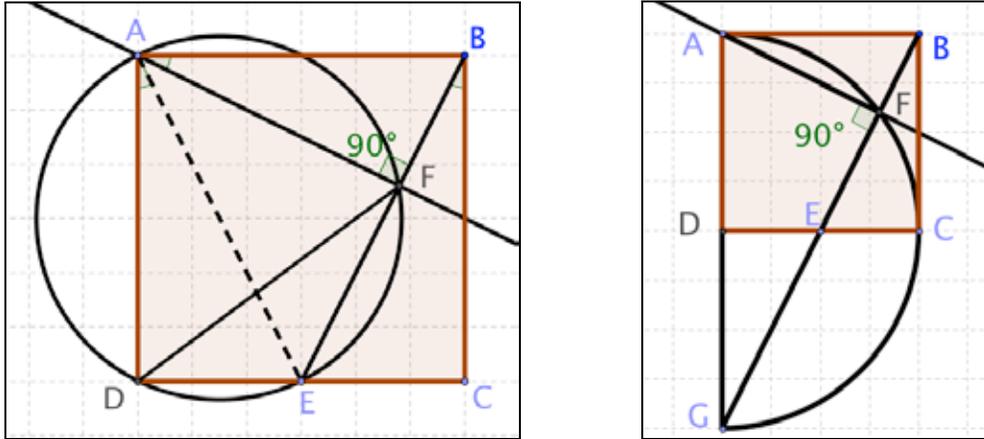

Figure 3: Approaches 5 and 6 use two different auxiliary circles.

So line segments AD and DF must be of equal length since the isosceles triangle theorem states that sides which are opposite of equal angles in an isosceles triangle must also be equal. So DF is the same length as the sides of the square since AD is one of the sides

ANALYSIS OF THE SOLUTIONS IN VIEW OF TEACHERS' TRAINING

Participants of this study were all enrolled in my graduate course on problem solving. Prior to solving the 'proof' problem presented in the previous section they practiced in solving several other problems individually and in groups. Their reading included the book by Mason et al (1982) regarding the stages of mathematical thinking and my paper (Konratieva, 2011a) regarding the theory of interconnecting problems. Each group was asked to create as many as possible (but at least three) distinct solutions, individually comment on the thinking process highlighting AHA and STUCK moments (Mason, 1982), and as a group reflect on each others' approaches, identify their place in mathematics curriculum and select the most appropriate solutions for submission. Leikin (2010) suggests that 'collective solution spaces' are sources for development of 'individual solution spaces' of the group members. Teachers were asked to comment on that effect and the perceived usefulness of this training method.

Teachers' solutions and responses were examined in order to compare contributions from primary and secondary teachers as well as to observe instances of *productive* collaboration (when participants reveal and build on mathematical connections between their individual ideas). Analysis of teachers' work shows the following.

First, while there was a disagreement about sufficiency of Approach 1 that involves direct measurement, it was included in almost all groups' reports. Many primary school teachers provided detailed lesson plans on using various instruments helping students to construct and measure elements of the picture. Other group members often commented that this approach is not qualified as a proof but still is very convincing and illustrative. This result concurs with literature stating that primary and secondary teachers may disagree about adequacy of some explanations. But, remarkably, this simple approach stimulated other group members to invent more rigorous justifications. The collective effort that converts a pictorial insight onto an analytic calculation (Approach 2) reveals a *cognitive unity* (Boero et al, 1996) of an empirical argument and rigorous proof construction. Moreover, the participants agreed that due to such experiences they started to view learning to prove deductively as a gradual and multimodal process originated from reflections on empirical actions.

Second, the majority of solutions dealt with concrete numbers. As it is evident from Approach 3, the teacher uses side of length 6 throughout her solution. While teachers had read about specialization and generalization techniques (Mason, 1982) and discussed them with their peers, still the tendency to use concrete numbers without further generalization was evident in the majority of papers. However, some teachers either made a comment on how to generalize their solution (see Reflection in Approach 4), and some had a proof in a general form (see Approaches 2 and 5).

Third, many teachers used approximate calculations. For example, in the trigonometric approach they would typically write “take $\arctan(0.5) = 63.4^\circ$ ”, and then used approximate values of $\cos(63.4^\circ)$ and $\sin(63.4^\circ)$ to calculate the length of segment DF despite that the equality they were proving was exact.

Fourth, many submissions were very wordy and far from being mathematically efficient in reporting their final solutions. Even though the participants were asked to submit the best possible solution, many papers contained lengthy algebraic calculations that could be easily optimized. This likely reflects teachers' belief that every little detail must be brought up. But in doing that they often unnecessarily repeated or rephrased the same idea, and explained obvious things (“ $\overline{DY} = \overline{DY}$ common side”), as can be seen e.g. in Approach 3.

Fifth, some groups submitted several solutions that employed the same mathematical idea and differed in very little details. It seems that the group members were hesitant to make their judgement and delegated the responsibility to choose the best solution to their instructor.

And finally, while the group members' collaboration was evident on several occasions and participants as a whole had produced a great deal of approaches, still there were solutions missed by the groups, even though elements of those solutions were present in the collective pool of generated ideas. As an example, the following approach was never proposed by the teachers, but when suggested by the instructor,

they agreed that they were very close to discovering it by combining ideas from their Approaches 1, 2, and 5.

Approach 6. Extend lines AD and BE and call the intersection point G (Figure 3, right). Note that DE is the midline in ABG, that is points, E and D are midpoints of sides BG and AG respectively. Since AFG is a right triangle then its vertices lie on a circle, and hypotenuse coincides with the diameter of the circle. Thus \overline{DF} , \overline{DC} and \overline{DA} are all equal to the radius of the circle.

For completeness, I give another approach that employs a bit more advanced technique and can be used to illustrate the advantage of learning some further theorems in Euclidean geometry.

Approach 7. Based on Ptolemy's Theorem for cyclic quadrilaterals.

For cyclic quadrilateral AFED (Figure 3, left), the Ptolemy's theorem reads: $\overline{AF} \cdot \overline{DE} + \overline{AD} \cdot \overline{FE} = \overline{AE} \cdot \overline{DF}$. Let $\overline{DE} = a$. Then $\overline{AD} = 2a$, $\overline{AE} = \overline{BE} = \sqrt{5}a$. Set up equations $\overline{BF} + \overline{FE} = \sqrt{5}a$, and $(2a)^2 - (\overline{BF})^2 = 5a^2 - (\overline{FE})^2 = (\overline{AF})^2$ from right triangles AFB and AFE. Solving the system, we get $\overline{BF} = 2a/\sqrt{5}$, $\overline{FE} = 3a/\sqrt{5}$, $\overline{AF} = 4a/\sqrt{5}$. Substituting these values in Ptolemy's equality we find $\overline{DF} = 2a$, which is the side length of the square.

CONCLUSION

This paper analyses a collection of proofs produced by groups of in-service mathematics teachers whose expertise ranged across all grade levels. Based on their responses, all participants of this study found it very informative to collaborate on one problem and produce proofs employing various methods and ideas capitalizing on the “interplay of empirical and theoretical argumentation” (Jahnke, 2008). In words of one teacher, “I never thought before of a possibility to prove the same claim in multiple ways. I was really amazed to see how many different approaches were proposed by my teacher-colleagues and how they all fit in different grades' math topics”. This study reveals the potential of the use of interconnecting problems for teachers' training in mixed groups. Such setting allows teachers (1) to learn, evaluate, and criticize each other's solutions, (2) to share their ideas and to persuade their peers, (3) to collaborate on connecting intuitive and experimental methods with general argumentation, (4) to produce more efficient proofs, and (5) to choose appropriate tools and means to communicate their reasoning. Note that all these experiences are recommended in the literature for teachers' professional development. In addition, this training method allows teachers to see how different approaches are pertinent to different grades. Perceiving mathematics curriculum as a whole process of knowledge accumulation, teachers begin to acknowledge that many secondary school arguments are deeply rooted in primary/elementary level activities. At the same time, some study participants did not fully benefit from the offered exercise. This suggests the necessity of more focused supervision and advising of mathematics teachers during their training. In particular, such advising should aim at

developing habit of spontaneous moving from specialization to generalization, conscious distinction between exact and approximate calculations, and reviewing one's own solutions in order to eventually present them in a more general, insightful and concise form. Resonating with Koichu (2010), this study also poses the questions: Why did all groups of teachers overlook certain approaches that clearly were within their capacity to produce? What can be done to ensure that teachers' collaboration realises the entire potential present in the individual contributions?

NEW OBJECTIVES FOR THE NOTIONS OF LOGIC TEACHING IN HIGH SCHOOL IN FRANCE: A COMPLEX REQUEST FOR TEACHERS

Zoé MESNIL

Université Paris Diderot, Laboratoire de Didactique André Revuz

If everyone agrees that logic is needed to do mathematics, there are divergences concerning the role of mathematical logic in acquiring the necessary and sufficient knowledge in this area. In France today there are new syllabuses in which notions of logic are explicitly mentioned. How do teachers integrate them into their teaching? In this paper, through a study of the French syllabuses and textbooks, I show the strong constraints and ill-defined conditions for this teaching of logic notions. I also describe the contents of an in-service training course for teachers, which aims to give them tools for this teaching.

Key words: logic-language-reasoning-textbooks-teacher's training

INTRODUCTION

In the introduction of the proceedings of the 19th ICMI Study Conference: Proof and Proving in Mathematics Education (2009), the authors note that some research should be pursued to understand the role of logic in the teaching of proof. The experience of teaching formal logic in high school during the time of "modern mathematics" in the 1970s in different countries has shown that this approach does not directly provide students with effective tools to improve their abilities in expression and reasoning. In most of these countries, logic then disappeared from high school syllabuses, but students' difficulties in expression and reasoning persist and the debate on the role of logic in the treatment of these problems remains open.

In France, logic was briefly re-introduced in the 2001 syllabus. The 2009 syllabus, which is still in application, goes even further: it includes objectives for "mathematical notations and reasoning" which are linked to notions such as connectives AND/OR, negation, conditional propositions, equivalence, different types of reasoning. Behind these notions there are objects which are defined and studied by mathematical logic. But the aim stated by the syllabus is not to teach mathematical logic, but to convey the knowledge in logic necessary to mathematical activity. Then, two main questions emerge: How can teachers identify the logic they have to teach? What kind of (pre-service and in-service) training should they have to efficiently organize their teaching? The French context, where logic has been re-introduced in high school syllabus, is suitable for providing elements of answers to these questions.

These questions brought me to study the system of conditions and constraints in which the teacher makes his teaching choices. A more detailed study of syllabuses and textbooks from 1960 highlights the features of this system. First of all, the history

of teaching logic in mathematics in France is a tormented history, and some teachers never got courses about notions of logic during their studies. Furthermore, since this teaching has been absent from syllabuses over the past years, teachers did not really have to think about it during their preservice training. Finally, a first glance at the activities proposed in the textbooks and at the content of the pages dedicated to the notions of logic mentioned in the syllabus shows diversity in the interpretation of this syllabus, but also a certain lack of knowledge of the notions at work. But prior to this study, more general questions should be raised about the links between logic and mathematics and between logic and mathematics teaching. One of the aims of this study is to contribute to the reflection on the necessary training in logic for teachers, so they could teach the underlying logic in mathematical activity.

In this paper, I will mainly present this study. It shows the difficulties encountered by French high school teachers in integrating notions of logic in their mathematics teaching. One axis of this work is to show the importance of language¹ issues in the contribution of logic to the mathematical activity. This dimension is not taken into consideration in a precise way in the documents used as resources by teachers. Logic is often seen as linked to reasoning, in general and more specifically in mathematics. But it is also linked to the setting-up and the functioning of a language which allows to describe the structure of propositions and of reasoning, and the links between both. I see mathematical logic as a reference theory dealing with objects which may be tools to analyze our mathematical discourse and to understand the ambiguities inevitably linked to the use of certain formulations which are informal or implicit in the mathematical language.

First of all, I will present some quick thoughts on logic and language, and some didactical studies that have shown difficulties for some students, probably linked to language. Later on, I will present the study of the system of conditions and constraints I have previously stated. Finally, I will briefly describe the content choices made for a training called "Initiation to logic" for teachers in activity.

LOGIC AND LANGUAGE IN THE MATHEMATICAL ACTIVITY

The study of different moments in the history of logic shows that the constitution and description of a logic is accompanied by a necessary formalization of language, in the sense of a codified formatting, whose codes vary of course depending on authors and eras. For example, in his logical work, *The Organon*, Aristotle (Greek philosopher, IV^e century BC) began to explain what he called a proposition (enunciative sentence, in which there is truth or error), and then classified these propositions according to two criteria, quality (affirmative or negative) and quantity (universal or particular). He obtained four types of propositions that are the building blocks of syllogisms, which could be treated in a formal way, because the propositions can be replaced by variables. Nevertheless, Aristotle did not want to formalize the relationship between

¹ The use of the term "language" does not refer here particularly to common language, or to the mathematical one, but to the use by someone of signs he organizes with the intention of communicating something.

the parts forming these propositions and did not use logical constants like connectives and quantifiers.

Since the beginning, some mathematicians have sought the necessary and sufficient formalization of their language that ensures the infallibility of reasoning. For some of these mathematicians, language had to be totally formalized, to reach the univocity of the meaning of expressions and the possibility of a formal treatment of these expressions, independently of their meaning. For another part of these mathematicians, too much formalization does not allow the intuitive progress of reasoning. Mathematical logic can be seen as the culmination of this research. An important step has been taken by modeling mathematical language and reasoning, allowing a further exploration of the properties of these logical systems using mathematical tools.

These epistemological considerations lead me to the assumption that mathematical logic can provide tools, probably first to the mathematician and mathematics teacher, to analyze the language they use in their mathematical activity, and to detect its ambiguities. For the teacher, an additional challenge is to provide tools for the analysis of students' reasoning, allowing to highlight another possible understanding. This can occur, for example with the propositions "if ... then ..." which are implicitly universally quantified, but quantification is not always perceived by the students. That may lead them to give a response which is not expected, and is yet the result of a correct reasoning. For example, some pupils could say that the sentence "if n is prime, then n is odd" is neither false, nor true, while almost all mathematicians say it is false (you can find a more detailed example with the "maze" task described in (Durand-Guerrier, 2004)).

In a more general way, various studies based on experiments with university students show the difficulties they have encounter in understanding and proving quantified statements (Dubinsky, Yiparaki, 2000, Arsac, Durand-Guerrier, 2003, Chellougui, 2009, Roh, 2010). For most students engaged in proving if a statement is true or false, the relationship between the quantified formulation of a statement and the framework of its proof is not clear. Thus, while recognizing the role of informal statements in memorizing mathematical results, J. Selden and A. Selden make the assumption that the ability to unpack the logic of an utterance by formally writing it is related to the ability to ensure the validity of a proof of this statement (Selden & Selden, 1995).

Unpacking the logic can be seen as writing the statements and making explicit some conventions, for example about quantification. The predicate language did not become the universal language in which the mathematicians express themselves, but a reference language, and, depending on the nature of their activities (research, drafting a communication, course ...), they use formulations whose logical structure is more or less exhibited. For example, calling a predicate P on a variable n which is a natural number, mathematicians commonly say " $P(n)$ when n is big enough." But to explain to students how to show this property, they may reformulate this as " $P(n)$ for

all n beyond a certain value". And in a course, they could write "there exists N_0 such that for all $n \geq N_0$, $P(n)$ ". This interplay between different formulations, which is easy for a mathematician, does not always seem so simple for students! Though, I believe that a rewording work is important because it contributes to the construction of what J. Selden and A. Selden call "statement images" (Selden & Selden, 1995, p 133):

These are meant to include all of the alternative statements, examples, nonexamples, visualizations, properties, concepts, consequences, etc., that are associated with a statement.

This invites us to think about activities for students to develop the ability to rewording, which is rarely an explicit goal of education and rarely proposed as an explicit task, and to think about the knowledge that teachers need in order to engage in such activities. S. Epp mentions the need for solid knowledge concerning language and logic (Epp, 1999, p3):

When given by teachers with a solid command of mathematical language and logic, such feedback can be of enormous benefit to students' intellectual development.

HOW CAN A FRENCH HIGH SCHOOL MATHEMATICS TEACHER TEACH LOGIC TODAY?

Research questions, study materials and methodology

There are some goals concerning "mathematical notations and reasoning" in the first high school year² mathematical syllabus, launched in September 2010. In these instructions, some objects of mathematical logic are explicitly mentioned. Therefore, teachers have to build up a teaching allowing to reach these aims. While doing so, they have choices to make, for which they are submitted to a system of institutional conditions and constraints. I think it is interesting to study this system in order to understand the teachers' practices concerning logic, and in order to think about the training they need for that. I have conducted this study with the three following questions: what is the scholarly knowledge of reference for this teaching? ("*savoir savant*" (Chevallard, 1985))? What are the notions to teach (the knowledge to be taught, "*savoir à enseigner*")? Where and why do we find logic in the high school mathematics teaching in France (ecological approach (Artaud, 1997))? I have looked for the answers by analyzing different documents from 1960³ until now. I think the epistemological approach is essential to understand the current choices.

The study of syllabuses and their joined instructions contributes to answer these three questions. I have noticed the notions of logic present in these documents, as well as the terms used to speak about logic. These terms give information about the specific function attributed to logic, in relation with language and reasoning. I have completed this study by searching in the APMEP⁴ periodicals for information on the reactions

² 15-16 years old students.

³ 1960 is the first year of the introduction of logic in the high school mathematics syllabuses in France.

⁴ Association des Professeurs de Mathématiques de l'Enseignement Public, the most important association

and expectations of the teachers who are on the field of teaching. I have searched for the presence or not of articles on logic, and of debates concerning its teaching. Finally, I have studied what was said about logic in the textbooks. These textbooks are seen both as a possible interpretation of syllabus, proposing a "dressed knowledge" ("*savoir apprêté*") [Ravel, 2003] and as a resource for teachers. I have tried to determine if and how the notions of variable, proposition, connectives and quantifiers were introduced, more specifically if and how their syntactic and semantic aspects⁵ were present and linked. I have also searched what kinds of tasks were designed.

The analysis shows the complexity of the current demand: the conditions are ill-defined and the constraints are strong.

What is the scholarly knowledge of reference for the teaching of logic of mathematics?

A part of this complexity lies in the logic itself. The question that interests us here is not the teaching of mathematical logic as a branch of mathematics. The question rather has to do with the teaching of the logic of mathematics, which I defined as "the art of organizing one's speech in that discipline, seen under the double aspect of syntactic correction and semantic validity". One of the difficulties with this logic of mathematics is that there is no reference content, no consensus on the knowledge in this area that is needed to do mathematics and on the words which should be used to phrase this knowledge. Here is an example of the potential problems with the lack of common knowledge reference. In the objectives of the new syllabus, students must "be trained on examples to properly use the logical connectives "and", "or" and to distinguish their meanings from the common meanings of "and", "or" in the usual language." But neither in the syllabus, nor in the accompanying document on this subject, entitled "Resources for high school first year, Notations and mathematical reasoning" can we find a definition of the logical connectives "and", "or". However, the distinction between the use of these words in the language of mathematics and in everyday language is not limited to the inclusive or exclusive character of the connective "or". Yet it is the only thing mentioned in the textbooks or in the accompanying document.

Another essential difference lies in the fact that in mathematical language, the connectives "and", "or" link two propositions, which is not always the case in the everyday language, even if it is spoken about mathematics. For instance, if we try to show the logical structure of the proposition "Sets A and B are not empty and disjoint", there will be three "and" that will correspond to connectives between propositions (in capital letters), and one that will not match: "Set A is not empty AND set B is not empty AND sets A and B are disjoint". Not only is this distinction

of mathematics teachers in France.

⁵ In its syntactic aspect, a connective is an operator on propositions and its semantic aspect is given by the truth tables.

not mentioned, but in addition to that, the study of certain exercises proposed in textbooks show confused conceptions about notions that yet seem as simple and usual in mathematics as the connectives "and", "or". This shows that even if someone has studied mathematics and therefore had used logic for this activity, it is still not enough for him to constitute a knowledge that could sustain a teaching of certain notions of logic to students. I make the hypothesis that the part of the mathematical logic which is generally called "propositional calculus and predicate calculus" is a corpus of knowledge that can be a reference to teachers in their teaching of mathematics logic. The one condition for that is for it to be linked with the study of language and reasoning practices in mathematics. No such reference is explicitly proposed nowadays, as opposed to what happened at the time of modern mathematics: in 1970, the instructions along with the new syllabus of the first high school year gave definitions and first properties of connectives and quantifiers.

What is the knowledge to be taught ?

Concepts of logic are mentioned for the first time in the mathematics syllabus for students in their first year of high school in 1960. During the middle of the twentieth century, the French mathematicians were strongly influenced by the Bourbaki group of mathematicians, whose axiomatic style spread into teaching. The reform called "modern mathematics" came into force in high school with the syllabus for first-year high school students in 1969. This syllabus was based on the idea of a unified mathematic, that could be used in experimental sciences as well as in human ones. Mastering the language of mathematics was then essential, and it was the essential function of logic. All textbooks from that time start with a first chapter on set theory and logic, which are the foundations of this language. The syntactic and semantic aspects of the notions of logic were present. The instructions of 1970 specifically say that "the chapter *Language of sets* should become more of a practical introduction at any time in the course than of a dogmatic preamble", but they do not give examples of this practical introduction. The APMEP periodicals have published several articles between 1960 and 1975, linked to logic (theoretical presentations or stories of didactical experiences), and were spokesmen of animated debates such as the one concerning the use of quantifiers symbols. This introduction of logic in the high school mathematics syllabi then seemed like an ambitious project, linked to the acquisition of mathematical language, and was sustained by a certain wish to train teachers, not only to mathematical logic but also to modern mathematics in general. But if we look at textbooks, we can see that most of the time this logic has been reduced to simply a formal presentation of notions of logic, without linking it to mathematical activity. This presentation was not adapted to the initiation to mathematics logic for a mass of student reaching high school.

In 1981 came a radically different new syllabus. It was the time of the "counter-reform", in which logic was explicitly excluded from mathematics teaching. Modern mathematics have been vehemently accused of being too formal, elitist and not linked to mathematics applications. Logic taught by then and some representative elements

such as the tables of truth are almost symbols of this excessive formalism. This might be an explanation to the fact that none of the first high school year textbooks give tables of truth, even if some of them describe their contents, saying for instance that "the proposition **P and Q** is true only in the case where P and Q are both of them true".

This lasted until the implementation of the 2001 syllabus, which states that "training in logic is part of the requirements of high school classes". This text is included in the 2009 syllabus and is supplemented by a table setting targets for "notations and mathematical reasoning". These objectives relate to certain objects of mathematical logic, but are rather vague. It is also specified there that "the concepts and methods relevant of the mathematical logic should not be the object of specific courses but should naturally take their place in all the syllabus chapters". I will give as examples two of these objectives: "Students are trained, based on examples, to correctly use the logical connectives "and", "or" and to distinguish their meanings from the common meanings of "and", "or" in the everyday language. They are also trained to wisely use universal and existential quantifiers (the symbols \forall , \exists are not due) and to spot implicit quantifications in certain propositions, particularly in the conditional ones." We have already seen that these objectives are not clear, concerning the logical connectives "and", "or", and that the Resources document which come with the syllabus does not take in charge all the important aspects of these notions. The second example concerns quantifications, mainly the implicit ones. We have evoked p3 certain didactical studies that have shown how these quantifications created difficulty for the students, for instance in the understanding of the propositions "if...when... ". Still, this does not appear in the Resources document. The syllabus instructions put logic both on the side of language and the reasoning one (presentation of the different reasoning types). But the links between logic and mathematics are not the same as in the time of modern mathematics. Here, it is essentially about specifying the mathematical language's particularities related to the everyday language. Furthermore, the proposition, a base element of the mathematical language, is absent from syllabuses and the Resources document.

This tormented history of logic in teaching mathematics in high school mainly has two consequences that contribute to the complexity of what is actually asked from teachers. On the one hand, all of them do not have the same training for these notions. On the other hand, there has not been a continuous thinking, particularly a didactical one, about that teaching of logic notions in high school.

Furthermore, we have seen that logic should be taught along with other notions, which represents a strong constraint as far as time is concerned. It should also be caught were it lies, which implies that teachers should be lucid and serene enough to be able to spot it.

Logic in the textbooks

I will only talk here about the current textbooks. Textbooks authors should follow the directions, even though imprecise, given in the syllabus, to provide teachers with tasks for their students. Thus, in most textbooks published in September 2010, we can find pages offering a brief overview of the concepts of logic mentioned in the syllabus. These pages are not a separate chapter. They are a sort of glossary which students and teachers can refer to during certain tasks concerning logic. An analysis of ten mathematics textbooks published in 2010 shows a diversity in the presentations. Some books have one approach that can be called "propositional", which means they constitute a kind of "grammar of mathematical propositions". Other books have an approach that can be called "natural", which means that they take common language as the starting point to speak about mathematical language, while specifying the requirements for this discipline, in particular the requirements of univocal meaning for each word. Because the syllabus demands that logic does not constitute a course on its own, very few textbooks use the terms "definitions", "properties" in their pages, even though it is exactly what they give. Exercises associated to logic are essentially "True or False" ones, and do not allow to work on the language. Finally, we can find mistakes, such as the confusion between "if...then..." and "therefore", in the pages talking about logic or in the exercises of certain textbooks. The lack of knowledge of some teachers concerning logic makes it difficult for them to spot and analyze these mistakes.

We have seen through the study of the documents contributing to define the *knowledge to be taught* that this knowledge is not clear for the mathematics high school teacher today in France. It appears to us that it is therefore necessary to offer them trainings that will give them the tools needed for this teaching. Because logic is as essential to address language issues as it is to address the reasoning issues in the mathematical activity, I think that mathematics teachers should have tools allowing them to think about the way they speak, and about the ambiguities and implicits that lie under some usual formulations in our practice of mathematics. Mathematical logic seems a possible reference for this reflection.

AN INITIATION TO LOGIC IN THE FRAMEWORK OF A CONTINUOUS TRAINING FOR TEACHERS.

The Institut de Recherche pour l'Enseignement des Mathématiques (IREM)⁶ at the Paris Diderot University proposed in 2011 a training course called "Introduction to logic" as part of the continuous training for teachers (this training course had already been organized in 2010 and renewed in 2012). This course was led in collaboration with René Cori, professor in the logic team of the Paris Diderot University. Fifty teachers (the number of places was limited) enrolled in this course, forty of them

⁶ Research Institut for Mathematics Teaching

were effectively attending. The training took place during three days of 6 hours each (two consecutive days in January, then one separated day a month later). One of the training goals is to give the trainees knowledge in mathematical logic. This does not mean lecturing about mathematical logic. It is all about teaching logic for teachers, a logic in context, at the service of mathematical activity. What is proposed is an analysis and a critical look at mathematical language with which teachers are already familiar. An important place is given to the notion of variable, that we will present as being characteristic of mathematical language in relation to the common language, and the multiple ways mathematics use to implicitly quantify their statements. The logical connectives are then presented as operators on propositions, which means they allow, starting from one or two propositions, to "create" a third one. This syntactic aspect is separated from the semantic aspect broached by giving the truth tables of these connectives. The notions of tautology and propositions logically equivalent are defined and put in relation with the practices of reasoning. An important moment is dedicated to implication: establishing its truth table creates reactions. Then, it is essential to note that the negative of a conditional proposition is not a conditional proposition. We also discuss at length about the implicit universal quantification associated to the formulation "if... then...". We finally suggest few developments on the study of theories.

Another important part of the training is a more practical aspect, based on the study of the school textbooks. Basing themselves on selected parts, the trainees do a critical analysis in small groups. At the end, we share our work. This practical exercise allows to show the misunderstandings there can be about some notions, and was based on the taught theoretical components (this work was done after having spoken about variables, connectives and quantifiers). We also devote time during the third day for the trainees who wish to present activities they have done in class, so that we can discuss about it.

This training is a field for experimentation for my research. I am trying to implement data collection and analysis tools.

CONCLUSION

With this contribution, I wanted to participate to the reflection on teaching notions of logic, particularly in showing the importance of not neglecting the contribution of the logic in problematics related to language and not just to reasoning. Anyway, language and reasoning are not two isolated poles, there is an interaction between the structure of mathematical propositions and the structure of their proof. Moreover, rewording is a common activity in the proving process in mathematics.

In France today the new syllabuses for high school give goals concerning mathematical notations and reasoning, and mathematics teachers then have to explicitly teach some notions of logic. But through a study of documents defining the *knowledge to be taught*, we have shown that their choices for this teaching were made in ill-defined conditions, and were subject to strong constraints. It therefor seems

essential to me that the mathematics teachers have tools allowing them to think about the way they speak, and about the ambiguities and implicits that lie under some usual formulations in our practice of mathematics. Mathematical logic seems a possible reference for this reflection.

APPROACHING ALGEBRAIC PROOF AT LOWER SECONDARY SCHOOL LEVEL: DEVELOPING AND TESTING AN ANALYTICAL TOOLKIT

Francesca Morselli

University of Turin, Italy

In this contribution, I discuss two episodes from a teaching experiment performed in lower secondary school (grade 7) aimed at introducing proof and using algebraic language as a proving tool. The teaching experiment was conceived within a theoretical framework presented in a PME Research Forum (Boero et al., 2010). That theoretical framework was further developed in order to improve the a-posteriori analysis and refinement of the classroom intervention. The aim of this paper is to show how the increased theoretical framework shed new light on the students' processes. Moreover, the analysis suggested occasions for developing argumentation at the meta-level.

INTRODUCTION

In this contribution I present and discuss two episodes from a teaching experiment, performed in grade 7, aimed at introducing a “proving culture” in the classroom. The contribution is situated in the stream of research outlined in a PME Research Forum (Boero et al., 2010). From a theoretical point of view, the Research Forum proposed an integration between Toulmin’s model for argumentation and Habermas’ theory of rationality (see the “Background” section below). The Research Forum paper ended with a series of suggestions for further developments and implementations, which were the starting point for the teaching experiment that is the object of this contribution. In the meantime, the retrospective analysis of some teaching experiments performed in the past (see Morselli & Boero, 2011) suggested to integrate the theoretical framework presented in Boero et al. (2010) in order to better frame the modelling activity of the student when he/she moves from a problem situation (internal or external to mathematics) to its algebraic treatment. In this paper I show how the integrated framework can be used to analyse the processes carried out by the students, with a special attention to the dialectic between proof and algebra.

BACKGROUND AND THEORETICAL FRAMEWORK

According to Balacheff (1982), the teaching of proofs and theorems should have the double aim of making students understand what is a proof, and learn to produce it. De Villiers (1990) suggests that the teaching of proof should make students aware of the different functions that proof has in mathematical activity: verification/conviction, explanation, systematization, discovery, communication. Stylianides (2007) proposes the following definition of proof that can be applied in the context of a classroom community at a given time:

“Proof is a mathematical argument, a connected sequence of assertions for or against a mathematical claim, with the following characteristics: it uses statements accepted by the classroom community (set of accepted statements) that are true and available without further justification; it employs forms of reasoning (modes of argumentation) that are valid and known to, or within the conceptual reach of, the classroom community; and it is communicated with forms of expression (modes of argument representation) that are appropriate and known to, or within the conceptual reach of, the classroom community”. (Stylianides, 2007, p. 291).

This definition brings to the fore that a smooth and meaningful approach to proof requires the students’ progressive acquisition of basic content knowledge, but also the ability to manage (from a logical and linguistic point of view) the reasoning steps and their enchaining (modes of argumentation) and the ability to communicate the arguments in an understandable way. This is in line with the idea, exposed by Morselli and Boero (2009), that learning proof is approaching a specific form of rationality. The authors proposed an adaptation of Habermas’ construct of rationality to the special case of proving, showing that the discursive practice of proving may be seen as made up of three interrelated components:

- “- an epistemic aspect, consisting in the conscious validation of statements according to shared premises and legitimate ways of reasoning (cf. the definition of “theorem” by Mariotti & al. (1997) as the system consisting of a statement, a proof, derived according to shared inference rules from axioms and other theorems, and a reference theory);
- a teleological aspect, inherent in the problem solving character of proving, and the conscious choices to be made in order to obtain the aimed product;
- a communicative aspect: the conscious adhering to rules that ensure both the possibility of communicating steps of reasoning, and the conformity of the products (proofs) to standards in a given mathematical culture”. (Morselli & Boero, 2009, p. 100)

Boero et al. (2010) proposed the integration of the construct of rational behaviour, with Toulmin’s model of argumentation, thus creating a comprehensive frame that allows: (1) to better analyse students’ proving processes; (2) to plan and carry out innovative classroom interventions. As regards the analysis of students’ processes, the integrated model allows two levels of analysis: Toulmin’s model focuses on the single argumentation step, while Habermas’ construct allows to study each phase of the proving process, from the exploration to the final proof construction (thus shedding light on the legitimacy of reasoning steps, on the intentions behind each step, and on the communicational constraints). As regards classroom interventions, the integration suggests the importance of developing students’ awareness of the constraints inherent in the proving process. Indeed, within the integrated frame, two levels of argumentation are outlined: the meta-level, concerning the awareness of the constraints related to the three components of rational behaviour in proving, and the level concerning the proof content. Within the integrated frame, students’ enculturation into the culture of theorems is a long-term process where the teacher

must create occasions for meta-level argumentations aimed at promoting students' awareness of the epistemic, teleological and communicative requirements of proving.

Crucial issues are: how to create occasions for meta-level argumentation and how to manage them in the proper way. Boero (2011) analysed a mathematical discussion at university level, showing that dealing at the same time with the content level and the meta-level is quite difficult, and suggesting some a-posteriori activities so as to create *occasions* for meta-level argumentation. In the present paper, I illustrate some *occasions* emerging from another teaching experiment, aimed at the approach to proof in arithmetic. Here the approach to proof is in a dialectical relationship with the introduction of algebraic language as a proving tool (i.e. the means to perform proof).

Algebraic proof

Boero (2001) describes algebraic treatment as a cycle: the starting situation (*sem1*) is put into formula (*form1*) by formalization. The first formula (*form1*) is transformed into another one (*form2*) that may give new information to the reader (thus performing an interpretation from *form2* to *sem2*).

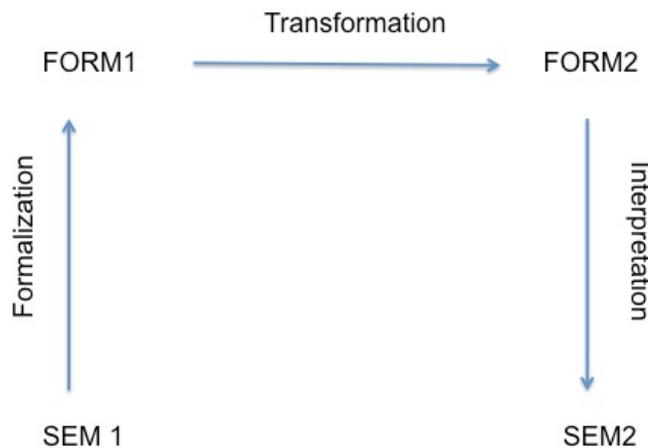

Figure 1: The cycle of algebra (Boero, 2001)

The fundamental cycle of *formalization*, *transformation* and *interpretation* is at the core of algebraic activity. In particular, algebraic proof is carried out by means of such cycles. When dealing with algebraic language as a proving tool, some crucial issues are: the choice of the formalism, that must be correct but also goal-oriented; the validity but also usefulness of the transformations; the correct and purposeful interpretation of algebraic expressions in a given context of use.

Morselli & Boero (2011), adapted the three components of a rational behavior in proving to the use of algebraic language in proving. In their elaboration, epistemic rationality consists of two distinct requirements: 1) *modelling requirements*, inherent in the correctness of algebraic formalizations and interpretation of algebraic expressions; 2) *systemic requirements*, inherent in the correctness of transformation (correct application of syntactic rules of transformation). Teleological rationality consists of the conscious choice and management of algebraic formalizations,

transformations and interpretations that are useful to the aims of the activity. Communicative rationality consists of the adherence to the community norms concerning standard notations, but also criteria for easy reading and manipulation of algebraic expressions.

The contribution of this paper relies in the integration of the fundamental cycle of Algebra with the construct of rationality (in the use of algebraic language in proving) in the analysis of students' behaviours.

RESEARCH PROBLEM

This paper concerns the experimentation of a task sequence aimed at approaching proof and introducing algebra as a proving tool. The main research questions are: can the analytic tool of rational behaviour integrated with the fundamental cycle of algebra be exploited to perform more in-depth analyses and interpretations of students' behaviours?

Previous research pointed out the importance of creating *occasions* for argumentation at meta-level, so as to make students aware of the epistemic, teleological and communicative constraints of proof. More specifically, with an eye to the use of algebraic language as a proving tool, it is important to promote reflection at meta-level on the nature of the actions to perform (*formalization, transformation, interpretation*). Thus, additional research questions are: are there *occasions* for meta-level argumentation? If yes, what are the themes for such an argumentation?

METHOD

The context

The teaching experiment is situated within the research project “Language and argumentation”, started in 2008, aimed at the design, experimentation, analysis and refinement of task sequences for the development of students' “proving culture”. Within the project, teachers and researchers share the same theoretical references and collaborate in the design activity, as well as in the analysis of the experimentation and the progressive refinement of the tasks.

The task sequences are conceived with argumentation as a core activity. Two types of argumentation are fostered: argumentation at content level, as a part of the proving process, and argumentation at meta-level, as a means for fostering reflection on the practices of mathematical proof related to the components of rationality. To this aim, tasks encompass: formulation of conjectures; comparison between different conjectures; justification of conjectures; comparison between individual processes and between individual final products. Didactical methodologies such as group work and mathematical discussions (Bartolini Bussi, 1996) are widely used. The team also explored the importance of making students to analyse students' written individual solutions, as it is advocated within the theoretical framework of the fields of experience didactics (Boero & Douek, 2008).

The task

The task sequence “*Sum of consecutive numbers*” was conceived for grade 7 (students’ age: 13-14); it encompassed exploration, conjecturing and proving in arithmetic. The approach to proof is in a dialectical relationship with the introduction of algebraic language as a proving tool. The students were at their second experience within the project. They had already experienced the task sequence “*Choose a number*”. In that occasion, they had appreciated the power of algebraic language for representing generality and showing the structure of the problem (see Morselli & Boero, 2011).

The task sequence was experimented in two classes, by two teachers involved into the project. The author, a researcher in mathematics education, attended all the class sessions, acting as a participant observer. This means that she observed the class sessions, could provide further explanations, if required, during the individual and group work and could intervene in the discussion that involved all the students. She realized video recordings of the mathematical discussions and collected all the individual and group productions provided by the students.

The whole sequence lasted about 10 hours. A description of the whole task sequence, as well a comparison between the two classes, is beyond the scope of this contribution. Here we confine ourselves to the first 4 hours. The students were proposed a first task (“*What can you tell about the sum of three consecutive numbers?*”). We may note that in both classes, in line with previous experiences in arithmetic, the students interpreted the task as referring to the sum of three consecutive *natural* numbers. The fact of working with natural numbers was not discussed with the teacher. The students worked individually, shared their solutions in small groups and after compared all the group solutions within a mathematical discussion. In each class, the discussion was devoted to the comparison of the conjectures and justifications provided by the students. For the aim of the paper, I selected from each discussion the excerpt referring to the classroom discussion about *how to justify the property by means of algebra*. The description of each episode is followed by a first analysis. Afterwards, an overall discussion of the results is presented.

TWO EPISODES FROM THE TEACHING EXPERIMENT

Episode 1: Three proofs for the same property

The students from the first class worked individually and produced different conjectures. Although the norms established in the classroom require that any answer should be justified, only one student accompanied his conjecture with a justification. Elio claimed that “*the sum is a multiple of three*”, performed three numerical examples (see figure 2 for the original production) and wrote down: “*Moreover, if the third number gives a unit to the first number, we have three equal numbers*”.

$$1+2+3=6$$

$$\overbrace{7+8+9}^{+1}=24$$

$$51+52+53=756$$

Figure 2: excerpt from Elio's individual solution

Elio's justification is firstly illustrated by means of a numerical example (7,8,9; see in figure 2 the line over the numbers, which represents the idea of 9 giving a unit to 7). This is a proof by generic example (Balacheff, 1982), since the numerical example is not aimed at "checking that the conjecture holds", rather to show "why the conjecture holds". The final sentence, although introduced by "moreover", is a justification in general terms. We may note that this proof by generic example has the function of *explanation*, not merely of *conviction*. This proof was shared by Elio to his group mates and, afterwards, presented to the whole class and discussed within a mathematical discussion. During the discussion, the observer and the teacher underlined that Elio's justification is a real *explanation* of the reasons why the conjecture holds. The observer also underlined that Elio's method shows that the property does not hold if the numbers are not consecutive, thus pointing to the function of *explanation*.

- 1 Observer: and in this way you understand why this is a property that not always holds. Some of you maybe tried to sum up three non-consecutive numbers. It is not sure that we still have this [*the divisibility by 3*], isn't it? This explains why we need three consecutive numbers to have it.
- 2 Elio: if we tried, here, instead of 503, with 504, I would get 503. I take away 1 [*from 504*] and I get 503, not 502.
- 3 Teacher: and you don't have anymore three equal numbers. The nice thing, using three consecutive numbers, is that if I take 1 away from the biggest number and I move it to the smallest number, I get three equal numbers. That why I always get three times the intermediate number, exactly because there is that "moving". [*they go on doing some numerical examples and applying the "taking away" strategy*]

Elio's individual solution contains also an algebraic proof:

$$a+a+1+a+2 \text{ could also be } a+a+a+1+2$$

thanks to the commutative property it would be $a*3+1+2$

$$a*3+3.$$

During the discussion, Elio explained his choice of providing also an algebraic proof: "But maybe they [*numeric examples*] did not work on great numbers and I could not do an example on all numbers". We may observe that Elio was not completely satisfied with his proof by generic example, probably influenced by the common idea that "examples don't prove". Actually, this proof by generic example was already acceptable. We also observe that when passing from generic example to algebraic proof, Elio did not perform a translation in algebraic language of the same type of

proof, rather he carried out a different proof. This fact was pointed out during the mathematical discussion. Elio, with the help of the teacher, created at the blackboard the algebraic version of his proof by generic example:

$$a+a+1+a+2=a+1 + a+1+ a+1=3(a+1)$$

In terms of cycle of algebra, the two algebraic proofs (the first one, carried out by Elio individually, and the second one, carried out during the discussion) may be modelled as it follows:

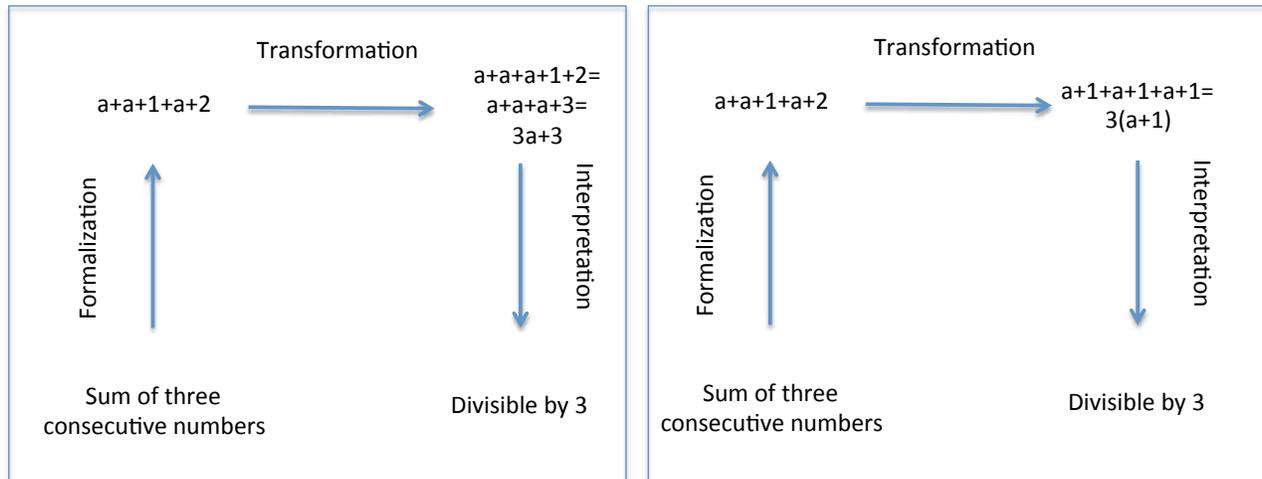

Figure 3. Elio’s individual proof and the proof carried out during the discussion

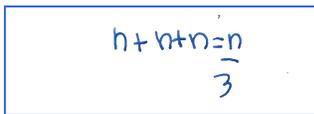

Both proofs are carried out properly and each action (formalization, transformation and interpretation) involves some aspects of rationality: formalization is correct (modelling requirements of epistemic rationality), and useful, since it allows the subsequent treatment of the algebraic expression (teleological rationality). All the transformations are performed correctly (systemic requirements of epistemic rationality) and in a goal-oriented way, so as to obtain the divisibility by 3 (teleological rationality). In the second algebraic proof the strategy of “taking away” 1 is guided by the goal of getting three times the same number. Thus, transformation is even more goal-oriented (tel. rationality). Finally, in both cases interpretation is correct (systemic requirements of epistemic rationality), since the final algebraic expressions ($3a+3$ and $3(a+1)$ respectively) are read in terms of “divisibility by 3”. In the first proof, $3a+3$ could be more developed so as to make more evident the divisibility by 3. In the second proof the divisibility by 3 is evident and one could also note that the result is three times the intermediate number (epistemic rationality).

The analysis in terms of cycle of algebra and construct of rationality reveals some differences between the two proofs: the first one is mainly syntactical and could be carried out without having in mind the property to prove; on the contrary, the second one can be performed only under the guide of a strong anticipation (one must already have the goal of getting three times the same number); the second algebraic proof seems to be possible only in continuity with the argumentation in natural language and numerical examples (proof by generic example). Both proofs have an educational

value and offer occasions for argumentation at meta-level. Indeed, the second proof is a telling example of proof as *explanation*, the first one may also convey the idea of algebraic proof as a means for *discovery*. Actually, also in second proof there is a discovery part, because also divisibility by the intermediate number turns to be evident. The second proof also highlights the importance of reflection on numbers. The analysis suggests that it would be important to promote an a posteriori comparison between them, thus fostering a meta-level argumentation on the way of carrying out algebraic proof (crucial role of *transformation*), and also on the value of algebraic proof (not only *conviction*, but also *explanation* and *discovery*).

Episode 2: struggling towards an algebraic proof

The same task was proposed in another class. One student (Edel) conjectured that “*the result is a multiple of 3*” and accompanied the conjecture by a first justification in natural language (“*because the summed numbers are three*”) and by a symbolic expression (see figure 4). From the mathematical discussion, we know that Edel’s intention was that of providing an algebraic proof for the property.

$$\frac{n+n+n=n}{3}$$

Figure 4. Excerpt from Edel’s solution

In terms of cycle of algebra, Edel’s attempt may be modelled in this way:

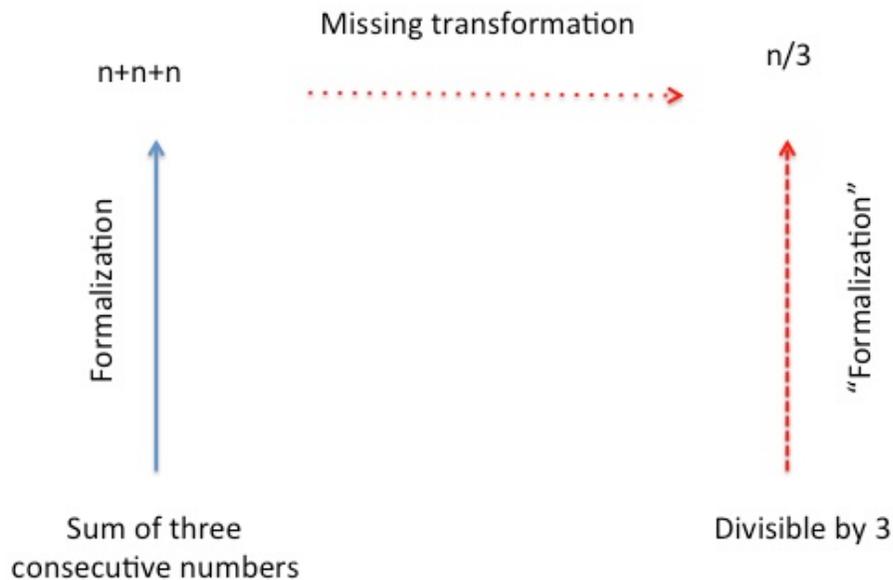

Figure 5: Edel’s attempt

The cycle of algebra is not working in the proper way: formalization is not correct (since $n+n+n$ is not a correct representation of three consecutive numbers) and $form2$ ($n/3$) is obtained by an (incorrect) formalization of the conjectured property “divisibility by 3” (*sem2*), rather than from a transformation of *form1*. Edel’s difficulty in formalizing the divisibility by three may be interpreted in terms of

difficulty in the first use of algebra or difficulty in dealing with multiples and divisors. Here we focus on the effect that such difficulties may have on the proving process and on the possible interventions. From the point of view of rationality, we note lacks in the modelling requirements of epistemic rationality. Anyway, we suggest that the formalization of $n/3$ lacks in terms of epistemic rationality, but is rational from the teleological point of view: Edel wants to translate in letters what she already discovered, that is the divisibility by 3. We may say that the missing issue is exactly the *transformational* power of algebra. What makes algebra a powerful proving tool is the possibility of passing from the starting situation to the conclusions by means of transformation. This awareness (at meta-level) is completely absent in Edel's solution. Edel's activity has a teleological rationality, but according to her own goal: translating into letters. This is linked to her "ritual" conception of algebra as a proving tool: it seems that, for her, the algebraic proof is just a symbolic translation of what is already known.

Previous analysis suggests the necessity of a reflection on how algebraic language works as a proving tool (teleological aspects). We point out that there is a rationality in the choice of using algebraic language as a proving tool, and a rationality in performing the algebraic proof. Awareness of the teleological aspects referring to the use of algebraic language as a proving tool (it is a useful proving tool because it allows to obtain the proof by means of transformation of symbolic expressions) has direct consequences on the awareness of the teleological aspects referring to algebraic activity (formalization and transformation must be goal-oriented).

CONCLUSIONS AND FURTHER DEVELOPMENTS

We described and analysed two episodes from a teaching experiment aimed at introducing algebra as a proving tool.

The new integrated framework allowed us to put the requirements of epistemic and teleological rationality in a dynamic perspective. This brought to the fore that, when proving by means of algebraic language, the student must be able to combine the adherence to syntactical rules on one side, and the goal-oriented management of the processes of formalization, transformation and interpretation, on the other.

In this way, the integrated framework allowed us to understand better the students' processes (in particular, as concerns the nature of some of their difficulties) and to detect some occasions for argumentation at meta-level, that is occasions in which students can be asked to reflect on some aspects/components of the complex process they are involved in.

Important issues, to be treated at meta-level, concern: the role and value of numerical examples and the legitimacy of proof by generic example and proof in natural language; the crucial role of transformation, and the consequent importance of transformation-oriented formalizations; the dialectic between syntactic manipulation

and more creative manipulation; and the possible links with the different functions of proof (from conviction, to explanation, to discovery).

The aforementioned task and the subsequent mathematical discussions can only partially achieve the goal of improving awareness on all these points. Further developments concern the design and implementation of tasks aimed at provoking such occasions.

THE EPISTEMIC STATUS OF FORMALIZABLE PROOF AND FORMALIZABILITY AS A META-DISCURSIVE RULE

Eva Müller-Hill

University of Cologne

The first two parts of this article report on a study that was part of my dissertation project at the interface of epistemology and sociology of mathematics. The study deals with the epistemic role of formalizability, which is traditionally held to be the main epistemic feature of mathematical proofs, in actual mathematical (research) practice. As a core result, it is argued that formalizability should be understood as a feature of discursive proving actions as the true bearers of epistemic value. As I discuss in the last part of the article, this insight opens the way for a shift to an educational perspective on proof in mathematical research practice. Sfard's approach to mathematical thinking as communication, with the concept of meta-discursive rules in particular, serves well as a conceptual framework to that end.

Keywords: mathematical proof, formalizability, epistemology, sociology, meta-discursive rules

INTRODUCTION

In science education, the so-called nature of science is a widely agreed upon aspect of scientific literacy that one has to teach more or less explicitly. Important components of nature of science are epistemic features of scientific inquiry, the epistemic status of laws and theories, the tentativeness of science, the theory ladenness of observation, etc. (Akerson, Abd-El-Khalick, & Lederman, 2000). Regarding mathematical research practice and university education, proof appears to be an essential component of a “nature of mathematics”. But are the essential epistemic features of proof in mathematical research practice relevant to school mathematics? If so, how could we teach them? Though these questions can only be touched in the last part of this article, they indicate an overall framework for employing the results from research on proof in actual mathematical research practice presented here, under appropriate re-interpretation where required, in thinking about teaching proof in school mathematics.

The work (Müller-Hill, 2011) that is presented in the first two parts of this paper was concerned with the epistemic role of formalizability of mathematical proofs in actual mathematical practice, with a major focus on research mathematics and a minor on mathematics education at university[1]. Regarding these contexts, one is traditionally inclined to demand formalizability—usually without further specification—as an essential epistemic feature of proof. Hence the main research question was:

In what sense of “formalizable” is formalizability an essential epistemic feature of proof in actual mathematical practice, and thus a necessary condition for accepting a proof?

Formalizability is a feature of informal mathematical proofs: A formalizable proof is a proof that can be transferred into a formal proof, that means it can be transferred into a formal derivation with respect to a formal axiomatic system with consistent axioms. However, this notion of formalizability is not sufficiently specified. Possible semantics of the phrase “formalizable proof” still vary in a spectrum spread between two extremes. One extreme would be the weak reading “a proof of p is formalizable iff the informally proven mathematical theorem is also formally derivable in a consistent formal axiomatic system”; the other extreme is the strong reading “a proof of p is formalizable iff it can be translated step by step into a formal proof”, which may refer to, for example, proofs that are written in some semi-formal language.

Formalizability is indeed an important feature of mathematical proofs, regarding foundational issues in the philosophy of mathematics[2]. Foundational issues, however, are not addressed in the following. What is addressed instead is the epistemic role of this feature, from the viewpoint of a socio-empirically informed philosophy of mathematics.

SOCIO-EMPIRICALLY INFORMED PHILOSOPHY OF MATHEMATICS

The epistemic role of formalizability has traditionally been investigated by analytical philosophy of mathematics. The focus of such investigations is on the project of conceptually grasping formalizability as an epistemic feature of proof. The default method of analytical philosophy is the semantic analysis of so-called ordinary language epistemic concepts like knowledge and justification. It investigates the adequateness of having a formalizable proof as a truth-condition for, e.g., knowledge attributions. The analytical philosopher thereby almost exclusively relies on his professional intuition as an expert for epistemic concepts like knowledge, belief, or justification (see recently, e.g., Glock, 2008, for an introduction to analytical philosophy).

However, concerning the question of the epistemic role of formalizable proof in actual mathematical practice, an investigation of decidable conditions under which a proof is actually acceptable because of being formalizable appears to be equally worthwhile (see also Moser, 1991).

A socio-empirically informed philosophy of mathematics aims at (ideally) establishing a reflective equilibrium between the outcomes of both kinds of investigation. An appropriate methodological framework to this end is conceptual modelling as developed in (Löwe & Müller, 2011) and (Löwe, Müller, & Müller-Hill, 2010). Conceptual modelling “of X ” takes the form of an iterative process:

Step 1 Theory formation Guided by either a pre-theoretic understanding of X or the earlier steps in the iteration, one develops a structural philosophical account of X , including, e.g., considerations of ontology and epistemology.

Step 2 Phenomenology With a view towards Step 3, one collects data about X and extracts stable phenomena from them to corroborate or to question the current theory.

Step 3 Reflection In a circle between the philosophical theory, the philosophical theory formation process and the phenomenology, one assesses the adequacy of the theory and potentially revises the theory by reverting to Step 1.

In particular contrast to analytic epistemology, a socio-empirically informed epistemology of mathematical practice strengthens step 2 by including data established via accepted empirical methods from empirical sociology.

DESIGN OF AN INTERVIEW STUDY AS PART OF STEP 2

The conceptual modelling cycle displayed above was employed iteratively in my study (Müller-Hill, 2011). As one part of step 2, I developed and conducted a qualitative, so-called problem-centered, semi-standardized guideline interview study (see, e.g., Mayring, 2002) among research mathematicians. The aim was to gather detailed empirical information about practitioner's interpretations of the epistemic role of formalizable mathematical proof in actual mathematical practice.

The interview guideline (see Müller-Hill, 2011, 148 ff.) was developed with respect to certain key aspects that came out of earlier iterations of the modelling cycle, including in particular a quantitative questionnaire study reported in (Müller-Hill, 2009, 2011) on the use of epistemic attributions in actual mathematical practice.

Six mathematicians of high standing, from various fields of professional specialisation areas in mathematical research practice, from different countries and different institutions, were chosen as interviewees. The interviews were audio-recorded and transcribed. As the method of data analysis, I chose so-called phenomenological analysis. The method of phenomenological analysis, in a nutshell (cf. Mayring, 2002), is to reconstruct units of meaning in a sufficient variety of subjective interpretations and viewpoints of the matter in question as a first step. In a second step, these subjective, idiosyncratic units of meaning are synthesized, and reduced to a common, invariant essential core.

RESULTS AND INTERPRETATION

In the following, I will present some exemplary quotes from the interview transcripts, a short summary of the philosophical interpretation based on the analysis of the transcripts, and a central aspect of the subsequent conceptual theory formation (see Müller-Hill (2011) for more details on the data and its analysis).

Example quotes from the transcripts

The following examples stem from four of the six interviews.

Excerpts from interview 2:

Interviewer: And what would you call a formalizable proof?

IP 2: [...] If something is obviously non formalizable, then to me it will be obviously not an acceptable proof.

Interviewer: Would you say that every proof that is accepted by the community is formalizable?[3]

IP 2: [...] That's my belief, and one should say this is a hygienic belief – I mean, that's more or less a definition of what we, as mathematicians, as a community, are thinking about [...] when we are talking about proofs.

Excerpts from interview 3:

Interviewer: Would you say that the proof about the classification of finite simple groups is a formalizable proof?

IP 3: [...] I think in principle, it's formalizable, this classification.

Interviewer: What does 'in principle' mean?

IP 3: With the present technology, or just by hand, it may not be doable for one person in a lifetime and maybe even for the group of people who have been working on this it may not be doable, but with advanced future computer technology it may be doable.

Excerpts from interview 4:

IP 4: So one thing: maths is in a sense something personal. [...] When do I think I understand something? Certainly if it's a relevant thing, during the next few weeks I would try to shoot holes in it, look at it from different directions, through different angles, ask questions why it is true, why it works this way, not that way. [...]

Interviewer: What would be formal proof for you?

IP 4: [...] I have to be able to understand both the global picture, to have an overview of the proof, explain to myself what the global idea is and why it works like this, and also to be able, and that's the details, to follow the proof from step to step, the logical consequences.

Excerpts from interview 5:

Interviewer: What do you mean by 'formal proof'?

IP 5: [...] One of my recent graduate students is almost incapable of writing down proofs. But he really knows mathematical truths. The problem is then to extract from him why it is true, which is the proof. [...] There are well respected mathematicians who are like this.

Interviewer: Can you make any sense of the term 'formalizable proof'?

IP5: It very much depends on the style of a mathematician, on a personal temper maybe, the attitudes of particular mathematicians, but it depends also on the field of mathematics. [...]

Interviewer: Would you say that every proof that is accepted by the community is formalizable?

IP 5: [...] Maybe I shouldn't think of myself as a mathematician if I don't believe that the proofs are formalizable. I think we act on assumption that the proofs that we produce are formalizable.

Excerpts from interview 6:

IP 6: When doing my Ph.D. thesis, I learned [...] something about the way to be careful [...] If you see a proof, then you start reading it, and say, o.k., can I understand all the implications. This can be very clear, or can sometimes be a little bit blurred in that you are at the point of sort of believing it rather than actually seeing it. [...]

Interviewer: Would you say that every proof that is accepted by the community is formalizable?

IP 6: [...] I think they look like formalizable proofs. I don't know how they do that, but I think that all the people who have looked at these proofs think they are formalizable.

Summary of the philosophical interpretation

The philosophical interpretation developed in (Müller-Hill, 2011) on the basis of the phenomenological analysis of all interview transcripts, including those that are not displayed above, can be summarized and condensed into eight main aspects. I will only refer to the following six of these aspects here (see Müller-Hill, 2011, 205ff., for the whole list), with an emphasis on aspect (5) as a major conceptual turning point in the philosophical understanding of proofs as bearers of epistemic value.

1. In actual mathematical practice, acceptable proof includes the inevitable possibility of error. Hence the whole proving process has no final point, and epistemic attitudes of practitioners are not categorical. Nevertheless, there exist well working, situative standards for the error robustness of the core argumentation of an acceptable proof.

2. Equally besides and even beyond the aim of secure knowledge-that, mathematical practice aims at understanding in the sense of knowledge-why.

3. Explanatory proofs contribute essentially to knowledge-why. Hence, depending on the professional skill level of the epistemic subjects, acceptable proofs ought to have a meaningful argument structure. To that end, they often rely on established meta-argumentations that are not formalizable *mutatis mutandis*, or by mechanical means.

4. Epistemic standards for acceptable proof are gradual and context-dependent. They concern surveyability, clarity of the core argumentation, error robustness and formal correctness, the use of meta-argumentations and the possibility of perspective change.

5. Formalizability of acceptable proof should consistently be interpreted rather as an essential epistemic feature of the embedding communicative action than of the static,

linguistic argument presented as a proof. (This is not to say that the mere linguistic argument presented as a proof of p does not bear *any* epistemic value.)

6. The concept of formal proof functions as an abstract, internalized model of proof shaping the self-image of practising mathematicians. Sophisticated mathematicians may have internalized the rules and principles of formal proving and work in agreement with these rules without explicitly and consciously employing them.

Formalizability as an epistemic feature of discursive proving actions

Moving from these results of step 2 towards step 3 of the modelling cycle, theory formation, the main question is how to specify the notion of formalizability as an epistemic feature of mathematical proof that properly fits the empirical findings. According to the interpretation of the results of the interview study, there are several essential aspects of acceptable proof in actual mathematical practice, with formalizability as one of them. However, some of these essential aspects appear to compete against certain others, such as formalizability and fallibility, formalizability and the frequent use of sophisticated meta-argumentations, or formalizability and explanatory power. Hence, to form a consistent notion of formalizability as an epistemic essential of proof within an epistemology of mathematics needs to supersede the concept of proof itself as a mere linguistic entity—an argument—by a proper alternative[4].

Such an alternative account of an epistemologically relevant notion of proof in mathematical practice that can consistently be seen as a bearer of the partly competing epistemic aspects mentioned above is provided, as I argue and develop in detail in (Müller-Hill, 2011), by the notion of discursive proving actions. I will give a brief sketch of this conception of formalizability in the following.

My account makes reference to the concept of informing dialogical communicative actions used in philosophy of language and linguistics (cf. Meggle, 1999):

An informing dialogical communicative action is an intentional act of communication in dialogue, with the communicative aim to make the receiver believe a certain thing.

Formalizability can thus be conceptualized as an epistemic feature of mathematical proof, in the sense that an epistemic subject X is justified to believe in the validity of a theorem p on the basis of an accepted proof, if X is able to carry out—given appropriate conditions—a certain kind of discursive proving action. I call these discursive proving actions “derivation indicating”[5]:

A *discursive proving action* for a mathematical theorem p is an informing dialogical communicative action (oral or written) where an epistemic subject X presents an argumentation for the validity of p to a certain audience under certain situative circumstances. The presentation of the argumentation includes contributing utterances of members of the audience. A discursive proving action is called *derivation indicating* iff the type of argument, the presentation of the argument, and the professional level of the audience meet the contextually given epistemic standards and X has sufficient

mathematical skills to produce a appropriately formalized argument out of the given presentation. This may involve modification, correction and supplementation of the given presentation up to certain, context-sensitive levels of error robustness and stability of the core argument. (Müller-Hill, 2011, 230 f., German in the original)

FORMALIZABILITY AS A META-DISCURSIVE RULE

The general conceptual turn from mere linguistic entities to discursive proving actions in analyzing the essential epistemic features of mathematical proofs opens the way for using certain perspectives and theoretical frameworks from research in mathematics education for a re-interpretation of the results of the presented study. If this is successful, it could be a fruitful interface between a better understanding of the nature of proof in actual mathematical practice and a didactically sustainable way of teaching the nature of mathematical proof in the classroom.

Regarding research in mathematics education, Sfard's approach of mathematical thinking as communication and her concept of meta-discursive rules (Sfard, 2001, 2002, 2007, 2008) seem to grasp the core of my socio-empirically informed account of the epistemic role of formalizability particularly well. According to Sfard, meta-discursive rules, in contrast to object-level discursive rules, are rules about the discourse[6]. Formalizability, understood as a feature of discursive proving actions, can be seen as such a meta-discursive rule in actual mathematical practice. Within the scope of this article, I can only highlight two characteristics of formalizability as a meta-discursive rule in the sense of Sfard.

First, according to Sfard (2002, 30) “meta-rules are usually not anything the interlocutors would be fully aware of, or would follow consciously”. Rather, “in concert with meta-discursive rules, people undertake actions that count as appropriate in a given context and refrain from behaviours that would look out of place”. This characterization of meta-discursive rules fits well with aspect (6), formal proof as an internalized leading picture, aspect (3) regarding the role of professional skills, and aspect (4), context-sensitive epistemic standards, from the general interpretation of the interview results. The first quote from interview 2 additionally stresses that formalizability can be, precisely in the manner of Sfard's conception, a regulative for discursive decisions (Sfard, 2001, 26 f.).

Second, formalizability, when interpreted as a meta-discursive rule, can be understood as responsible both for the way and for the very possibility of successful communication (cf. Sfard, 2002, 31). The given quote from interview 2, expressing that formalizability of all accepted proofs is a “hygienic belief”, and the second quote from interview 5, can be understood in this sense. Additional, socio-historical evidence corroborates this claim:

I interpret formalization as a symbolically generalized communicative medium, which was developed precisely when, due to profound institutional changes, the prior social-integrative mechanisms became deficient. (Heintz, 2000, 252, my translation)

Thus in research mathematics, formalization can be seen as a meta-discursive rule that guides discourse, especially in conflict situations, as a control tool: If doubt is cast on an informal argumentation regarding its principal conformity to formal rules and definitions, a higher level of formalization is chosen (which does not have to be already mechanically implicit in the original argument).

Still, formalizability does not fulfil all of Sfard's characterizing conditions of meta-discursive rules. This suggests that there are additional, competing as well as supplementing, epistemically relevant meta-discursive rules in actual mathematical practice. Some promising candidates can be read off the already presented empirical results, such as the possibility of perspective changes. Others need further empirical investigation, e.g., on use and acceptance of informal meta-argumentation strategies.

CONCLUSIONS AND THOUGHTS TO THE FUTURE

The results of the study presented here, and also the sketch of meta-discursive rules as an alternative conceptual framework for their interpretation borrowed from research in mathematics education, have several implications for understanding the concept of proof in actual mathematical practice.

Induced by, but not limited to the investigation of formalizability, a general conceptual turn from proofs as mere linguistic entities to discursive proving actions was made in analyzing the true bearers of consistently explicable epistemic features. This highlights the relevance of conducting more detailed empirical studies of discursive practices regarding oral and written communication in actual mathematical practice, both in research and in university education. A subsequent examination of concrete implications for the teaching of mathematical proof, or of possible epistemic impact of the use of formalization and proof for the teaching, understanding and clarification of mathematical concepts could, as a first step, concentrate on university level mathematics education.

Nevertheless, the concept of meta-discursive rules can also serve as a connection between the presented research on proof and school mathematics. If the essential epistemic aspects of proof, with proof being one main putative component of a “nature of mathematics”, are best understood as meta-discursive rules of actual mathematical practice[7], then teaching of the nature of mathematical proof should happen within proving discourses in classrooms, and include explicit reflections on meta-discursive rules in general, and formalizability as a special meta-discursive rule in particular. The use of formalization as a control tool, the validity of picture proofs, of the use of diagrams in proofs, and of argumentation assisted by geometrical representations are example topics for developing appropriate learning environments for such reflections on formalizability in, e.g., high school level maths courses.

In turn, such explicit reflections on meta-discursive rules in general and in particular should also become an integral part of pre-service and in-service teacher education.

NOTES

1. The study was embedded in a much broader agenda of developing a transdisciplinary approach of philosophical, sociological, psychological, historical and didactic research on actual mathematical practice that has been conducted by members of the DFG scientific Network PhiMSAMP (Philosophy of Mathematics: Sociological Aspects and Mathematical Practice) 2006-2010 (cf. Löwe & Müller, 2010).
2. Note that since the works of Boole, Frege, Russell, Hilbert, and Gödel there exists a highly sophisticated discussion in (philosophy of) mathematics and logic on what kind of formal logic (e.g., regarding order, or meta-theory of the axiom system) is appropriate to formalize the foundations of mathematics (see, e.g., Hintikka, 1996, 2011). I am not concerned with this question here, but refer to today's most common foundation of mathematics within the first-order Zermelo-Fraenkel axiomatics (ZFC) of set theory. However, this assumption does neither essentially draw on the spectrum of semantics for “formalizable proof”, nor on the essential features of formal proof like gaplessness and explicitness.
3. Possible bias was not taken into consideration here, as the interviewees were all professional mathematicians of high standing with arguably stable and grounded attitudes towards acceptable mathematical proofs in research.
4. Note that this is not to claim that such a conceptual turn is or should be part of the aware image of proving held by professional mathematicians; but it should be part of any consistent, empirically informed philosophical consideration.
5. Azzouni (2004) coined the technical term of a “derivation indicator”, but only for single arguments as linguistic entities, and with a different meaning.
6. As an example that illustrates the distinction, regard the following: “Investigate the function $f(x)=3x^3-2x$!” (see Sfard, 2000). An object-level discursive rule is that it is not allowed to divide the equation $0=3x^3-2x$ by x to determine the nulls of f . But only meta-discursive rules determine what to do with f at all: “You are not sure whether you are supposed to list the properties of the graph (yet to be drawn!) or to admire its aesthetics; [...] to make an investigation of the effects of real-life applications [...] or to check possibilities of transforming it, and so on.” (Sfard 2000, 177)
7. Moreover, this approach offers interfaces to include a historical dimension. See, e.g., (Kjeldsen & Blomhoj, 2011) on historical case examples as a way to reflect on meta-discursive rules in school.

$$0,999\dots = 1$$

AN EQUALITY QUESTIONING THE RELATIONSHIPS BETWEEN TRUTH AND VALIDITY

Judith Njomgang Ngansop

Viviane Durand-Guerrier

University of Yaoundé 1 (Cameroon)

University Montpellier 2 (France)

The relationship between truth in an interpretation and validity in a theory as developed in logic, is a crucial issue in mathematics. In this article, we examine how an activity based on the equality "1 = 0.999 ..." could permit students to experience this relationship. We first provide practical and epistemological reasons supporting the claim that we have here a good candidate for this purpose. We then report on an experiment with nine fresh undergraduate students in France enrolled as volunteer in a short course aiming to help them to overcome difficulties in logic, reasoning and proof met in the calculus course; we analyse some excerpts of students' discussion showing that questioning this equality could favour the emergence of discussion on truth, validity, defining and proving, proof and theoretical reference.

Key words: truth, validity, definition, decimal and real numbers, limit of series.

INTRODUCTION

The relationship between *truth* and *validity* was first pointed by Aristotle who made it explicit in the First Analytics by introducing a clear distinction between *de facto truth* and *necessary truth*¹. Modern logicians such as Wittgenstein (1922) and Tarski (1933) developed a semantic point of view in logic and provided a theoretical framework for the distinction between truth in an interpretation and logical validity². For example $[p \wedge (p \Rightarrow q) \Rightarrow q]$ is universally valid in propositional calculus (it is a tautology); that means that in any interpretation where p and q are interpreted by sentences A and B that are propositions³, the sentence "If A and if A , then B , then B " is true, and this whatever the truth-value of A and B . Universally valid statements support *inference rules* that allow deduction in interpretations (Wittgenstein, 1922). The previous one supports the Modus Ponens, i.e. the well-known inference rule: " A ; and if A , then B ; hence B ". While Wittgenstein restricted his approach to propositional calculus, Tarski developed it for quantified logic, by developing a semantics definition of truth that is *materially adequate* and *formally correct* (Tarski, 1933), through two crucial notions: the notion of *satisfaction* of an open formula by an element in an interpretation, and the notion of *model* of a formula. This last notion leads to the concept of *universally valid formula* as formula for which every relevant interpretation is a model.

¹ For development on this point see for example Durand-Guerrier, 2008, p. 374.

² See Durand-Guerrier, 2008, pp. 376-377.

³ In logic, a proposition is a linguistic entity that is either true or false.

It seems for us rather clear that understanding this distinction between *truth in an interpretation* and *logical validity* is a clue competence for proof and proving in mathematics: indeed, the correctness of a proof relies in an essential manner on the validity of the inferences that are involved in the proof. Moreover, it is clearly a challenge for mathematics education due to the fact that, as it is well documented in the literature, students often fail to understand why a proof is needed when they are convinced of the truth of a given statement. In this respect, it is necessary to introduce doubt in order to motivate argumentation and proof (Durand-Guerrier & al. 2012). Another important aspect in Proof and Proving in mathematics education is to make students aware that to provide a mathematical proof, it is necessary to work in a theory, at least a *local theory* (axioms), with theoretical objects that need to be defined.

It is well known in mathematics education that the equality “ $0,999\dots = 1$ ” that appears when considering that the real number set coincides with the set of terminating or non terminating decimal number looks strange for a number of students, some of them considering that it is false (Tall, 2000; Dubinsky & al. 2005). Many reasons have been advanced for explaining these difficulties (difficulties taking in consideration non terminating decimal number; difficulties with limits considered as process, not as number etc.). In this communication, we document a complementary approach on these difficulties under the light of the distinction between truth and validity, involving the interplay between proving and defining, and we provide arguments supporting the claim that working with this equality with undergraduate students may open discussion on this distinction with a benefice for both the mathematical and the meta-mathematical aspects (a better understanding of real numbers and an explicit example of the distinction between truth and validity). We first provide a brief *a priori* analysis; then we present some results of an experiment with fresh undergraduate students that we analyse through this lens.

SOME *A PRIORI* ARGUMENTS ON THE RELEVANCE OF QUESTIONING THE RELATIONSHIP BETWEEN TRUTH AND VALIDITY

For fresh undergraduate students in France, the familiar back ground for examining at first this equality is the terminating decimal numbers set, well known by students from elementary school, although it is generally not the case that they know well the specificities of this set among the others numbers sets. Anyway, they master the operative algorithms for sums, difference, product and decimal division; they have also met the case of those rational numbers whose decimal expansion has infinitely repeated sequence (repeating decimal). As a consequence, they have an empirical reference for the equality “ $1/3 = 0,333\dots$ ” (1), that is get by executing the algorithm for decimal division. By multiplying each side of the equality by 2, one gets a new equality “ $2/3 = 0,666\dots$ ” (2); for this equality, there is also an empirical reference by making the division; this fact supports the conjecture that the calculating rules define on terminating decimal can be applied to non terminating decimal. But of course, it does not provide a proof that it is possible to extend the rule. In this respect, we have

here a first aspect of the distinction between truth and validity. On the one hand, taking the result of the division algorithm as the definition of the decimal expansion of a rational number, then equality (2) is true. Accepting this equality is in general not problematic for students, but this equality could be perceived rather as the result of the process of dividing than as equality between two numbers. On the other hand, considering the set of decimal numbers, with addition, difference and multiplication algorithms on terminating decimal, it is not possible to deduce equality (2) in that theory using addition or multiplication by 2, due to the fact that we have change the nature of number and that we have no theory, even local, in which proving that multiplication could be extended. A fortiori, it is not possible to prove that we get a new equality by multiplying each side of equality (1) by 3. As a matter of fact, there is no empirical reference relying on division allowing considering the writing $0,9999\dots$ as referring to a concrete process. At this point, arises the question of the possibility to find a theoretical justification of equality “ $0,999\dots = 1$ ” (3)

A natural candidate for justification: extension of operative algorithms

The extension of the operative algorithms from terminating decimal to non-terminating decimal seems to be the more natural candidate. We have seen that the empirical reference for equality (2) supports this conjecture. However it is not granted that the operation on integers or decimals should be extended to real numbers; this necessitates elaborating a theory, in which the theoretical definitions are supposed to correspond with the empirical aspects of the concept that are formalized. Dedekind (1872) did it by developing a construction of the real number sets with cuts, providing a formalisation of the intuitive notion of continuum (Longo, 1999) in which it is possible to extend the operations on rational numbers, and hence on decimal number. However, this does not mean that it is possible to extend the addition or multiplication algorithms on finite decimal numbers. Indeed, there are practical reasons that prevents such an extension, some are well known by students:

1. The algorithm for multiplication for terminating numbers is initiated on the right digit; in a non-terminating decimal number, where should we begin?
2. The product by 3 of a terminating decimal number that is not an integer is never an integer.
3. It is not possible to extend the algorithm for comparison, due to the fact that it could occur that it does not terminates.

There are also epistemological reasons:

4. As soon as one works with infinite, strange things may appear, so it is necessary to be cautious.
5. One can wonder if a non-terminating decimal writing refers to an object or to a process.

Point 2 pleads against the extension of the multiplication algorithm due to the fact that it leads to equality (3) that violates this theorem, and comforts point 4. Moreover,

point 3 prevents an algorithmic comparison, which could be useful to decide if the two writings denote the same real number. All of these aspects are likely to converge to rejecting equality (3). Point 5 open on a new question: how do we operate with process?

Process *versus* object – “tend to” *versus* “is equal to the limit”

Point 5 could be seen as an inheritance of the dividing process; although this question has already largely been discussed in the mathematics education community (e.g. Cornu 1981; Tall 2000; Dubinsky & al. 2005), it is still in debate, as it can be seen in a letter to Educational Studies in Mathematics’ editors published on line on the website of the journal in 2011⁴. In this letter addressed to the editors the author discusses a sentence out of a posthumous paper from Fischbein (Fischbein 2001) arguing that in mathematics the sum of infinite multiplicity cannot be equal to a number that is finite. Referring to the sum of the relevant geometric series, she concludes that the expression “0.333... tends to 1/3” will be mathematically true.

What interest us in this example is the fact that although the author of the letter refers to the theoretical point of view involving the sum of series, which defines the limit as a number that of course can be finite, the author considers that 0,333... does not represent a number. We interpret this as an indication that the theoretical framework relying on sequences, series, limits and their operations could be insufficient to encompass the conception that such writing is referring to a process⁵. Notice that this point could be related to the distinction between potential and actual infinite.

Coming back to our equality “0,999... = 1”, such a position leads to reject this equality and to replace it by “0,999... tends to 1”:

“In general, “limit” and “tends to” are not used in the same context. The limit designates something precise while it is possible to tend to something more vague. An example: we will say that the sequence “ 0,9, 0,99, 0,999, 0,9999, ... “ has for limit 1” or “tends to 0,9999...” (...) For some students, an unlimited sequence has no limit ... because it is unlimited. We observe that some students use the term “limit” for sequences whose limit is reached, and use the expression “tends to” when the limit is not reached” (Cornu, 1981, p. 325⁶).

The author added that even among advanced students, the initial conceptions of limit are still present.

Truth *versus* validity

Relying of the previous considerations, we consider that this equality has a potential for questioning the relationship between truth and validity in the following sense: it is possible to consider that the equality is not true due to the fact that there is not an

⁴ For the whole argumentation, see the « Letter to the editors ».

<http://www.springerlink.com/content/1182j7w55h264602/>

⁵ This is also attested by blogs and forums that can be found on the web on this topic.

⁶ Our translation

empirical reference allowing considering it as the result of a process. As we have said before, the natural candidate for a theoretical framework (extension of algorithms for non-terminating decimal) is not satisfying (introduces a new result that does not suit with a solid result for terminating decimal). On another hand, it is possible to consider that this equality is true and to be convinced by arguments that could not be accepted as proof, in particular because they rely on the extension of operative algorithms.

As a matter of fact, behind this equality lies the question of the definition of the notion of equality for real number: “two real numbers a , and b are equal” *if and only if* “for every strictly positive real number ε , the distance between a and b is strictly inferior to ε ”; this definition is beyond algebraic calculation and classical comparison algorithm.

In the second part of the paper, we report on an experiment with fresh undergraduates students in France (Lyon, January 2008) where the discussion opened on some of these questions.

FRESH UNDERGRADUATE STUDENTS STRUGGLING WITH TRUTH AND VALIDITY

The experiment that we report here took place in Lyon (France) in January 2008 with nine first year university students (three girls and six boys). They had followed in fall semester a calculus course. They were volunteers for following a short course (eighteen hours in three days) aiming to help them to overcome difficulties in logic, reasoning and proof met in the calculus course. Seven of them were fresh students facing difficulties; one was in reconversion after having prepared during two years the medicine competitive exam; the last one was a very good student who wanted to deepen his logical and proof and proving competencies. We focus on a session that took place on day 2 and was devoted on proof and more precisely on the work around the equality “ $0,999\dots = 1$ ”. The students were asked whether the equality were true.

Possible students’ answers to the question

The question is to evaluate equality were one side refers clearly to an integer, while the second side is a writing referring to a non-terminating decimal “number”. As said in previous paragraph, the nature of $0,999\dots$ is not obvious. Theoretically, non-terminating writings refers to real numbers, while empirically, in some cases, it refers to process; the specificity of $0,999\dots$ is that it is difficult to imagine a natural concrete process leading from integers to such writing, so that there is no available empirical argument supporting the equality. We list below the classical answers that we should expected

Answering NO, with various justifications

N1: The two numbers are different in nature

N2: That is obvious

N3: The whole parts are different

N4: It is always possible to add a 9 to the sequence

N5: 1 is the limit; it is not reached.

N1 refers to separate classes of numbers while the theoretical point of view consider that integers belong to the real number set. N2 corresponds to identification between *form* and *object*, while in a theoretical point of view different writings may refer to the same object. N3 correspond to an application of a rule valid for terminating decimal expansion, but not for non-terminating one. N4 and N5 could be interpreted as the consideration that the writing $0,999\dots$ represents a non-ending process (potential infinite) while the theoretical point of view acknowledge that this writing refers to an object (actual infinite).

Answering Yes, with various justification:

Y1: I know it because I have learned it.

Y2: " $1 = 3 \times 1/3 = 3 \times 0,333\dots$ " This uses the implicit extension of the algorithm of multiplication for terminating decimals to non-terminating decimals. As we have said, this arises the question of the validity of this extension.

Y3: Using a classical technics for identifying the rational number associated to a periodic decimal expansion. Let $a = 0,999\dots$; multiplying a by 10 gives $9,99\dots$; subtracting a to $10a$ gives $9a$; hence $9a = 9$ and then $a = 1$. Once again, this technic relies on the extension of the algorithms of multiplication, and also of subtraction, that should be questioned. In this respect, it is not a proof.

Y4: Showing that for every positive real number ε , $|1 - 0,999\dots| < \varepsilon$. This could lead to the following justification using a geometric sequence, or a geometric series.

Y5: Considering $0,999\dots$ as the limit of the sequence $u_n = 0,999\dots9$ with n digits 9, for $n \geq 1$, and then show that the limit is equal to 1.

Y6: Considering $0,999\dots$ as the limit of the series $\sum u_n$ where $u_n = 0,9 \times 10^{-n}$. The infinite sum $\sum_{n=1}^{+\infty} u_n$ is a theoretical mean to express the decimal expansion $0,999\dots$; it is possible to prove that the series converge to 1.

Y1 corresponds typically to the consideration that things are true because they are said to be true. This is precisely something we should like the students to overcome during the short course. Y2 and Y3 correspond to the justification of algebraic type relying on the extension of algorithms. Y4 is a theoretical justification, whose validity is proved in the theory of real numbers, but it is difficult to use it without introducing sequences. Y5 and Y6 rely on the theoretical framework of numerical sequences and series. Their introduction along with the notion of limits, the operation on the sequences and their compatibility with limits, and the uniqueness of limit allow to provide a proof of the studied equality.

According to us, this *a priori* analysis enlightens the fact that debate on truth and validity is likely to emerge from the discussion. We present now selected excerpts of the exchanges in the different phases of the session; we will use our classification of answers and justifications as a grid for our analyses.

Analyse of students' exchanges

Students had to decide if the sentence were true or not; they worked individually for 10 minutes; then they were invited to present their production in front of the group. The session has been led by the second author of this paper; the first author attended the session as observer, took photos and audio recorded the debate. We point now some phenomena that have been observed.

"1 is equal to 1, and nothing else"

Student G1 rejected the equality, insisting that

9-G1: "1 is equal to 1 and nothing else"

We could interpret this answer as asserting a *material adequation*. Indeed, during the individual work, this student had said that: "It sees itself". Another student, F1, that had at first answered: "Yes", seemed convinced by G1 argument:

11-F1: I said yes because I was once told that it is true, but I agree with G1, it is very disturbing. I said yes because it's said to me.

Her trouble seemed to come from the fact that she knew the sentence is true, but she did not know why. Opposite with G1, she did not explicitly reject the equality.

A tentative to prove

Student G2 proposed a theoretical justification of its answer, trying to provide the "epsilon proof" relying on the equality between real numbers, which corresponds to the justification Y4.

16 G2 In fact I have said yes, but I went to euh, with a positive epsilon. In fact, the euh only, the only " $1 - 0,999 \dots$ " which is less than epsilon is zero.

18 G2 If we find one " $1 - 0,999$ " which is lower than an positive epsilon; we consider that 0,99 is fixed, finished.

26 G2 We know that 0.999... . It is an infinity of 9 after zero, after the comma. But if " $1 - 0.9999 \dots$ " is less than epsilon, 0.999... is finite, which leads to an absurdity because in the beginning, it is assumed that it is ... it is assumed that it is an infinite number..

The tentative did not convince other students who address remarks to G2:

E: "I don't know why absurd is! "

E: " I don't see what is the used of epsilon!"

G2, G3 and T try to clarify the project of G2; G3 introduced the sequence $1 - u_n$ for which the sequence 10^{-n} is an upper bound. The explanation becomes clearer to others, but *epsilon* disappeared. G2 goes back to his demonstration, reintroduced epsilon, trying to clarify its role, and explaining that he planned to show that $0,999\dots$ is not different to 1 (proof by contradiction).

93 G3 Let us look for an epsilon such that the difference is greater than epsilon.

94 T So if we want to show that 1 is different from 0,999... we should show that we can find an epsilon such that $1 - 0,999\dots$ is greater than this epsilon.

95 G2 This is what I wanted to do

97 G2 In fact, just to assume that it is different and show the opposite.

G2 finally did not managed to clearly expose his proof, the technical steps remaining confuse. As we said in the *a priori* analysis, the proof with epsilon is difficult if the sequences are not introduced. The other students give up following him and turn to other proofs.

“Equal to the limit versus tends to the limit”

Later in the session, a student proposed the proof *Y5*, and another one tried without success, to implement the proof *Y4*.

While she recognizes that proof *Y5* is clear, F1 is still not convinced; she engaged in a discussion with the teacher on the difference between “to be equal to the limit” or to “tend to the limit”; considering that the limit is not reached, she asserts that the proof “does not prove”, and finally staked anew that she knows that it is true, but she does know why.

110 T: For you, 1 is 1. You are right, but what about the limit of u_n for you?

111 F1: It tends to 1! It tends only; it is not equal.

112 T: No, it is the sequence that tends.

113 F1: yes

114 T: But the limit?

115 F1: It is not reached

127 F1: Ben? Then, we proved nothing?

134 F1: That approaches

141 F1: I know that it is yes, but I don't understand

This position of F1 is in line with the results of Cornu (1981) and makes an echo to the position of the author of the letter to editor we presented in paragraph I.

Extension of operations on non-terminating decimal numbers

T intervenes to ask F1 providing another writing of $1/3$. She gave 0,333... with infinitely many digits equal to 3; this does not disturb nor shock her, she argued that it is different:

F1 157 It is not the same thing, because if you say $1/3$, it is a finite number.

Then she said

163 F1 Ah, but if you multiply everything by 3, it runs, it gives the same thing here.

At that moment, F1 seems to become convinced.

We should consider that for F1, the facts that “There is an empirical evidence for the decimal expansion of $1/3$ ”, and “Multiplying both sides by 3 provides the equality” are solid enough to ground the truth of the equality, answering her « why » pending interrogation, this although the extension of multiplication to non-terminating decimal number has to be established.

A discussion on proof Y3

Students F2 who arrived while the discussion was already engaged (round 144) asserted that the equality is true and that it can be easily proved. She proposed the proof Y3.

The teacher asked F2 if multiplying by 10 the decimal expansion is allowed. F2 then move to proof Y2, but the teacher asks again if it is possible to extend the operations; finally F2 gives up. The intervention of F2 and the teacher question introduces anew in the debate the discussion on truth *versus* validity.

178 T: [...] " What allows us to still apply the operations while we have no more the process of division? For $2/3$, we had a process of division?

183 F2: We can also demonstrate by $1/3$. $1/3$ is 0, 333...; $2/3$ is 0, 666...; $3/3$ is normally 0,999....

185 F2: We have no right

At the end of the session, the student F1 remains disturbed by the equality; this leads her to accept the proofs while remaining sceptical on the truth-value of the equality.

221 F1: It always disturbs me

225 F1: It is good the proofs, it is attractive. But it is proved OK, but "one is one".

F1 seems to consider that the statement could be proved in a theory, while it would be false in a given relevant interpretation.

CONCLUSION

In this communication, we intend to show that working on the equality " $0,999... = 1$ " is likely to open rich discussion on the relationships between truth in an interpretation and logical validity of a proof in a theory, involving the interplay between proving and defining. The exchanges reveal four main attitudes: knowing that the equality is true and knowing that there is a theoretical proof, even if exposing the proof is difficult – knowing that it is true and knowing a proof relying on the extension of operations to non-terminating decimals, without having a proof that this can be done – knowing that it is said to be truth, but without knowing why – understanding a proof, but remaining doubtful concerning the truth of the equality, opening the possibility of a discrepancy between theoretical and empirical assumptions. It is more usual for students to be sure that a statement is true, and do not understand the need for proof. In the case we have presented, it seems that students express a need to proof that implicitly engaged toward a need for theory. These results confirm our hypothesis that we have here a good candidate for discussing these topics, but it is clear that going deeper on these questions with students necessitate to design more cautiously a didactical situation, in order to allow students

“ (...) to experience not only how to validate statements according to specific reference knowledge and inference rule within a given theory, but also how the “truth” of statements depends on definitions and postulate of a reference theory.” (Durand-Guerrier & al. 2012, 358)

THE BIOLOGICAL BASIS FOR DEDUCTIVE REASONING

David A Reid

Universität Bremen

This paper explores the basis of deductive reasoning from a range of psychological, biological, evolutionary and neurological perspectives. The basic structure of deductive reasoning is seen as being common to all primates and based on evolutionary pressures to perceive causes and effects. However, deductive reasoning at higher levels of abstraction is unique to humans and linked to language use. The feeling of necessity that is associated with deductive reasoning is also accounted for by the presence of somatic markers for deductive conclusions that also have an evolutionary basis.

Deductive reasoning, epistemology, necessity, abstraction, evolution

INTRODUCTION

It is clear that some human beings are capable of proving in very sophisticated ways (see, e.g., the paper by Annie and John Selden in these proceedings). There is also abundant evidence that many school and university students find proving and reading proofs difficult (see, e.g., Reid & Knipping, 2010). But proving as practiced by professional mathematicians involves the coordination of a large number of capabilities. To understand the educational task of teaching proof it is essential to understand the nature of these capabilities, how they develop with maturity and how they can be influenced by teaching. In this paper I attempt to identify capabilities essential to proving that may be common to all humans. The existence of such capabilities means that teaching related to them is a matter of developing existing capabilities rather than introducing new ones, which is a distinctly different educational task.

As my focus is on *human* capabilities my paper will draw largely on biological perspectives. Philosophical and historical approaches to epistemology have told us much about the nature of deductive reasoning, but not in relation to the *people* who actually do it. For that we need to turn to what McCulloch (1960, 1965) called “experimental epistemology”, inquiry into the physiological substrate of knowledge, or what Donald Campbell (1974) called “evolutionary epistemology”, “an epistemology taking cognizance of and compatible with man’s status as a product of biological and social evolution.” (cited in Rav, 1989, p. 51 & 2006, p. 73).

In contrast to the various philosophical epistemologies, evolutionary epistemology attempts to investigate the mechanism of cognition from the point of view of its phylogeny. It is mainly distinguished from the traditional position in that it adopts a point of view outside the subject and examines different cognitive mechanisms comparatively. It is thus able to present objectively a series of problems [including the problems of traditional epistemologies] not soluble on the level of reason alone [but, which are

soluble from the phylogenetic point of view]. (Riedl, 1984, p. 220; 1988, p. 287, cited in Rav, 1989, pp. 51-52 & 2006, p. 73)

Here I focus on two capabilities, being able to reason from a general rule and antecedent data to a specific consequence (reasoning represented in logic by *modus ponens*) and feeling that such consequences are necessary.

REASONING FROM A GENERAL RULE: MODUS PONENS

Modus ponens links a datum to a conclusion via a general rule. It can be considered to be the most simple instance of deductive reasoning, it is the only rule of inference needed for propositional logic, and it is difficult to imagine how anyone could prove anything without making use of *modus ponens*. The nature of *modus ponens* has been considered from a philosophical perspective by, for example, Aristotle, Bacon, Descartes, Kant, Schopenhauer, and Wittgenstein. Here, however, I am concerned with a biological question: Are all human beings capable of reasoning in this way, and if so, why?

Can humans reason deductively?

There is a large body of research that starts from the assumption that not only can humans reason deductively, deductive reasoning is the basis for all human thought (recently, Rips, 1994. Cosmides, 1989, p. 191, cites as examples Henle, 1962; Inhelder & Piaget, 1958; Johnson-Laird, 1982; and Wason & Johnson-Laird, 1972). However, such claims must account for circumstances in which humans do not reason deductively, even though the context clearly requires it.

For example, on the Wason (1966) card selection task [1] “performance is relatively poor” (Goel, 2007, p. 436). “Relatively poor” is an understatement; in some studies only 10% of subjects turn over the correct cards. Given that the task involves only deciding what data and conclusions must be checked to verify a general rule used in *modus ponens*, the difficulty many people have with this task makes it implausible that deductive reasoning is the basis for human thought. There is also a growing body of work that argues for another possible basis for human thought, analogical reasoning (see, e.g., Lakoff, 1987, Hofstadter, 2001).

If deductive reasoning is not the basis for human thought, but we know that some humans can reason deductively, then we must explore two possibilities: that deductive reasoning is learned at some point, or that deductive reasoning comes with being human, having been acquired at the species level in the course of human evolution.

If deductive reasoning is learned, then it must be learned fairly early, as Richards and Sanderson (1999) report that four year old children can give a logically correct answer to the question: “All fish live in trees. Tot is a fish. Does Tot live in a tree?” Hawkins, Pea, Glick and Scribner (1984) also found that in some circumstances four year old children are capable of making deductive inferences. Stylianides and

Stylianides (2008) provide an excellent summary of the psychological research on deductive reasoning by children.

I know of no research into the process by which deductive reasoning is learned in pre-schoolers, and in fact there is evidence that humans are born already able to reason deductively, just as we can recognise faces and distinguish two from three.

Part of this evidence for is the capability of some animals to make simple deductive inferences. One experiment that has been used to test for the capability to make simple deductive inferences involves two opaque cups, one of which contains a treat. The empty cup is shaken (the animals previously experienced that the cup with food makes a noise when shaken). In order to know that the other cup contains the treat the animals must do two things. First, they must associate the noise with the treat. Then they must infer A from {A or B, not B}. Apes (Call, 2004) and grey parrots (Schloegl, Schmidt, Boeckle, Weiß & Kotrschal, 2012) are able to do this, without training, as are children (Hill, Collier-Baker & Suddendorf, 2012). No other animals have yet been found that can make this inference.

Of course, there is a significant difference between the reasoning of animals and the reasoning of humans. Humans can express their thinking in language, but the exact relationship between language and reasoning is in debate. It may be that the structure of language itself forms our thoughts into general rules (Bickerton, 1990) or that the social use of language does so (Vygotsky, 1986) or that general rules emerge from our making sense of the world and language reflects this (Devlin, 2000). In any case, the ability of people to reason using general rules is intimately tied to the ability of people to express general rules in language.

There is evidence that using language to express general rules increases markedly after a child's second birthday. Bruner and Lucariello (2006) analyse the use of words that mark "sequence" and "canonicity" or normalcy, in the monologues of Emily, a toddler whose bedtime language use was recorded from the time she was 21 months old until she was 36 months old. Of special interest here are sequence markers of causality and canonicity markers of necessity. Bruner and Lucariello contrast the number of causality and necessity markers in two periods, when Emily was 22-23 months old, and when she was 28-33 months old. They find that "just as expressions of causality emerge as the dominant, later form for binding sequences, expressions of necessity and appropriateness emerge as Emily's more advanced form of indicating canonicity" (p. 87). And in this later period, Feldman (2006) reports, she "begins to play with reasoning, to reason about fictional and invented worlds" (p. 107).

Emily's playing with reasoning, using it in imagined contexts, is very interesting. It reveals something important about the way humans use deductive reasoning, and perhaps begins to explain why a child can answer the question "Does Tot live in a tree?" while adults fail at the Wason task. Hawkins et al. (1984) asked four year olds to answer questions based on chaining two general rules using modus ponens. In

“congruent” cases the correct answer conformed to the children’s experiences. In “incongruent” cases it contradicted their experiences. And in “fantasy” cases it involved imaginary creatures, so prior experience did not apply. The children answered almost all congruent questions correctly, and almost all incongruent questions incorrectly (from the perspective of logic; from the perspective of their experiences their answers made sense). They were quite good at answering fantasy questions correctly, especially if those questions were asked first. This suggests that deductive reasoning and prior experiences are both used by humans, but that prior experiences carry more weight. Worlds of imagination provide contexts where deductive reasoning has priority, because experience does not apply. And interestingly, if children are prompted to use their imaginations, even when dealing with familiar objects (like fish and trees) they come to deductively correct conclusions. As Richards and Sanderson (1999) put it, “2-, 3- and 4-year-olds can solve deductive reasoning problems when they are given cues to use their imagination to create an alternative reality where different outcomes are possible” (p. B8).

The ability to abstract

To express a general rule and to invent an imaginary world both involve working with abstractions. It is worth looking more closely at that process, and especially at different levels of abstraction related to *what* is abstracted.

Devlin (2000) divides abstraction into four levels. Level 1 abstraction refers only to things that are present. My seeing many present birds as the same kind of bird is such an abstraction. This is the kind of abstraction animals engage in by perceiving in categories. Level 2 abstraction involves familiar things that are not present. The food that is not in the shaken container when it makes no noise is an abstraction of this type. Level 3 involves “real objects that the individual has somehow learned of but never actually encountered, or imaginary versions of real objects, or imaginary variants of real objects, or imaginary combinations of real objects” (p. 121) like dodo birds, fish that live in trees, unicorns and centaurs. For Devlin, level 3 abstraction amounts to having language, and so only humans can do it. Finally, level 4 abstraction involves objects that are themselves abstract.

Where do such abstract objects come from? From a process of abstracting that goes beyond forming categories. Rather than just perceiving a group of birds as “all the same” I can observe properties that are the same, for example, colour, or size, or the shape of the beak, or the pattern of the song. Such properties are also abstractions, but of a different kind. When I perceive that a cup is the same colour as a book, I create a new category of things that are that colour. The colour becomes an abstract object. “We reify our abstracting: the end of the process of abstraction—paying attention to only some of our experience—begins to be treated as a thing, an abstract thing.” (Epstein, 2012, p. 252). The same thing happens with other properties, like number and shape. I form a category of all the (roughly) triangular objects I perceive, and then a triangle becomes a level 4 abstract object.

I suspect that Devlin's level 4 has further divisions. When thinking about triangles I can refer directly to a present triangular object to aid my thinking. But the same process that took me from level 2 to level 3 (recombining objects in my imagination) can be applied to abstract objects. From my abstract triangle and tetrahedron I can use my imagination to go to a four dimensional figure that is somehow like them, but at the same time even more abstract. I can model an abstract triangle with a concrete triangular object, but I cannot do that with an abstract object that is itself based on an abstract object. The higher the level of abstraction, the harder it is to think about it.

Deductive reasoning involves using general rules, and general rules involve using abstractions. This dependence means that deductive reasoning ought to be different if it involves different levels of abstraction. And it is. When dealing with level 1 and level 2 abstractions, deductive reasoning is essentially a way of describing causal relationships between things. If an ape selects the container that was not shaken it can be said to conclude "The treat is in here" from the general rules that "If there is a treat then it makes a noise when the container is shaken," "If the treat is not in one container then it is in the other" and the datum "That container did not make a noise when shaken." This is more complicated reasoning than *modus ponens*, but limited to level 2 abstractions. Of course, the ape is probably not aware of these rules, but behaves as if it knows them.

Deductive reasoning with level 3 abstractions is more complicated, as it involves imagined things expressed in language. For example, the question "Does Tot live in a tree?" (Richards & Sanderson, 1999, p. B2) and the version of the Wason task using the rule "If a person is drinking beer, then he must be over 20 years old" (Cosmides & Tooby, 1992) involve level 3 abstractions. Children prompted to use their imaginations can answer the question about Tot correctly, and most adults succeed at the Wason task if it is clearly presented in a social context. Humans can reason deductively in these contexts because humans can use language and level 3 abstractions.

Deductive reasoning with level 4 abstractions, especially abstractions that cannot be modelled easily, on the other hand, is difficult for most humans. That is why most people cannot do the abstract Wason tasks, and why most people find mathematical proofs hard to follow. It is not that they cannot reason deductively; it is that reasoning deductively gets more difficult the more abstract it becomes.

Language makes it possible to reason with level 4 abstractions, but doing so involves not only having such abstractions, but also formulating them so that they can be objects for reasoning. As Bishop (1991) puts it:

The language of "if" and "suppose" and the conditional tense also forces an imagined reality onto the conscious level and thereby enables it to be manipulated *as if it were* an objective reality. Thus, as well as encouraging children to develop their ability to abstract, we need also to encourage them in the ways of concretising and objectivising abstract ideas. (p. 67)

In summary, *modus ponens* encapsulates a particular way of relating abstract categories back to specific cases. Language allows the relationship to be expressed, and allows *modus ponens* to be applied to abstract categories that are not based on direct experience. Because human beings evolved in a world in which relating abstract categories back to specific cases is useful, we can reason deductively, and because we can use language, we can learn to do so in abstract contexts. This suggests that the main challenge in teaching people to reason deductively in very abstract contexts like mathematics is not teaching them deductive reasoning. Deductive reasoning comes with being human. However, the abstractions of mathematics are not the context in which humans came to reason deductively, so learning to reason deductively in such contexts requires learning to cope with abstraction better.

FEELING NECESSITY

I am considering logical necessity from a biological standpoint, and so I am addressing the question: Why do (some) humans associate the conclusions of deductive reasoning with certainty, while conclusions reached in other ways are recognised as being only probable? When I come to a conclusion by deductive reasoning, I feel not only that the conclusion is so, but also that it *must be so*. This feeling does not occur with other kinds of reasoning.

Damasio's (1996ab) concept of somatic marker offers a neurological basis that can be used to account for the feeling of necessity. A somatic marker is the juxtaposition of knowledge, emotion and bodily feeling related to a decision or a thinking process. Every decision a person makes activates not only knowledge relevant to making the decision but also emotional markers triggering bodily feelings. These "somatic markers" are not activated in patients with certain kinds of brain damage, with consequences for their everyday decision making.

If a deduction is seen as a kind of decision making, then the feeling of necessity is accounted for as a somatic marker associated with any use of deductive reasoning. Why do humans feel this way about deductive reasoning? There are two possibilities: the somatic marker may be acquired through individual experience, or it may now be innate, having been acquired at the species level in the course of human evolution.

If the somatic marker is acquired through experience this would account for the observation (reported Galotti, Komatsu, & Voelz, 1997, p. 77) that while young children (about seven years old) have higher confidence in conclusions reached through deductive reasoning than conclusions reached through inductive inferences, they are less certain of the conclusions of deductive reasoning than they should be.

However, as we have seen above, the ability to reason deductively is tied to the degree of abstractness of the context, and it may be that children are less certain simply because they recognise that they are not completely fluent in abstract reasoning. Children may already have the somatic marker for necessary conclusions,

but feel less certain because of unfamiliarity with abstractions. In that case, we must account for the presence of this somatic marker in humans by making reference to evolutionary pressures.

Some somatic markers (such as fear of snakes) are clearly innate, and Damasio accounts for the origins of somatic markers evolutionarily.

Let us assume that the brain has long had available, in evolution, a means to select good responses rather than bad ones in terms of survival. I suspect that this mechanism has been co-opted for behavioural guidance outside the realm of basic survival. ... It is plausible that a system geared to produce markers ... to guide basic survival, would have been pre-adapted to assist with ‘intellectual’ decision making. (1996b, pp. 1416-1417)

Rav, without using the language of somatic markers, accounts for the origin of the feeling of necessity through a similar process.

But whence comes the feeling of safety and confidence in the soundness of the schemes which formal logic incorporates? To an evolutionary epistemologist, logic is not based on conventions; rather, we look for the biological substrata of the fundamental schemes of inference. Consider for instance *modus ponens*:

$$\begin{array}{l} A \rightarrow B \\ \underline{A} \\ \square B \end{array}$$

If a sheep perceives only the muzzle of a wolf, it flees already for its life. Here, ‘muzzle→wolf’ is ‘wired’ into its nervous system. Hence the mere sight of a muzzle—any muzzle of a wolf, not just the muzzle of a particular wolf—results in ‘inferring’ the presence of a wolf. Needless to say such inborn behavioral patterns are vital. ... The necessary character of logic, qua codified logico-operational schemes, thus receives a coherent explanation in view of its phylogenetic origin. (Rav, 1989, p. 63, 2006, p. 83)

I hypothesise that when humans developed language sufficiently to express abstract general rules in words, the rules they first articulated also existed as behavioural patterns (like that of the sheep) tied to somatic markers. The first human to say “If you see a wolf, run!” was articulating a general rule that when applied in *modus ponens* activated the somatic marker of necessity. This marker remained associated with *modus ponens* in other contexts, simply because evolution does not select out attributes that have survival value.

In summary, deductive reasoning comes with a feeling of necessity. But necessity is not a property of deduction, it is a property of deductive reasoning being done by people who have learned to feel the necessity of deductive conclusions. We cannot assume that students automatically have the somatic maker that makes them feel necessity in abstract contexts like mathematics, but I believe that all humans do in less abstract contexts, as a result of our evolutionary history. That would account for Galotti, Komatsu, and Voelz’s (1997) finding that children shows signs of associating deduction with certainty early in their schooling. But feeling necessity in

mathematics might involve creating a new somatic markers, which would account for the children's lack of complete confidence. In either case, mathematics educators must explore how such a somatic marker is activated, and how it interacts with other somatic markers.

The idea of a somatic marker for necessity provides a new viewpoint from which to reexamine Fischbein's (1982) process of elaborating new intuitions.

A new "basis of belief", a new intuitive approach, must be elaborated which will enable the pupil not only to understand a formal proof but also to believe (fully, sympathetically, intuitively) in the a priori universality of the theorem guaranteed by the respective proof. (Fischbein, 1982, p. 17)

Fischbein suggested that preformal proving (that is, deductive reasoning in less abstract contexts) might help in the development of such a basis of belief, but if the somatic marker for necessity is already present then the task is not to develop it, but rather to understand what might interfere with it when encountering formal proof. Further research in this direction is needed, supported by a theoretical framework that sees deductive reasoning in human terms.

CONCLUSION

Warren McCulloch, in his 1960 Alfred Korzybski Memorial Lecture, asked the question "What is a number, that a man may know it, and a man, that he may know a number?" (1960, p.7, 1965, p. 1) which inspired me to ask here "What is deductive reasoning, that humans can reason deductively, and what are humans, that they can reason deductively?" In other words I have sought to account for key aspects of deductive reasoning, the use of *modus ponens* and the feeling of necessity, by bringing together psychological, biological, evolutionary and neurological perspectives. The biological bases for deductive reasoning have two important implications for teaching proof. We do not need to begin by teaching students how to reason deductively. And we do not have to teach them the feeling of necessity. However, we must begin in contexts where abstraction is not an obstacle to reasoning, and we must be attentive to other somatic markers (for example associated with feeling of mathematics anxiety) that will interfere with feeling necessity.

ACKNOWLEDGEMENTS

My gratitude to the members of the CERME 8 Argumentation and Proof Working Group, whose comments and discussion inspired significant revisions to this paper.

NOTES

1. The task is to determine which of four two-sided cards need to be turned over to verify a general rule. The task exists in many versions, based on the original in which the cards have a letter on one side and a number on the other and the rule is "If a card has a vowel on one side, then it has an even number on the other side.". The visible sides of the cards show one vowel, one consonant, one even number and one odd number and the correct answer is to pick the vowel and the odd number, corresponding to the logical proposition $P \ \& \ \text{not } Q$.

MULTIMODAL PROOF IN ARITHMETIC

Reinert A. Rinvold, Hedmark University College, Norway

Andreas Lorange, NLA University College, Norway

This theoretical paper develops further the concept of multimodal proof from the perspective of the multimodal paradigm, phenomenology and Luis Radford's theory of knowledge objectification. The study of such proof is motivated by its possible use in mathematics education, especially in school, but possibly also with adult students. We discuss one type of generic multimodal proof in arithmetic using a proof principle called schematic generalisation. It is argued that this type of proof both can establish truth in arithmetic and give phenomenologically explanations.

Key words: multimodal proof, embodied cognition, objectification, phenomenology

INTRODUCTION

The concept of multimodal proof was introduced in Rinvold and Lorange (2011). A multimodal proof is a generalized proof which beside written symbols and sentential reasoning can also include the visual modality, speech, the tactile and motor action, (p. 633). The idea of combining sentential and visual reasoning has been developed in mathematical logic and its learning by Barwise and Etchemendy (1996) under the name of heterogeneous reasoning. Their ideas have been used and followed up by several other researchers. An example is Oberlander, Monaghan, Cox, Stenning and Tobin (1999) who characterize heterogeneous proofs as multimodal. Williams et al. (2012) refers to the multi-modal nature of proof. Their study investigates how gestures and actions are related to the ascertaining and persuading phases of proof. It is about students' justifications and does not discuss what a valid multimodal proof might be as part of a mathematical community. We will now develop the concept of multimodal proof further within the multimodal paradigm of Arzarello and Robutti (2008). As far as we know, no other researchers have developed multimodal or heterogeneous proof as a concept within this framework.

The multimodal paradigm is an emerging view of thinking and reasoning. It combines the embodied mind paradigm and sociocultural theory. Mind is part of a physical body, and the cognising man acts physically and verbally in a physical and cultural world using artefacts and signs. Thinking is not only internalized speech, maybe supplemented by inner visualization, but is linked to all the senses and motor action. Thinking is made possible and restricted by our bodily life in the physical world, but has reached an advanced level through culturally developed language and artefacts. Multimodality is a direct consequence of this view of thinking. Fallacies and idiosyncrasy have been a problem with visual and intuitive proof. However, we agree with research that opens for the possibility that some non-sentential proofs are legitimate.

The mere existence of fallacious proofs is no more a demonstration of the illegitimacy of diagrams in reasoning than it is of the illegitimacy of sentences in reasoning. Indeed, what understanding we have of illegitimate forms of linguistic reasoning has come from careful attention to this form of reasoning, not because it was self-evident without such attention. (Barwise & Etchemendy 1996, p. 6)

We study communication and learning of proof by applying the theory of knowledge objectification, Radford (2006a, 2006b, 2008). Objectification has to do with the learning of the individual when thinking is seen to have an intimate and dialectical relationship with the material and cultural world, LaCroix (2012, p. 2464). It is a process using semiotic means in order “to draw and sustain the attention of others and one’s own attention to particular aspects of mathematical objects in an effort to achieve stable forms of awareness, to make apparent one’s intentions, and/or to carry out actions to attain the goal of one’s activity.”, (ibid, p. 2464).

Our discussion is restricted to one type of proof principle in arithmetic called schematic generalisation. We look at this through an example proof which is normally described as visual or diagrammatic proof. We argue that schematic generalisation can establish truth in arithmetic. These kinds of proofs have also been studied from the perspective of generic proof, which is a less precise concept. Referring to Tall (1979), Aliebert and Thomas (1991) write that “Such a proof works at the example level but is generic in that the examples chosen are typical of the whole class of examples and hence the proof is generalizable.” Tall (1979) argues that generic proofs are explanatory in the sense of Steiner (1978), which writes that “It is not, then, the general proof which explains; it is the *generalizable* proof.” (p. 144)”. We argue that from the perspective of multimodal proof, proof by schematic generalisation are also explanatory in another way, which we call phenomenological explanation. A problem with many formal proofs, especially algebraic ones, is that the proofs are not explanatory. Students may be able to follow the rules which are applied in the proof, but they do not get any reason why the proved theorem is true.

WHAT IS MULTIMODAL PROOF?

It is common in the literature on proof in mathematics education to make a clear distinction between proof production or proving and the final proof object. From a sociocultural point of view it is plausible that the latter is an artefact accessible for public validation. In the rest of this paper proof is seen in this way. For a long period of time proof has been written or printed on paper. In this medium visual and sentential are the only possibilities. The existence of animation, film and video give a possibility of including other modalities, but also challenges the distinction between “the proof” and proof presentation. If the presentation of a proof is videotaped, the record is an artefact. However, we do not go further into this. In this paper both proving and proofs involve artefacts and several modalities.

Multimodal or heterogeneous proving is a kind of multimodal reasoning and thinking. One core idea of multimodal thinking is that human reasoning always applies at least two modalities of thought.

Multimodality, however, proceeds on the assumption that representation and communication always draw on a multiplicity of modes, all of which have the potential to contribute equally to meaning. (Jewitt, 2009, p. 1)

Except some proofs generated by computers, proofs are meant to be read by humans, and as such are part of communication. Because of this, words and visual diagrams are used together with mathematical formalism in the proofs. But, a common idea is that formal proof could be represented without visualisation by mathematical formalism only. The concept of visual proof indicates similarly the belief that visual arguments can be represented just by diagrams. The phrase “proofs without words”, Nelson (1993, 2000), indicates the latter. According to Barwise & Etchemendy (1996), heterogeneous proof consists of more than one mode of reasoning, in their case primarily the visual and sentential modality. By proof those researchers mean proof inside proof systems. Such a system consists of the allowed rules of inference and the allowed objects transformed by the inference rules. Since the formalism of Hilbert was developed, the objects of proof systems have mostly been formal sentences. The contribution of Barwise and Etchemendy is important for the question of legitimacy and possible acceptance of multimodal proof. Proof systems make validation of proofs easier and also support the comparison with classical proof.

THE MULTIMODAL EXAMPLE PROOF

The example proof of our further discussion is given by a visual diagram and an explanation by words. As such it is multimodal, but it is open if it can be represented by a proof only in the visual mode. The proof is not formal, in the sense that it is not based on a proof system, and that mathematical symbols are not applied.

Looking at the diagram in figure 1 below, it is not obvious what it is going to prove.

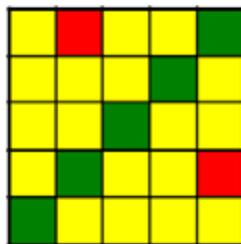

Figure 1

To be told that the statement concerns odd numbers may help some readers. The diagram shows the square of the odd number five. The diagonal in green consists of the same number of small squares as the side, and the red small squares above and below the diagonal make a pair.

Each small square in the upper triangle makes a pair with the corresponding symmetrically placed small square in the lower one. The complement of the diagonal thus is a set of disjoint pairs. Since the diagonal is a set of disjoint pairs together with a single small square disjoint from them, the large square is an odd number.

The argument shows that the square of an odd number is odd. But, we have more. The decomposition of the square into its diagonal and a pair of triangular numbers do not use that the side is odd, and hence is valid for all natural numbers. This can be used to show the opposite implication. If the square is odd, then also the diagonal is odd, for taking away a set of pairs from an odd number, results in an odd number. Since the diagonal equals the side, the side is odd when the square is odd. Formally the implications in both directions can be written

$$\forall x[\text{Odd}(x) \leftrightarrow \text{Odd}(x^2)]$$

RECURSIVE ω -PROOF AND SCHEMATIC GENERALISATION

We argue that the proof principle used in the example proof can be formalized by the concept of recursive ω -logic, a proof principle which legitimacy hardly can be disputed. Beside this legitimacy argument, we also use ω -logic to make clear what the example proof is meant to exemplify. The origin of ω -logic is proof theory as a branch of mathematical logic, but the original use, called cut-elimination, is technical and outside the scope of this paper.

Jamnik, Bundy and Green (1997) introduced the formalization by recursive ω -logic for diagrammatic proofs like the example proof with the intention to argue that this kind of reasoning is legitimate. Each case of the theorem can be proved directly from a diagram by geometric operations. One given diagram plays a schematic role, which make it possible to generate the other diagrams and the proofs for each case. Those authors have developed a system for automated theorem proving called DIAMOND, which successfully have turned several diagrammatic proofs into recursive ω -proofs.

A recursive ω -proof of $\forall n \varphi(n)$ is a procedure which let us calculate a proof of $\varphi(n)$ for each n . In the example this means that we see the decomposition of the square as a procedure which can be done for all possible integer squares. Intuitively, this means that we can draw “the same kind of diagram” for all integer squares. In arithmetic $5^2 = 2 \cdot T_4 + 5$ is certainly not implying the general claim $n^2 = 2 \cdot T_{n-1} + n$, where T_4 and T_{n-1} are triangle numbers. What is different with the diagram is that it shows the decomposition to be more than an accidental identity between numbers.

A direct algebraic proof of $\varphi(n)$ is also a recursive ω -proof of $\forall n \varphi(n)$. The use of symbolic algebraic variables is based on some rules or properties which are common for all numbers in question, for instance the commutative and distributive laws in arithmetic. This is seen in the direct example proof **D1** of

$$\forall n[(n + 1)^2 = n^2 + 2n + 1]$$

The proof is given by

$$\mathbf{D1}: (n + 1)^2 = (n + 1) \cdot (n + 1) = n \cdot n + n \cdot 1 + 1 \cdot n + 1 \cdot 1 = n^2 + 2n + 1$$

We normally see this as one proof of one conjecture, but an alternative is to consider it as a collection of proofs, one for each natural number. For instance the substitution of $n = 4$, gives a proof that $(4 + 1)^2 = 4^2 + 2 \cdot 4 + 1$.

Recursive ω -logic is an alternative to induction in the formalization of proofs in arithmetic and implies induction. The premises of induction is for an arithmetical formula φ the claims $\varphi(1)$ and $\forall n[\varphi(n) \rightarrow \varphi(n+1)]$. From this we get an algorithm which gives proofs of $\varphi(n)$ for each n .

$\varphi(2)$ is proved by $\varphi(1)$ and $\varphi(1) \rightarrow \varphi(2)$

$\varphi(3)$ is proved by $\varphi(1)$, $\varphi(1) \rightarrow \varphi(2)$ and $\varphi(2) \rightarrow \varphi(3)$, and so on.

This means that we have a recursive ω -proof of $\varphi(n)$, which entails $\forall n\varphi(n)$.

Technically, induction proofs are a good solution, but typically such proof does not give an explanation understandable by students. As an example of the latter we prove the statement related to figure 1 by an induction proof **IN** setting $\varphi(n)$ to be $n^2 = 2 \cdot T_{n-1} + n$, where $T_0 = 0$ and $T_n = T_{n-1} + n$ are the triangle numbers inductively defined. Using the statement proved in **D1**, we get

$$\begin{aligned} \mathbf{IN}: (n + 1)^2 &= n^2 + 2n + 1 = (2 \cdot T_{n-1} + n) + 2n + 1 = \\ &2 \cdot (T_{n-1} + n) + (n + 1) = 2 \cdot T_n + (n + 1) \end{aligned}$$

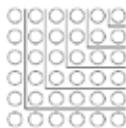

It can be seen that $\varphi(1)$ also follows. The statement related to figure 1 can be proved by a direct algebraic proof **D2** too, but this appears as a rabbit thrown from a hat:

$$\mathbf{D2}: n^2 = n^2 - n + n = 2 \cdot \frac{1}{2} (n - 1) \cdot n + n = 2 \cdot s(n) + n$$

Now, $s(n) = \frac{1}{2} (n - 1) \cdot n$ is always a natural number, since $(n - 1) \cdot n$ has to be an even number.

PHENOMENOLOGICAL EXPLANATION

The phenomenology of proof has to do with how proof is experienced. The example diagram gives us the experience of knowing, understanding and believing. Jamnik, Bundy & Green (1997) formulate this about the same type of diagram,

$$1 + 3 + 5 + \dots + (2n - 1) = n^2$$

“Not only do we know what the diagram represents, but we also understand the proof of the theorem represented by the diagram and believe it is correct (p. 51).” But, the diagram does not only give subjective belief. It is what Kitcher (1983) calls warranted belief (p. 17). The belief has to be justified in a way that is accepted by the mathematical society. Recursive ω -logic is one way of giving such a warrant, but an

alternative place to look for it is embodied cognition. Arithmetic has a phenomenological and semiotic foundation which is profounder than axiomatic formalisations. According to Longo (2005), mathematics has cognitive roots:

We cannot separate Mathematics from the understanding of reality itself; even its autonomous, “autogenerative” parts, are grounded on key regularities of the world, the regularities “we see” and develop by language and gestures.

This physical and perceptual basis of arithmetic can be used both to argue for the legitimacy and the experienced qualities of diagrammatic proofs. The legitimacy argument is to show that the kind of reasoning used in the diagrammatic proof is also needed to verify the formal axioms of arithmetic, but it is out of the scope and space of this paper to go further into this.

The possibility of arithmetic has to do with the stability of matter, that objects has permanence and do not suddenly appear, split or disappear like clouds. It also depends on our ability to discern some things as being a collection of objects of the same type. Freudenthal (1983, p. 75) points to Euklid book VII as an origin of the set or cardinal approach to number, and cites Felix Klein for the idea of numbers as collections of things of the same type. The concept of set is based on the invariance of physical or visual collections under spatial placement. The multimodal example proof is based on perceptible sets and spatial invariance. The objects of same type are small squares which together make up a square formed lattice. The decomposition of the square in the proof is related to spatial invariance, as it can be seen as moving the triangle parts away from the diagonal part. Both the concept of natural number and the proof also depends on our faculty of visual pattern recognition. That the proof uses the perceptual roots of arithmetic can thus be a reason behind its explanatory power. It is a phenomenological explanation not only by giving the experience of explanation, but also by using the phenomena behind the conjecture to be proved.

OBJECTIFICATION IN EMBODIED COGNITION

From the embodied mind point of view mathematics originates in our perception and ordering of physical reality. Even if the connection between parts of advanced mathematics and reality is not always obvious, this view makes it natural to look for reasoning with a perceptual basis, especially for the learning of the subject. But, we know from experience and research that students, or even mathematicians, are not able to immediately grasp the intended meaning of a proof from a diagram. This can be explained by the multimodality of thinking, that more than one modality is needed, but a semiotic approach gets deeper into the learning and communication aspect. Radford’s theory of knowledge objectification is a theory about how individuals can be able to notice and make sense of what they do and see.

..., objectification becomes related to those actions aimed at bringing or throwing something in front of somebody or at making something apparent –e.g. a certain aspect of

a concrete object, like its colour, its size or a general mathematical property. Now, to make something apparent, students and teachers make recourse to signs and artefacts of different sorts (mathematical symbols, graphs, words, gestures, calculators and so on). These artefacts, gestures, signs and other semiotic resources used to objectify knowledge I call semiotic means of objectification... (Radford, 2006b, p. 6)

The means of objectification are actions and semiotic resources. The example proof was given by a diagram and words. The words are semiotic resources which direct the attention of the reader to the appropriate aspects of the diagram. The concepts ‘triangle’ and ‘diagonal’ help the viewer to see the large square as composed of three parts. In the diagram also colours are used to make apparent the decomposition of the square into two triangle numbers and the diagonal, and also show how the small squares above and below the diagonal make pairs.

As an alternative or supplement, a physical diagram can be made of unifix or multilink plastic cubes. Then one of the triangular parts can be laid onto the other, both showing congruence and how to make pairs of cubes. We can pair a cube with the cube lying above it. This physical approach makes the red squares superfluous. These red squares are confusing as long as communication of the decomposition is in focus, so it would be an advantage if they could be painted yellow. Showing congruence does not mean proving, but pointing to. What looks like or feels like equality, can mistakenly be taken by the student to be a proof of equality. The physical process of making pairs of corresponding upper and lower small squares in the triangles, is a proof when the side equals five, but its generalisation requires an argument. A general proof requires another way of seeing.

The explanation by words introduces a process ordered in time, in which different aspects and parts of the diagram are in the foreground. Concepts like ‘odd number’ and ‘set of pairs’ helps the viewer to see the diagram as a general pattern. It is possible for a student to grasp everything else, but to see the diagram just as the case of five times five. It is a well known misconception among students that showing one or a few cases is enough to prove a result. We know that many mathematically trained persons experience to see a general proof through diagrams like the one in the example, but we also know that this does not come easy to many students. It is necessary to see the diagram like an informal ω -proof, that is, a procedure for generating the proof in all other cases. A possibility is to let the students draw and paint the five by five square and, notice how this is done and ask them to draw and paint squares of other sizes. Alternatively, the students can build squares by coloured plastic multilink cubes. The dynamic process of painting or building makes it more likely to see an algorithm than looking at a static diagram.

Husserl made a distinction between simple and categorial intuition. The latter means to ‘intuite’ the conceptual, the general or the Aristotelian form through seeing something concrete. According to Cobb-Stevens (1990), “Rather than presenting some particular thing, say a red chair, categorial intuition presents the chair’s *being*

red, the red quality's *belonging* to the chair (p. 44).” By intuition Husserl underlines the richness or fullness of actual experience compared to thought and speech. Cobb-Stevens exemplifies this as the difference between strolling through the streets of a foreign city and vague plans of a visit (p. 43). The grasping of the general in the multimodal example proof in visual or physical version probably has the same richness compared to the induction and direct algebraic proofs **IN** and **D2**.

ALGEBRAIC AND VISUAL PROOF COMPARED

The visual or physical multimodal proof related to figure 1 seems to work considerably better than the algebraic alternatives in order to give students meaning and richness of experience when understood or objectified. The former kind of proof gives at least another kind of explanation, which for many students probably is better. Since warrant for truth is the simultaneous establishing of truth and meaning, we think that even in this aspect multimodal proof is a good alternative. However, as some hints have indicated, objectification is not straight forward to achieve. For instance it can be difficult to see the conjecture to be proved directly from diagram 1, and seeing the diagram as general is demanding. Algebraic proof has some clear advantages compared to visual proof. Algebraic proof in arithmetic has well established proof systems which have an undisputed status among mathematicians. The system of algebraic and arithmetic signs are standardised, used almost everywhere and are institutionalised by schools, universities, books etc.

Like the visual diagram 1, also the arithmetical and algebraic notations are spatial and compact. The latter are not phenomenological or iconic, but symbolic. The signs together make a system giving meaning to terms and statements. Algebraic identities like $2x + 3x = 5x$ are linked to the objectified meaning of $2 + 3 = 5$ and the addition operator. Even the algebraic system has a link through objectification to physical and perceptual phenomena behind arithmetic, but not in the direct and full way as in categorial intuition. A relevant reference for the spatial aspects of algebraic symbolism is Bergsten (1999). As long as the complexity of an algebraic statement or a diagram is restricted, both have a good potential of objectification. Ordinary language composed by words lacks spatiality and compactness and are delegated to an intermediate role in learning and objectification. Proofs given by words are not alone a good way for students to objectify proofs. But, neither algebraic formulas nor diagrams give all the necessary information directly. Visual proof has to be supplemented by symbols, standards and transformation rules which make communication, objectification and validation easier.

CONCLUSION AND FURTHER RESEARCH

The paper has contributed to clarification of the concept of multimodal proof. Multimodality means that at least two different modalities occur simultaneously in the proof. Also, a multimodal proof is an artefact, but the distinction between proving and proof is challenged. A proof performance or presentation can be turned

into an artefact by the use of video recording. Still the proof will normally be the end result of refinements of more immature attempts of proving. We have restricted the attention to a type of generic visual proof which can be formalized and legitimated by recursive ω -logic.

The learning and recognition of the generality of the proofs are studied by the theory of objectification. This prescribes active learning supported by what Radford calls semiotic means of objectification. One possible action and semiotic mean is building of physical versions of the diagrams. The idea is to put the procedural aspects in the foreground, giving a link to recursive ω -logic. The explanatory power of the visual proof has been discussed from the perspectives of phenomenology, categorial intuition and objectification. The perceptual and cognitive aspect of the proof lying beyond the concept of number is suggested as a reason for the strikingly potential of explanation. A drawback of visual proof is the lack of standardisation. Proof systems and appropriate semiotic signs can also make both interpretation and validation of the proofs easier. The development of these missing aspects both theoretically and by design is central in further research.

WAYS OF ANALOGICAL REASONING – THOUGHT PROCESSES IN AN EXAMPLE BASED LEARNING ENVIRONMENT

Markus Ruppert

University of Würzburg (Germany)

This study is about analogical reasoning in problem solving situations. As one part of the study, task sequences for an example-based learning environment were developed with the aim of initiating processes of analogical reasoning. While solving these tasks the subjects were asked to verbalize their thoughts. Their problem approaches were recorded by video camera and transcribed to Think Aloud Protocols. Referring to a two-dimensional process-model of analogy the protocols were used to trace, visualize and quantify ways of analogical reasoning in order to become accessible for classification. It appears that different ways of analogical reasoning occur and there seem to be suitable attributes to describe them as different classes of ways in the two-dimensional model.

Key words: Analogy, Analogical Reasoning, Transfer, Example Based Learning, Think Aloud

INTRODUCTION

“ALL [sic] our reasonings concerning matter of fact are founded on a species of Analogy, which leads us to expect from any cause the same events, which we have observed to result from similar causes.” (Hume, 1748, Sec. IX, Par. 82)

David Hume refers to the possibility of drawing on experience to extend the (collective) knowledge as one of the main characteristics of analogical reasoning. Yet, students' transfer performances in mathematical problem solving situations are not – in general – very successful. In order to make strategies of analogical reasoning available to students, the significance of processes of analogical reasoning within the scope of mathematical activities has to be clarified.

Thus, the starting point of the below described empirical study is the following question: How do students use analogical reasoning as a possibility of drawing on mathematical experience?

TWO DIMENSIONS OF ANALOGICAL REASONING

The principle aim of analogical reasoning is to make the structure of an untapped issue (*target*) available to learners by comparison to structures within the learner's field of experience (*source*) (cf. English, 1997, p. 5). The most simple form of analogical reasoning, often used in intelligence tests measuring general intelligence *g* by analogy formation skills (e. g. Culture Fair Test CFT, CFT20 Catell & Cattell, 1963, Weiß, 2006), is seen as the establishment of a relational identity like ‘A is to B, as C to D’. The concept of this identity is based upon the comparison of *object*

attributes and especially upon the comparison of *relations* between objects involved (cf. Alexander, White & Daugherty, 1997, p. 117f; Ruppert, 2012).

Dimension 1 – Levels of analogical reasoning

Nevertheless, within the scope of learning mathematics not only the necessary skills to solve tasks, as those mentioned above, determinate the value of analogical reasoning. In fact, students are to be enabled to assess possibilities of mathematical action with regard to common structures. They finally transfer mathematical options to unfamiliar situations ('Do you know a related problem?', Pólya, 1949). In the latest cognition research, this process is described by the concept of *structure mapping* (cf. Gentner, 1983). In addition to finding equivalents on the levels of objects and relations, analogues to the mathematical operations that lead to a solution in the source domain have to be found (cf. Ruppert, 2010).

Thus, analogical reasoning occurs on the levels of objects and relations. In accordance with an actor oriented approach, transfer is seen as "the influence of the learners' prior activities on their activities in novel situations." (Lobato, 2006). Hence, analogical reasoning also occurs on the level of mathematical operations. These levels constitute the *First Dimension of analogical reasoning*.

Analogical reasoning and proving – A historic example

The relevance of analogical reasoning for proving as well as the relevance of the different levels of analogical reasoning themselves can be shown by the following excerpt of Archimedes' "Method of Mechanical Theorems":

"From this theorem, to the effect that a sphere is four times as great as the cone with a great circle of the sphere as base and with height equal to the radius of the sphere, I conceived the notion that the surface of any sphere is four times as great as a great circle in it; for, judging from the fact that any circle is equal to a triangle with base equal to the circumference and height equal to the radius of the circle, I apprehended that, in like manner, any sphere is equal to a cone with base equal to the surface of the sphere and height equal to the radius." (Heath, 2007, S.20/21)

Archimedes himself states that, by transferring a given 2D situation to the 3D space, analogical reasoning on object and relation level lead him to a hypothesis about the surface of the sphere. In the further text it becomes clear that, having the proof for the circumference of the sphere in mind, analogical reasoning on the level of mathematical operations (proving steps) lead him to a proof of his hypothesis.

Usually, once a proof is written down, the chronology of its genesis is lost. In our historic example, especially the chronology of the underlying process of analogical reasoning cannot be reconstructed in detail. Therefore it seems important to have the process character of analogical reasoning in mind if we want to know what is going on while the learner is drawing on his mathematical experience by analogy.

Dimension 2 – Components of analogical reasoning

In this regard, Sternberg (e. g. 1977) was able to identify several components of analogical reasoning by a variety of experiments. According to Sternberg, the study at hand takes the following four components as a basis (cf. Ruppert, 2012):

- (1) Structuring (Sternberg: Encoding, Inferring)
- (2) Mapping
- (3) Applying
- (4) Verifying (Sternberg: Justification, Response)

These components constitute the *Second Dimension of analogical reasoning*.

So the statements mentioned above suggest studying processes of analogical reasoning in the field of the two dimensions: ‘Level of Analogical Reasoning’ and ‘Component of Analogical Reasoning’.

As a consequence the working hypothesis of this research is: Processes of analogical reasoning can be illustrated as ‘ways’ in a two-dimension model (cf. Ruppert, 2012).

Thus, the analysis of analogical reasoning processes leads to diagrams of this type:

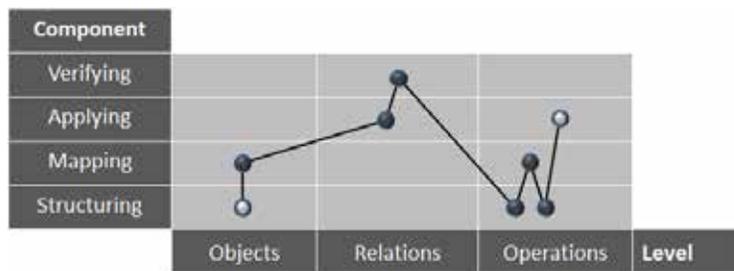

Fig. 1: Two Dimensions of Analogical Reasoning

Fig. 1 is read in the following way: The reasoning process starts with structuring statements on the level of objects and ends with the application of mathematical operations transferred from the base to the target domain. The outline itself passes different phases on different levels. The extraction of diagrams of different analogical reasoning processes defines the starting point of this present inquiry.

RESEARCH QUESTIONS

On this basis, the following questions should be particularly clarified by the given research (cf. Ruppert, 2012):

- How do specific processes of analogical reasoning appear as ‘ways’ in the outlined two-dimensional model and how do they look?
- Is it possible to classify these ‘ways’ regarding both successful and failed processes of analogical reasoning?

- Which particular importance is attached to the transitions from the structural (object and relation) level to the operation level?

RESEARCH-DESIGN: A FOUR-PHASE METHOD

To establish an empiric study on thought processes in general and especially on analogical reasoning several questions have to be answered in advance. The answers to these questions determine the research design.

1. How can processes of analogical reasoning be initiated?
2. How can processes of analogical reasoning be made visible and observable?
3. Which data can be used for the description of analogical reasoning?
4. Which criteria are suitable and necessary to systematize data on the basis of the two-dimension model?

Results of studies on *Example Based Learning* (cf. Atkinson, Derry, Renkl & Wortham, 2000) lead to a two-stage study design in which the subject is given different exercises out of one sequence of tasks.

During a ‘learning phase’ the *source* of analogical reasoning is established. The subject is offered sample tasks with solutions and some instructions during this phase. Afterwards, the subjects complete further tasks of this sequence single-handed during a ‘testing phase’. Now the intended transfer performance in form of analogical reasoning shall occur.

In a first step, various sequences of tasks from different domains have been developed in accordance with research results on *Example Based Learning* and tested in a preliminary study.

Yet, in this inquiry on thought processes, relying only on the originated results like for instance students’ documents would fall considerably short in answering the research questions formulated above. That is why the main study resorted, in compliance with results of Schoenfeld (1985) and Haastrup (1987), to the process-related, introspective method of *Pair Thinking Aloud*, a variant of the *Think Aloud* method (Ericsson & Simon, 1980, 1999), as one possible method for integrating verbal data into empirical studies. The creation of a natural situation and the necessity to keep the verbalization process of thoughts as complete as possible constituted, above all, the main reason for this kind of data collection. Haastrup (1991) writes concerning the advantages of Pair Thinking Aloud:

„(...) by using pairs, one stimulates informants to verbalize all their conscious thought processes because they need to explain and justify their hypotheses (...) to their fellow informant. Furthermore, thinking aloud in pairs seems quite natural (...); It comes close to a real life situation.“ (p. 85).

So, in each case two students were asked to verbalize their thoughts loudly during the completion of tasks. Their statements were recorded by video.

In order to ensure a better reconstruction of the underlying thought processes, the data can be secured by a range of additionally measures (Haastrup, 1987; Borrromeo Ferri, 2004). In the present study the following two dispositions were made:

On the one hand, the phase of task completion was divided in two phases. During a phase of *partner work* two students worked together on two tasks related to the domain they received instructions to. During a phase of *expert work* two students who did instructions and partner work on different domains worked together. Now it was their job to complete tasks on each of both domains. It was expected that the student who was familiar with the current content would assume a leadership position. In fact, it appeared that in nearly any case, even during the phase of partner work, one of the students takes over a leading role. It is assumed, that the process of observed during the study is close to the thought process of the leading student.

On the other hand, after the completion of each task one of the students was asked to track back the line of thought once again in a *Teach Back Phase* (cf. Wallach/Wolf, 2001, p. 25; Vora/Helander, 1995, p. 375).

In conclusion, the study consisted of four phases (cf. Figure 2):

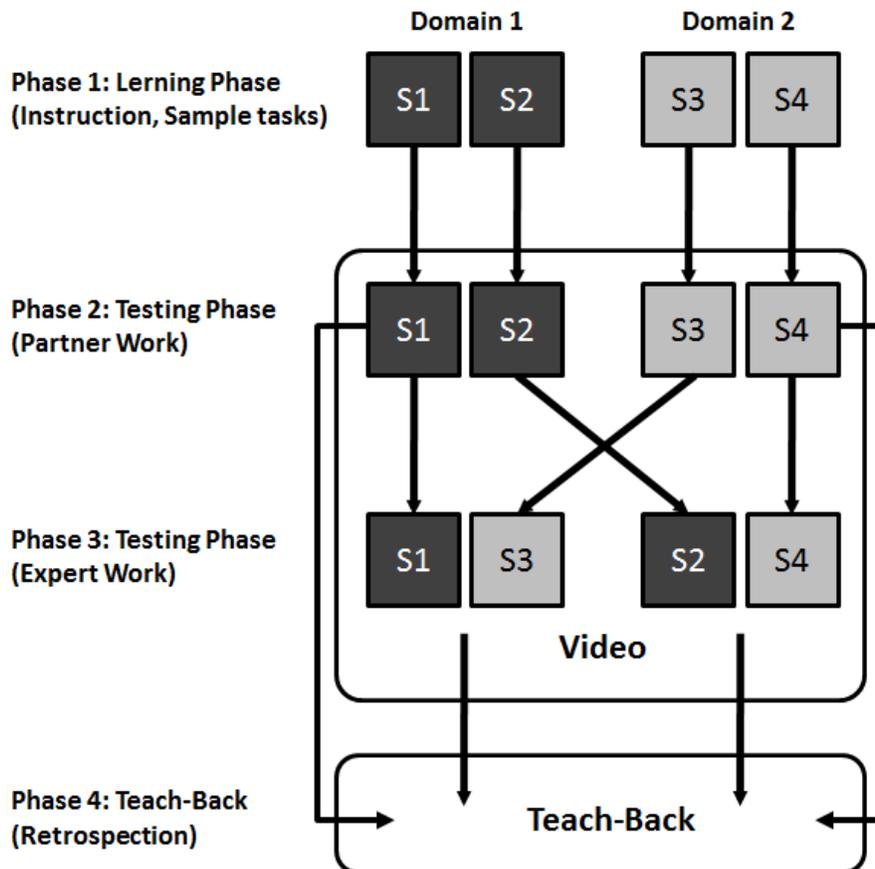

Fig. 2: Four-Phase-Design of the Study

DATA ANALYSIS

With regard to analysis the following data are available:

- transcripts of students' verbalizations and gestures (of Phases 2 and 3)
- video material of the *Teach Back Protocols*
- students' documents (solutions of tasks in written form)

On the basis of a coding guideline which was developed within the framework of another preliminary study, all verbal statements during the phases 2 and 3 of the inquiry were assigned to the different areas of the two-dimensional model (Fig.1). Therefore, different attributes of the students' statements were outlined and anchoring examples were identified to characterize each area of the two dimension model. Teach Back Protocols, graphic material and students' documents were used to bridge gaps in the verbalization processes as well as to substantiate the allocation to areas of the two-dimension model (for example by gestures like pointing at a distinctive part of an example task).

An example

The following dialogue is recorded during the *Testing phase*. Two students work on the problem of finding the number of different loop trails passing two villages A and B depending on the number of connecting trails between A and B. In the *Learning Phase* worked out examples of *complete graph problems* were presented.

- 1 S1: A and B are the vertices.
- 2 S2: Yes. And the trails are the edges.
- 3 [S2 draws a figure with two vertices and two edges]
- 4 S2: Loop trail means that you walk in a circle and that you don't walk back on the same trail.
- 5 [S1 marks two trails between A and B to highlight a loop trail]
- 6 S1: Rather like this.
- 7 S2: Exactly.
- 8 S1: That means a loop trail needs two connecting trails.
- 9 S2: Yes.
- 10 [S1 writes]
- 11 S2: Now we have to calculate the number of days depending on n, isn't it?
- 12 S2: 'Cause we don't know how many trails, it could be infinitely many, so to speak.
- 13 S1: Mhm.
- 14 S2: And since you want to walk one loop trail every day ...
- 15 S1: ... you need two different connecting edges a day.
- 16 S2: Exactly.
- 17 [S1 writes, S2 takes the worked examples and points a finger on example 2]

- 18 S2: That means you have to, hm, ..., here in the second (points on the worked example) ... you mustn't divide by two.
- 19 S2: Because you have to count pairs, hm?

Both students begin their argumentation (l. 1-2) by applying an analogy on object level. Commonalities in the relations between the objects are used to visualize the relational situation (l. 3, mapping on relation level) and to argue about the mapped relations in the target domain (l. 4-16, applying on relation level). The argumentation by analogical reasoning in this time segment is confirmed by the use of the terms “connecting edges” instead of “trails”. For the transition to the operation level the worked examples are explicitly used (l. 17, mapping on operation level; l. 18, applying on operation level). Finally, the assumption is evaluated (l. 19, verifying on operation level).

The diagram of this short dialogue in the two dimensional model is shown in Fig. 3:

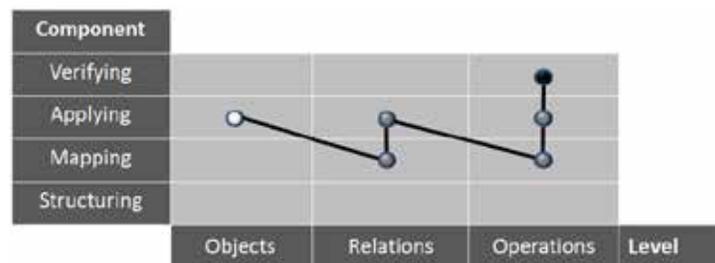

Fig. 3: Example of a “way of analogical reasoning” in the 2D-Model

Different kinds of visualization

For the coding of the data the software Videograph was used. The user interface of Videograph is partitioned into different windows which can be handled simultaneously: one window shows the video recording, a second window allows the transcription of the recorded dialogue and a third window shows a timeline on which time segments can be determined and assigned to predefined categories with respect to the coding scheme. One result of the work with Videograph was the graphic presentation of phases and levels of analogical reasoning on the timeline. In Fig. 4 the levels of analogical reasoning define the main categories and the phases appear as subcategories.

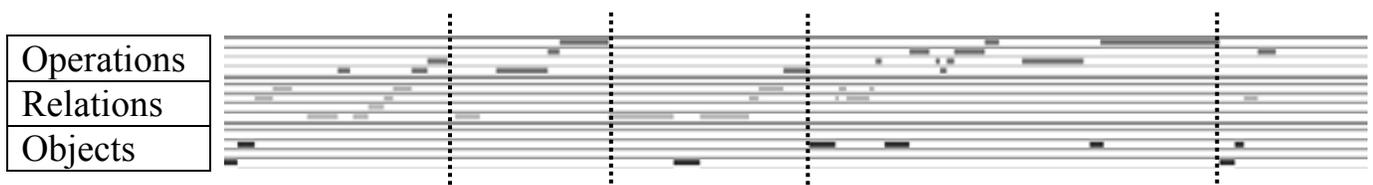

Fig. 4: Ways of analogical Reasoning in form of a graphic representation created by the software Videograph

These diagrams could be already used for a first interpretation of analogical reasoning processes. For example, it could be noticed that there are several discontinuities in the graphic presentation. Drawing the attention back on the verbalizations it could be shown, that these discontinuities often coincided with an abandonment of one line of thought (dotted lines in Figure 4). With respect to this observation the processes of analogical reasoning could be split into sections by the use of the verbal data.

Moreover, the ‘ways’ in the two-dimension model represented (like in Fig. 1) a basis for further interpretation.

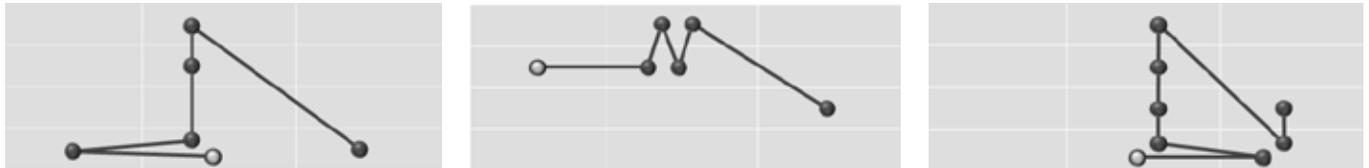

Fig. 5: Ways of analogical Reasoning in the two-dimension Model

Based on these diagrams, one can try to find a classification of ‘similar ways’ during the investigation.

In order to have quantitatively substantiated statements, the ways of the two-dimension model are translated into a ‘Stopover Matrix’, too (conf. Figure 6). By means of a cluster analysis the data should help to establish a classification of ways.

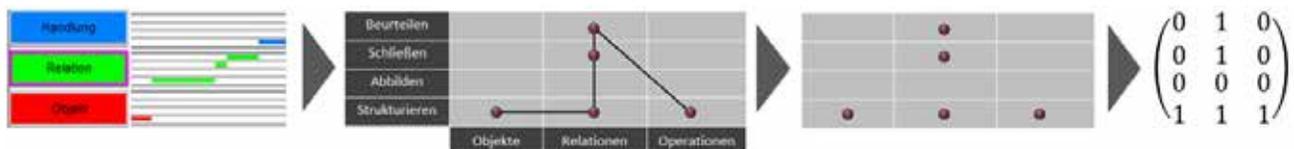

Fig. 6: The Videograph diagram (left), the corresponding ‘way’ of analogical reasoning in the two dimension model (2nd left) and the ‘Stopover Matrix’ (right)

FIRST RESULTS AND CONCLUSION

As mentioned above, the visualization of the software Videograph leads to the following interpretation (cf. Ruppert, 2012):

- Sometimes thought processes were abandoned. Thus, the processes can be divided in several sections (see above).
- In the Videograph diagram the starting point of a new section after an abandonment of the thought process is always lower than the ending point of the previous section.
- Mainly, the sections (s. a.) show an upward trend when taking them separately.

Furthermore, the interpretation of the graphical representations on the basis of the two-dimension model shows the following:

- The recorded ‘ways’ run, generally speaking, from ‘left to right’ and from ‘bottom to top’.
- A new section in thinking basically starts at the object level and/or at the stage of mapping.

Now it becomes clear that the Stopover Matrices do not lose all of their way information because the matrices also have to be read “from left to right and from bottom to top”. Moreover these matrices can be seen as vectors in a vector space. An appropriate distance measure makes it possible to define the grade of difference between the matrices and thus between the ways of analogical reasoning. It occurs that grouping these ways in an interpretative way almost leads to the same results as grouping the corresponding matrices by some kind of cluster analysis. Regarding first results of grouping, it appears that ways which share sections at one level or within one component of analogical reasoning often fall together in one group. Thus, at least two types of analogical reasoning can be identified: One type prefers structuring on all levels before connecting the source and the basis domains. The other type prefers analogical reasoning on the object level before reasoning on the levels of relations or operations.

A CASE STUDY OF THE ENACTMENT OF PROOF TASKS IN HIGH SCHOOL GEOMETRY

Ruthmae Sears

University of South Florida, USA

This paper describes how a midwestern geometry teacher enacted proof tasks with respect to levels of cognitive demands. Data were collected via teacher interviews, observation protocol, audio, and video recording of the enacted lessons and teacher artifacts. The results suggest that the guidance offered during whole class discussion often reduced the level of cognitive demand of potentially richer tasks. Furthermore, whenever the teacher talked less and allowed students to work independently or in groups, the enacted proof tasks generally maintained higher-levels of cognitive demand.

Key words: proof, geometry, high school, teaching

INTRODUCTION

Proof plays various roles in mathematics, such as to verify, explain, discover, communicate, systemize or create an intellectual challenge (De Villiers, 1999). Within the classroom setting, to carefully unpack these roles of proof, teachers must seek to provide opportunities for students to engage in proving. According to Harel and Sowder (2007), “The essentiality of opportunity to learn must be recognized not only at the intended curriculum level but also in the teachers enacted curriculum”(p.827-828). Therefore, if we seek to increase students’ opportunity to engage in proving, it is important to examine proof in both the intended and enacted curriculum. However, little is known about how proof is taught, in relation to curriculum materials which conveys the intended curriculum (Mariotti, 2006). Therefore, this paper sought to provide insight into how a geometry teacher enacts proof tasks by answering the following question: How does a geometry teacher enact proof tasks, with consideration to the levels of cognitive demands?

PERSPECTIVES

The manner in which teachers use curriculum materials can impact how proof is presented and what aspects of mathematical proofs are emphasized. Therefore,

it is important to consider not only the curriculum materials used, but also how they are used during instruction. McCrone, Martin, Dindyal, and Wallace (2002) acknowledged that the four teachers in their study followed the textbook rather closely to structure the enacted lesson on proof, as well as for allocating homework assignments pertaining to proof, and used technology or hands on investigation activities sparingly. Since the mathematical content emphasized in textbooks can pose a challenge to teaching authentic proofs (Cirillo, 2009), it may not always be ideal for teachers to follow the curriculum rather closely. For example, Schoenfeld (1988) conducted a year long study of teaching and learning in a 10th grade geometry course. He found that, although the teacher exhibited “good teaching”, the teacher’s actions might have had a negative impact on students’ perceptions of proofs. He suggested that the teacher’s strict adherence to the curriculum might have caused students to differentiate between constructive and deductive geometry, consider the form of the mathematical argument to be paramount, and view doing proofs as a quick activity.

Bieda (2010) conducted one of the few studies that have examined curriculum materials during the enactment of proof-related tasks during instruction. Her results highlighted that when an opportunity to prove arose, students did not provide adequate justification approximately half of the time; and that 42% of the time teachers did not provide a response, 34% of the time teachers sanctioned students conjectures, and 24% of the time teachers requested the input of the class. She acknowledged that teachers were likely to provide positive feedback for non-proof arguments as if it were general arguments. Bieda concluded that “teachers in the classrooms observed did not provide sufficient feedback to sustain discussions about students’ conjectures and/or justifications...[and] when a teacher provided feedback to students’ justifications, it was not sufficient to establish standards for proof in a mathematics classroom” (Bieda, 2010, p. 377).

METHOD

This case study employed qualitative methods to investigate how a geometry teacher enacted proof tasks, with consideration to levels of cognitive demands (*memorization, procedures without connections, procedures with connections, and doing mathematics*). It is drawn from a doctoral dissertation, which examined how 3 geometry teachers use their geometry textbooks to teach proof. During the 2011 Fall Semester, I examined how a teacher used *McDougal Littell Geometry* (Larson, Boswell, Kanold, & Stiff, 2007) to facilitate students learning to prove. Before observing lessons pertinent to reasoning and proving (Chapter 2), parallel and perpendicular lines (Chapter 3), and congruent

triangles (Chapter 4), I conducted a textbook analysis of task features and levels of cognitive demand of proof tasks, for the identified chapters. Of the 977 tasks analyzed, only 13.1% were proof tasks (tasks which explicitly required students to write a complete proof, or complete a skeletal proof such that the finish product illustrated a complete proof).

The Mathematical Task Framework (Henningsen & Stein, 1997; Smith & Stein, 1998), which defines levels of cognitive demand, was used to code proof tasks as written, planned and enacted. Proof tasks coded as *memorization* reflected skeletal proofs, in which students had to fill in the blank to complete a proof argument. *Procedures without connections* proof tasks included tasks that require matching statements, or are clones of examples provided in the chapter. Proof tasks that reflected *procedures with connections* included writing proof plans, or tasks that can utilize procedures to facilitate some degree of thinking. Such tasks can help students make connections between diagrams, postulates, and symbolic representations. Finally, proof tasks coded as *doing mathematics* required students to write a complete proof that was not similar to previous tasks and examples or is not algorithmic, and may change the context or utilize a different representation. Such tasks requires great depth of critical thinking, and facilitate students engaging in evaluating the merit or lack thereof for using a particular postulate to develop a proof argument.

To triangulate data, I utilized multiple data sources: interviews, physical artifacts, audio, and video recording of the enacted lessons and an observation protocol. The observation protocol used during the enacted lesson documented the classroom climate, instructional tools used, how the tasks were facilitated, levels of cognitive demand of the tasks, and proof schemes observed. Multiple researchers assisted with coding the written tasks. We had an inter-rater reliability agreement of 89%. Furthermore, an additional researcher accompanied me to more than 25% of the observed lessons. Our coding of the observed lessons on the observation protocol was generally consistent.

Participant

Purposeful sampling was used to identify the teacher studied. Mr. Walker (pseudonym), a fifth year teacher and head of the mathematics department, taught at a rural school, and used *McDougal Littell Geometry* (Larson et al., 2007) for at least three years. Mr. Walker obtained his undergraduate degree in Statistics, and subsequently obtained a Master's degree in Mathematics Education. Additionally, he has taught high school geometry every year since he began teaching. Being one of the two mathematics teachers at the school, he taught introductory algebra, college credited algebra and statistics courses, and calculus. Mr. Walker believed that proof was needed in teaching mathematics

because it fostered students gaining an appreciation for mathematics, and the work of mathematicians who contributed to the theorems and postulates that is visible within textbooks. He also believed that proof assists students to “become a little more logical in their areas of thought; not just math”. Mr. Walker asserted that teachers’ experience can influence how proof is taught, and acknowledge his preference for using the two-column proof representation. He stated, “...the two-column proofs are the easiest to see logical steps, so that is what I spend the most time teaching. Also, I may be more rigid in the steps that the students must show me... I don’t like to find missing steps in logic according to our geometric postulates or theorem” (September 29, 2011-Follow up interview- sent via email).

In Mr. Walker’s class students were first required to prove a theorem, before they could use it as supportive reasoning in a future proof. To facilitate students writing proofs, Mr. Walker required students to work in groups to construct proof arguments for proof on cards, or organize shuffle proof arguments to create logical arguments to exchange with other groups.

Mr. Walker acknowledged that the students whom he taught generally had a negative disposition towards proof tasks. He suggested that students’ peers tell them that proofs are difficult, and therefore students are biased against proofs before entering the class. He also believed that students’ negative disposition towards proofs were due in part to a lack of motivation to state their ideas with appropriate reasoning.

Furthermore, Mr. Walker was aware that proof can play multiple roles within a mathematics classroom, and suggested that the procedural nature of proof in geometry reduces the potential value of the proof.

He acknowledged that the textbook provided limited opportunity for students to engage in proving; hence, he often sought to provide supplementary proof tasks. Therefore, he was chosen as a unique case since he intentionally sought to increase the opportunity for students to engage in proving in his geometry course despite students’ disposition towards proofs, and limited amount of proof in textbooks. Moreover, he was selected because he had a greater flexibility to progress through the textbook at his own rate, unlike the other two teachers studied for the dissertation who planned instructional activities and assessments with their geometry team. I observed Mr. Walker teach 75 minutes geometry lessons, 13 times, during the 2011 fall semester, in which he sought to expose students to proving. His high school geometry class consists of 9th and 10th grade students. The allocation of class time was devoted to reviewing solution to homework assignments, working on proof tasks in groups, and concluding lessons by providing solutions to assigned proof tasks.

RESULTS

Mr. Walker desired for his students to learn to reason effectively, and emphasized that the order matters in how a proof argument is presented. Supportive reasoning was emphasized for each step of the proof. He gave students a list of 28 reasons and regularly quizzed students about the content on the list. The list included definitions, properties of basic operations, properties of equality (such as reflexive and symmetric), theorems about congruent, and segment and angles postulates. The list of reasons had all of the necessary information to complete proof tasks that were commonly assessed. Hence, the list could be used to complete lower-level task rather quickly, and was used as a reference point for higher-level tasks. Thus, it could be argued that the list was an implicit form of teacher intervention, even when the teacher remained silent while students worked on proof tasks independently. Most of the proof tasks posed required six or fewer steps and used the two-column proof representation.

The textbook was used to assign homework, and structure the lesson. If he deviated from the textbook, the tasks he used aligned with the lesson objective of the textbook, and were meant to facilitate students learning how to prove. Mr. Walker frequently supplemented the textbook with additional proof tasks. The supplementary tasks posed increased opportunities for students to engage in higher cognitive thinking. Based on conversations with Mr. Walker, his deviation from the textbook was due to his desire to pose more higher-level cognitive demand tasks. He acknowledged that the textbook had limitations, and he tried to overcome them. Mr. Walker remarked, “I guess, there’s just not enough like, if I look in this section in the book there’s one, there’s two proof of how we want them to be thinking about like” (November 3, 2011- Follow up interview at the end of the lesson). He also noted that sometimes the order in which content is presented in the book might not be logical, so his goal was to ensure the content progressed logically.

Although Mr. Walker’s whole class instruction often reduced higher-level cognitive demand tasks to *memorization* or *procedures without connections*, when students worked in groups higher cognitive thinking was evident. An example of Mr. Walker reducing the level of cognitive demand of a proof task was visible on November 10, 2011, in which he required students to prove two triangles were congruent, which shared a common side. He said, “All right, I’ll get you started” and proceeded to complete the proof in its entirety. In doing the proof he asked students to select one of the 6 theorems of congruency from the board to support the premise that the triangles were congruent. When a student selected an incorrect reason, the teacher continued by stating the correct reasoning and concluded the proof. Hence, the opportunity for students to

engage in doing a higher-level cognitive proof task was not provided due to the excessive guidance provided by the teacher. Therefore, although the proof task had the potential to be considered a *procedures with connections*, if completed by students, when enacted by the teacher, the level of cognitive demand of the task was reduced. Mr. Walker did not pose any tasks that reflected *doing mathematics*. Although he had good intentions (which was to facilitate learning how to prove), the guidance offered during whole class discussion often reduced the level of cognitive demand of potentially richer tasks.

Cognitive Demand of Tasks during Mr. Walker's Enacted Lessons

Many of the tasks enacted in Mr. Walker's lessons were higher cognitive demand tasks. Table 1 indicates the level of cognitive demand of tasks for the original, planned, and engagement with the task during the enacted lessons as documented on the observation protocol. The original task depicted task as written, the planned task is the teacher's stated intention of how he intended to use the task during the lesson, and the engagement with the task is how the teacher actually used the task during the enacted lesson. In three lessons there existed multiple levels of cognitive demands for the various tasks posed. The shift from the original tasks to engagement with tasks suggests that when enacted the level of cognitive demand was reduced. It further suggests that half of the tasks Mr. Walker posed reflected *procedures with connections*.

Mathematical Tasks in Relations to the Levels of Cognitive Demands	Lower-Level Demands (<i>Memorization</i>)	Lower-Level Demands (<i>Procedures Without Connections</i>)	Higher-Level Demands (<i>Procedures with Connections</i>)	Higher-Level Demands (<i>Doing Mathematics</i>)
Original Tasks	2	6	8	0
Planned Tasks	2	6	8	0
Engagement with the Tasks during the Enacted Lesson	2	8	6	0

Table 1. Levels of cognitive demands observed during 13 of Mr. Walker's geometry lessons.

Mr. Walker's *memorization* tasks often required students to restate postulate, theorems, and rules. He believed that, in order for students to prove, they must know a list of reasons. For example, he reminded students that the definition of angle bisector could be used to prove that, if an angle is bisected, the two angles

formed are congruent. Mr. Walker said,

Good, definition of angle bisector. So this is on your list of 28 items. Basically what the definition of an angle bisector just says; it's a ray, or a line, or a segment that divides and angle into two congruent triangles (October 18, 2011- Enacted lesson).

He readily referenced the list as a tool to identify appropriate reasoning to support claims made.

Writing statements about congruent triangles often were *procedures without connections*. He required students to place marking on the diagrams, identify corresponding sides and angles, solve equations, and draw diagrams. For example, Mr. Walker stated,

We've got a lot of problems with segments and whenever we do a proof with segments, and we're going to have to set an equation, there are usually two things that are going to help us set up an equation. With segments, it's either that constant to midpoint or the segmented addition postulate. With angles, it's the exact same thing except instead of, you usually have a midpoint of an angle but we've got angle bisectors so we could use an angle bisector to set up an equation or the angle addition postulate. So you're going to have to look at the given information and kind of decide which of these can I use to set up an equation. Let's keep that in mind. (September 8, 2011 - Enacted lesson)

Figure 1 shows an example of a proof he used to illustrate the procedure of using the segment addition postulate on September 8, 2011. This was categorized as a task of *procedures without connections*.

Given: $AC = BD$
 Prove: $AB = CD$
 Proof

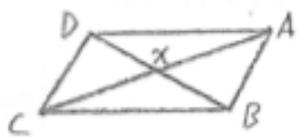

Statements	Reasons
1. $AC = BD$	1. Given
2. $AB + BC = AC$	2. Segment addition postulate
3. $BC + CD = BD$	3. Segment addition postulate
4. $AB + BC = BC + CD$	4. Substitution
5. $AB = CD$	5. Subtraction property

Figure 1. Mr. Walker's proof tasks used to illustrate segment addition postulate.

Among the tasks that Mr. Walker posed involving *procedures with connections*, include: asking students to write complete proof, organizing shuffled proof statements and reasons to make logical proof arguments, and assigning projects in which students had to construct a town that preserved the placement of buildings in relations to parallel and perpendicular lines, or write a story that logically links 10 conditional statements.

Admittedly, enacted tasks that reflected *procedures with connections*, the teacher was a silent participant in the group discussion. Based on my classroom observations, although students evidently engaged in higher-level thinking in their respective groups, during whole class discussion, the teacher merely provided the solution to the proof without requiring students to share how they constructed the proof. Figure 2, is an example of a proof task Mr. Walker wrote (November 15, 2011- Teacher artifact) to complement Section 4.6- Use congruent triangles).

Example 4) Given: X is the midpoint of \overline{BD}
 X is the midpoint of \overline{AC}
 Prove: $\triangle DXC \cong \triangle BXA$

Statements	Reasons
1	1
2	2
3	3
4	4
5	5

Figure 2. Proof task Mr. Walker wrote that reflected *procedures with connections*.

IMPLICATIONS

The results suggest that Mr. Walker provided excessive guidance when he discussed solutions to proof tasks. Excessive guidance is not ideal, since it can potentially limit the opportunity for students to write proofs independently and engage in discourse about their proofs. The teacher led discussion was merely to provide solutions to proof tasks rather than have students share their reasoning and possibly critique the reasoning of others. Although he provided the opportunity for students to engage with proof tasks during the enacted lessons, his whole-class discussion provided little opportunity for students to reflect on the merit of their arguments or other means to make the same conclusions. The weak questioning strategies employed during whole class discussion, which

required generally recollection of facts, did not require students to reflect on or critique the reasoning employed in constructing the proofs. Such practices could potentially devalue the importance of proof, or hinder students from conceptualizing the validity of their mathematical arguments or developing mathematical habits of minds (Cuoco, Paul Goldenberg, & Mark, 2004). Although this study is not generalizable, since it focused on only one teacher from the Midwest region of the United States, it sheds light on how a teacher enactment of proof tasks can potentially reduced the level of cognitive demands of a task.

Requiring teachers to pose *procedures with connections* and *doing mathematics* proof tasks does not guarantee that students will engage with the tasks at the same level; considering that a teacher's actions during the enacted lesson can diminish the level of cognitive demands. Therefore, future researchers ought to examine roles teachers can play to ensure teachers' enactment of proof tasks maintains higher-levels of cognitive demands. Pre-service teacher programs, and in-service professional development need to encourage teachers to pose and enact proof tasks that require critical thinking. Hence, video recordings of effective and ineffective teaching of proof in geometry are needed, such that teachers can visualize practices that should be emulated, and avoided. The videos can provide opportunities to reflect on effective questioning strategies that can be employed and instructional strategies that can increase students' engagement with proof tasks.

Additionally, textbook developers ought to increase the number of proof tasks that requires higher-level thinking, in an effort to provide students more opportunity to prove. The guidance offered to teachers in teacher's edition of textbooks ought to promote the importance of having students prove, and should suggest strategies of how to unpack proof tasks to facilitate opportunities for students to engage in *doing mathematics*.

THE ROLES OF BEHAVIORAL SCHEMAS, PERSISTENCE, AND SELF-EFFICACY IN PROOF CONSTRUCTION

Annie Selden and John Selden

New Mexico State University, USA

We first discuss a theoretical perspective on proof, proof construction, and proving actions, as well as the need for persistence. Persistence is important for successful proving because it allows one to “explore”, including making arguments in directions of unknown value, until one ultimately makes progress. Persistence can be supported by a self-efficacy belief, which is “a person’s belief in his or her ability to succeed in a particular situation” (Bandura, 1995). We next examine actions needed for a successful proof construction of a theorem given to mid-level U.S. undergraduates in a transition-to-proof course. We contrast those actions with the actual actions of a mathematician proving the same theorem. Finally, we give some teaching implications.

Key words: proof construction, persistence, self-efficacy, undergraduates, mathematicians.

INTRODUCTION

We first discuss a theoretical perspective on proof, proof construction, and proving actions. Then, drawing on observations from a multi-year teaching experiment, we point out three proving actions that appear to be especially difficult to teach. We suggest that the teaching difficulty arises from a need for students to have a kind of persistence, which in turn may depend on students’ sense of self-efficacy. After discussing self-efficacy, we illustrate the usefulness of it and of persistence by examining a hypothetical proof construction of a specific theorem that students in the teaching experiment are asked to construct. We also describe how a mathematician approached proving that theorem. Then, after a brief discussion, we end with some teaching implications.

A THEORETICAL PERSPECTIVE

We view a proof as the result of a certain kind of deductive reasoning and as a text written in a certain genre (Selden & Selden, to appear). We also treat a proof as having two parts: the formal-rhetorical part and the problem-centered part. The *formal-rhetorical* part of a proof is the part that one can write based only on logic, definitions, and sometimes theorems, without recourse to conceptual understanding, intuition, or genuine problem solving. We call this a “proof framework” and suggest to students that this framework (Selden & Selden, 1995) be written first, leaving blank spaces where needed. We call the remainder of the proof the *problem-centered*

part, and it does require conceptual understanding and genuine problem solving (Selden, McKee, & Selden, 2010).

We view constructing a proof as a sequence of “actions” (Selden, McKee, & Selden, 2010). Some of these are physical, such as writing a line of the proof or drawing a diagram, and some are mental, such as focusing on the conclusion or “unpacking” its meaning. Some actions may influence the prover’s own cognition, such as taking a break for “incubation.” Many such actions, taken during the construction of a proof are not visible in the final written proof. This may be why it is sometimes difficult for a student to mimic a given proof when constructing another proof.

Understanding proof construction would probably be greatly aided by understanding what drives the individual actions involved. However, although one might reasonably suppose such actions generally arise from working memory that is of little help in explaining the origins of individual actions. Thus, we turn to dual-process theory, the idea that there are two systems of cognition, called S1 and S2, with S1 being more intuitive and S2 being more analytic (Leron & Hazzan, 2005). At first glance, one might view reasoning as S2 cognition. That is, the kind of cognition that is slow, evolutionarily recent, effortful, and conscious. However, we suggest that as one learns to construct proofs, the burden on working memory is reduced because much of what drives particular actions shifts to S1 cognition. That is, it shifts to cognition that is fast, evolutionarily ancient, effortless, and nonconscious. (For additional details, see Selden and Selden, 2011). This shift from System 2 to System 1 takes place because, in constructing a number of proofs, repeatedly occurring proving situations often occur immediately before corresponding repeatedly occurring actions. The situations may then become linked, in an automated way, to a tendency to carry out the corresponding actions. We see such automated situation-action pairs as persistent mental structures and call the smallest of them *behavioral schemas* (Selden, McKee, & Selden, 2010). We suggest they contribute to S1 cognition and are stored in procedural memory which, in contrast to other forms of memory, is very persistent -- indeed, it does not degrade with age.

In the above, by a *situation* we mean a reasoner’s inner, or interpreted, situation as opposed to an outer situation that may be visible to an observer. However, we have found, in teaching, that we can often gauge approximately what the inner situation is from the outer, observable, situation, and the ensuing action.

Behavioral schemas

We next give an example of a behavioral schema. In situations involving a function f from X to Y and a subset A of Y , many university mathematics students will know that $f^{-1}(A)$ is defined as $\{x \mid f(x) \in A\}$. In the context of proving, some students given $b \in f^{-1}(A)$ [the situation] will automatically, without bringing the definition to mind, claim that $f(b) \in A$ [the action]. However, other students, who lack the schema, will often *not* do this. We suggest the following six properties of behavioral schemas:

1. Within a broad context, behavioral schemas are always available – they do not have to be searched for or recalled.
2. Behavioral schemas operate outside of consciousness. One is not aware of doing anything immediately prior to the resulting action.
3. One becomes aware of the resulting action of a behavioral schema as it occurs or immediately afterwards.
4. Behavioral schemas cannot be “chained together” outside of consciousness so that one only becomes aware of the final action. E.g. If the solution to a linear equation would take several steps, one cannot give the answer without being conscious of the results of some of the intermediate steps.
5. An action due to a behavioral schema depends in large part on conscious input.
6. Behavioral schemas are learned through practice. To acquire a schema, a person should carry out the appropriate action (correctly) a number of times. Changing a detrimental schema requires similar, perhaps longer, practice. (Selden, McKee, & Selden, 2010)

Three useful proving actions

In several iterations of teaching a U.S. second-year university transition-to-proof course in a modified Moore Method way (Mahavier, 1999), we have observed the following three useful proving actions that can be called upon. (1.) *Exploring*. In constructing part of a proof, one may understand both what is to be proved and what is available to use without having any idea of how to proceed. In such situations, one might reasonably try to prove something new of unknown value. However, we suspect many students are reluctant to do this, perhaps lacking confidence in their own ability to use whatever new they might prove. (2.) *Reworking an argument in the case of a suspected error or wrong direction*. In constructing a proof, one may come to suspect one has made an error or is arguing in an unhelpful direction. An appropriate response would be to rework part of the argument. However, we suspect many students are reluctant to do this, perhaps because they lack confidence in their own abilities to produce something new and better than before. (3.) *Validating a completed proof*. Upon completing a proof, one should read it carefully for correctness from the top down, checking whether each line follows from what has been said above. We suspect that few students do this, perhaps because they do not think that they are able to find errors in their own, just completed, proofs.

Some student errors may depend on a wrong belief about mathematics or logic or on a misinterpretation of a definition. Such errors can be pointed out and an explanation can be provided by a teacher. However, the above three actions in proof construction are not about correcting an error, but about habitually acting appropriately in particular situations. They seem to depend on students’ views of their own abilities,

that is, on a sense of self-efficacy and on persistence. We suspect that encouraging this kind of appropriate behaviour may require some kind of teaching, or facilitation, beyond merely explaining errors.

SELF-EFFICACY

Self-efficacy is “a person’s belief in his or her ability to succeed in a particular situation” (Bandura, 1995). Of developing a sense of self-efficacy, Bandura (1994) stated that “The most effective way of developing a strong sense of self-efficacy is through mastery experiences,” that performing a task successfully strengthens one’s sense of self-efficacy. Also, according to Bandura, “Seeing people similar to oneself succeed by sustained effort raises observers’ beliefs that they too possess the capabilities to master comparable activities to succeed.”

According to Bandura (1994), individuals with a strong sense of self-efficacy: (1) view challenging problems as tasks to be mastered; (2) develop deeper interest in the activities in which they participate; (3) form a stronger sense of commitment to their interests and activities; and (4) recover quickly from setbacks and disappointments. In contrast, people with a weak sense of self-efficacy: (1) avoid challenging tasks; (2) believe that difficult tasks and situations are beyond their capabilities; (3) focus on personal failings and negative outcomes; and (4) quickly lose confidence in personal abilities.

Bandura’s ideas “ring true” with our past experiences as mathematicians teaching courses by the Moore Method (Mahavier, 1999). Typical Moore Method (advanced undergraduate or graduate) courses are taught from a brief set of notes consisting of definitions, a few requests for examples, statements of major results, and those lesser results needed to prove the major ones. Exercises of the sort found in most textbooks are largely omitted. In class meetings, the professor invites individual students to present their original proofs and then very briefly comments on errors. Students are typically forbidden to read anything on the topic or to discuss it with anyone other than the professor. Once students are able to successfully prove the first few theorems, they often progress very rapidly in their proving ability, even without apparent explicit teaching, and even when subsequent proofs are more complex. Why should this be? We conjectured then, and also conjecture now, that students obtained a sense of self-efficacy from having proved the first few theorems successfully, and this helped them persist in explorations, re-examinations, and validations when these were needed in proving subsequent theorems.

This idea is supported by de Villiers (2012). In discussing geometry conjectures, he pointed out places where a novice might

lose hope of getting anywhere as it’s not obvious from the start this will lead somewhere useful. However, students should be encouraged to persist ... and not so easily give up ... One might say that a distinctive characteristic of good mathematical problem solvers [and

provers] are that they are ‘stubborn’, and willing to spend a long time attacking a problem from different vantage points, and not easily surrendering. (p. 8)

Thus, it would seem that a sense of self-efficacy, that is, a belief in one’s ability to succeed on a particular kind of task, enables one to persist despite frustrations or wrong paths and that this is an important part of doing mathematics, and in particular, of constructing original proofs. Indeed, we suspect that it is an important part of much creative cognition in general.

A HYPOTHETICAL PROOF CONSTRUCTION

In this section we describe hypothetical proving actions for a theorem chosen from a set of notes used in our one-semester, 3-hour per week, mid-level undergraduate transition-to-proof course. In this course, the students present in class their proofs of theorems from the notes and receive substantial criticisms and advice. There is no textbook and there are no lectures. The notes include theorems about sets, functions, real analysis, and abstract algebra, as well as definitions and requests for examples. The required proofs progress from straightforward to fairly difficult. The hypothetical proof construction we describe is for one of the more difficult theorems and occurs near the end of the algebra section: *Theorem: If S is a commutative semigroup with no proper ideals, then S is a group.* We have found that constructing a proof of this theorem is challenging for mid-level undergraduate mathematics students, and indeed, for some beginning mathematics graduate students.

The relevant background information for this proof construction is quite small. A semigroup is a nonempty set S with an associative binary operation that we will write multiplicatively as xy for elements x and y of S . Associativity means that for all elements x , y , and z of S , $(xy)z = x(yz)$. S is commutative means that for all elements x and y of S , $xy = yx$. If A and B are subsets of S , we mean by AB the set of elements ab where a and b are elements of A and B respectively. In this setting, a nonempty subset I of S is an ideal of S provided SI is a subset of I . Such an ideal is called *proper* in S provided it is not all of S . In this commutative setting, S is a group if it has two additional properties. First, there must be an “identity” element e of S so that for any element s of S , $es = s$. Second, given any element s of S there must be an “inverse” element s' of S so that $s's = e$.

In constructing a proof of the above theorem, it is easy to see that if I is an ideal of S , one can conclude I is not proper, that is, $I = S$. What is not so easy is trying to construct an ideal that “looks” different from S , and what that might have to do with producing an identity element e of S and inverses, in order to prove that S is a group. Since there is nothing else to work on, one must persist in trying to find an ideal of S without any idea of whether, and how, that would be helpful. One might ask if s is any element of S , is $S\{s\}$ (also written Ss) an ideal of S , and hence equal to S ? Once the idea has been articulated, it is not so hard to prove that Ss is an ideal. But how

might $Ss = S$ help in proving that S is a group? Nothing in the students' notes says anything about solving equations in semigroups. However, if t is also an element of S , the above set equation means that there must be an element x of S so that $xs = t$. That is, the equation $xs = t$ can always be solved for x . It turns out that one can use the solvability of this equation in several ways to collect information which, for many students, is of unknown utility. Nevertheless this information, once collected, can be organized to show the existence of an identity element and inverses in S . To do this requires both persistence and a willingness to obtain whatever results, in the form of equations, that one can without knowing whether those results will ultimately be helpful.

We could have added two lemmas to our course notes that would have made the proof of the above theorem much easier for our students. However, the purpose of the course is to learn to construct a variety of hard, as well as easy, proofs, and having relevant experiences is important in developing the students' ability to do so. We view learning to persist in "exploring" mathematical situations by obtaining "whatever one can get," even without knowing its ultimate usefulness, as an important part of developing students' proving abilities.

While the proof of the above theorem calls for persistence and exploration, proving in general can call on a whole "tool box" of knowledge and abilities, such as the use of proof by contradiction or mathematical induction, or looking for inspiration by proving easier theorems, perhaps by adding a hypothesis such as finite-dimensional or finite. However, discussion of such topics is beyond the scope of this paper.

A MATHEMATICIAN'S PROOF CONSTRUCTION

Milos Savic (2012), investigated nine mathematics professors' proving using tablet PCs with screen capture software, as well as Livescribe pens and special paper, so that they could take the devices home and construct proofs in a naturalistic setting (without the time constraints and influences of an interview setting). All nine mathematicians' writing and speaking was recorded with time and date stamps. Several of the mathematicians acknowledged getting "stuck" on the above *Theorem 20: If S is a commutative semigroup with no proper ideals, then S is a group*, in a short set of notes containing only the material on semigroups. However, none gave up, as most students might, but persisted. One mathematician proved it the next day and another proved it after taking a break for lunch. Later, in a focus group interview, the professors indicated several ways they have of getting "unstuck" in their own research. These included getting up and walking around or doing something else for a while, as well as strengthening the hypotheses in order to prove an easier conjecture. It seems clear these mathematicians took the construction of the proofs in the semigroups notes as a positive challenge and had a sense of self-efficacy. Apparently this provided the motivation to persist, a crucial component of their success.

Several of the nine mathematicians volunteered that the material was both accessible and unfamiliar. However, they were unaware of the origin of the notes, that is, that they came from the course described above. Perhaps for this reason, several mathematicians attempted to construct counterexamples to some of the theorems. In attempting to prove Theorem 20, all nine mathematicians at some point considered “principal” ideals, a concept not in the notes, when considering the ideal Ss , where s is an element of S . This probably comes from remembering facts about ideals in rings; however, our students could not have had such memories as the course notes did not cover rings, and this course is a prerequisite for abstract algebra which would cover rings. Note that $Ss = S$ is one of two key ideas in proving Theorem 20--ideas without which it is difficult to make progress.

Dr. G’s Construction of a Proof of Theorem 20

Below we describe most of the work that one of the nine mathematicians, Dr. G, did when attempting to prove Theorem 20, which he eventually did successfully. Our description is taken from transcripts of Dr. G’s speaking and writing (that included metacognitive comments) while he worked alone using a Livescribe pen and special paper that recorded his writing and speaking with time and date stamps (Savic, 2012).

As seen below, Dr. G took a meandering path as he explored how to prove Theorem 20. His various “twists and turns” are indicated in bold typeface. Dr. G started at 7:02 a.m. by considering the statement of Theorem 20, but decided to **think about it** and have breakfast. At 8:07 a.m., he returned from a walk and **realized that gS** (where g is an element of S) **is an ideal, so $gS = S$** . He then **thought about inverses** and **struckthrough his entire previous argument**. At 8:09 a.m., he **noted that he needed an identity element** which is not given. At 9:44 a.m., he became suspicious that **Theorem 20 might not be true**, but **noted that he had few examples** which might show that.

At 9:48 a.m., Dr. G started **“tossing around” the idea** that a [commutative] **semigroup with no proper ideals must have an identity**, in which case, he could show it is a group. However, he didn’t see why S should have an identity. He **began to think that translating by a fixed element** [an idea not in the notes] would move every element, which would mean there was no identity. Consequently, he **then began to look for a counterexample**. By 9:50 a.m. he **neither saw how to prove Theorem 20 nor how to find a counterexample**.

He then looked ahead to Question 22, the final task in the notes, which has three parts that ask whether certain semigroups are isomorphic. He **saw how to answer that and then looked at Theorem 21: A minimal idea of a commutative semigroup is a group**. He thought that he could probably prove that, so **he went back to Theorem 20**. By 9:51 a.m. Dr. G **recalled that he had earlier rejected Theorems 3, 9, and 12**

of the notes and also **did not believe that there are unique minimal ideals**. By 9:53 a.m., he **recalled that he had not been told any of the theorems were false and looked at the non-negative integers** under multiplication. He saw that $\{0\}$ is a minimal ideal and noted that the non-negative integers under multiplication do not form a group. He **thought that this was a counterexample** to Theorem 21, but had interpreted Theorem 21 incorrectly – something he later discovered and fixed.

At 9:54 a.m., he **started actually answering Question 22**. By 9:58 a.m., he had answered its three parts correctly. At 9:59 a.m. Dr. G. **took a break to think about Theorem 20** and at 10:08 a.m. he again attempted a proof of it. This time **he saw that for $a \in S$, there is $e \in S$ so that $ae = a$** and saw that e is “**acting like ...a right identity on a . Now why does it have to act that way on [an arbitrary] b ?**” By 10:12 a.m. **he found e' so that $be' = b$** , but that **didn't help** since he couldn't show that $e = e'$. Then at 10:13 a.m. he **saw that there is an f so that $b = af$** , and then by 10:14 a.m., he **saw that $be = afe = aef = af = b$** . At 10:15 a.m., he **saw that e is the identity element**. By 10:18 a.m., he had **used a similar technique to show S has inverses** and is thus a group.

Perhaps the most important thing about the above description of Dr. G's work is what is not there. There is no evidence that Dr. G thought there was anything wrong with having gone in all of those unhelpful directions or with having thought that some theorems were false, that he later discovered were true. What seemed to matter to him was the generation of ideas. If those ideas resulted in errors, one fixed them and learned from them. He exhibited persistence and a willingness to try argument directions that he clearly didn't know ahead of time would be helpful, and he altered directions when the need arose. It seems clear that Dr. G had the needed persistence, which was probably supported by a sense of self-efficacy with respect to his own mathematical research.

DISCUSSION

We are not the first to have considered the effect of affect and self-efficacy on mathematicians', and others', proving or problem-solving success. In their study of mathematicians' problem solving, Carlson and Bloom (2005) concluded that the mathematicians' effectiveness “appeared to stem from their ability to draw on a large reservoir of well-connected knowledge, heuristics, and facts, as well as their *ability to manage their emotional responses* [italics ours].” Also, in a study of non-routine problem solving, McLeod, Metzger, and Craviotto (1989) found that both experts (research mathematicians) and novices (undergraduates enrolled in tertiary-level mathematics courses), when given different experience appropriate problems, reported having similar intense emotional reactions such as frustration, aggravation, and disappointment, but the experts were better able to control them. This suggests

that the mathematicians in the two studies had a mathematical self-efficacy belief that allowed them to persist.

TEACHING IMPLICATIONS

The emphasis on actions in the theoretical perspective, described at the beginning of this paper, is linked to the view that proof construction is about doing mathematics. Thus, it can perhaps best be learned by having students independently construct a sequence of proofs of increasing difficulty. In this setting, teaching is largely a matter of facilitating students' proof constructions, encouraging helpful actions, and discouraging detrimental ones.

Further, it seems to us that in order to do things that require persistence and exploration, a student is likely to need to believe that he or she can personally benefit from his or her persistence or exploration. That calls for a self-efficacy belief, which in turn calls for, perhaps numerous, successes in what is to be done. Thus, it would be good to have students constructing their own proofs as early as possible. However, this is often delayed by an initial rather formal treatment of logic. While correct logic is essential for proof construction, we think its early and abstract treatment can be replaced by explanations of the relevant logic when needed in the context of the students' own work (in a "just-in-time" manner). This is because logic, beyond what most people know, actually occurs fairly rarely in student-constructed proofs (Savic, 2011).

While teaching logic can be integrated into discussing students' proofs and need not delay the start of their constructing proofs, there is an aspect of proving that is not usually explicitly taught early and that could be very helpful in facilitating students' successes. There is the relationship between the structure of a proof, the logical structure of the theorem being proved, and the theorems and definitions used in constructing the proof. This relationship appears as part of the final written proof, but it can be isolated and considered first. One can write it first leaving blank spaces for the remaining work. We have come to call this a *proof framework* (Selden & Selden, 1995).

Teaching students to build proof frameworks allows them to experience early successes. However, sometimes constructing a proof framework helps only a little in obtaining the final proof; this is the case for Theorem 20 discussed above. For other theorems, such as the theorem that states that the sum of two continuous real functions is continuous, constructing a proof framework can be very helpful (Selden & Selden, 2013).

THE NATURE OF ARGUMENTATION IN SCHOOL TEXTS IN DIFFERENT CONTEXTS

Chrissavgi Triantafillou^{1,*}, Vasiliki Spiliotopoulou^{1,*}, Despina Potari²

¹The School of Pedagogical and Technological Education (ASPETE),

²University of Athens

In this study we explore the substantial argumentation developed in Greek mathematical and science textbooks in specific topics related to the notion of periodicity. After analyzing a number of texts from both subjects the nature of argumentation was realized in a form of a systemic network. This network presents the complexity of the argumentative activity (the process developed and the modes of reasoning identified) in the different subjects and the tools mediate this process. Finally, by comparing and contrasting the argumentation in two texts that share a closely related thematic content we get some evidence of how the contextual activity via reasoning is shaped.

Key words: argumentation, textbook analysis, mathematics, science, modes of reasoning, nomo-logical, logical-mathematical, logical-empirical and empirical inferences

INTRODUCTION

The study of mathematical and pedagogical practices is important as these influence students' conceptions. Two factors are considered critical for the formation of students' pedagogical practices: the textbooks used and the teachers' cognitive and didactical knowledge. In most countries (Greece included) textbooks are used by teachers as the main source for their classroom activities. In textbook writing, meaning is not constructed on verbal language alone, but on the basis of graphical information and the produced argumentation and reasoning, as well. Love and Pimm (1996) note, that although the implied relation between the reader and the text is inherently passive, "*the most active invitation to any reader seems to be to work through the text to see why the particular 'this' is so*" (p. 371). Chi and her colleagues' (Chi, deLeeuw, Chiu & LaVancher, 1994) research in the science context highlighted the importance of the argumentation developed in textbooks in the meaning-making process. Specifically, they argue that students, in order to understand the text material, generate self-explanations, since even quality expositions require the reader to fill in substantial details.

*The current research is part of a research project (SH4_3510 EDARCPADSS) that is implemented within the framework of the Action «Supporting Postdoctoral Researchers» of the Operational Program "Education and Lifelong Learning" (Action's Beneficiary: General Secretariat for Research and Technology), and is co-financed by the European Social Fund (ESF) and the Greek State.

In spite of the crucial role that textbooks play in schooling and educative practices, few research studies have focused on textbook analysis and particularly on the argumentation adopted by the authors in these texts. Stacey and Vincent (2009) by analyzing the nature of reasoning presented to students in Australian mathematical textbooks in specific topics identified the following categories: (a) deductive reasoning (by using a model, or a specific or a general case); (b) empirical reasoning (concordance of a rule with a model and experimental demonstration), (c) external conviction (appeal to authority) and (d) qualitative analogy or metaphorical reasoning. Cabassut (2005) by comparing the reasoning presented in proofs in French and German school mathematics textbooks argues that deductive arguments often occur in conjunction with empirical arguments, presumably to obtain an additive effect.

The work presented in this paper is part of a research project that aims to identify epistemological and didactical aspects among different educational practices concerning the concept of “periodicity”. Periodicity is an essential scientific concept because it plays a central role in the school curriculum and is expressed in different educational fields where it acquires practical importance. By adopting the position that argumentation and concepts are interwoven inside a text (Boero, Douek, Ferrari, 2008), we analyze the nature of reasoning developed in topics related to periodicity in math and science textbooks. The research on argumentation developed in school texts in different subjects for a common topic is rather limited. Analyzing the argumentation produced is didactically important since these texts are addressed to the same student who is ‘responsible’ for making the appropriate conceptual connections.

Our specific research questions are:

- What is the nature of argumentation that is employed in the textbooks to support the meaning of periodicity?
- How is argumentation differentiated in the mathematical and scientific context?

THEORETICAL FRAMEWORK

We adopt Vergnaud’s (2009) theory of conceptual fields that addresses the process of conceptualization of reality. It is a pragmatic theory as it presupposes that knowledge acquisition is shaped by situations, problems and actions for the subject. It is, therefore, through the situations that a concept acquires meaning to a student. Vergnaud considers that a concept is a triplet of a set: $C=(S, I, L)$ where **S** stands for the set of situations which give sense to a concept (*the referent*); **I** stands for the set of operational invariants associated to the concept (*the meaning*); **L** stands for the set of linguistic and non-linguistic representations which allow for the symbolic representation of a concept, its attributes, the situation to which it applies and the procedures it nourishes. In this paper, the thematic units, where the concept of periodicity appears in school texts, are considered as situations (S); the schemes of argumentation developed by the author in these units, as operational invariants (I); and

the tools employed by the author in the argumentation process as linguistic and non-linguistic representations (L).

Since our interest is on argumentation practices used in textbooks to reason about the new knowledge presented we are interested in what Toulmin (1969) calls ‘substantial argumentation’ (p. 234). Substantial argumentation does not have the logical stringency of formal deductions but is used for gradual support of different statements. Toulmin establishes the importance of practical arguments and their logical canons, which may not be entirely secure as formal mathematical arguments are, but are however necessary tools of thinking in general. Argumentation here is taken to mean the use of reasoning for the construction of new knowledge presented in a text for the purpose of convincing the students of the truth of a conclusion. The complex interplay of reasoning and the new concepts to be learned is considered to affect students’ ways of understanding and conceptualizing the field, in the case that they are consciously using and connecting the three dimensions (S, I, L) with the notion of periodicity.

Argumentation and reasoning in mathematics and in science contexts

The argumentative process that mathematicians develop to justify the truth of mathematical propositions, which is essentially a logical process, is usually called *mathematical proof* (Recio & Godino, 2001). Daily life reasoning is characterized as *informal* since people draw inferences from uncertain premises and with varying degrees of confidence; scientific reasoning, on the other hand, is based on experimental verification and has a validating intention which leads to generating scientific knowledge (Over & Evans, 2003). Szu and Osborne (2012) claim that arguments in the science context may be either *deductions* about the world based on a set of a priori premises; *inductive generalizations* when reasoning is typified by laws; or *inferences to the best explanation* as in Darwin’s development of evolutionary theory.

Stinner (1992) classifies the knowledge provided in science textbooks in two planes: (a) The *logical plane*, where he encounters the finished products of science, such as laws, principles, models, theories, and the mathematical and algorithmic procedures establishing them; and (b) the *evidential plane*, where he encounters the experimental, intuitive, and experiential connections that support the logical plane. Kuhn (1962) in his influential work, ‘The Structure of Scientific Revolutions’, claims that textbooks are pedagogic vehicles for the perpetuation of science and identifies two levels of activity in science classes the *logical-mathematical* and the *evidential-experiential* levels of activity.

METHODOLOGY

A grounded theory research approach (Strauss & Corbin, 1998) is adopted in this study. Our methodological framework is based on the qualitative inductive content analysis. Moreover, the technique of systemic networks (Bliss, Monk & Ogborn,

1983) has been adopted not only as a form of representing our scheme of categories, but also as an analytic tool. In particular, we aim to produce a quantitative elaboration of the arguments which underlie the text in 11 Greek textbooks on topics related to the notion of periodicity.

The sample: The texts analyzed are taken from the subjects of Mathematics, Physics and applied technologies (Electrology, Electronics and Informatics) used in Greek lower secondary and upper secondary General and Vocational school. In each textbook we restrict our analysis to topics that are related to periodicity. Specifically in Mathematics the topics are trigonometry and periodic functions, in Physics the topics are related to Periodic phenomena (e.g. oscillations, simple harmonic and circular motion) while in applied technologies the topics are related to Alternate Currents. In order to implement our analytic plan, we divided the text into units of analysis by restricting analysis to all the parts which aim at delivering mathematical and scientific knowledge (we did not include worked examples, exercises and historical notes). In this paper the word ‘text’ is used to denote a section of textbook material and the accompanying visual representations.

Unit of analysis: Our unit of analysis is every conceptual thematic unit that has an independence from the rest of the text and produces an argumentation. It is conceived as a part of the topic that we analyze; it has a beginning and an end; and has a relative independence in its content: we can identify it and distinguish it from the other units. Each unit of analysis is characterized by its thematic content (e.g. “Define periodic function” or “Define periodic motion” or “Describe the generation of alternate current”) which is organized in a particular way. One unit of analysis several times coincides with a textbook unit as it is defined by the author. But in some cases we have to split the textbook unit in more units of analysis when a change in its thematic content and the argumentation produced is identified. After defining each unit of analysis we separately analyze the structure of the argumentation developed in terms of its process and its ingredients (parts). The process of argumentation is realized as a sequence of interdependent and logically connected statements. So, a secondary unit of analysis is chosen, expressed by a sequence of sentences. This usually corresponds to one or more paragraphs and the accompanying visual representations, and supports the generation of argumentation developed in the unit. Semantically, in each unit of analysis we can identify different explanations, justifications and/or proof of new knowledge. We call these types of reasoning ‘modes of reasoning’ as this term is used in Stacey and Vincent’s (2009) study.

Analysis of data: Subsequently, we analyze the modes of reasoning applied and the tools that mediated this reasoning. These tools are in the linguistic (i.e. verbal language) or non-linguistic form (i.e. physical models or mathematical representations). Within a feedback loop, the main codes were developed and negotiated among the researchers. Those codes were revised and eventually reduced to main categories and checked in respect of their reliability. As a result, categories and

subcategories were formed and their interrelations were recognized by matching our emerging classification to our data. Finally, the nature of argumentation was realized in the form of a systemic network (Bliss, et al. 1983), presented in Figure 3.

RESULTS

In the first part of this section we exemplify our analysis in two texts. At the end we compare the nature of the argumentation developed in each case. The texts are from the subject of science and mathematics and share a closely related thematic content. In the second part, we present in the form of a systemic network the structure of the argumentation as it was developed after analyzing a number of texts from the above subjects.

Examples from texts

We present below a text from the subject of Physics. The text is from the topic ‘Oscillations’ and its specific thematic content is: “Define periodic motions”

“When you were younger you would have got into a swing many times or you would have even noticed the other kids playing with it. The swing has a high starting point, goes up and down and back to its starting point and keeps on moving in the exact same way. The yo-yo is a popular game, widely used in many countries in the world (maybe you have played with it several times). You hold the string from the one edge and you let the circle move. The string winds and unwinds around the spinning axle several times in exactly the same way.

*The movements of the swing or the yo-yo are examples of **periodic motions**. This means **that they are motions that are repeated at equal intervals**.*

The normal circular motion is periodical as well as the annual motion of the Earth around the Sun. The muscle of the heart performs a periodic motion as presented at the electrocardiogram”

(Physics, 3rd Grade of Lower Secondary School. (2008). Athens, Greece: OEDB, p. 89)

We can see how the development of argumentation in this thematic unit is produced. In the first paragraph two examples of periodic motions taken from everyday life (the swing and the yo-yo game) are presented. The properties that seem to characterize every periodic motion are presented in the key phrases: “moving in exactly the same way” or “repeated at equal intervals”. In the second paragraph the definition of periodic motions are presented as generalization of the above properties. Finally, in the third paragraph additional examples of periodic motions are provided. The process of argumentation was realized as follows: introducing two special cases - providing

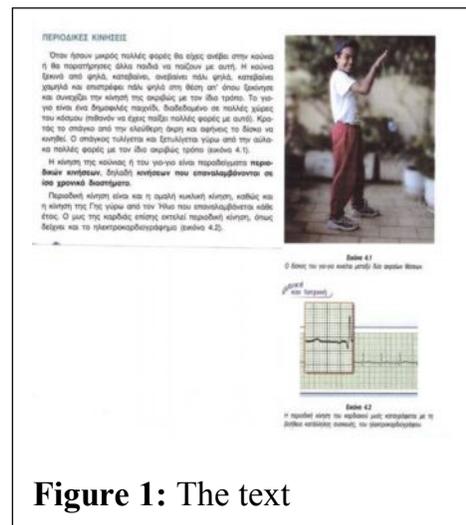

Figure 1: The text

scientific generalization with the aim of solidifying the scientific truth - giving more examples in order to reinforce students' understanding.

The parts of the argumentation are the modes of reasoning applied i.e. *empirical* based on every day experiences (when moving from the special to the general case), *nomological*, when defining periodic motions and finally *logical-empirical*, when starting from a general idea of logical type (the definition) and ending up by implementing it in certain empirical situations. These modes of reasoning as the units/parts of the argumentation developed aim to communicate to students the periodic motions, their characteristics and properties existed in a number of real life situations and to convince for their truth.

We present below a text from the topic of Trigonometry. Its thematic content is: "Define a periodic function and its period".

"Suppose that a ferry travels between two ports, A and B, and the graphic representation of its distance from port A as a function of time is presented in the following graph [Figure 2a]. We notice that every 1 and 1/2 hour the ferry repeats the exact same movement. This means that in whatever distance it is from port A in some time (t) it will be at the same distance at the time $(t+1\frac{1}{2})$ hours and it was at the same distance on the $(t-1\frac{1}{2})$ hours. Consequently, the function that presents the distance of the ferry from port A, in respect to the variable t takes the same values at t , $t + 1\frac{1}{2}$ and $t-1\frac{1}{2}$. We suggest that this function is periodic with a period of $1\frac{1}{2}$ hours.

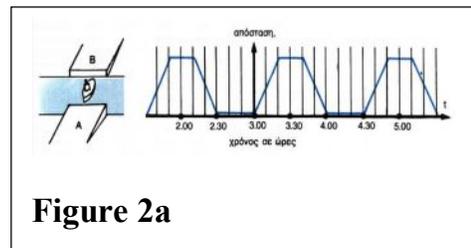

Figure 2a

The following graph [Figure 2b] is a graphic representation of the height of the swing as a function of time (t). We notice that despite the height of the swing in a certain moment (t), it will have the same height at the time $(t+2)s$ as well as at $(t-2)s$. We say that the function (that models the height of the swing with respect to t) is periodic with a 2 sec period.

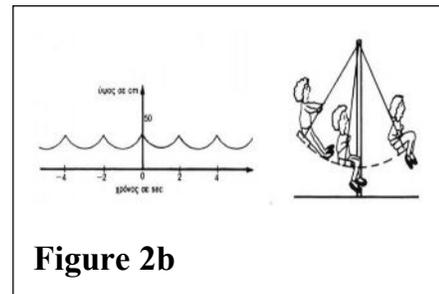

Figure 2b

In general: A function f with domain the set A is called **periodic**, when there is a real number $T > 0$ such that for every $x \in A$: i) $x + T \in A$, $x - T \in A$ and ii) $f(x + T) = f(x - T) = f(x)$. The real number T is called the **period** of f " [Figure 2c].

(Algebra, 2nd Grade of Upper Secondary School. (2012). Athens, Greece: OEDB, p. 73)

Examples of periodic functions are presented in the first two paragraphs while in the third paragraph the definition of periodic function comes as a generalization of the two examples. Hence, the structure of the argumentation in terms of its process is inductive since it moves from special cases of the situation to a general case ($S_1, S_2 \rightarrow G$). The modes of reasoning identified are based on empirical observations on mathematical models of periodic motions. These observations were 'evidence' identified in the

graph representations where the reader must ‘spot’ the specific points on the graphs, identify patterns and end up in a general conclusion. We classify this reasoning as *logical-empirical* since reasoning starts from empirical situations and ends up in a general conclusion. Finally, we acknowledge this conclusion as a *nomo-logical* that emerges as a result of previous generalizations and its main aim is conceptualizing periodical behavior in the form of a mathematical object (periodic function) that satisfies certain conditions.

Comparing the structure of argumentation in the two texts

Both texts refer to periodic motions and the functions that model their behavior. The structure of the argumentation developed in mathematics and science differs in its process ($S_1, S_2 \rightarrow G \rightarrow S$) and ($S_1, S_2 \rightarrow G$) and its parts (the modes of reasoning employed). The modes of reasoning identified when moving from the special to the general cases were empirical in the science text and logical-empirical in the mathematical text.

The definition of periodic motions in the science text comes as a generalization of verbalized properties while the definition of periodic functions in the mathematical text comes as a generalization of mathematical and symbolic properties. Moreover, the different definitions support different perspectives of the notion. Particularly, according to Van Dormolen and Zaslavsky (2003), the science text supports a holistic perspective while the mathematics text a point-wise one. Some of these differences could easily be explained due to the difference in readers’ school level (different school grades), while some others characterize the context in which each argumentation is developed.

In concluding the two reference situations differ in their goals, in the structure of the argumentation developed and in the language used by the authors when solidifying the scientific knowledge. Students have to uncover all the above differences and consciously and intentionally constructing links between them (Boero et al., 2008).

The systemic network

After analyzing a number of textual units (this research is still in progress) in our attempt to synthesize our results, we present the nature of argumentation developed in a systemic network (Fig. 3). The BAR (\square) notation signifies that all the categories are mutually exclusive, whereas the BRA ($\{$) notation signifies that any number or even all of the categories can be selected simultaneously.

The structure of the argumentation was characterized in terms of its process and its parts. The parts of the argumentation are the modes of reasoning acknowledged in this process. These two dimensions are viewed in interrelation. Four processes were identified: (a) Moving from special to general case and then exemplifying. (b) Moving from examples to general case (c) moving in the inverse way i.e. from general to

special cases and (d) deductive reasoning i.e. remaining in the general case through out the entire textual unit.

The parts of the argumentation were acknowledged in terms of the kind of modes of reasoning developed by the author and the tools that mediated this reasoning. The modes of reasoning identified are the following:

- *Nomo-logical reasoning*, when a definition or a law emerges as a result of previous generalizations.
- *Logical-Mathematical reasoning*, when the inference is based on mathematical relations and techniques.
- *Logical – Empirical reasoning*, when the inferring process either starts with general statements and ends to specific situations (as in the science text), or the other way around (as in the mathematical text).
- *Empirical reasoning* when inference is based on experiences either from everyday life, or from experimental activity.

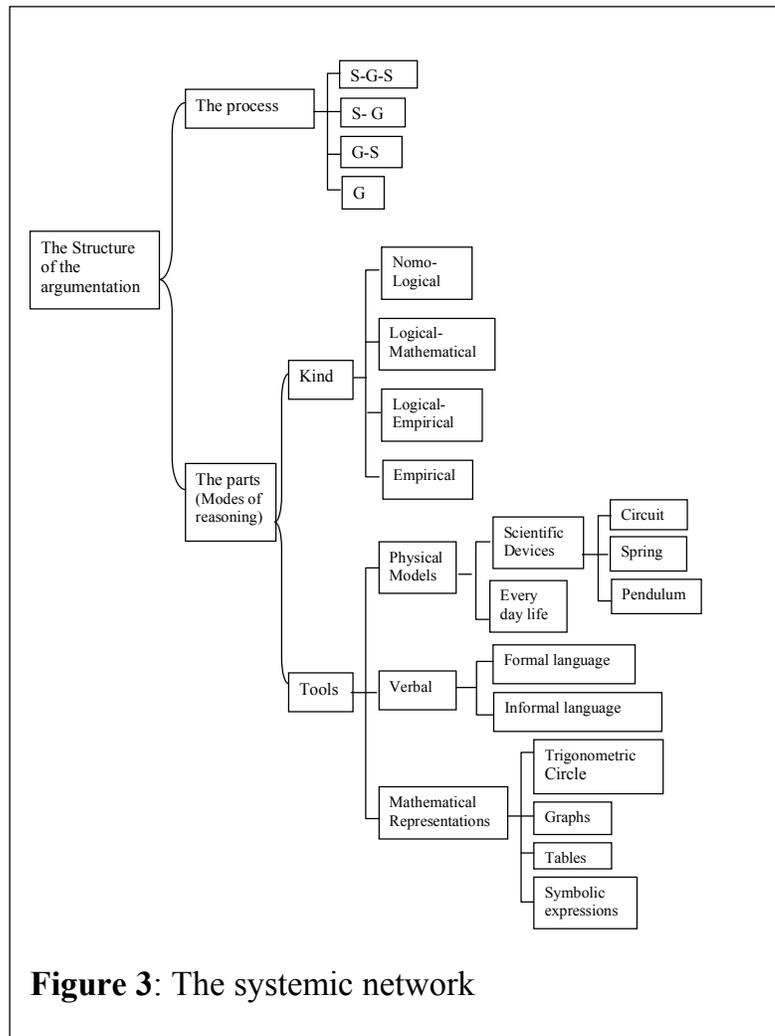

Figure 3: The systemic network

Different tools mediate the reasoning process such as physical tools (either scientific devices or every day life); mathematical representations (i.e. the trigonometric circle, graphs, tables and symbolic expressions) and verbal (i.e. informal or formal language). Finally, all the above categories and subcategories were associated and interrelated in the generation of the argumentation process.

CONCLUDING REMARKS

In this study we explore the nature of substantial argumentation developed in Greek mathematical and science textbooks in specific topics related to the notion of periodicity. In order to implement our plan we developed a methodology of analyzing the argumentation developed in texts from different subjects. Our methodology defines

two units of analysis: the argumentation of each conceptual thematic unit and the mode of reasoning. In this way we can compare the argumentation, the generative activity and the tools mediated this argumentation in different texts in different grades and/or subjects.

After analyzing a number of textual units from the subjects of science and mathematics, aspects of the nature and the structure of argumentation were identified and presented in a form of a systemic network. This network is a generalized description of the complexity of the argumentative activity and its ingredients met in the different contexts. The basic modes of reasoning, parts of the argumentation process, are expressed in the form of nomo-logical, logical-mathematical, logical-empirical and empirical inferences. These inferences are mediated through a number of linguistic and non-linguistic tools. All these tools incorporate aspects of the conceptual field; while at the same time nourish the argumentation process.

Finally, by comparing and contrasting the argumentation in two texts that share a closely related thematic content, we get some evidence of how the contextual activity via reasoning is shaped in different subjects and in different grade levels. Particularly, through our analysis, we spotted differences in the argumentation produced and the linguistic and non-linguistic tools that mediate it that could illuminate aspects of the conceptual field in different ways. Such kind of evidence points out the need for a conscious connection of the above alternative procedures in order to support students' conceptualizing activity. This also implies the crucial role of mathematics and science teachers in integrating the different approaches to periodicity and in making links apparent in their classrooms.

MODELLING ALGORITHMIC THINKING :

THE FUNDAMENTAL NOTION OF PROBLEM

Simon Modeste

Institut Fourier, University of Grenoble, France

The notion of a problem plays a very important role in algorithmic thinking. We propose a definition of 'problem' which is suitable to model this thinking. Then, we detail how it enables us to express the tool-object duality and describe conceptions.

Keywords : algorithm, problem, tool-object, didactical transposition, conceptions

In many countries, algorithms and algorithmics are taking a growing importance in the curricula of mathematics¹. This phenomenon raises many epistemological and didactical questions (Modeste & Ouvrier-Buffet, 2011). Algorithms are mathematical concepts shared with computer science and their present-day role in mathematics and their place in the mathematical activity in the classroom have to be questioned. The concept of algorithm is also strongly linked with the mathematical proof.

So, it seems important to have a better understanding of advanced algorithmic thinking and how it interplays with advanced mathematical thinking (Tall, 1991, Harel & Sowder, 2005). We propose a model of advanced algorithmic thinking from an epistemological point of view, based in particular on Knuth (1996) and Chabert (1999). This model enables to study how algorithmics is transposed in different institutions (curricula of mathematics, curricula of computer science, textbooks...).

One fundamental element of this model is the notion of problem. It links many other aspects of algorithm: proof, effectivity, complexity. It is also very important in the theoretical models of algorithm (to study decidability questions, for example).

A SPECIFIC DEFINITION OF PROBLEM?

We propose to adapt a definition which comes from the theory of algorithmic complexity. Giroud (2011) also used such a definition to describe the concept-problem in problem solving activities. Since this definition, a **problem** (e.g. finding the gcd) is:

- ***I*** a set of **instances** (e.g. \mathbb{N}^2 , all the pairs of two integers)
- ***Q*** a **question** about these instances (e.g. what is the gcd of the 2 integers?)

This definition is perfectly suitable for algorithmics: an algorithm is a systematic method which must give an answer to a question, *for all instances of the problem*, and after a finite number of steps (e.g. Euclid's algorithm solves the problem of gcd for any couple of integers). A problem is *instantiated* when one choose a particular instance ***i*** and try to answer the question ***Q(i)*** for this particular case (e.g. what is the gcd of 3654 and 76?). To deal with the concept algorithm, it is important not to solve only instantiated questions but to study a problem with all its instances.

WHAT IS THIS DEFINITION USEFUL FOR?

First, with this definition, we can rephrase the tool-object duality (Douady, 1986): Algorithm is a tool when it is used to solve a problem. Algorithm is an object when algorithms are in the instances or when questions involve algorithm (e.g. when we study the complexity of an algorithm or try to prove its termination).

It also enables us to use the cK ϵ model (Balacheff, 1995) to describe conceptions in the academic knowledge (μ -conceptions) for algorithm in order to model algorithmic thinking and also to analyse people's or institutions' conceptions.

We used this model to study the didactical transposition of the concept algorithm in the French high school: the analysis of curricula, textbooks and online resources revealed a partial transposition of the concept, focused on tool aspects and programming activities and leaving apart the notion of problem.

Finally, this model is also useful to characterise problems with potential for the learning of algorithmic thinking, in order to design and study teaching situations.

NOTES

1. For example, the National Council of the Teachers of Mathematics dedicated his 1998 Yearbook to this issue (NCTM, 1998), and since 2003, algorithmics has been introduced in high-school curricula of mathematics in France.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG 2 “TEACHING AND LEARNING OF NUMBER SYSTEMS AND ARITHMETIC”

Sebastian Rezat, University of Paderborn (Germany)

Lisser Rye Ejersbo, Aarhus University (Denmark)

Keywords: *Numbers; fractions; decimals; proportion; negative numbers; arithmetic; strategies; mental calculation; flexibility; representations*

INTRODUCTION

Working Group 2 first assembled at CERME 7 as a forum for presenting and discussing theoretical and empirical research on the teaching and learning of number systems and arithmetic (including models for operations in the number systems, ratio and proportion, rational numbers and number theoretical aspects). For CERME 8 the scope was extended to grades 1-12. An emphasis was put on:

- research-based specifications of domain-specific goals (What should be learned? What can be learned? Which priority is given to particular aspects and why?)
- analysis of learning processes and learning outcomes in domain-specific learning environments and classroom cultures;
- new approaches to the design of meaningful and rich learning environments and assessments.

SYNOPSIS OF RESEARCH QUESTIONS

The papers in WG2 deal with issues related to natural numbers, fractions and decimals, proportion and negative numbers. An overview of the research questions tackled in the papers provides that most of the papers in WG 2 are mainly concerned with learners' behaviour and thinking, related to particular mathematics contents:

- In which ways do learners understand the notion of the whole within a particular task and how does this notion unfold through different tasks? (Bednarz & Proulx)
- What are critical components for categorizing student's response patterns in ratio tasks and what are students' response patterns in the task? (Gomez et al.)
- Which procedures do students have for ordering integers and which previous knowledge is taken into account? (Schindler & Hußmann)
- What kind of representations do grade 3 students use and how do they relate to mathematics reasoning when the students work on a mathematical problem? (Velez & da Ponte)

- How do grade 6 students' mental computation strategies with positive rational numbers (represented as fractions) develop through a teaching experiment based on mental computation tasks with rational numbers involving the four operations and the discussion of strategies? (Carvalho & da Ponte)
- How do students use multilink cubes and mathematical signs equipped with a cultural meaning to express and communicate their thinking in social interaction? (Lorange & Rinvold)
- Which mental computation strategies do students use when solving addition and subtraction problems and how are these strategies influenced by the addition or subtraction problem situations? (Morais & Serrazina)
- Are students' error patterns in solving computational problems with fractions consistent? (Wittmann)

Only few papers are concerned with the design and evaluation of learning opportunities to tackle particular problems in students' mathematical development:

- Can an explicit focusing on the way in which children with mathematical difficulties realize number patterns and structures in mathematics education motivate a replacement of counting strategies and if so, how? (Häsel-Weide & Nührenbörger)
- How can children develop an understanding of how multi-digit-numbers are constructed from a semiotic point of view and how the written-multi-digit-numbers and the spoken-numbers denote a determined quantity? (Houdement & Chambris)
- How can we foster all students' mental constructions of the intended structural relations between part and whole by initiating activities with fraction bars? (Prediger)
- How can students develop a better understanding of the equality $0.\bar{9}=1$? (Vivier & Rittaud)

Finally, Rathgeb-Schnierer and Green introduce a new perspective on flexibility in mental calculation in their paper and implement it into a theoretical framework for a study of different degrees of flexibility in mental calculation.

The teacher was only considered as a learner, but not in its role as a teacher.

THEMES

Strategies

This synopsis of research questions of the papers of WG2 at CERME 8 shows that developing an understanding of students' strategies in terms of development, influencing factors, flexibility, and consistency related to different number domains

and different ways of calculation (mental, written), has been an important topic in WG2 at CERME 8. Lorange and Rinvold analyze levels of objectification in students' strategies while solving tasks, which involve the expansion of fractions to a common denominator. Wittmann challenges the idea of error 'patterns' by analyzing the consistency of students' strategies. The results show that "students' work on computational problems quite often appears as a barely controlled and only partly aware process". As a new perspective Rathgeb-Schnierer and Green introduced a conceptualization of flexibility, which relates strategies to recognized number patterns and relationships of a given problem.

Mental calculation

Another prominent topic in the papers of WG2 at CERME 8 has been mental calculation. In the papers, mental calculation was not only treated related to natural numbers, but also related to fractions (Carvalho & da Ponte). Even related to natural numbers, it appeared that mental calculation was conceptualized differently in different papers. Consequently, defining characteristics of mental calculation is still an issue: Is mental calculation dependent on the extent to which external representations are used? This definition seems especially useful with regard to the fact that calculation is always a mental process. However it comprises the mental use of the standard algorithm and thus seems not to grasp the main idea of mental calculation. In order to avoid this problem, it seems more appropriate to define mental calculation as calculating with numbers as opposed to digits. This definition raises the question of the meaning of mental calculation in other number domains.

Conceptual development and "relative thinking"

Conceptual development and understanding, related to different concepts, has been another prominent topic in the papers of WG2 at CERME 8. Houdement and Chambris' paper is concerned with the conceptual development of (natural) multi-digit-numbers in view of a particular curricular development in France. Vivier and Rittaud deal with the conceptual development of rational numbers by focussing on a better understanding of the equality $0.\overline{9} = 1$. Schindler and Hußmann address previous knowledge of students related to comparing integers as an important aspect of conceptual development. Bednarz and Proulx draw attention to the "relativity or the whole" as an important sub-construct of the "part-whole-concept".

The notion of "relativity of the whole" is an example for another topic that has emerged in the papers of WG2 and the discussions. This topic might be called 'relative thinking' and was discussed as an important aspect of conceptual development. Relative thinking is concerned with relative aspects of concepts such as the relativity of the whole in the contexts of fractions and proportion (Bednarz & Proulx; Gomez et al.) and structural relations of numbers (Häsel-Weide & Nührenbörger; Prediger) and number operations and how they are represented. Although not explicitly related to it, this theme seems to be closely related to early

algebra, which is also a current theme in the research on algebra and algebraic thinking. In order to focus on relative thinking Prediger suggested “explicitly focusing structural relations” as a design principle for the development of learning environments, which aim to foster conceptual development.

CONCLUSION

In the discussion of WG2, two general topics emerged, which we would like to report, because we believe that it is worth considering them more explicitly in the future.

The first topic is related to the question of the similarity of mathematical situations. Questions such as the consistency of students’ solution patterns or adaptive strategy use always have to relate to similar mathematical situations. On the one hand, it only makes sense to investigate questions like students’ adaptive strategy use or the consistency of students’ solution patterns if it is possible to identify similar mathematical situations. Usually similar mathematical situations are defined from a mathematical perspective by identifying similar mathematical structures. This view was challenged in the discussions of WG 2 and it was discussed, whether it seems reasonable to define similar mathematical situations psychologically from the learner’s perspective. On the other hand, it might also be regarded as a goal to achieve that learners perceive mathematical similar situations as similar.

Another topic that emerged several times in the discussions of WG2 was about the cultural context of research. It appeared, that some research reacts upon curricular developments in a country and is not comprehensible, if the cultural context is not clear (see e.g. Houdement & Chambris). This also relates to the use of particular algorithms in a country (see e.g. Rinaldi) or the use of number representations and materials (see e.g. Häsel-Weide & Nührenbörger). The group agreed upon the need to make cultural contexts explicit in order to make research internationally comprehensible and useful. If we want to learn from studies in other countries it is inevitable to be aware of the cultural conditions of the research as something that is inseparable from the motivation of the research and its results.

ACKNOWLEDGEMENT

We thank Véronique Battie (France) and Luciana Bazzini (Italy) for all their work in the preparation of the conference. Both of them were official group leaders, but unfortunately were not able to participate at the conference.

THE (RELATIVITY OF THE) WHOLE AS A FUNDAMENTAL DIMENSION IN THE CONCEPTUALIZATION OF FRACTIONS

Nadine Bednarz & Jérôme Proulx

Université du Québec à Montréal, Canada

This paper focuses on a fundamental element in the conceptual development of fraction, the part-whole sub-construct. This focus is grounded in a research project with elementary teachers in which 3 days were spent on fractions and where issues related to the (relativity of the) whole, occupied a significant space of learning. Through outlining the unfolding of teachers' meanings of the whole in the session, we illustrate the fundamental role of the (relativity of the) whole in learning about fractions, and highlight the complex ramifications that underpin its learning.

INTRODUCTION

In the teaching and learning of mathematics, fractions have long been seen as one of the most difficult concepts to understand (see e.g. Ball, 1990; Charalambos & Pitta-Pantazi, 2007; Tobias, 2013). Following Kieren (1976) and Behr et al. (1983), these studies confirm the complexity of this concept, which is not a single but mainly a multifaceted one. This complexity of fractions has been first developed by Kieren (1976) and extended by Behr et al. (1983), creating a model of different interpretations of fractions, mainly the part-whole, ratio, operator, quotient, and measure, integrated and linked to operations, fraction equivalence, and problem solving (cf. figure 1).

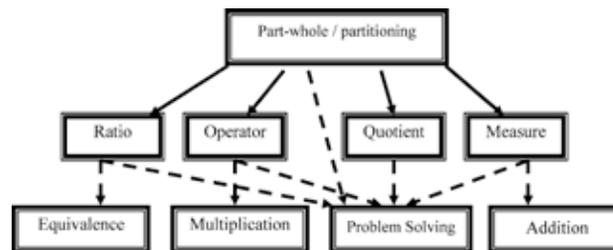

Figure 1. Behr et al. (1983) model (taken from Charalambos & Pitta-Pantazi, 2007)

While focusing on the importance of developing flexibility to handle these different interpretations, to move from one to the other in operations and problem solving (see e.g. Charalambos & Pitta-Pantazi, 2007), this model outlines that the part-whole sub-construct is of fundamental importance in the process of fraction understanding.

One aspect we focus on in this paper, and that we argue is of paramount importance in that part-whole sub-construct, is *the (relativity of the) whole*; what came to be called the “referent” by the teachers engaged in the project. Below, we show how this *(relativity of the) whole* is of particular importance and explain what we mean by it. Then, after having explained the study’s objectives and methodological considerations, we detail its intricacies through analyzing its multifaceted meanings within a group of in-service elementary teachers.

PART-WHOLE SUB-CONSTRUCT AND (RELATIVITY OF THE) WHOLE

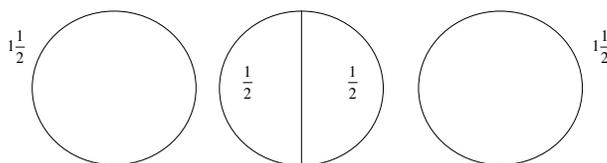

The (relativity of the) whole, albeit not explicitly outlined in Behr et al. model, has been alluded to by a number of researchers, particularly in studies involving teachers (e.g. Ball, 1990; Simon, 1993; Schifter, 1998; Prediger & Schink, 2009). For example, in Simon's study, prospective teachers were presented with a division of fraction problem for finding the number of cookies 35 cups of flour make if one cookie needs $\frac{3}{8}$ of a cup. In their answers, numerous teachers who arrived at a remainder of $\frac{1}{3}$ defined it as the remaining flour ($\frac{1}{3}$ of a cup of flour) instead of seeing it as $\frac{1}{3}$ of what it takes to make a cookie ($\frac{1}{3}$ of $\frac{3}{8}$ of a cup of flour). This raises the significant issue of referring to the *proper whole* when discussing fractions in the part-whole sub-construct. As well, more recently, Tobias (2013) developed an entire paper on the notion of the whole of a fraction, addressing it through issues of language use. Through highlighting various difficulties elementary teachers experience with fractions (e.g. Ball, 1990; Simon, 1993), she focuses on the importance, in fractions teaching and learning, to well conceptualize the whole of the fraction in order to contextualize situations, to understand the procedures to use and to interpret various solutions. She argues that a number of difficulties lived by learners with the notion of whole comes from language difficulties in defining wholes. She gives the following example (p. 2):

In the context of subtraction, problems such as $3-2$ can be stated as starting with three objects and taking away two of them. When the situation involves fractions, such as $3-\frac{1}{2}$, it is incorrect to interpret this as starting with three objects and taking away half of them.

Even if we agree with Tobias' argument that language issues are of importance, we believe that there are deeper ramifications that are at play in understanding the whole of a fraction. One of these deep ramifications is related to the whole itself. We address it as *the (relativity of the) whole*.

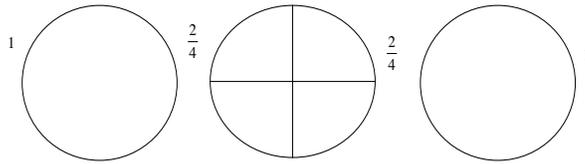

In order to clarify what we mean by *the (relativity of the) whole* and to see its importance, a Grade-4 classroom vignette is used, taken from a previous study on fractions. In this vignette, an extract of the classroom discussion related to the following problem: "Share three pizzas equally between two children" (three circled pizzas are drawn on the board for visual support) is presented. Children had to find as many ways as possible to solve it:

Marlene: One child has a pizza, the other one also has an entire pizza, then one child has half, and another half. A pizza and a half each (she draws it on the board).

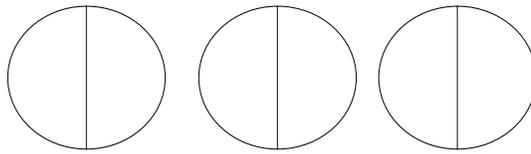

Teacher: Ok, does it work? [pupils: yes!] Does anyone else have a solution?

Manon: There's one child that has one pizza, the other one has another pizza. I split the remaining one in four, one child gets two fourths and the other one two fourths. One child has a pizza and two fourths and the other one a pizza and two fourths.

Teacher: Ok, another solution?

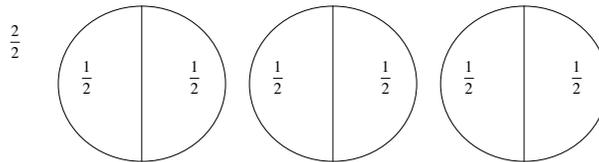

Veronique: I separated my pizzas like this: half of a pizza for a child, the other half for another child, another half for the first child, another half for the second, another half for the first, another half for the second; which means each child has three sixths.

Teacher: What do you think? Is this right?

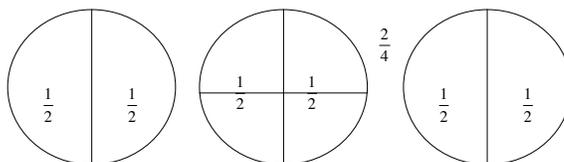

A student: No! Half plus half, that's two halves.

Teacher: Two halves (writing it on the board). Does this mean two over two?

Martin: No, one over two and one over two, that's two over four.

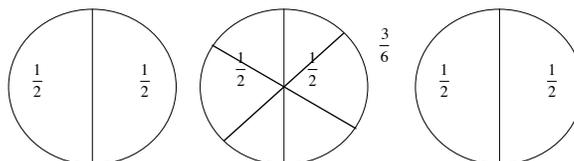

Teacher: You mean I divided a pizza in four, and I took two pieces.

Michel: No, it's not two over four [referring to Martin solution] it's one pizza and a half, because it's two halves together, one pizza plus one half, that's one pizza and a half.

Veronique: Yes, but three sixths [returning to what she said previously], that works...

Teacher: Does this mean we divided a pizza in six pieces, to find something like that?

Veronique: No, in the end it's all the same.

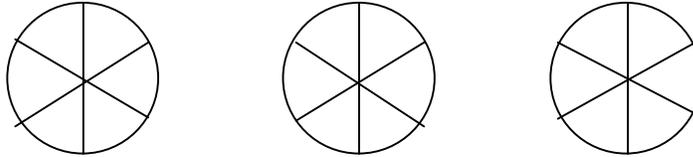

Teacher: You mean we divided by the same thing, and have the same parts of the pizza?

Veronique: We have the same result.

Teacher: Ok! Let's go back to $3/6$, how do I get this? What bothers me is the three sixths.

Gabrielle: Oh, I know! There's three because there's six in total, six pieces...

Teacher: Oh, as if one pizza was divided in six pieces. Alright, it's like the pizzas were divided in six pieces, right?

Gabrielle: No, we need to divide it in two, it makes three pieces each... All the pizzas, all of them together are divided in six parts.

Another student: Does this happen by chance, because you know, there is one out of two, you take one pizza and each pizza you take one out of two, and one out of two, and one out of two, it makes three sixths.

Of interest in this vignette is not if the teacher reacted well to students' answers and questions or if students themselves understood well the concept of fraction. Of significance, within the myriad of answers given, is the possibility of the validity of these answers and on what grounds. When Manon says 1 and $2/4$, the whole she refers to is one of the pizzas, her answer being 1 pizza and $2/4$ of one pizza. When Veronique says $3/6$, the whole she refers to is the entire three pizzas, making her answer $3/6$ of the pizzas. When Martin adds $1/2$ and $1/2$, that gives him not 2 over 2 but 2 over 4 , is he wrong or could he be adding $1/2$ of one pizza with $1/2$ of one pizza which gives him 2 of those halves out of 4 halves? And, again, could the student question about the coincidence of $1/2+1/2+1/2$ giving $3/6$ be along a change in the whole to represent the total? Those for us are important questions and are not answerable by a right/wrong dichotomy. This view of *the (relativity of the) whole* is closely aligned with Schifter's (1998) view, who for example queries "How can that piece of cake be $1/2$ and $1/4$ at the same time?", a kind of question frequently heard. In the part-whole sub-construct, fractions always need to be related to a whole. And, that whole can change, leading to the mathematical validity of what is offered. This *relativity of the whole*, mainly through relating the fraction to different possible wholes, is of fundamental importance in the mathematical reasoning about fractions. We document in this paper how this issue took form, through analyzing interpretations of a group of elementary teachers in different tasks.

RESEARCH OBJECTIVES

Though a number of studies (e.g. the ones mentioned above) have reported on issues of *whole* in teachers or students' understanding of fractions, few have detailed the ways in which this notion takes form through different tasks in learners/teachers, and how it interacts with the meaning of fraction itself. In examining the construction of *the (relativity of the) whole*, as one central aspect of the part-whole sub-construct, our

report offers an analysis of different meanings of this fundamental aspect as well as of the intertwined meanings of the fraction concept itself; aspects of central importance for better understanding the phenomenon of teaching and learning fractions. In that sense, the paper is oriented by the following questions: (1) in what ways do learners, here practicing elementary teachers, understand the notion of whole within a particular task (meanings developed-in-action)? (2) In what ways does this notion unfold through different tasks?

METHODOLOGICAL CONSIDERATIONS

A group of 10 elementary teachers (Grade-4 to 6) participated in a 2-year professional development (PD) research project. This PD-research project intertwined professional development and research concerns, and can be related to a teaching experiment methodology (Steffe, 1983) through its preoccupation for documenting students' conceptualization overtime. In the teaching experiment methodology, the researcher – who is also the teacher – builds models of meanings developed-in-action by students, and confronts, during the teaching episodes, these models to the reasoning's and actions mobilized by students in new situations (leading to a continual restructuring of the models built). This methodology helps to understand a conceptual development in all its complexity and over time. In this research project, our preoccupation is similar. The intention is not to develop an in-service project for showing its potential in terms of learning outcomes. This PD-research project is an occasion to document the conceptualization about a specific arithmetic content. As teacher educators-researchers, we designed and conducted sessions, participating in the development of the mathematical understandings occurring in them, pushing their elicitation and modeling the conceptual development (as Steffe did).

The initiative is structured around day-long monthly sessions (15) during 1 ½ school years, all of them being videotaped, to keep a record of the sessions' unfolding, and a researcher journal was kept about salient events and reflections these provoke. The sessions activities revolved around “mathematics” tasks for teachers to engage with, articulated on their practice, about different mathematical topics [fractions, division, measurement (perimeter, area, volume), decimals numbers]. Teachers were invited (in small groups followed by plenary discussions) to engage with those mathematical events and to explore/discuss/make emerge the mathematical ideas inherent in these tasks. The focus here is on the first block of 3 sessions on fractions, where tasks were about the part-whole understanding of fractions through partitioning contexts.

The data analysis procedures adapted the approach proposed by Powell, Francisco, & Maher (2003), and focused on an *emergent* coding of data. Oriented by the notes from the research journal to pay attention to specific events of significance that happened in the sessions, the first stage of analysis involved (re-)becoming familiar with the sessions in full, viewing the tapes in their entirety to get a sense of their content. Specific events of importance were pointed to for orienting the continuity of the data analysis. In the second stage, the video data were described through writing

brief, time-coded descriptions of each video's content and grouping it in "events". In stage three, data were reviewed anew to explore more precisely possible "significant events", which led, in stage four, to precise data transcriptions (verbal, gestures, drawings on the board, etc.) regarding these events. Each event was then analyzed in details and related to the previous and following ones to develop an evolving pattern concerning the (relativity of the) whole understandings. We outline these below.

ANALYSIS OF MEANINGS OF THE WHOLE OF FRACTION

The relevance of the whole, that came to be called the "referent" during the sessions with teachers, emerged progressively as a significant issue to consider. We present some of the tasks worked on below, and the different meanings given to the "referent" through these tasks as they emanate from the analysis. Because of space constraints, only a synthesis of the different conceptualizations, and their unfolding meanings, are outlined. The main idea is not here to document an evolution overtime from one meaning to the other during the professional development sessions. Our concern is to document how different meanings (about the whole and fractions) unfold within, and throughout, different tasks, and the way they can interact.

As teachers explored this first problem about "John and Mary" (with sample solutions), a number of meanings about the referent were engaged with.

John and Mary problem. John and Mary each have pocket money. Mary has spent $\frac{1}{4}$ of her amount and John $\frac{1}{2}$ of his. Who spent more money, John or Mary?

Student solution 1:

John because $\frac{1}{2}$ is more than $\frac{1}{4}$.
Ex.: $\frac{1}{2}$ of 16 = 8 but $\frac{1}{4}$ of 16 = 4

Student solution 2:

Mary $\frac{1}{4}$
John $\frac{1}{2} = \frac{2}{4}$
John spent more and Mary less

(1) **Referent absent from the solving process.** In some explanations of teachers (e.g. below), the referent is *not* present in the way they make sense of the solutions, highlighting at the same time that these fractions are considered in-action as "absolutes".

M.: We don't know how much money they [John and Mary] have, but it is not important. This child understands well the meaning of fractions, that $\frac{1}{2}$ is more than $\frac{1}{4}$. And, he offers an example to confirm it.

One could be tempted to say that fractions are here treated as numbers, an important meaning in the learning process on fractions (i.e. from elementary to secondary school, from natural to rational numbers). However, the analysis of the transcripts shows that fractions were not explained as numbers but mainly taken for granted as a "things in itself", an evidence ($\frac{1}{2}$ is simply a bigger fraction than $\frac{1}{4}$).

(2) **Contextual referent.** Another meaning emerged, in interaction with the previous one, in which the referent is considered. Even if in this case the referent emerges as

important, this new meaning does not really affect the meaning of fraction itself, but is mainly related to the context of the problem.

Interaction 1.

G.: My students, on the contrary, could have said that we can't answer this question because we don't know how much money they have at the beginning. Then if one has several millions dollars and the other has little money, the $\frac{1}{4}$ could be more.

M.: Right. If I have 100\$ and you have 10\$, even if you spent half I stay richer. Our group did not see it like that.

Interaction 2.

M.: For the meaning of the fraction, this student would get a good mark. For me, he understands the meaning of a fraction, that $\frac{1}{2}$ is more than $\frac{1}{4}$.

J.: But, if he does not mention that there is no referent, no amount of dollars, then we can't say that his solution is good. [...] If the child does not say that it depends of the beginning amount, I can't give him all the marks, since it could be different amounts.

In this case the context of the problem creates the necessity of considering *the referent* (the amount at the beginning) but this contextual referent does not affect the meaning of the fraction ($\frac{1}{2}$ remains bigger than $\frac{1}{4}$). It stays independent of the fraction, only impacting the resulting amount, the fraction continuing to be treated as an absolute.

(3) **Fixed referent.** Later on in the discussions about the same task, the consideration of the referent evolved toward a new meaning influencing the meaning of fraction itself, for which not only the context provoked its consideration. This referent is, at this moment, conceived as fixed, determined in advance, so that it is possible to operate on fractions and conclude when its value is known *a priori*.

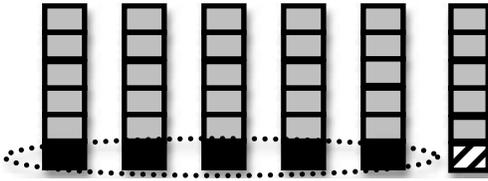

M.: If we want to practice the meaning of fraction, then give children a referent, and stop playing with it. Hence, it would be necessary in the problem to say that each person has the same amount. Our group started with the fact that each had the same amount.

Mi.: We could also, when there is missing data, work with situations where there is the same amount and other situations where there are different amounts.

Even if here there is a relation linking the fraction to a whole, there is a need to make this referent fixed so that one does not have to consider it afterwards when operating on fractions. This referent can vary from one situation to the next, but it needs to be fixed for each of those situations (like one fixes the parameters of a function when treating a specific case).

(4) **Relative referent:** This previous meaning (fixed referent) contrasts with another one (relative referent), that appeared much later in the sessions. We present here some interactions that occurred regarding the “ribbon problem” (Schifter, 1998).

Mali has 6 meters of material. She wants to make ribbons of $\frac{5}{6}$ meters for a birthday at school. How many ribbons can she make and how much material will she be left with?

Student solution 1: 7 and $\frac{1}{5}$

Student solution 2: We can make 7 ribbons

Student solution 3: 7 and $\frac{1}{6}$ of a ribbon

Student solution 4: 7 and $\frac{1}{7}$

A.: [discussing the solution 1] I mean the ribbon is finally $\frac{5}{5}$.

Mi.: No! $\frac{5}{6}$.

A.: No, no, no. In the end, it becomes $\frac{5}{5}$ [M.: Oh my god!]

A.: And then the last piece remains a part of my whole, it remains $\frac{1}{5}$.

Mi.: Yes, I understand what she means. We change the whole!

The fraction is here clearly related to a whole, and relative to this whole: the same piece can take several values (e.g. $\frac{1}{5}$, $\frac{1}{6}$, $\frac{1}{36}$) depending of the whole considered (it was not the case when the referent needed to be fixed, determined). In this case, somehow the referent is seen as variable, whereas in the previous case it was conceived as parametrical (that is, changing but to be fixed for a specific problem).

This sophisticated meaning about the referent was developed, explained and refined on a long-term basis, through various tasks and interactions between participants. However, along this process, other interrelated meanings emerged. We present below, through short excerpts, three other meanings given to the referent.

(5) Referent as pictorial representation. For a number of tasks where students used pictures in their solutions (e.g. the ribbons problem), the referent became linked to a pictorial representation, seen as the whole. In this case of partitioning, the part needed to be completely included in the whole (in the picture of it). We found here an idea of inclusion according to which the parts are considered as elements of the whole. This is linked to a conception of fraction as a comparison between the part (a number of pieces) to the whole (the total number of pieces in which the picture is partitioned).

Interaction 1: on a problem involving a comparison of $\frac{5}{6}$ and $\frac{3}{4}$

S.: When we have to compare fractions, we know what is the partitioning. When you understand the partitioning of the fraction, you make a drawing, dividing it e.g in four and you take 3 of them.

Interaction 2: on the “ribbons problem”, concerning the 7 and $\frac{1}{5}$ solution

S.: It can't be $\frac{1}{5}$ of ribbon. A ribbon is $\frac{5}{6}$, so it is $\frac{1}{6}$ of ribbon, you can't say $\frac{1}{5}$. The remaining piece is not inside the ribbon.

It is the picture, acting as the whole, that impregnates the meanings of the referent and the fraction itself. The pieces considered must be “inside” this whole, being part

of it. This referent is dependant on the drawing done, based on a view of fraction as a comparison between a part and the whole in which it is included.

(6) **Referent as common denominator.** Sometimes the referent becomes the common denominator, and is seen as the basis on which to compare fractions (as we see below in a problem involving a comparison of $\frac{5}{6}$ and $\frac{3}{4}$).

S.: We need to compare with the same whole, oranges with oranges, apples with apples.

M.: There are quarters and sixths, so it is apples and oranges.

A.: We need to make it on twelve.

M.: You have to put them on the same denominator to compare, so it becomes our referent. We make it in twelfths and this is the referent.

Of interest here is that through making the common denominator the referent, implicitly teachers are transforming the comparison of fractions to a comparison of natural numbers [$(\frac{5}{6}=\frac{10}{12}$ and $\frac{3}{4}=\frac{9}{12}$, compare 10 (twelfths) and 9 (twelfths)].

(7) **Referent as a number linked to a fraction operator.** In the “ribbons problem”, the following discussion happened concerning the remaining piece being $\frac{1}{6}$.

N.: It means that it is $\frac{1}{36}$ of 6 meters of material. But it can be also $\frac{1}{6}$ of one meter.

S.: Because we can simplify the fraction, $\frac{1}{6} \times 36$.

Teachers here use an operator to arrive at $\frac{1}{6}$ of a meter ($\frac{1}{36}$ of 6m = $\frac{1}{36} \times 6 = \frac{6}{36} = \frac{1}{6}$). They thus agree that the same piece of material can have different values ($\frac{1}{36}$ of 6m, $\frac{1}{6}$ of 1m), *through the operation*. Hence, it is not the consideration, for the same piece, of different wholes that leads to this acceptation, but a multiplication and simplification on numbers (fractions are here considered as operators).

DISCUSSION AND CONCLUDING REMARKS

The varied meanings given to the referent in the reconstruction over the sessions show a complex picture of its unfolding (even if more excerpts would be needed, but space constraints forbids). Different meanings emerge, interact and influence each other, taking form, being explained and refined, etc., all along the process of exploring and discussing the various tasks. These meanings, for the same or different persons, oscillate between one another; showing that these do not follow a linear path. These interacting aspects illustrate well the richness of this development. It shows that the part-whole sub-construct is a complex one, involving not only an understanding of what many researchers refer to the partitioning scheme with its different components (e.g. Charalambos & Pitta-Pantazi, 2007), but also a rich conceptualization of the whole (reasoning on the fraction in relation to the whole, seeing the relative value of the part, re-organizing the whole, etc.).

Even if many researchers point to the fundamental dimension of the sub-construct part-whole in the process of understanding fractions, the place occupied by a reflection on the meaning of the whole in this conceptual development has not been

amply considered. The understanding of “the whole” acquired a broader significance through this research project. This question of referent is more than a question of language as Tobias (2013) e.g. would say. The notion of defining the whole is related, as we have seen, to the underlying meaning of the concept of fraction itself in a part-whole context. This “change” or “relativity” of the chosen whole is central in relation to comparison, equivalence, problem solving and operations (e.g. $\frac{3}{4} \times \frac{1}{2}$, where $\frac{3}{4}$ is seen as having $\frac{1}{2}$ as its whole, something often seen as “taking a part of a part of the whole”). This awareness about changing referent appears as a fundamental component to develop confirming and extending previous studies about operations on fractions (Prediger et al., 2009). In addition, even if we haven’t highlighted it here, the various meanings developed about the referent are often nested with other sub-constructs. For example, issues of “referent as number on which to operate” is closely linked with the sub-construct “operator” of the fraction, as well, important issues concerning ratios were dealt with through the sessions. Those issues are to be developed in another paper.

João Pedro da Ponte

Instituto de Educação, Universidade de Lisboa

Carrying out mental computation with positive rational numbers represented as fractions may contribute to students' development of rational number sense. We analyze the development of grade 6 students' mental computation strategies with fractions through a teaching experiment based on mental computation tasks with rational numbers involving the four operations and the discussion of strategies. In the beginning of the study, the students used mainly instrumental strategies and, along the teaching experiment, they used more and more conceptual strategies.

Keywords: Mental computation, fractions, students' strategies, relational thinking, tasks.

INTRODUCTION

Mental computation with rational numbers tends to assume a marginal role in the school curriculum and in teaching practice. Given the difficulties that children have in computing mentally and in learning rational numbers, combining these two aspects may be fruitful for mathematics learning. To develop students' mental computation with rational numbers, it is important to understand students' strategies, given the kind of tasks proposed, and to realize how these strategies may evolve.

Following Reys, Reys, Nohda and Emori (1995), we regard mental computation as the process of computing an exact arithmetic result without an external support. Systematic work in mental computation may help to develop computation skills (Heirdsfield, 2011) as well as students' reasoning strategies and number and operation sense. Assuming this perspective, the mathematics curriculum for basic education (grades 1-9) in Portugal (ME, 2007) indicates that mental computation with natural numbers must be developed from grade 1 on and later be extended to other number sets. However, despite such recommendation, most students have very poor ability in mental computation with rational numbers. Our aim is to analyze the development of grade 6 students' mental computation strategies with positive rational numbers (represented as fractions) through a teaching experiment based on mental computation tasks with rational numbers involving the four operations and the discussion of strategies.

MENTAL COMPUTATION AND OPERATIONS WITH FRACTIONS

For students fractions are difficult to understand. A fraction is written using two numerals but represents only one number; although $2 < 4$, we have $1/2 > 1/4$; the same

quantity may be represented by several fractions; the rules for multiplication of fractions are easy to accept (e.g., $1/2 \times 2/5 = 2/10$) but the rules for adding and subtracting fractions are not the most intuitive ones ($1/2 + 1/4$ is not $2/6$) (Lamon, 2006) and these similarities and differences may induce students in misunderstandings about rational numbers and fractions.

For Galen, Feijs, Figueiredo, Gravemeijer, Herpen, and Keijzer (2008), fractions must receive a special attention in elementary school, as a starting point for understanding decimals and percent, giving meaning to them, and also because they play an important role in mental computation. We often think using fractions even when they are not explicitly involved. These authors call “network of relationships” the knowledge that students develop about different types of fractions and refer that this network does not develop just by practicing. They also consider that students’ knowledge about fractions may be increasingly vast and formal, however it may be not specifically associated to a context but to a given fraction, that is, a student who understands that $3/4$ is smaller than $4/5$, is not necessarily ready to understand that $14/15$ is less than $15/16$.

To work with fractions with understanding, students need to be aware of the relationship between numerator and denominator. For Cramer, Wybeg and Leavitt (2009), a student with number sense is reflective about numbers, operations and results and is flexible in using comparison strategies and operations with numbers. Concerning fractions, number sense is related with the ability to use relational thinking (Empson, Levi & Carpenter, 2010), to compare and work with this rational number representation and to understand the quantities involved. Behr, Post and Wachsmuth (1986) and Cruz and Spinillo (2004) indicate that using benchmarks is important to compare and to operate with fractions. Cruz and Spinillo (2004) consider that the benchmark half plays an important role in students’ initial understanding of complex logical-mathematical concepts associated with rational numbers, and the use of this benchmark may facilitate the addition of fractions.

Furthermore, students need to understand that multiplication is much more than repeated addition, and this, as Lamon (2006) suggests, brings in a new challenge. Newton and Sands (2012) consider that students must be encouraged to make conjectures about the division of fractions, leading them to use methods that are not usually taught in school. This allows them to understand efficient methods in relation to the context in which they are working. Often, students can use their knowledge about the multiplication of fractions to develop methods to divide fractions.

Empson et al. (2010), consider that learning fractions may be strongly supported if children develop relational thinking. The focus on relational thinking may help children to turn fractions into something that a drawing or a close attention to the properties of numbers and operations may lead them to reason about the quantities involved. The authors also consider that a child begins to think in a relational way about the quantities involved in a fraction, when he/she manages to relate the number of equal parts that he/she must share with the whole number of persons for which

he/she must also distribute these parts. For Empson et al., (2010), relational thinking may be used to make sense of operations with fractions. When children understand fractions as a set of relationships, they are able to compose and decompose quantities for transforming expressions and simplifying them in the computation. A key point in developing a child's understanding is reached when he/she start using relational thinking in his/her strategies to make repeated additions or subtractions of fractions more efficiently by applying fundamental properties of operations and equalities to combine quantities. A child who, to compute 8 groups of $\frac{3}{8}$, thinks that if 8 groups of $\frac{1}{8}$ is equal to unity, then $\frac{3}{8}$ will be three units, is making a reasoning based on the commutative and associative properties of multiplication. Thus, the development of basic knowledge to think about fractions in an efficient way integrates knowledge of properties of natural numbers, their operations and their relationships and anticipates the generalization of algebraic quantities. The authors state that the use of algorithms to develop some fluency with operations with numbers is useful, but argue that if the development of students' relational thinking is supported, the knowledge about the generalization of the properties of numbers and operations becomes more explicit and may be the basis for the learning of algebra in the subsequent school levels, reducing students' errors and misconceptions.

The student who only uses instrumental mental computation strategies, just involving known facts and memorized rules (Caney & Watson, 2003), does not show relational thinking. To compute $\frac{3}{4} - \frac{1}{2}$ the student may apply the rule of subtraction of fractions with different denominators with no understanding of the quantities involved. In contrast, the student who uses knowledge about numbers, their relationships and operations provides evidence of conceptual strategies (Caney & Watson, 2003) and builds an important conceptual foundation for learning algebra (Empson et al., 2010). For example, to do this computation, a student may decompose $\frac{3}{4}$ in $\frac{1}{2} + \frac{1}{4}$ and, by subtracting the halves, see that the result is $\frac{1}{4}$, showing some understanding about numbers. In our perspective, the use of conceptual strategies involves understanding numbers and operations but instrumental strategies may be used with no understanding. Sometimes students' strategies seem to have instrumental and conceptual features, especially when students apply a memorized rule but show some understanding of numbers and operations. However, in working with fractions that yield repeating decimals (i.e., $\frac{1}{7}$) it may not be possible to use conceptual strategies, giving the complexity of the number involved. In this case, instrumental strategies are a powerful way of doing the computation.

The use of relational thinking is implicit in the framework of Heirdsfield (2011), who stresses that students, to compute mentally, need to understand numeration (the size and the value of numbers), recognize the effect of an operation on a number, know number facts, and make estimates to check the reasonableness of a solution. These concepts and understandings are based on number sense (McIntosh, Reys & Reys, 1992) and operation sense (Schifter, 1997; Slavit, 1999) and on a set of numerical

facts that students learn in school (Wolman, 2006) and use to create their personal strategies' based on relational thinking.

Social interactions (especially collective discussions) play an important role in supporting students in sharing and building a repertoire of mental computation strategies. Thompson (2009) suggests that, to develop students' mental computation, teachers must: (i) create a classroom environment where students feel comfortable talking about their strategies; (ii) listen attentively to students' explanations about their computation methods; (iii) reinforce students' positively as they use specific strategies; (iv) enhance students' knowledge about numbers and capacity to implement effective strategies; and (v) ensure that students go through different experiences to gradually develop increasingly sophisticated strategies. In summary, the focus on the development of students' relational thinking, through the use of different representations of rational numbers, benchmarks and shared strategies in collective discussions may be an asset to learning of rational numbers.

RESEARCH METHODOLOGY

This study is qualitative (Bogdan & Biklen, 1994) with a teaching experiment design (Cobb, Confrey, diSessa, Lehere, & Schauble, 2003). The participants are a mathematics teacher and a grade 6 class with 20 children who previously worked with rational numbers in different representations (decimals, fractions, and percent) with the four operations. In the classroom setting, the first author was a participant observer. Data collection took place between February and May of 2012, through video and audio recordings of the classroom moments with mental computation tasks. Audio recordings of the preparation and reflection meetings with the teacher and researcher's notes were also taken. In data analysis the dialogues (audio and video recorded) that show students' mental computation strategies in collective discussions, were transcribed to identify how these strategies evolved during the teaching experiment. The students' mental computation strategies were categorized as instrumental or conceptual (Caney & Watson, 2003), and students' use of relational thinking (Empson et al., 2010) was analyzed.

THE TEACHING EXPERIMENT

The design of the teaching experiment was discussed with the mathematics teacher who carried it out with a grade 6 class. The anticipation of students' strategies supported the choice of tasks as well as the preparation of collective discussions. Class management, including collective discussion moments, were led by the teacher, with the first author making occasional interventions to clarify aspects related to students' presentation of strategies. The design of tasks stands on principles related to (i) context; (ii) representations of rational numbers and use of benchmarks, (iii) students' strategies; (iv) cognitive demand (Henningsen & Stein, 1997); and (v) social interactions. Concerning the context, we use tasks framed in mathematical terms and word problems because we assume that such diversity is important to develop mental computations skills. We use three representations of rational numbers

(decimals, fractions and percent), in an integrated way and taking advantage of benchmarks. We favor tasks that may promote the development of mental computation strategies (based on Caney & Watson, 2003) and tasks with different levels of cognitive demand to engage students in different kinds of reasoning (Henningsen & Stein, 1997), some involving numbers which lead to simple computations and others requiring the use of numerical relationships. And, finally, we promote social interactions, especially collective discussions that we assume as a fundamental aspect in the development of mental computation strategies because they provide students with the opportunity to share ideas, reasoning and to improve their language by communicating mathematically, as they try to explain their reasoning.

The teaching experiment includes ten mental computation sets of tasks with rational numbers (with the four operations) to carry out each week for about 15-20 minutes at the beginning of a mathematics class. Seven sets of task are mathematical exercises that require students to compute the result of an operation or the value that makes a given equality true; two sets of tasks have four word problems each; and a set of tasks has a mix of exercises and problems. The rational number representation and the problems were related to the topics that students were working in class. When they were working with algebra, they computed with fractions, when working with volumes, they computed with decimals, and when working with statistics they computed with percent, fractions, and decimals. We integrate the mental computation tasks into the teacher's overall planning. This is one of the aspects that we consider important in our study compared with other studies in this field (i.e., Reys et al., 1995). The questions are presented using a timed PowerPoint, allowing 15 seconds for each exercise and 20 seconds for each problem. The students recorded their results on paper. After finishing the first five exercises, there was a collective discussion of students' strategies. Then, the students solved the second part of the task and that was followed by another collective discussion. These discussion moments allowed the students to reflect on how they think, what strategies they use, and what errors they make. This is another aspect of our study that we highlight, because this allows students to construct a collective repertoire of strategies.

In the teaching experiment, the students solved two mental computation tasks in mathematical terms using only fractions (addition/subtraction and multiplication/division), three tasks in mathematical terms with fractions, decimals and percent (with the four basics operations) and word problems where fractions appeared in combination with the other two representations. However, several times the students' used fractions in tasks that present only operations with decimals or percent, especially involving benchmarks as 0.25 or 75%. In table 1 we present some examples of tasks (exercises and problems) where we used fractions that students solved mentally throughout the teaching experiment.

The tasks were prepared taking into account several aspects important in mental computation. These tasks suggest the use of benchmarks such as $\frac{1}{2}$, $\frac{1}{4}$ and $\frac{3}{4}$ (Cruz & Spinillo, 2004; Galen et al., 2008), as well as the use of halves, because

recognizing and using them is a basic skill in mental computation with rational numbers represented as fractions (Callingham & Watson, 2004). We also used less common fractions such as $\frac{1}{3}$ or $\frac{4}{6}$ expecting that the students would apply the knowledge developed with benchmarks with these kind of fractions.

We start with addition and subtraction because these operations are the first that students study in grade 5, and then we use multiplication and division that the students learn in grade 6. The operations involve fractions with the same denominator or denominators involving multiples so that students may use equivalence.

Task 1 $\frac{3}{4} - \frac{1}{2}$ $\frac{3}{6} + ? = 1$	Task 2 $\frac{4}{6} : \frac{2}{6}$ $? \times \frac{5}{6} = \frac{1}{6}$	Task 3 $0.75 : \frac{1}{4}$ $\frac{8}{10} - 0.2$
Task 6 A tank has a capacity of 22.5 l of water. How many buckets of $\frac{1}{2}$ l are needed to fill the tank completely?	Task 8 $\frac{1}{3}$ of $\frac{1}{3}$ $\frac{1}{5}$ of $? = 8$	Task 9 $\frac{4}{6} \times \frac{6}{7}$ $\frac{2}{3} \times ? = 1$
Task 10 Every day, 400 students eat lunch at Johns' school. Of these students, $\frac{3}{4}$ always eat soup. How many students eat soup?		

Table 1. Example of tasks where we used the fraction representation.

In the case of word problems, the context is related to the mathematical topics that the teacher was working in the classroom (e.g., statistics, measurement, comparison of rational numbers and percent). We created problems that could lead to expressions similar to those discussed during the teaching experiment.

STUDENTS' MENTAL COMPUTATION STRATEGIES WITH FRACTIONS

In mental computation with rational numbers in fraction representation, students use mostly instrumental strategies by applying known facts and memorized rules (Caney & Watson, 2003). However, it is possible to identify the development of conceptual strategies along the teaching experiment. In these conceptual strategies, students' use equivalence, numerical relationships and properties of operations or mixed strategies combining instrumental and conceptual features.

In tasks 1 and 2, involving first addition and subtraction, and then multiplication and division, students' strategies were more instrumental. To compute $\frac{1}{2} + \frac{1}{2}$, Elsa explains how she applied the rule of addition of fractions: "As the denominators are the same, I put the same denominator and I added the numerator. (...) It is equal to 1. [It is] $\frac{2}{2}$ that is equal to 1". In this case we do not know Elsa's understanding of $\frac{1}{2}$. But when Marta uses a known numerical fact (two halves form a unit) to compute the result of the same expression, we can understand that she knows that $\frac{1}{2}$ means a half.

She quickly made “half plus a half” knowing that this gives 1. Marta’s strategy has instrumental and conceptual features because she applies a known fact showing some understanding of numbers. To compute $3/4 \times 2/3$, Eva explains how she used a memorized rule: “It gives $2/4$. When we have the same numerator and denominator, we can cut [the equal numerator and denominator] because this fraction gives 1”. To compute $4/8 : 1/2$ Rita used the invert-and-multiply algorithm in the division of fractions, as she explains: “I inverted the 2 with the 1 and did 4×2 that gives 8. So this yields a unit [$8/8$] and I wrote 1”. In dividing fractions, even when the numerators are the same, Maria computes $4/6 : 2/6$ also using the invert-and-multiply algorithm: “I did... I changed the 2 with the 6 and then did 4×6 and 6×2 . It gave me $24/12$ ”. She shows little flexibility to find a new method to divide fractions.

In task 3, some students continue to use instrumental strategies. However, conceptual strategies begin to emerge. That may have been influenced by the collective discussions of the previous tasks and also because fractions appear in combination with decimal representations. For example, João uses a conceptual strategy to compute $3/4 + 0.5$. He explains that: “I took 1 from $3/4$ [took $1/4$] and, as $2/4$ add with $1/2$ gives 1, in the end I added what I had taken, and that gives $5/4$ ”. He decomposed $3/4$ in $2/4 + 1/4$, and added two halves to obtain a unit ($2/4 + 1/2 = 4/4$) without calculating the same denominator. Finally, he added the amount taken from $3/4$ and obtained $5/4$.

In task 6, to solve the problem presented in table 1, Eva refers that “It gave me 45 buckets. I multiplied 22.5 by 2 (...) Because [we have] $1/2$, to get the unit we have to add 0.5 twice, so, I multiply by 2”. This student thinks in a half using fraction and decimal representations, showing no confusion, and establishes a relationship between the capacity of the bucket and the capability of the tank (“with a bucket of 11 I can take 22.5 buckets. With a bucket with half of capacity, I have to take the double number of buckets”). Eva does not use the invert-and-multiply algorithm, but she uses a conceptual strategy based on numerical relationships that gives meaning to this rule (Newton & Sands, 2012).

In task 8, some students continue to use instrumental strategies (such as Ana), but also conceptual strategies (such as Maria). Ana explains how she computed $3/4$ of 60: “I wrote it in a fraction way, and it gave me $180/4$. I did 3×60 , 180 and 4×1 , 4. The division gives 45”, using the algorithm of multiplication of fractions [She considers that 60 has denominator 1]. Maria shows to have number sense by explaining that $1/3$ of $1/3$ it is 0.111... This student describes her reasoning: “I know that $1/3$ it is 0.333... dividing by 3... is like a kind of the multiplication table by 11 (...) $11 \times 1 = 11$, $11 \times 2 = 22$... here it is $33 : 3$ which gives 11”. She operates the decimal development based on the knowledge of the 11 multiplication table. It seems that her strategies evolved. In task 2 she used an instrumental strategy to divide fractions with the same denominators and in this task, to multiply fractions, when most of the students used instrumental strategies, Maria used a strategy based on numerical relationships.

In task 9, to compute $2.2 - ? = 1/5$, José used a conceptual strategy and to compute $2/3 \times ? = 1$, Pedro used an instrumental strategy. José changed the representation: “We

transform $1/5 \dots$ it is 0.2” and used a property of subtraction “So, $2.2 - 0.2$ gives 2” – to get the subtractive, he subtracted the remainder from the additive. Pedro used a known numerical fact and says that: “It is $3/2$. They are inverse fractions”. This student memorized that the multiplication of a fraction by its inverse gives the unit.

In task 10, to solve the problem that we presented in table 1, Ana used an instrumental strategy applying the rule of multiplication of fractions by a natural number: “ 400×3 gives 1200 [and] dividing by 4 it is 300”. João uses equivalence showing a conceptual strategy: “ $300/400$ is equivalent to $3/4$. As 400 was the unit, it had to be 300”.

In working with mental computation tasks, we underline the importance of collective discussions to promote sharing of strategies and to identify tasks that prove to be useful to promote students’ conceptual strategies. Discussions allow students to make conjectures, to reflect on errors and misunderstandings, and the reasons why they made them, and to validate strategies and errors. Collective discussions also allow students to find different strategies that they did not use initially.

CONCLUSIONS

The analysis of the seven mental computation tasks that the students carried out with rational numbers represented by fractions shows that in the first two tasks their strategies were mostly instrumental (Caney & Watson, 2003). The students mostly used known numerical facts or memorized rules, for example, rules that they learned to operate with fractions. In addition and subtraction, the students computed the same denominator and added the numerators. In multiplication, they multiplied numerators and denominators and in division, they used the invert-and-multiply algorithm (as Elsa, Eva, Maria and Rita did).

From task 3 on, conceptual strategies begin to emerge (Caney & Watson, 2003) based on numerical relationships, equivalence and properties of operations, indicating increasing use of relational thinking by students (Empson et al., 2010) (as João, Eva, Maria and Ana did). We highlight the cases of Eva and Maria who, in the first tasks used instrumental strategies, and, in task 6 (Eva) and task 8 (Maria) used conceptual strategies that involve relational thinking. The strategy used by Eva is useful for making sense about the “invert-and-multiply” rule that most of the students tend to learn without understanding (Newton & Sands, 2012).

The choice of tasks and the classroom collective discussions contributed to this evolution. Using tasks in two contexts allowed students to diversify their strategies. In tasks in mathematical terms, the students tend to use instrumental strategies (as in tasks 1 and 2) and in problems they tend to use more complex strategies based on relational thinking (as in tasks 6 and 10). After task 2, students have to compute with fractions together with decimals and percent which facilitate the change of representation and equivalence, an important strategy in mental computation with rational numbers (Caney & Watson, 2003). The use of benchmarks and different representations of rational numbers in the same task along the teaching experiment

helped students to make sense of rational numbers (Galen et al., 2008) since they often used fractions when operating with decimals and percent. The variation of cognitive demand of tasks, in different contexts, provided students with opportunities to develop increasingly complex personal strategies (as the case of Eva). Furthermore, social interactions (especially collective discussions) promoted sharing of strategies, contributing to the increase of the students' repertoire of strategies and for their validation of strategies, improving their capacity to conjecture and to justify how they reason in mental computation.

These results support the perspective that mental computation with rational numbers is important for the development of number and operation sense and that the work with fractions supports the understanding of decimals and percent (Galen et al., 2008). Systematic work in mental computation may promote the development of personal strategies increasingly based on numerical relationships and properties of operations, enabling students to develop relational thinking that will be useful in learning algebra. To achieve this goal, tasks must be designed so that they may facilitate the progressive development of students' relational thinking.

PERFORMANCE ON RATIO IN REALISTIC DISCOUNT TASKS¹

Bernardo Gómez¹, Javier Monje¹, Patricia Pérez-Tyteca¹ & Mirela Rigo²

¹ Department didactic of mathematics. University of Valencia, Spain ² Center for Research and Advanced Studies, Mexico.

This paper is focused on the design of a protocol for teaching and learning ratio tasks, structured around metacognitive principles and Socratic maieutic method.

The data presented in this paper illustrate the categorization of responses that a group of pre-service elementary mathematics teachers gave to a ratio discount task. This categorization outlined the students' response patterns, which is considered essential for the design of the maieutic proposal and metacognitive questioning.

Keywords: Ratio, Discount, Comparison, Metacognition, Maieutic.

INTRODUCTION AND RESEARCH STRUCTURE

This study is part of a broader project – theoretical, empirical, and educational – which consists of the design, elaboration and implementation of a teaching proposal for ratio and proportion tasks, aimed at pre-service teachers.

This proposal follows the idea that “effective learners recognize the importance of reflecting on their thinking and learning from their mistakes”, as pointed out by research and curricular orientation such as the NCTM (2000, p.20) in the United States. It highlights the role of metacognition in the mathematics classroom, as indicated by Lester (1985) and Schoenfeld (1985).

Teaching proposals based on metacognitive practices rest on the assumption that “metacognition demands to be taught explicitly” (Desoete, 2007 p.709). Despite this, “teachers still pay little attention to explicit metacognition teaching” (Ibid, p.709).

In this regard, Socratic maieutics (conceived by Socrates and put forward in Plato’s dialogue Meno), is considered to be a suitable pedagogical method as it promotes and specifies metacognitive processes to “foster learning in students from self-recognition of their ignorance” (Rigo, 2011, p.523).

In the Socratic Method three key moments are identified: Construction, De-construction, and Re-construction (Rigo & Gómez, 2012).

In the moment of construction, the teacher poses a task that he/she knows students will answer confidently but in an incorrect or limited manner. On being asked to justify the answer, students engage in metacognitive reflection, which takes into account individual variables (confidence in the answer), task variables (knowledge of the mathematical notions involved and the degree of difficulty of such a task), and strategy variables (which strategies were available to solve the task and which was chosen and why). These reflections are necessary to prepare students for the transition towards the moment of de-construction.

¹ This research was supported by a grant from the Spanish MEC. EDU2009-10599EDUC & EDU2012-35638

Next, the teacher leads the students to confront cognitive and metacognitive conflicts. Cognitive conflicts arise when students are confronted with the contradictions that emerge from wrong answers. Metacognitive conflicts arise when students reflect and become aware of the limitations of their answer and ideas about the subject matter. This is the so-called moment of de-construction.

Finally, at the moment of re-construction, the teacher guides the students so that they can produce a new answer that will enable them to understand what, up to that moment, has been unknown in terms of the proposed task.

Key points and research questions

For this process the chosen task must be maieutic, that is:

- Rich in interpretations and meanings
- Rich in mathematical concepts
- Can be solved in different ways
- Familiar
- The answer is likely to create a high degree of confidence, apparently simple, but can create difficulties

Furthermore, for the maieutic process to be effective and have the expected cognitive and metacognitive impact the students' response patterns are considered essential. Knowing them beforehand will allow us to design the questions introduced during maieutic stages, and to plan the cognitive conflicts which could eventually be used as learning opportunities.

Due to limited space, the data presented in this paper refers to a categorization of response patterns given by a group of pre-service elementary mathematics teachers in a numerical comparison task called "the discount comparison task". This is considered essential, as mentioned earlier, for the design of our maieutic proposal. For this purpose the questions that orient the investigation are the following:

- Which are critical components for categorizing student's response patterns in ratio tasks?
- What are student's response patterns in the task?

METHODOLOGY

To categorize the students' responses we used an interpretation scheme focused on common features to group the different responses given by pre-service elementary mathematics teachers when try to solve the tasks.

The task was presented on a worksheet (paper and pencil format) administered during a regular one-hour class session, to 314 third-year students undertaking a course in mathematics teaching (didactic) of elementary mathematics teacher training degree at

the University of Valencia (Spain). These students had already completed an annual course in mathematics.

The discount comparison task

Three typical advertisements are presented to the students. The question is which discount is better (Figure 1).

Figure 1. The discount comparison task

The three advertisements are phrased differently. The first advertisement shows a percentage, “70% off second item”. The second one shows “3x2” and the third “Second item half price”.

The last two discounts are applied to a particular product: the “3x2” advertisement offers three bottles of “Rioja” wine for the price of two; the other advertisement offers the second bottle of “Extremadura” wine at half price.

In order to avoid arithmetic calculations the different offers include unit values: in 3x2, the price of each bottle is given before and after the discount: €5.58 and €3.72; and in the second bottle half price, the price of the bottle before the discount is given, €9.74 and the price of the second bottle after the discount is given, €4.87.

Critical components of the task

The difficulty in the discount comparison task lies in two critical components. One is to perceive that what is asked is not about the magnitude of the discounts; that is, the quantity to deduce from the cost, rather about the relativity of the discounts, in the sense of Freudenthal, that is, “in the sense of “in relation to”...with the criterion of comparison filled in at the dots” (1983, p. 194), in this case, in relation to the purchased items.

In the task the word relatively is not explicit, but it is implicit in the ratios 3x2, 70% off second item, second item half price.

The other critical component is that these ratios are not directly comparable, because they are formulated in different ways and have different references (price, and number of bottles).

To compare them a transformation process is required in order to express the ratios in the same way (percentage, decimal, fraction or verbal ratio “a to b”), and to “unitizing”, in order to construct a common reference unit and then to interpret the situation in terms of that unit (see Lamon, 1996, for an overview for “unitizing”).

Based on this, there are a number of strategies to answer which discount is better. For example:

1. To calculate the discount in relation to total cost of purchased items (Part-whole strategy) to determine which fraction is larger/smaller:

3×2	second item half price	70% off second
$\frac{5.58}{3 \times 5.58} = \frac{5.58}{16.74}$	$\frac{9.74/2}{2 \times 9.74} = \frac{4.87}{19.48}$	$\frac{\frac{70}{100} \times 5.58}{2 \times 5.58} = \frac{3.9}{11.16}$ or $\frac{\frac{70}{100} \times 9.74}{2 \times 9.74} = \frac{6.9}{19.48}$

2. To calculate the discount (or the cost) per item in each offer (Unit rate strategy) to determine which per-cent is larger/smaller:

3×2	second item half price	70% off second
$\frac{1}{3} = 33.\hat{3}\%$	$\frac{50\%}{2} = 25\%$	$\frac{70\%}{2} = 35\%$

3. To calculate the discount (or the cost) of a same number of items in each offer to determine which verbal ratio (“a to b”) is larger/smaller, in a sort of “pattern recognition and replication” strategy, which was named “building up strategy” by Hart (1981), where, with the help of a table of values, children may notice a pattern which is then applied to answer the problem.

3×2	second item half price	70% off second
1 to 3 (1 save every 3)	0,5 to 2 (0.5 save every 2)	0.7 to 2 (0.7 save every 2)
2 to 6	1.5 to 6	2.1 to 6

These three strategies yield the same result: the best discount is 70 % off second item. The reason for this is that the three strategies used ratios that (although in different forms) express the same values, since a ratio express an invariant relationship between the terms of a pair, so the ratio does not change the value when the reference is changed (see the next table).

3×2	second item half price	70% off second
$\frac{5.58}{3 \times 5.58} = \frac{1}{3} = 33.3\%$	$\frac{9.74/2}{2 \times 9.74} = \frac{1/2}{2} = 25\%$	$\frac{\frac{70}{100} \times 5.58}{2 \times 5.58} = 35\% = \frac{\frac{70}{100} \times 9.74}{2 \times 9.74}$
2 to 6 is $\frac{2}{6} = \frac{1}{3} = 0.\hat{3} = 33.\hat{3}\%$	1.5 to 6 is $\frac{1.5}{6} = \frac{0.5}{2} = 0.25 = 25\%$	2.1 to 6 is $\frac{2.1}{6} = \frac{0.7}{2} = 0.35 = 35\%$.

To the majority of students this invariability is not obvious, due to the influence of the context. The influence of the number of items, 3 or 2, to which the discount applies is susceptible to discussion, because the advantage of the discounts is not applicable simultaneously if the number of purchased items is not a common multiple of 3 and 2

The scheme of response patterns

These critical components and strategies provide a scheme to categorize students' outputs, organized with categories subcategories, classes and subclasses, with the purpose to have a more detailed description of the students' response patterns.

The first criterion considered to group the responses is if students perceive the relativity of the discounts in the task or not. This determines two categories: focus on ratios and focus on specific elements of the offers.

A criterion to distinguish subcategories in this first category is if the students convert and unitize or not. This determines two subcategories: compare elements that are comparable or compare elements that are not comparable.

The criterion for distinguishing classes is if students focus on a unit value or on a same number of items; that is, if the students use the “unit rate strategy” or the “building up” strategy.

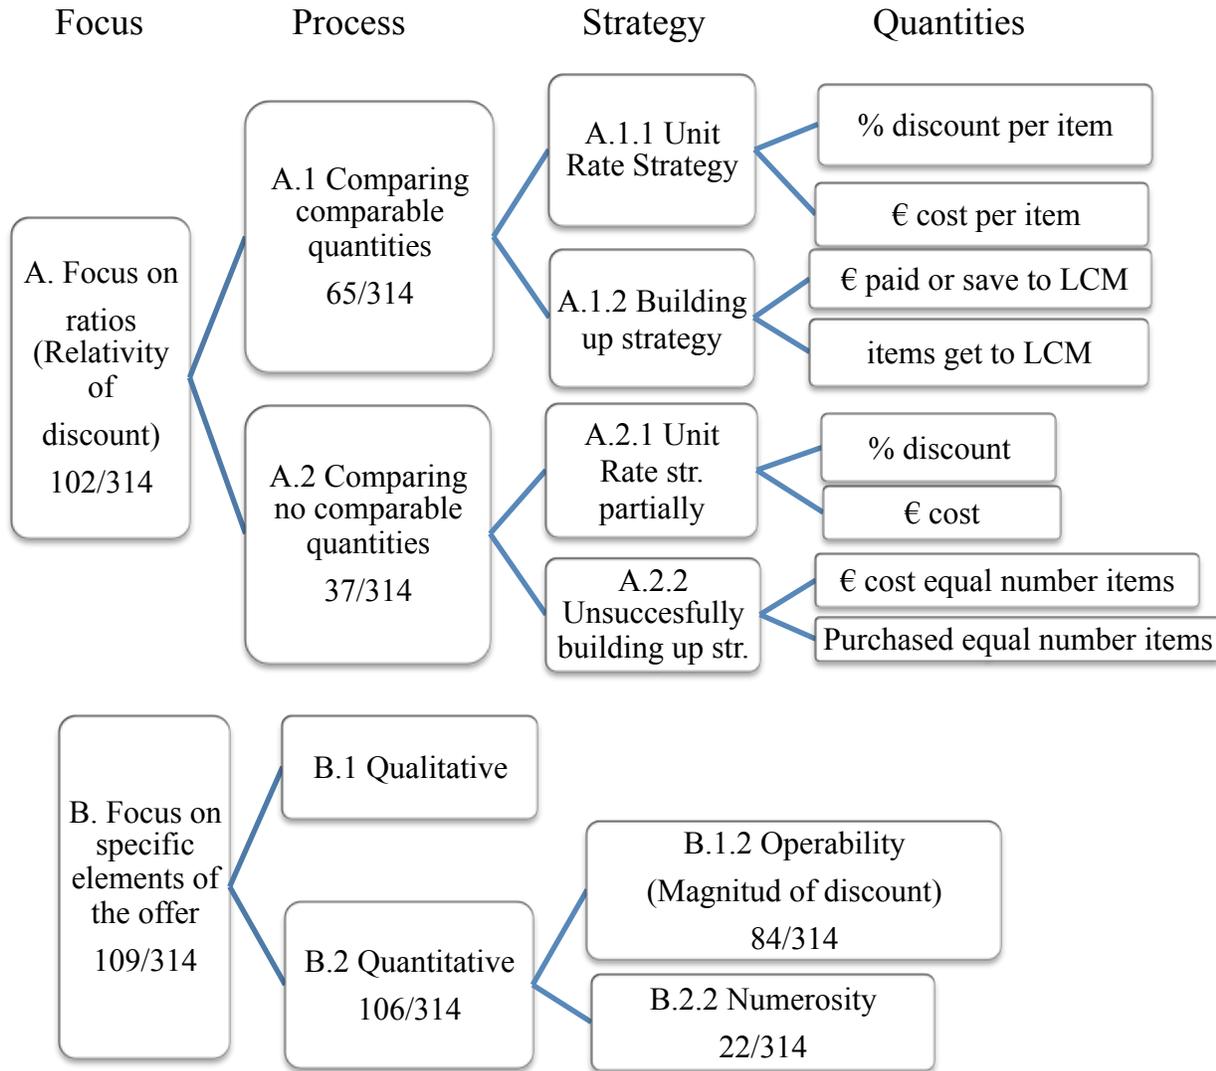

Finally, subclasses are obtained according to the quantities that are compared: discount per item or cost per item related to the unit rate strategy; cost of the LCM items or paid items purchasing the same number of items in building up strategy.

The second category comprises responses by students who perceive the discount as a feature depending on the item to be purchased.

Subcategories are established by distinguishing between qualitative and quantitative approach. The first subcategory gathers those responses that focus on aspects such as quality of the product, size of the bottle, and so on. The second subcategory includes responses that focus on particular numerical data of the discount.

In the quantitative subcategory, as a criterion to distinguish between classes, we observe whether the students focus on the operation (with the prices in the ads) or the number (how many bottles I am given).

Figure 2 graphically organizes these categories, subcategories, classes, and subclasses, as well as the frequencies obtained.

Incomplete or not identified answers were 103

Figure 2. Categories, subcategories and classes

EXAMPLES

A description of examples of each class follows.

A.1.1. Unit rate strategy

In this class there are two response patterns: in the first one the percentage of the discount is calculated and in the other one the unit price.

Example 1. In the first offer, Maria uses the rule of three to calculate the percentage paid for each item. Her calculations are: $100/5.58=x/3.72$; $x=100 \times 3.72/5.58=66.66\%$. From this, she obtains the percentage of discount per item by subtracting $100-66 \approx 33\%$. In the second offer, she divides $50\% \div 2 = 25\%$. In the third offer she divides $70\% \div 2 = 35\%$. Finally she states that "the best deal is 70% off the second item.

Example 2. Juan says: "the item costs €5. Applying $3 \times 2 \rightarrow$ items €10, $10 \div 3 = €3.3^{\wedge}$ for each item. Applying second item half price: 1st item is €5, 2nd item is €2.5, adds

up to €7.5, I divide $7.5 \div 2 = €3.75$ for each item. Applying the discount to 70% off second item, the 1st item is €5, 2nd item $70/100 \times 5 = €3.5$; $5 - 3.5 = 1.5$ 2nd item". Next, he writes: $5 + 1.5 = 6.5$, he divides $6.5 \div 2 = 3.25$, and he states: "The best deal is 70% off second item".

These students have compared comparable quantities. Both have applied the unitizing process to refer the offers to one bottle, and the converting process to transform offers in percentages. One student has used the offered price 5.58 to converted 3×2 ; the other, has assigned the same price €5 to all the offers.

A.1.2 Building up strategy

In this class there are also two response patterns: in the first one the number of items we get free buying the same number (LCM) of items is calculated, and in the other one, the discount or the cost to a same number (LCM) of items is calculated.

Example 3. Paco claims that "at first glance we wouldn't be able to make comparisons so we took the least common multiple of the items we purchase, which in this case is $\text{LCM}(2, 3) = 6$. Now we can make comparisons. In the table we can see that the best deal is the third one (70% off second item)."

	Items we get	Purchased items
3x2	6	4
Second item half price	6	4.5
70% off second item	6	3.9

Example 4. José states the following: "If a bottle costs €10: 3x2 means that you get 3 and pay for 2, e.g. 3 bottles for €20, 6 bottles for €40, 9 bottles for €60. 70% off second item: 70% of €10 is €7 → second bottle €3, so 2 bottles €13, 4 bottles €26, 6 bottles €39, 8 bottles €52; 50% off second item (half price), 50% of €10 is €5 → second bottle €5, so 2 bottles €15, 4 bottles €30, 6 bottles €45, 8 bottles €60. The best deal is 70 % off second item".

These students transform the ratios given in the advertisement into a verbal form in order to compare comparable quantities: "a to b", using the least common multiple of the number of bottles offered; in one case this is done without prices and in the other one the same price is assigned to all the items.

A.2.1 Unit rate strategy partially

In this class a unit rate strategy is not used in all the offers since the students end up comparing the percentage of discount or the unit price in the 3x2 offer with the percentage or cost of the discounted item (the second item) in the other two cases.

Example 5. Jesus says "the highest discount percentage is the best". First he calculates the price of three bottles of Rioja without a discount: " $5.58 \times 3 = 16.74$ "; next he calculates the price with a discount: " $3.72 \times 3 = 11.16$ ". He uses the difference between these two prices ($16.7 - 11.16 = 5.58$) to calculate the percentage of discount

by using the rule of three: $5.58 \times 100 \div 16.74 = 33.33\%$ ". However, he compares this with the percentages of discount in the second and third offer that only refers to the second item: "70% and 50%"

Example 6. Susana writes the following: "Price: 3€. Discounts: 70% off $\rightarrow 3 \times 70 \div 100 = 2.1$ which is 70% that must be subtracted from the item, $3 - 2.1 = \text{€}0.9$. R: €0.9 applying 70%. $3 \times 2 \rightarrow$ the product costs €3 and we would purchase 2, $3 \times 2 = 6$, as we get 3 products we divide: $6 \div 3 = \text{€}2$. R: €2 applying 3×2 . 50% $\rightarrow 3 \times 50 \div 100 = 1.5$ which is 50%; $3 - 1.5 = \text{€}1.5$. R: €1.5 applying 50% off. As we can see the best deal is 70% off."

These students have compared no comparable quantities. Both have applied the converting process to transform 3×2 in percentage, but fail in unitizing since they do not calculate the discount per item purchased in the second and third offer and they directly deduct 50% and 70%, to compare it with the discount per unit purchased that has been calculated for the first offer.

A.2.2 Arbitrary building strategy

In this class, the students apply the discount to the same number of bottles, but they do not use a common multiple, thus making it meaningless to compare these items.

Example 7. Patricia points out for example "5 items: 70% off \rightarrow you pay for 3.4 (mistake, is 3.6) items, $3 \times 2 \rightarrow$ you pay for 5 items, second item half price \rightarrow you pay for 4 items. The best deal is 70% off".

Example 8. Marta writes "each item costs the same, for example €10, and in the 1st I would buy three items for €20 (€10 savings); in the 2nd three products would cost €25 (5€ savings); and in the 3rd three items would cost €27 (€3 savings); therefore the best deal is the 1st".

B.1 Qualitative

This subcategory includes those responses that are not a consequence of numerical calculations but rely on superficial aspects of the products that appear in the advertisements.

Example 9. Ana says "I would say that it depends on the product and the quality as to whether it will be cheaper or more expensive. In addition, it is important to see the amount in each bottle. With this information, relations can be established."

For this student, the concept of discount is linked to qualitative elements of the wine.

B.2.1 Quantitative, operability.

In this class the students perform arithmetic operations with the intention of calculating the magnitude of discount, without relativizing or making the required transformations to obtain comparable elements.

Example 10. Laura carries out the following operations: 3×2 , $3.72 \times 3 = 11.16 \rightarrow 3$ bottles. In the case of the second item half price: $4.87 + 9.74 = 14.61 \rightarrow 2$ bottles. She

concludes by saying: “1st =3 bottles=€11.16 ; 2nd =2 bottles=€14.61; Here you can see the cheapest option”

This student’s solution is dependent on the prices and number of bottles that appear in each advertisement. Thus, she ends up comparing the total cost of buying three bottles of the first wine (which has a price) with the cost of buying two bottles of the other wine (which have a different price). She does not use the 70 %'s option because there no number of bottles is given it can be applied to.

B.2.2 Quantitative, numerosity.

This class groups together those responses in which the quantity of purchased items is the solution to the proposed task. The other aspects (such as those that are related with the cost) are neglected.

Example 11. Pablo writes “With 3x2 you buy two bottles and get one free, without having to pay anything. $9.74 \times 2 = €19.48$ for three bottles. With 50% you pay €9.74 for one and €4.87 for the other, so you buy two and you do not get one free. With 70% you buy two bottles, one for €9.74 and the other for €2.92 so you pay for two bottles. Therefore, the best deal is 3x2 because you buy two and get one free.”

For this student the best discount depends only on the number of items you get for free. In the case of 3x2 you get three bottles and in the other two cases you only get two bottles.

FINAL REMARKS

In this paper we categorize data related to a maieutic task that involves ratio notions.

Based on the classified response patterns, we should continue with the teaching maieutic protocol, working with pre-service teachers. Now, in a same session, we can propose the task and implement the metacognitive maieutic questions because (although unknown the student’s specific answers) we know their way of thinking and their possible response patterns in advance. Consequently, the maieutic questions are not improvised, because they relate to the response patterns that have been found in this study.

In our current stage of investigation we attempt to test the maieutic protocol. With the questions for the moment of reconstruction: How did he/she solve it? What is the base he/she used? What do you think about the subject? On what does the discount depend? We expect that students are confronted with their intuitive notions of discount and ratio and become aware of the limitations of their ideas. Furthermore, we expect that students explain their reasoning, listen and make sense of other’s solutions, focus on the relativity of the discount and on the equivalence of the part-whole strategy, the unit rate strategy, and the building up strategy. Thereby, we expect that with this reflection students will not feel ashamed and will not get the feeling, that they are only competent with teachers’ help.

REPLACING COUNTING STRATEGIES: CHILDREN'S CONSTRUCTS WORKING ON NUMBER SEQUENCES

Uta Häsel-Weide & Marcus Nührenbörger

IEEM, TU Dortmund, Germany

In mathematics didactics, consensus widely prevails on the importance of using patterns and structures for effective and flexible computation. It is equally known that children who are using counting strategies when solving problems do not perceive relations between numbers and operations. Because of this, the central objective is to replace counting strategies by realizing, recognizing and using structures. Within the context of the project ZebrA (Zusammenhänge erkennen und besprechen – Rechnen ohne Abzählen¹) different lessons were developed to encourage children to use different interpretations of patterns and structures instead of counting. In this paper, the results of the video-based qualitative analysis of teaching/learning situations in the field of number sequences are discussed.

Key words: counting, difficulties in learning mathematics, number sequences, cooperative learning, interpretative approach

INTRODUCTION

Counting as computational strategy

Several studies have shown that young children are able to solve simple arithmetic problems using counting strategies (Krajewski & Schneider, 2009). Therefore, on the one hand, procedural knowledge of counting is needed. Fuson (1987) describes five levels in counting development beginning with string level, where the children interpret the number sequence as whole like a poem, followed by the levels unbreakable list, breakable chain, numerical chain and on highest level the bidirectional chain. Now it is possible for the children to count in stages forward and backward from a lower to a higher boundary. On the other hand, conceptual knowledge is necessary, like understanding the cardinal principle. During and in addition to the development of counting competency, an understanding of cardinals is developing and has to be developed (Desote, Ceulemann, Roeyers & Huylebroek, 2009). The approach to numbers by counting has to be combined with an approach to an understanding of quantities. As a result of both competences, children are able to see relationships between numerical quantities and between numbers in the numerical sequence (Krajewski & Schneider, 2009). The awareness of structural relations can be used for solving an addition or subtraction task, for example children calculate $8 + 6$ no longer counting six steps on from eight but rather decomposing 6 in 2 and 4 and compute like $8 + 6 = 8 + 2 + 4 = 14$. A central aim in mathematics education must be

¹ Recognizing and speaking about connections – calculating without counting out

to develop these structural relations in the numerical sequence and between quantities and use them in problem solving.

But mathematical understanding does not develop in every case in the way described above. There are children who do not build up an awareness of numbers as quantities and relations. They get caught in the interpretation of numbers as ordinals and do not use structural relations between numbers when solving problems. In an actual study (Gaidoschik, 2010), a central result is that changing the strategy from deduction to the use of memorized facts takes place significantly more often by first-graders than changing from a counting strategy to memorized facts. Gaidoschik (2010) supposes a reason in the facility of counting strategies which could lead to a persistence of counting on. In the number range up to 10 or 20, counting strategies can be used successfully instead of efficient computational strategies. But counting computation is not a strategy that works in higher number ranges. Furthermore, it often comes along with a mechanical, non-reflected procedure as well as an isolated problem solving. There is a risk that the missing insights develop into comprehensive problems in mathematics education. Children with learning disabilities in mathematics are often using persistent counting strategies as their main computational strategy (Moser Opitz, 2007).

Whereas the importance of an awareness of mathematical structures for non-counting computation is stressed and can be caused in different ways, little is known about the way in which children with mathematical difficulties realize number patterns and structures. The primary question is if and how an explicit focusing on these structures in mathematics education can motivate a replacement of counting strategies. The replacement is necessary because non-counting calculation works only when using structures. Interventions focusing on the fostering of structures have led children with difficulties in mathematics to better results in standardized tests (Dowker, 2001; Kroesbergen & van Luit, 2003). But these studies do not answer the questions as to how the children realize structures and which steps are important for them to do so. Empirical findings are missing how children who are using persistent counting as their main strategies interpret numbers, operations and how they develop a structural focus on arithmetical patterns.

Interpretation of structures as a constructive and social process

As concepts of mathematics, structures and patterns are abstract and not visible. They must be constructed individually when sighting signs (Steinbring, 2005). Numbers, operation-signs, representations can be taken as signs into consideration and also as arithmetic patterns. All signs have to be interpreted. Interpretation is an active process that each child has to perform on its own, although the community in a class is important. Studies focusing the development of new mathematical knowledge of children emphasize the relevance of interactive settings (Steinbring, 2005). The new knowledge could be built up in situations where children reflect their own perception and relate it to the perception of others. As such, the students participate in the mathematical practices in the classroom, create interpretations and negotiate

meanings or resolve conflicts (Cobb, Wood & Yackel, 1991). But not every cooperative and interactive act leads to new knowledge. On the one hand, the given tasks and the cooperative discourses about them seem to have great influence, on the other hand the suggestions of the teacher seem to play a central role. Directed suggestions, interventions or instructions for cooperative organized learning situations can cause communication between children, which can lead to the construction of new mathematical knowledge (Nührenbörger & Steinbring, 2009).

PRESENT STUDY

The difficulties of children using counting as their main computational strategy can be reduced to arithmetic contents of the first two years at school (Moser Opitz, 2007). In fostering children, it is important to not only revise the contents, because an education without results becomes not more successful if it is revised in the same way (Lorenz, 2003). It must be examined if cooperative learning leads to an enhancement of individual interpretations – especially to a (more) structured focusing view of the children with persistent counting strategies.

The present study is a part of the project ZebrA. In the project, learning environments with cooperative elements for second grade in primary school or for fourth grade in special education schools have been developed, field-tested and evaluated (Häsel-Weide, Nührenbörger, Moser Opitz & Wittich, resp. 2013). Twenty units have been constructed to support children in replacing persistent counting strategies. The learning environments focus on understanding, demonstrating and imagination numbers and operations as well as the relations between them. All children of the class are taking part in the lessons. The tasks permit a fundamental awareness of mathematical structures and at the same time a deeper understanding of structures. The engaged material is sophisticated and allows learning at different stages of understanding. To initiate various interpretations, the students are working together in pairs. Each child who uses counting as its main computational strategy works with a partner who uses other strategies. The methodical design of the learning environments encourages them to exchange views on the given tasks. The tasks are given in a discursive way, so that they cause different interpretations to the end that an awareness of structures is stimulated and interpretations are enlarged. This design is innovative because fostering children usually happen in one-to-one situations or in small groups with up to 10 children outside the normal lessons. However in the ZebrA-project an integrative approach is chosen regarding different competences of children as a change for development.

The study was realised from September to December 2010. The teachers of the participating classes gave the lessons. They had taken part two times in an advanced further training, where they became confident with the concept of ZebrA. The ZebrA Project is accompanied by two empirical studies which allow focusing the replacement of persistent counting strategies from different empirical points of view. Whereas the quantitative study researches the effects of cooperative fostering

(Wittich, Nührenbörger & Moser Opitz, 2010), the study presented in this paper focused on the interpretations of children dealing with the problems and discussing with the partner. The aim of this study is to identify and describe interpretations of children with mathematical difficulties and their development during fostering.

In order to identify children using counting strategies as persistent computation strategies as well as children using non-counting strategies the data of the quantitative study was used (results of different tests, rating of the teacher). Five children and their partner – belonging to four different classes and three schools - were chosen for the qualitative study. Their work was video-graphed in ten lessons of the ZebrA-project. Corresponding transcripts were interpreted by a group of researches (Krummheuer & Naujok, 1999). The analysis has been compared in an interactive way with empirical findings of other studies and theoretical approaches, with the result, that new insights about the interpretations of children with mathematical difficulties could be constructed. This procedure allows for the development of new theoretical elements analyzing individual cases. Concerning the present study, these could match with a characterization of typical interpretation of children using persistent counting strategies.

ANALYSIS OF AN EPISODE

The procedures and interpretations of the student Kolja (fourth grader of a special education school) working on the learning environment “number sequences” are analyzed exemplarily. First, the content of the environment is explained, followed by the presentation of the documents, procedures and interpretations noticed in the discourse with his partner Medima.

Content of the learning environment: number sequences

In this lesson, the students work on number stripes, which correspond to arithmetic sequences (Fig. 1). The sequence reflects on ordinal and relational interpretations of numbers by counting development described by Fuson (1987). Some of the stripes initiate counting in steps of one, others counting in steps of two or ten. Some sequences allow counting on, some require counting back. The number sequences are given to the students on stripes and their first task is to fill them. In a second step, the students sort the stripes focusing on the relations between them (such as distance between numbers of a sequence, starting number, multiplication of number or constant difference between sequences). Afterwards, the students are asked to find other compatible number sequences and note them on free stripes. These self-productions could illustrate the insight of the relations on the one hand, and on the other hand, they enable children to work on their individual level of understanding. The use of number sequences seems to be astonishing in the first view, but number sequences allow the children to bring in their common strategies and develop them further. Children with persistent counting strategies often only are used to count on in steps of one, but filling the stripes encourage other more elaborated strategies like

counting in steps. Sorting stripes and finding new fitting ones should change the attention towards the realizing of mathematical structures.

Kolja completes number sequences

Kolja, a student using persistent counting as his main computational strategy, completes the sequences as shown in figure 1².

10	20	30	40	50	60	70	80
1	2	3	4	5	6	7	8
6	7	8	9	10	11	13	15
12	14	16	18	20	22	24	26
1	2	3	4	5	6	7	8

Figure 1: Reconstructed number sequences filled by Kolja

The documents show that Kolja seems to be able to find sequences with the difference of one. Equally, it seems to be no problem for him to count on in steps of ten. Sequences with the difference of two, which can be found by counting on are filled correctly, too. Only the number sequence which requires counting back in steps of two seems to be difficult for him. Using the document only, it is not possible to point out if Kolja does not realize the mathematical structure in the given number sequence or if he is not able to keep the distance when counting back. But it is striking that the wrong sequence corresponds to the highest level of the counting development described by Fuson (1987). Considering Kolja's approach in the videotape, it could be seen that Kolja counts on when he finds the numbers in the sequence $_ , _ , _ , _ , _ , 6, 7, 8$. Starting with one, he counts on and controls if the sequence fits, as it does in that case. Similarly, Kolja finds the sequence 6, 7, 8, 9, 10, **11, 13, 15**. Two times he seems to count on tapping with a pen from left to right on the free fields before he then filled the numbers starting with 10. This may suggest that Kolja has problems in counting back generally, as pointed out by Moser Opitz (2007) to be typical of children with mathematical difficulties.

Kolja and Medima sort the stripes

After completing the stripes the teacher tells Kolja and Medima that they now should sort the stripes. She asks if the stripes fit together.

- 1 Kolja: Yes, that (*points to the number stripe that is located at the very bottom in front of him*)

² The numbers in bold print were given; the other numbers were notated by Kolja. The stripes are present in chronological order.

1	2	3	4	5	6	7	8
---	---	---	---	---	---	---	---

fits to that (points to the number stripe that is located as the second from the top in front of him)

1	2	3	4	5	6	7	8
---	---	---	---	---	---	---	---

- 2 Medima Sorry? I didn't understand.
- 3 Teacher Put together in order these sequences of numbers, ok?
- 4 Kolja One, one, two, two, three, three, four, four, five, five, six, six, seven, seven, eight, eight
- 5 Medima Oh, yeah
- 6 Teacher Why do these fit?
- 7 Medima Because they are the same (*pointing alternately to the numbers of the upper and lower number stripe*).

Kolja's first idea to sort the number sequences is to match identical stripes. He explains this in reading out the numbers in pairs (4). Medima seems to understand immediately (5) but the teacher asks for a further explanation (6), which is given by Medima. She explains the matching with the equality of the numbers and underlines her statement in pointing to the numbers by turns.

In the further course of working, the children try to sort the other stripes in the same way, but there are no more identical sequences. Afterwards, they attempt to find matching sequences with the same starting number. Because they regard the distance between the numbers as a second factor at the same time, they do not find matching stripes. The consideration of both factors engender that they are searching for identical sequences again. To the children it is, however, not clear that considering both aspects is already the same as looking for identical stripes. They try to fit the stripes by shifting (Figure 2). But they do not find a position which allows a pair-wise order for a couple of numbers and then they give up these tries.

14	15	16	17	18	19	20	21
14	16	18	20	22	4	26	28

Figure 2: Shifted stripes

The relations considered by the children seem to be guided by the appearance of the number sequences. Exact congruence of stripes seems to be critical. They are comparing the numbers one after another with each other and are looking for identity. Matching relations like same distance between numbers or sequence initiate counting on or counting back are not discussed so far. This corresponds to other empirical findings of the Zebra Project (Häsel-Weide, 2013). As this way to sort does not lead to results, Medima suggests a new possibility to order. She matches number sequences with the difference 10 between each position to another.

- 8 Medima: Found another one (*pulls two stripes over to her*).

2	4	6	8	10	12	14	16
12	14	16	18	20	22	24	26

- 9 Kolja: Yay

- 10 Medima: (laughs) You see? Eight (*points to the "12" on the bottom number stripe*) oh, twelve (*points once again to the "12"*), two (*points to the "2" on the top number stripe*), fourteen (*points to the "14" on the bottom number stripe*), four and so on (*moves the pair of number stripes below the one she had previously found*).

- 11 Kolja: (*moves two number stripes that were located in front of him together*) Look. Six, ten, seven, twenty, eight, thirty (*points each time to the number mentioned on the number stripes that are located right underneath one another*) (*points to the "9" of the top number stripe*) (.) doesn't fit

6	7	8	9	10	11	13	15
10	20	30	40	50	60	70	80

Medima explains to Kolja why the sequences match, in spite of the acknowledgement of Kolja before (9). In her explanation, she names the numbers pair-wise (10). She does not give a general description or an argument as she did in the dialogue with the teacher. Kolja seems to adopt the idea and tries to realize it with the residual stripes. He takes two of them and compares the numbers pair-wise, responding to their positions in the number sequence. After he has looked at three pairs, he decides that the sequences do not fit. He does not give a reason either, but reads the numbers aloud. Possibly the children check if there is a phonetic matching when reading the numbers. It is not clear if the students consider structural relations between the stripes at that time or if they confine themselves to phenomena which can be realized at the surface such as same digits at the unit position or same sound at the beginning of the numeral.

In the ongoing partner work, the children are asked to find matching sequences in free stripes. Kolja produces identical stripes, copying existing sequences. At the same time, Medima goes on with her idea to increase the numbers. Thereby she seems to mix different techniques to construct matching sequences. The single digit numbers are decupled by appending a zero, while the two digit numbers are increased by ten, changing the ten-position by one. The different chosen techniques show that Medima considers relations between pairs of numbers (3, 30 and 11, 21) more than relations between the number sequences. The different distances between the numbers do not strike her. Once all free stripes are filled out and sorted the children are approaching the teacher.

- 12 Teacher: I think you are so quick, you could probably think of a lot more that fit to them
- ...
- 13 Kolja What is with 100, 200, 300, 400, 500, 600, 700, 800, nine, ten
- 14 Teacher That is great. Where would those fit? To which that you put in order there? When you write down 100, 200, 300, 400
- 15 Kolja (*points to the first box of the empty stripe that is located right in front of him*)
- 16 Medima (*grabs the number stripe depicted below, laughs and displays it*)
- | | | | | | | | |
|----|----|----|----|----|----|----|----|
| 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 |
|----|----|----|----|----|----|----|----|
- 17 Kolja (*fills out the empty stripe*) Yes.
- | | | | | | | | |
|-----|-----|-----|-----|-----|-----|-----|-----|
| 100 | 200 | 300 | 400 | 500 | 600 | 700 | 800 |
|-----|-----|-----|-----|-----|-----|-----|-----|
- ...
- 18 Teacher Great. And now you could think of which other would fit with it. (.) How they then (*incomprehensible*).
- ...
- 19 Medima Do you already have that? Ok. (*grabs two empty number stripes that the T left on the table*) Then we have to put'em together like that (*pushes her stripe briefly underneath Kolja's stripe, then pulls it towards herself again*) But what should we then write?
- 20 Kolja (*pulls his stripe a little towards himself and looks at it*). Infinity, two infinity, three infinity, four infinity, five

In this episode, Kolja seems to modify Medima's idea of multiplication. Kolja's words (13) indicate that he wants to construct a sequence with big numbers and begins counting in steps starting with hundred. The question is whether Kolja realizes a relation between the existing sequences and the new ones and whether he is aware of the multiplicative relations between his sequence and an existing one. At the time when he constructs the sequence, it seems that he refers to a counting context and does not focus on relations to an existing number sequence. Medima seems to understand his idea immediately and detects a stripe that matches her idea of decupling (16). She combines Kolja's suggestion with the activity of sorting stripes. In this way, a relation between both sequences is constructed.

After the sequence is noticed, Medima asks Kolja for an idea to find another fitting stripe. He creates a new number sequence with considerably larger numbers (20). Again, it is not sure whether this sequence refers to a counting context or shows the idea "starting with a power of ten and going on in appropriate steps leads to matching sequences". Because the children have not considered the difference between the numbers in any sequence yet, the last interpretation seems perhaps too optimistic. But relations within a sequence starting with a decimal power may have been realized by Kolja.

INTERPRETATION AND CONCLUSION

The learning environments of the ZebrA Project are intended to help children using persistent counting as main computational strategy to realize mathematic structures. In the analyzed episode we were able to show that in the cooperative partner work an awareness of mathematical structures had happened.

The difficulties to count back in steps pointed out by Fuson (1987) and Moser Opitz (2007) could be seen in the solving process of Kolja. Nevertheless, Kolja has found a way to generate number sequences by testing the fitting of sequences that he generated while counting on. He may show an approach which can be observed in a similar way when children are looking for a previous number. They count on until the given number and in doing so they recognize the previous spoken one.

Sorting the stripes, but most of all finding further sequences, leads the children to dealing with the relations between the number sequences. Kolja succeeds in expanding his interpretation of equality; first he reconstructs structural relations and then uses them to find matching sequences on his own. In the realized relations, a general understanding is indicated. Both children exceed their common number space. Nevertheless, the realized relation of Kolja is limited to only one and that requires a long period of working with the material. This indicates that children with mathematical difficulties may need an extensive period of working with materials and several opportunities to become aware of mathematical structures. The ZebrA Project shows that it is possible to initiate children using persistent counting as the main computational approach to realized relations between structures, but an intensive fostering may be needed for them to become familiar with structures.

There are positive effects from Kolja's interpretation, resulting from the collaboration with Medima. She initiated an alternative interpretation and as a result the children take into consideration the mathematical relation of multiplication. The intended cooperation between a child using persistent counting as the main strategy and another works out in these instances. But Kolja is not a passive partner either: Sorting started with his idea to find equal stripes and he comes up with the number sequences with decimal power. Notwithstanding the good cooperation and communication of the students, the episode shows that the communication changes in the presence of the teacher. While the students among themselves are speaking mostly without descriptions and are using gesticulations to demonstrate their thoughts, they try to find arguments when they are asked to do so. It appears as if asking for a description or an explanation to explain the structures may be the job of the teacher.

WHY AND HOW TO INTRODUCE NUMBERS UNITS IN 1ST-AND 2ND-GRADES

Abstract. Learning and teaching the decimal number system is well known by researchers as more difficult than the common adult user thinks of. This paper aims at studying some semiotic problems -how are denoted the quantities and what quantity denote the whole numbers- from different points of view, epistemological, institutional, didactical. It develops a few propositions for solving them, based on the introduction of a language referring explicitly to tens (numbers units) and specific materials (hand fingers) giving meaning to this language.

INTRODUCTION

According to our function as teachers educator we were asked by the whole team of a school (grades 1 to 5) for helping with the teaching of natural numbers. This request was the pretext for pursuing the reflexion about the teaching of the written- in the Hindu-Arabic and spoken-number systems, learning from recent French didactic research, notably through institutional (Chevallard 1992) aspects.

This paper focuses on the teaching and learning of the spoken- and written-multidigit-numbers by 6-to-8-years-old students (in France, grades 1 and 2). In our paper, "26" is called a *written-number* whereas "twenty-six" is called a *spoken-number* and "2 tens 6 ones" a *numbers-units-number*. Among the knowledge young children have to learn and to understand: how the multidigit-numbers are constructed from a semiotic point of view? How the written-multidigit-numbers and the spoken-numbers denote a determined quantity? We will address the question of the teaching of spoken- and written-numbers between 1 and beyond 100 from a semiotic, didactic and institutional point of view.

Our main question is: what tasks should contain a guide in order to engage 1st-and-2nd-grades-teachers to revamp their teaching of the written- and spoken-decimal systems of numbers?

SOME ELEMENTS ABOUT THE WRITTEN AND SPOKEN NUMBERS

Written numbers: semantic and syntactic aspects

We consider the multidigit-numbers like a language with its semantic and syntactic aspects. Why this point of view? The syntax seems simple, but powerful: any digit-concatenation denote a numeral and a quantity. Each digit of the ordered list 1 to 9 denotes a quantity, one for one object, and the successor, one more than the precedent. For a quantity bigger than 9, 1 moves to the left and a digit 0 takes the right place, following by 11 12 13...: the going on written-numbers list respects again

the same progression for the right digit, up to 9; then the digit on the left becomes 2 and the right one follows again the progression from 0 to 9, and so on. It is what we named the recursive aspect of the written-numbers list. A good understanding of written-numbers recursive algorithm permits to order written numbers without understanding the semantic aspects.

With regard to semantic aspect, how to know what quantity denote a multidigit-number? "Written numbers as partially iconic signs" (Ejersbo & Misfeldt, 2011, p.301), we will precise only very little iconic: number of different lengths can be easily compared; but how to understand that 52 is different and major than 25? The place value system owns genius aspects, but these aspects remain not known by young students who often consider 52 as 7.

The specific role played by the digit 0 in the written numbers is a semantic aspect: 0 indicates the lack of an isolated power of ten, e.g. 0 indicates no isolated one in 450, no isolated ten in 203, still there are 450 ones in 450 and 20 tens in 203.

A few words about spoken-numbers in French language and research

The names of the numbers units are different from those of the powers of ten, as summarized in the table below: with units, 423 is 4 "centaines" (4 hundreds) 2 "dizaines" (2 tens) 3 "unités" (3 ones), it is also 4 cent (4 hundreds) vingt (twenty) trois (three). Another difficulty: the same word "unité" is used in a context of units of measure or account, but also to describe the quantity "one".

	1	10	100	1000
English	one the ones	ten the tens	hundred the hundreds	thousand the thousands
French	un, une les unités	dix les dizaines	cent les centaines	mille les milliers

Table 1: Names for numbers and for numbers units in English and French

Mounier (2010) highlights four aspects of the spoken-numbers: "forty six" is 1) four times tens plus six: multiplicative, 2) forty plus six: additive, 3) a place in an ordinate list of words, one, two..., forty five, forty six: ordinal, 4) a place in a list of words (ten, twenty, thirty...) with counting words (one, two, three..., nine), six after forty: ordinal with marks.

NUMBERS UNITS: A DIDACTICAL NECESSITY

To tackle with the signification of spoken- and written-numbers, we stress the introduction of another system of denotation of quantities, using "numbers units" (Chambris 2008): ones, tens, hundreds, etc. - which are units of account - and not only the names of the places of the digits. Freudenthal (1983, p. 90) spoke of "decimal bundling" and "positional arrangement of the bundles", but like Fuson & al (1997), Chambris (2012) emphasizes the necessary and difficult double point of view on the bundling: 10 ones is 1 ten, 1 ten must be understandable as a multiplicity (10) and a whole (1 unit of ten), that Thanheiser (2009 p.253) names "a flexible view of unit types (e.g. ten)". This is an important stage aiming for spoken and written

number systems understanding, a part of numbers "profound understanding" (Ma 1999 p. 122).

Why to introduce these numbers units? We synthesize some arguments of Chambris (2008), partially used in Van de Walle (2007). First, they enable teachers to reveal and students to approach the coherent iterative organisation concatenating digits and to estimate the "order of magnitude" of the number. Second, they were used in pedagogic arithmetic theory to describe numerations -for example Condorcet 1794- and in text books prior the new math reform. Third, they enable to express the systemic relations between the different units which are represented by places in a number: 1 ten = 10 ones = 10; 10 tens = 1 hundred = 100 ones = 100... Naturally: the use of numbers units needs the introduction of activities that help students construct the sense of these units. Fourth, they highlight many useful relations for computation: $24+58$ is first 7 tens and 12 ones, and thus 82 (this explains the carries in the column operation); for the integer division of 245 by 7: the decimal aspect takes into account that 245 is also 24 tens and 5 ones, 245 doesn't contain only 4 tens, but 24 tens, and thus the quotient is 3 tens and 5 ones. Fifth, in the later teaching they will prepare and strengthen the SI units (length, weight....). There is a sixth reason to introduce the numbers units: forty six is four tens and six ones, it may help to switch from an ordinal to a multiplicative aspect of the spoken-numbers.

Numbers units own the property to be said and written exactly the same way whereas written-numbers and spoken-numbers are often no congruent in French like in other languages (Ejersbo & Misfeldt, 2011), that is a big problem for teachers when speaking about quantities (Mounier 2010). **Numbers units bridge a gap between spoken- and written-numbers** as a flexible "*base-ten language*" (Van de Walle 2007 p189): standard oral name *forty two*; base-ten oral name *4 tens and 2* ; standard written *42*; explicit base-ten written *4 tens and 2 ones*. *4 tens and 2 ones is also 3 tens and 12 ones*, etc. This conversion IN the base-ten-language is formed and proved by two partitions (Ross 1989) of the same collection. This is a seventh reason to teach numbers units and it has something to do with the third reason.

THE FRENCH INSTITUTIONAL STATE OF MULTI-DIGIT NUMBERS TEACHING

For US researchers and many teachers (e.g. the readers of Van de Walle 2007) numbers units and their consequences may be very usual. But in France, as we will partially see, it is not: the contexts of national curricula (contents and developments of theses contents), usual teaching and training practises, type of national dominant researches... can be very different. So, we now present how multidigit-numbers are taught at French primary school.

At pre-school, children are used to seeing and reading the written-numbers (usually from 1 to 30) like they are used to the written-language. The French curriculum texts don't give any indications about natural numbers teaching complexity: in the most

recent ones (2008) "place value" or "base-ten-number system" is not written anywhere. For example, what concerns expectations:

- 1st grade-students should "know (write and name) natural numbers less than 100; produce and recognize additive decompositions of numbers less than 20 (addition table); compare, order, frame numbers less than 100; write numbers in ascending or descending order ; know numbers-less-than-10 doubles and numbers-less-than-20 halves".
- 2nd grade-students should "know (write and name) natural numbers less than 1000; place and locate these numbers on a number line, compare them, order them, frame them; write or tell sequences of numbers 10 by 10, 100 by 100, etc; know usual-numbers doubles and halves." (MEN 2008 p2)

Further, Chambris (2008), using the anthropological theory of didactics (Chevallard 1992), shows that in the French primary school, from the 1980's, numbers-units have "disappeared". They remain as "names places". As "units", they have been replaced by powers-of-ten, written in figures (1, 10, 100, 1000). For instance, $2 \times 100 + 3 \times 10$ (or even $200 + 30$) has replaced 2 hundreds 3 tens but 3 is still called the tens digit in 230. We don't know what is the institutional state in other countries but there are clues that similar things may have happened at other places: Fuson (1992) wondered why students wrote such writings and indicated that these types of writings do not help to learn the number words; Ma (1999), Thanheiser (2009) let us think that numbers-units may be taught as places, and not as units, in the USA.

Recent French didactic research highlights the weak knowledge of the in-service teachers. It may be a possible consequence of the curricular text that don't focus on these points: the students are taught the positional aspect of the written numeration, 52 is different from 25, they don't have the same position in the usual well-ordered number list 1, 2, 3..., 25..., 50, 51, 52; but the teachers don't systematically emphasize the decimal reason of the order of written numbers: 52 denotes 5 tens and 2 ones while 25 denotes 2 tens and 5 ones. Even in greater numbers, many teachers (especially in the studied school) reduce the tens in a number to the isolated tens, highlighting the tens digit. That teaching can create a didactical obstacle (Brousseau 1997) preventing the students from constructing and/or understanding computation algorithms. When the teachers intend to teach the decimal aspects of the written-numbers, they use the spoken numbers, especially the known order of the multiples of ten: ten, twenty, thirty... (Mounier 2010).

The question is now: how to provide teachers some tasks to teach 1st-and-2nd-grades students numbers-units in relation with the written-numbers and quantities so that they better understand the semantic of written multidigit-numbers? First we must choose materials, easy to find and to manage, giving sense to numbers units. Second we must convince them of the usefulness of the introduction of the numbers units.

HOW TO CHOOSE MATERIALS?

We share many of the "base-ten ideas" of (Van de Walle 2007 chapter 12: counting plays a key role, especially the dialectic between counting by ones and by tens.

Unlike Van de Walle (2007, p193) we think we don't let the students choose their way of grouping, we have to impose grouping by ten, even if grouping by two or five may be more spontaneous. Certainly grouping by five and counting orally (by five or by ten...) could be interesting and it is easier to control 5 bundles than 10. But there is a bigger semiotic distance between numbers of fives and decimal standard spoken- and written-numbers: 43 and forty-three is 8 fives and 3 singles and also 4 tens 3 ones which looks more like 43. Moreover, whatever the way of grouping, students need to learn what is *a ten*. Even if they spontaneously group by 5, they need to learn what a ten is -which is not a group, not even a group of ten but a unit of account-. So, they have to learn to count one by one (one, two, three), ten by ten (ten, twenty...) and tens (one ten, two tens...). This last way of counting does not lie in (Van de Walle 2007).

Guitel (1975, p.25) stressed the predominance of usual bases in written numerations: 10, 20, 60 as principal basis; 5, 100 and even 10000 as secondary one. From a historical point of view this common characteristic of the mankind offers a credible hypothesis for the choice of ten in many base-numerations over the world and the times. It is a track to analyse how numeration "is bodily- grounded that is, embodied within a shared biological and physical context" (Nuñez & al 1999 p.46). The English language gives another track: the word *digit* literally means finger or toe too.

Counting activities will be in the heart of our didactical proposition in 1st-and-2nd-grades. Our semiotic approach makes us vigilant on the first material we offer to students, it must integrate and naturalize so far as possible the grouping by tens : we choose the hands fingers.

Many school practitioners suggested and suggest their students to use their fingers in order to denote quantities less than 10 or to construct the different additive decompositions of 10. We agree with Ladel & Kortenkamp (2011, p.1795): the 10 fingers qualify the hands to work out questions about the decimal number system, e.g. "*How many children do we need to see 30 fingers all at once?*": 3 children

Seeing ten (or several tens) as the set of my hand-fingers (or a reunion of several-persons-fingers) would contribute (as mental picture and associated properties and processes) to create "a concrete internal mental image" (Thomas & al. 2002) of the ten unit with its double meaning: a one is a unit of account, but a ten (the ten hand-digits of a person) too, 2 tens is not 2, it is bigger than 2, it is twice ten. It is not easy to exceed 100 fingers, but the amount of one hundred will have a strong image, 10 students raise their fingers, as many students as fingers of the hands of a student. Using special expressions (numbers units), writing relations of one unit to another in the context of fingers and of numbers, expanding formally these relations contribute to reinforce the conceptual understanding of written-numbers.

Lamon (1996, p.88) shows that, for older students faced to in partitioning tasks (aiming the fractions), decomposition of a given all into small units appears quite immediately but unitization into composite pieces appears later. The hand fingers

permit to work simultaneously two aspects (decomposition and unitization): showing a quantity of fingers like 32 with few children makes visible 32 singles (the fingers) and its decomposition in 3 tens (the fingers of 3 children) and 2 fingers.

Using first the fingers of the students to describe or produce a quantity owns the three properties (Stacey & al, 2001 p.201) of interesting materials for teaching young children: appeal to the students, accessibility, but especially epistemic fidelity (representing order of magnitude, bundling into tens for numbers under 99, constructing of an incorporated semiotic flexibility of the unit). Later, the students will use other “groupable” material (Van de Walle 2007) like wooden sticks so that they have opportunities to abstract the unit and transfer the ten fingers model in another context.

A DESIGN PROJECT FOR GRADES 1 & 2

The school asking for help is situated in what is named in France "a sensitive zone". The students of these zones suffer simultaneously bad socioeconomic conditions and weaker evaluation results than other schools despite more State helps. We present in this paper the design of a type of activities that respond to certain conditions: short (15 min), repetitive (each day), dynamic, very little expensive in materials and engagement of the students. These activities represent only a part of an entire design about numbers, the part that would consist to embody the concept of unit.

They aim for constructing relation between written-numbers, numbers units and quantities. The usual way the numbers are said in France is not specifically studied in this design. The students are supposed to know (spoken and written) numbers from one to ten at the beginning and also how to realise such sets with their fingers.

Examples of questions that pursue ancient questions with more little numbers:

Type 0: introducing the ten as the first unit that is not a one

The students are asked 1) how many students there are in this group (5, 7, 11, 15, the entire class), 2) to show quantity using their fingers and 3) to write or to say the number if they can. Thanks to the different numbers the students will find a way to show more than ten fingers: several students to produce the quantity... The teacher could say and write: *a student has 10 fingers, a ten of fingers. To show with fingers more than 10, more than one person is needed. Two persons with all fingers up correspond in mathematics with what is named 2 tens, e.g. there are 2 tens of fingers and 3 fingers again, there are 23 fingers, there are twenty five fingers.*

This collective activity is aiming for the construction of the unit, a ten, as a multiplicity (the ten fingers) and a whole: the person - with all fingers up - as a ten. The following propositions are pursuing this construction, giving the students more and more individual responsibility in their responses and so, more and more occasion to understand. Two types of collective activities are described: production activities (P), communication (C) ones. In the first ones, it is more the teacher that validates the responses; the second ones enlarge the interaction between students so that they

validate the responses and argue about the reasons. Type E refers to individual training.

Type P1: production of a set from a written- or spoken- already known number

The students form teams of 4, 5 or 6; the teacher writes a digit-number on board and asks students for showing this quantity of fingers - in the list of numbers students know - for example 8, 20, 26, 32.... Each time some configurations are observed, a realisation with the less students as possible will be encouraged.

8: 1 student with 8 fingers up (and 2 fingers down); 8 units

26: 2 students with all fingers up, 1 student with 6 fingers up (and 4 fingers down); 2 tens and 6 units... Progressively the teacher can let the team propose a solution before trying it.

Type P2: producing a way to write a quantity from a set of fingers

The teacher shows fingers and the students are asked for the quantity. The set of fingers is not showed simultaneously, but successively: producing 23 fingers consists on showing ten fingers twice (twice: fists first closed, then fast opened with all fingers up) and again 3 fingers up.

First the teacher shows quickly quantities in the list of known numbers, then quantities of bigger numbers: students can no longer count one by one, or ten by ten (ten, twenty, thirty..), they must quickly count the times when the teacher shows all her fingers raised, therefore they must count the number of tens... and the isolated ones: the constraints of the situation can change their way of thinking (Brousseau 1997)

Type P3: production of a set from a numbers-units-number

Same activities as P1, but a student can produce its set in front of the classmates, showing the tens successively as learned from the teacher in P2. The way to write or speak the number can be either found by students or given by the teacher or be pended. The teacher may conclude the activity with mathematical words and write a lesson:

8	8	<i>1 student with 8 fingers up</i>	<i>8 doigts</i>	8 unités
26	vingt-6	<i>2 students with all fingers up, 1 student with 6 fingers up</i>	<i>2 dizaines de doigts et 6 doigts</i>	2 dizaines et 6 unités

Table 2: What must being remembered

Type C1: communication between students about quantities denotations.

The teacher gives a paper with a number in numbers units to a team, lets students of the team show their fingers (corresponding the quantity) to all the other students who write the response on their slate. The response is then compared to the original that enables to validate the communication, comparing same writings (in number-units) or both writings (in number-units and written).

The same can be played by team, two teams A and B are associated, in the first time, team A receives the number and shows the collection of fingers to team B, then the role are reversed, the teacher looks at the students

After collective discussion the number is written with numbers units, drawn fingers and digits.

<i>3 dizaines et 4 unités</i>	<i>7 dizaines</i>
3 tens and 4 ones	7 tens
	
34	70
Trente-quatre	Soixante-dix

The name of the number is said and written, with an oral advertising for "oral irregular" names like *soixante-dix* (notice that number names are less irregular in the Belgian French language: *septante* - "seventy" - instead of *soixante-dix* - "sixty-ten") :

The chosen numbers are written by the teacher in canonical form (5 tens and 6 ones), non-canonical form (6 ones and 5 tens OR 2 tens and 16 ones) and will engage specificities: no one (6 tens OR 3 tens and 30 ones) or, more simple, no tens (5 ones).

Type E1: Individual exercises with prepared drawn hands labels and persons:

Labels of a person (conventionally supposed with all the fingers up) or labels of hand are available.

1) A numbers-units-number is given, constructing the fingers collection (with person labels or hand labels) and writing the multidigit number are asked the students. Notice that succeeding using "hand labels" reflects a better understanding of the ten unit. 2) A set of drawn fingers is given, writing the quantity with numbers units and with digits are the questions the students must face to. 3) A written-number is given, constructing the fingers collection (with digits or persons labels) and writing it with numbers units are asked the students.

It would be progressively important that the teacher proposes too "fingers not totally regrouped in hands".

Type C2: activities of communication but with more than ten ones, for example 5 tens and 12 ones. The teacher emphasizes the conclusion: 5 tens and 12 ones is also 6 tens and 2 ones. It is usually written 62, then need all the fingers of 6 persons and again 2 fingers up.

Type E2: Individual exercises

Type C3: activities of communication with more than ten tens, for example 13 tens and 7 ones. The number of persons with all fingers up is 13, and again 7 fingers. *Ten persons with all fingers up form ten tens of fingers, in mathematics a hundred of fingers. 13 tens and 7 ones is also 1 hundred 3 tens and 7 ones*, usually written 137.

Type E3: Individual exercises

CONCLUSION

The previous activities have a main goal: to teach the concept of unit -with the instance of ten- betting on the incorporation of the ten as privileged grouping. Using numbers units enable to improve the semantic understanding of 2-digit or even 3-

digit numbers; it also enables to speak numbers without using their difficult names. Concerning number names, the core is to memorize the relation between the tens names and how many tens in the tens names: e.g. four tens (and five) are forty (five).

The activities are expected to give progressively students more and more responsibility in the control of their responses, integrating the role of tens in written- and spoken-numbers.

We are conscious of the lack of experimental facts that would moderate our development. We would just share our a priori thinking. On the one hand, it is based on some research on learning (base-ten concepts, numbers units as mathematical and pedagogical mean...) and teaching (little trace of numbers-units in French curriculum: if they are used in usual practices it is as places...). On the other hand, it takes into account the constraints we had to face to: convincing the teachers of the utility of a new notion (numbers units), proposing short and regular meaning activities, so that they are not afraid to try them and we can examine in true the effects of their integration.

Nevertheless, some questions rose. How written- and spoken-numbers overlap in the teachers practice? How to manage with the problem of the very irregular number words in French -3 stages from 1 to 100: from ten to 10 to 19 (*dix, onze, douze...*), from 60 to 79 (*soixante to soixante-dix-neuf*), from 80 to 99 (*quatre-vingts to quatre-vingt-dix-neuf*)?

LEVELS OF OBJECTIFICATION IN STUDENTS' STRATEGIES

Andreas Lorange, NLA University College, Norway

Reinert Rinvold, Hedmark University College, Norway

The aim of this paper is to identify students' strategies while solving tasks which involve the expansion of fractions to a common denominator. In this case study we follow two groups of 11 year old students and their use of the artefact multilink cubes in the solution process. The analysis of the students' strategies is based upon a semiotic-cultural framework. Five different types of strategies are reported: trial and error, factual, contextual, embodied-symbolic and symbolic. The naming of these strategy types is inspired by Luis Radford.

Key words: Artefact, common denominator, strategy and levels of objectification.

INTRODUCTION

A lot of research has been carried out involving embodied cognition and the multimodal paradigm (Arzarello & Robutti, 2008; Gallese & Lakoff, 2005). Such studies also encompass gestures and the use of various artefacts. Within the semiotic-cultural framework, learning has been formulated in terms of objectification (LaCroix, 2012; Radford, 2008), but to our knowledge this theory has not yet been applied to physical artefacts in the learning of fractions. In this paper we follow two groups of 6th grade students who use the physical artefact multilink cubes to solve tasks which involve expanding fractions to a common denominator. We focus on how students use multilink cubes and mathematical signs equipped with a cultural meaning to express and communicate their thinking in social interaction. Radford (2010b) has described mathematical thinking in the following way: “[...] thinking is considered a sensuous and sign-mediated reflective activity embodied in the corporeality of actions, gestures, and artifacts (p. XXXVI).” A main point here is that mathematical thinking entails the use of resources located outside of the brain, and that such resources play an important role in mathematical activity. Radford’s theory of objectification (2006) will be a theoretical foundation for our study:

The term objectification has its ancestor in the word *object*, whose origin derives from the Latin verb *obiectare*, meaning “to throw something in the way, to throw before”. The suffix – *tification* comes from the verb *facere* meaning “to do” or “to make”, so that in its etymology, objectification becomes related to those actions aimed at bringing or throwing something in front of somebody or at making something apparent – e.g. a certain aspect of a concrete object, like its colour, its size or a general mathematical property (p. 6).

An important point in this theory is that learning is closely connected to actions aimed at noticing different aspects of the mathematical object at hand. We use Radford’s definition of a mathematical object (2008): “[...] mathematical objects *are fixed patterns of reflexive human activity incrustated in the everchanging world of*

social practice mediated by artifacts (p. 222).” This definition emphasises that mathematical objects are patterns of activity closely linked with the use of artefacts. The mathematical object we study is “the expansion of two fractions to a common denominator”. This procedure is a “*fixed pattern of reflexive human activity*”, so it fits well with Radford’s definition of a mathematical object. The theory of objectification is used as an analysing tool in order to identify deeper levels of objectification in the students’ strategies of expanding two fractions to a common denominator. The research questions that guided our work were: “Which strategies do the students employ as they expand two fractions to a common denominator, and what aspects of the expansion process are at the centre of the students’ attention in these strategies?”

We regard Radford’s theory of objectification as the most appropriate for our study compared to other alternatives such as Treffer’s approach of progressive schematisation (1987) because Radford’s theory focuses more on the use of various artefacts, gestures, motor actions and the semiotic resources the students use in the learning process. His theory also encompasses descriptions of three levels of objectification which fit our data well.

RADFORD’S LEVELS OF GENERALITY

In relation to students’ generalisation of number patterns, Radford has described the factual, contextual and symbolic layer of generality (2006, 2010a, 2010b). Radford also refers to these levels as levels of objectification. Koukkoufis and Williams (2006) have applied these levels to students’ generalisation of the compensation strategy in connection with the “dice games instruction method” (Linchevski & Williams, 1999) which is related to integer addition and subtraction through objects on a model, i.e. red and yellow cubes on a double abacus. In our paper Radford’s levels are generalised and applied to the students’ strategies of expanding fractions. We will now give a short description of these levels of generality, and we start with the factual level (Radford, 2006). The students he referred to were to generalise a number pattern which was expressed by a visual representation, see figure 1 to the left.

Figure 1: One of the patterns in Radford’s studies.

An example of a way to determine the number of circles in a figure on the factual level of generality was: “One plus one plus three, two plus two plus three, three plus three plus three (ibid., p. 11).” Here the circles were grouped by pointing gestures of the student as described in figure 1 to the right:

No mathematical symbols were used in this generalisation. The crucial element of the generalisation is to express the variable quantity, i. e. the figure number, in some way. On the factual level of generality this quantity is not articulated in a direct way:

“[...] in factual generalizations, *indeterminacy* [...] does not reach the level of enunciation: it is *expressed in concrete actions* [...] (ibid., p. 9).”

Like the factual strategy, the contextual strategy also originates from a visual approach to the process of generalisation. An example of a contextual generalisation of the number pattern shown in figure 1 is: “You have to add one more circle than *the number of the figure* in the top row, and add two more circles on the bottom row (Radford, 2010b, p. XLI)” The pivotal element of the generalisation is to express the variable quantity, i. e. the figure number, in some way. On the contextual level of generality, this quantity reaches the level of enunciation. In the example above this was done through the formulation “*the number of the figure*”. According to Radford (ibid.), the explicit mentioning of the figure number is a hallmark of the contextual level of generality:

The indeterminate object variable is now explicitly mentioned through the term “number of the figure.” However, [...] the new form of algebraic thinking is still contextual and “perspectival” in that it is based on a particular way of regarding something (p. XLI).

On the symbolic level of generality, a formula for the number of circles in a figure is obtained. In connection with the number pattern which is shown in figure 1, an example of a symbolic generalisation is $2n+3$. About this level of generality Radford says (2010a): “The understanding and proper use of algebraic symbolism entails the attainment of a disembodied cultural way of using signs and signifying through them (p. 56).”

METHOD

A lot of research has been carried out in the design of learning sequences in connection with rational numbers, see for example Brousseau’s work on didactical situations and didactical engineering (1997), and such studies have inspired the design of the learning activities employed in this case study. However, the design of such learning activities is not a theme in this paper. The case study was carried out in a 6th grade classroom in the autumn of 2011 in Norway. In cooperation with the teacher we selected two groups of three students who were medium to high achievers. We did not choose low achievers because the students would encounter the expansion of two fractions to a common denominator one year before what is normal in Norwegian schools. Every group had 13 sessions of 45 minutes with one of the researches, and all of these sessions were videotaped. The groups were given a problem to solve by the researcher, and afterwards they were asked to explain how they reasoned as they were working with the task. The students used multilink cubes to build rectangular “chocolate bars” to depict different fractions. The brown cubes illustrated brown chocolate, and they corresponded to the numerator. The white cubes illustrated white chocolate, and the total number of cubes, regardless of colour,

corresponded to the denominator. The students started to build bars corresponding to fractions like $\frac{1}{2}$, $\frac{1}{3}$ and $\frac{2}{5}$. Figure 2 and 3 show some examples of such bars.

SOME DEFINITIONS

In order to be able to communicate and analyse the students' strategies, we will define the concepts *strip*, *length*, *height* and *congruent bars*. These definitions presuppose that the bars are oriented in the same way as in figure 2. A *strip* is a bar with *height* 1. The left part of figure 2 shows a strip that corresponds to $\frac{2}{5}$. We say that the *length* of this strip is 5. If a fraction were to be expanded, the students usually increased the *height* of the bar. The bar to the right in figure 2 is made up of two strips, and this bar corresponds to the fraction $\frac{2}{5}$ expanded by 2. The height equals the expansion factor which is 2. When we use the concept *physical* length or height, we do not mean the number of cubes, but the physical measure of the corresponding distance. Two bars are said to be congruent if the corresponding rectangles are congruent, regardless of the colour of the cubes.

Figure 2: To the left is a strip that corresponds to $\frac{2}{5}$. To the right is a bar that corresponds to $\frac{2}{5}$ expanded by 2.

THE TRIAL AND ERROR STRATEGY TYPE

The students were shown a rectangular piece of cardboard, and they were asked to solve the following task: “If this was a real chocolate bar, and you could choose between $\frac{2}{5}$ or $\frac{1}{3}$ of the whole bar, what would you choose?” They were not able to solve the problem. Then they were given a task which instructed them to build some bars where $\frac{2}{5}$ of the cubes were brown and put them in a heap, and to build some bars where $\frac{1}{3}$ of the cubes were brown and put them in another heap (see figure 3 for an example of such bars). Finally they were instructed by the task to find two congruent bars, one from each heap, and count the brown cubes in the two congruent bars. In this way they found out that $\frac{2}{5}$ is greater than $\frac{1}{3}$. This strategy corresponds to an elementary level of objectification because it is a trial and error strategy, and the students focus on building two congruent bars.

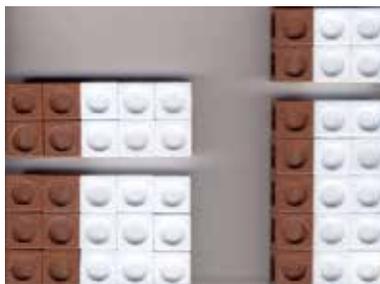

Figure 3: Bars used to order $\frac{2}{5}$ and $\frac{1}{3}$.

THE FACTUAL STRATEGY TYPE

In this section we will describe the factual strategy of expanding two fractions to a common denominator which was frequently used by the students. This strategy was invented by the students without any influence from the researcher, and it was more effective than the labour-intensive trial and error strategy. We will now give an example of this type of strategy. The students were working on the following task:

Make a chocolate bar where $\frac{3}{5}$ of the chocolate is brown, and make another where $\frac{2}{3}$ is brown. The bars are to have the same size. Which of the bars has more brown chocolate? Which of the fractions $\frac{3}{5}$ and $\frac{2}{3}$ are the biggest?

Mary has built two congruent bars, and she was asked to pretend that she was a teacher and explain to the others what she had done.

Mary: First you build a strip with three fifths (*showing a strip which corresponds to $\frac{3}{5}$, picture 1*). Then you build on as much as you think it shall be. If I for example build four of these (*picture 2*). Then you build two thirds (*showing a strip which corresponds to $\frac{2}{3}$, picture 3*) and see whether it fits or not (*picture 4*). So now you have found out how it should fit (*removes one of the four strips so that the bar corresponding to $\frac{3}{5}$ consist of three strips, picture 5*). Then you enlarge it (*expanding the strip that corresponds to $\frac{2}{3}$ so that it gets the same size as the bar corresponding to $\frac{3}{5}$, picture 6*).

Figure 4: Picture 1 to 3 is on the first row, and picture 4 to 6 on the second.

An important element of the procedure is to find the physical heights of the two congruent bars. In the factual strategy, these heights are found through the physical lengths of the two strips which correspond to the fractions that are to be ordered. The physical heights of the bars are variable quantities in the expansion procedure which are not explicitly articulated, but expressed through actions. Thus the factual strategy reported in this section resembles Radford's factual level of generality. In the factual strategy, the students focused on the physical lengths of the strips which

corresponded to the fractions that were to be expanded. This means that a deeper layer of the mathematical structure in the expansion procedure has become apparent to them, and thus they seemed to have reached a deeper layer of objectification.

THE CONTEXTUAL STRATEGY TYPE

In this section we will delineate the contextual strategy of expanding fractions to a common denominator which was often used by the students. This strategy was discovered by the students without any influence from the researcher, and it was an improvement of the factual strategy. The following task was given to the students in the example of the contextual strategy we will now analyse:

Make a chocolate bar where $\frac{2}{3}$ of the chocolate is brown, and make another where $\frac{5}{7}$ is brown. The bars are to have the same size. Which of the bars has more brown chocolate? Which of the fractions $\frac{2}{3}$ and $\frac{5}{7}$ is the biggest?

Cathie has built two congruent bars, and she has written down an explanation as to how she built the bars which she was asked to read aloud.

Cathie: First you make a strip with five sevenths (*showing a strip that corresponds to $\frac{5}{7}$, picture 1*). Then you make another one that shall be two thirds (*showing a strip that corresponds to $\frac{2}{3}$, picture 2*). Then you see that on two thirds, that the bottom number is three. So you build three strips with five sevenths (*gliding pointing gesture with the pencil, picture 3*). Then you see that the bottom number in five sevenths is seven. Then you take seven lengthwise (*gliding pointing gesture with the pencil, picture 4*).

Figure 5: Picture 1 to 4 is ordered from the left to the right.

In the factual strategy the heights of the two congruent bars were found through the physical lengths of the two strips which corresponded to the fractions that were to be expanded. In the contextual strategy these heights were found through the denominators of the fractions which the students referred to as “the bottom numbers”. These denominators are two variables in the expansion procedure which are now explicitly articulated through the words “the bottom numbers”. Thus the contextual strategy reported in this section resembles Radford’s contextual level of generality. The students focused on the denominators of the fractions which were to be expanded. This means that a deeper layer of the mathematical structure in the expansion procedure has become apparent to them, and thus they seemed to have reached a deeper layer of objectification.

THE EMBODIED-SYMBOLIC STRATEGY TYPE

At this stage of the objectification process the students had never encountered the expansion of fractions with mathematical symbols. Therefore the researcher showed them how this could be done and the connection between symbolic expansion and the expansion of bars. After this the students started to add fractions with different denominators, and the embodied-symbolic strategy arose. We will now give an example of this type of strategy. The students were working on the following task:

One Saturday Peter makes a pizza for himself and his friends. When they have eaten, there is $\frac{1}{3}$ pizza left which he puts in the freezer. The next Saturday he also makes a pizza for his friends. Then there is $\frac{2}{5}$ pizza left which he puts in the freezer. How much pizza has Peter frozen after the two Saturdays? (*The task was accompanied by a picture of two rectangular pizzas of equal size.*)

Cathie has solved the task by building two congruent bars, and she has also carried out the calculation by writing down mathematical symbols, see figure 6. Then she was asked to explain what she had done.

$$\frac{1}{3} + \frac{2}{5} = \frac{1 \cdot 5}{3 \cdot 5} + \frac{2 \cdot 3}{5 \cdot 3} = \frac{5}{15} + \frac{6}{15} = \frac{11}{15}$$

Figure 6: Cathie's calculation of $\frac{1}{3} + \frac{2}{5}$.

Cathie: First I wrote one third plus two fifths. Then the equal sign. Then I wrote one third again with a long fraction line. Then I counted how many I had to expand it to, which was five (*gliding pointing gesture along the bar that corresponds to $\frac{1}{3}$, picture 1*). Then I wrote times five over and under the fraction line. Then plus two fifths. Then I counted how many strips I had expanded it to (*gliding pointing gesture along the bar that corresponds to $\frac{2}{5}$, picture 2*), which was three. Then I multiplied that (*pointing at $\frac{1 \cdot 5}{3 \cdot 5}$ on her sheet*) which became five fifteenths. Plus that (*pointing at $\frac{2 \cdot 3}{5 \cdot 3}$ on her sheet*) which was six fifteenths. Which equals eleven fifteenths.

Figure 7: Picture 1 and 2 is ordered from the left to the right.

In the factual and contextual strategy the students' attention was directed at how to build two congruent bars, but now the building procedure is no longer in focus, and the students gave no explanation as to how they built the congruent bars. Instead their attention was directed at the connection between the bars and the mathematical

symbols. The expansion factors in the symbolical representation of the procedure were found through the heights of the two congruent bars. A new aspect of the expansion procedure had become apparent to them, and consequently they seemed to have reached a deeper level of objectification.

THE SYMBOLIC STRATEGY TYPE

After some time the students discovered that it was not necessary to build bars in order to add fractions with different denominators. The following task was given to the students in the example of the symbolic strategy we will now analyse:

Each of the two brothers Bill and Benny won a chocolate bar at the charity bazaar. Bill gave away $\frac{2}{3}$ of his chocolate to his mother, and Benny gave away $\frac{1}{5}$ of his chocolate to his mother. How much chocolate did their mother get? (*The task was accompanied by a picture of two rectangular chocolates of equal size.*)

Peter had on his own initiative solved the task without using the multilink-cubes, and he had written down the mathematical symbols shown in figure 8. He had also written down an explanation of what he had done and was asked to read it aloud.

$$\frac{2}{3} + \frac{1}{5} = \frac{2 \cdot 5}{3 \cdot 5} + \frac{1 \cdot 3}{5 \cdot 3} = \frac{10}{15} + \frac{3}{15} = \frac{13}{15}$$

Figure 8: Peter's calculation of $\frac{2}{3} + \frac{1}{5}$.

Peter: First I wrote two thirds plus one fifth which equals two thirds with a long fraction line. Then I put times five on top and bottom because the denominator of the other fraction was five. Then I wrote plus one fifth with a long fraction line, times three because the denominator of the other fraction was three.

The students' attention was removed from the interplay between the bars and the mathematical symbols, and they focused only on the symbolic representation of the calculation. There was no longer any reference to the building process. Consequently they seemed to have reached a deeper layer of objectification. The symbolic strategy reported in this section resembles Radford's symbolic level of generality (Radford, 2010a) because it "entails the attainment of a disembodied cultural way of using signs (p. 56)".

CONCLUSION AND FURTHER RESEARCH

Our starting point was the following research questions: "Which strategies do the students employ as they expand two fractions to a common denominator, and what aspects of the expansion process is at the centre of the students' attention in these strategies?" At different stages of the objectification process, different aspects of the expansion procedure have been at the centre of the students' attention. In the trial and error strategy, the students' attention was directed at building two congruent bars, but this procedure was rather labour-intensive because they did not know how to find the

heights of the two congruent bars. In the factual strategy the students focused on the physical lengths of the strips that corresponded to the fractions that were to be expanded. These physical lengths were used to find the physical heights of the two congruent bars that were central in the process of expanding the two fractions. In the contextual strategy, the students' attention was directed at the denominators of the two fractions. These denominators were used to find the heights of the two congruent bars. In the embodied-symbolic strategy, the students focused on the interplay between the two congruent bars and the mathematical symbols used to represent the procedure. The expansion factors in the symbolic representation of the procedure were found through the heights of the two corresponding congruent bars. In the symbolic strategy, the bars were no longer used, and the students' attention was directed at the mathematical symbols representing the calculation. In this case the expansion factors were found through the denominators of the fractions. These strategies correspond to different levels of objectification, and on these levels the students relate to the structure of the mathematical object – “the expansion of two fractions to a common denominator” – in more sophisticated ways.

In addition to generalising and applying Radford's levels of generality to the students' strategies of expanding fractions to a common denominator, we have also described the trial-and-error and the embodied-symbolic strategy. Because the two latter strategies were induced by the researcher, we have no evidence which implies that these strategies can be used in connection with other artefacts and other mathematical subjects. However, our hypothesis is that the factual, contextual and symbolic level of generality described by Radford also can be used as an analysing tool in connection with other artefacts and other mathematical subjects. The fact that Koukkoufis and Williams (2006) describe these types of generalisations in connection with integer addition and subtraction support this hypothesis. Still, there is a need for more research to elucidate to what degree these levels of generality might be applied to other fields.

The transition to the embodied-symbolic strategy was induced by the researcher because the researcher had shown the students the connection between the expansion of bars and the expansion of fractions with mathematical symbols, but the other transitions to higher levels of objectification were not initiated by the researcher. Because the building of the congruent bars entailed a lot of work, and the expansion process was repeated many times by the students, our hypothesis is that these transitions arose in order to carry out the expansion process in more efficient ways. Still, the transitions to higher levels of objectification remain somewhat opaque. We need to know more about how to design learning activities which may facilitate such transitions. Interesting questions for further research are: “What is the role of the teacher in connection with transition to higher levels of objectification, and which actions are suitable to throw a new aspect of the mathematical object into the centre of the attention of the learner?”

MENTAL COMPUTATION STRATEGIES IN SUBTRACTION PROBLEM SOLVING

Cristina Morais

Instituto de Educação, Universidade de Lisboa (PhD student)

Lurdes Serrazina

Escola Superior de Educação, Instituto Politécnico de Lisboa

This paper refers to part of a qualitative study made by the first author that had the main goal to understand which mental computation strategies are used by first grade pupils in addition and subtraction problem solving, namely to understand how the different addition and subtraction situations influence the mental computation strategy used in its resolution.

In this paper, we will present and discuss the strategies used at different subtraction problem situations by a pupil, Cátia, that constituted one of the three case studies held in the large study. The strategies used by Cátia seem to be related with the subtraction situations of the problems.

Keywords: number sense, mental computation, subtraction, strategies, problem solving.

INTRODUCTION

Mental computation is closely connected to one major goal in mathematics education of the elementary years: the development of number sense (e.g. NCTM, 2007).

Sowder (1992) associates number sense to an intuition and defines it as a well organized, conceptual network that allows the relationship between numbers, operations and its properties, and a flexible and creative way of problem solving. Similarly, Dehaene (1997) refers to number sense as an intuition about numerical relations, describing it as “a short-hand for our ability to quickly understand, approximate, and manipulate numerical quantities” (Dehaene, 2001, p.17).

McIntosh, Reys and Reys (1992) describe number sense as:

“a person’s general understanding of number and operations along with the ability and inclination to use this understanding in flexible ways to make mathematical judgments and to develop useful strategies for handling numbers and operations” (p. 3).

Thus, in addition to other aspects, a good number sense implies a thorough and flexible understanding of numbers and their relationships, essential for the development of efficient and useful strategies, like mental computation strategies.

THEORETICAL FRAMEWORK

The importance of mental computation in the development of number sense is highlighted by several authors, but what is mental computation?

Buys (2008) briefly describes mental computation as “moving quickly and flexibly through the world of numbers” (p. 122) and characterizes it as a computation involving: a) numbers and not digits; b) computation properties and number relationships; c) a good understanding of numbers and a thorough knowledge of elementary facts up to twenty and up to one hundred; and d) the use of intermediate notes, but mainly calculating mentally. Verschaffel, Greer and De Corte (2007) add that “it’s not the presence or absence of paper and pencil, but rather the nature of the mathematical entities and actions that is crucial in our differentiation between mental arithmetic and (written) algorithms” (p.566). Should be noted that this is the understanding of mental computation we will consider throughout the paper.

The subtraction strategies used by children depend on and evolve from strategies used in this operation with numbers smaller than twenty (Fuson, Wearne, Hiebert, Murray, Human, Olivier, Carpenter & Fennema, 1997). Thus, in this field of numbers, Thompson (2009) refers the following subtraction strategies: i) count out; ii) count back from; iii) count back to; iv) count up; and v) use known subtraction facts and use derived facts. Included in the strategies with known numeric facts, the author emphasizes the importance of strategies of jumping via ten.

For subtraction of numbers higher than twenty, in Dutch literature different types of strategies¹ are identified, organized into two categories: N10 and 1010 (e.g. Beishuizen, 2009).

In the N10 category (number+10 or number-10), at the first number is subtracted a multiple of 10. In this category, distinguishes itself a more complex strategy, N10C (compensation), in which at the first number is subtracted a multiple of 10 approximated to the second number to facilitate the computation. The result is then compensated. Another type of strategy, belonging to the N10 category, is identified as A10 (adding on). In this strategy at the first number is subtracted a part of the second number, so that the result is a multiple of 10. Then, the remaining part of the second number is subtracted.

In 1010 category, numbers are split into tens and units that are subtracted separately and the final result is obtained through rearrangement of the number. A 1010’s variant is 10S (sequential), in which the numbers are initially split into tens and units that are subtracted sequentially. Beishuizen (2009) refers that 1010 strategy may cause conflict in computations like 74-38, because pupils cannot be able to solve 4-8 and wrongly compute 8-4. The author adds that the difficulty of this type of strategy

¹ Conscious that perhaps we are using the term “strategy” to what Beishuizen refers as computation procedures, in this paper, this term refers to the strategies as N10, 1010 and their variants.

it's not the decomposition procedure but the correct rearrangement of numbers. According to the same author, N10 strategy is less vulnerable to these mistakes, so it is more efficient. However, its use requires a good ability when subtracting multiples of 10 from any number.

According to empirical research data presented by several authors (e.g. Beishuizen, 2001; Carpenter, Franke, Jacobs, Fennema & Empson, 1998; Thompson & Smith, 1999), pupils seem to prefer strategies from N10 category when solving subtraction computations. Furthermore, the success when using N10 strategies to solve subtraction computations is higher than with 1010 strategies. This last aspect, as Beishuizen (2001) states, seems to confirm the frailty of 1010 strategies, particularly regarding the lost of number sense while using the strategy.

In the elementary years, contexts provide the basis for computation (Treffers, 2008) and the support of the pupils' thinking (Ministério da Educação, 2007). For this reason, different subtraction situations were chosen to provide the basis for the use and development of mental computation strategies. There are different subtraction situations and, in this paper, we consider the situations presented by Ponte and Serrazina (2000): i) *take away*: part of a quantity is removed; ii) *compare*: two quantities are compared in order to find the difference between the two; and iii) *complete*: a value is found in order to add to a quantity so that a specific number is obtained.

METHODOLOGY

This paper refers to part of an empirical research made by the first author, as part of a master's dissertation, that had the main goal to understand how first grade pupils develop mental computation strategies, in an addition and subtraction problem solving context. To do that tried to answer three questions: a) Which mental computation strategies do pupils use when solving addition and subtraction problems?; b) How do these strategies evolve?; and c) Do the addition or subtraction problem situations influence the mental computation strategy used in its resolution?

In this paper, we will focus on mental computation strategies used in different subtraction problems.

The study was a qualitative one and three case studies were carried out. Data were collected by the first author in her first grade class, in a private school in Lisbon. Two problem chains² were solved in pairs³ by pupils, between January and June 2010. All

² The word "chain" is use to identify the set of problems that were developed by the researcher and solved by the pupils. These sets of problems are identified as a problem chain because they were design to cover all the different subtraction problem situations. Also, the numbers involved in each problem were thoroughly selected so that they were progressively higher, increasing the difficulty of the computations.

³ The pupils' pairs varied according to how the work was usually developed in the classroom.

problem solving lessons had the following moments: i) presentation of the problem, in which it was read by a pupil and possible doubts were clarified; ii) solving the problem in pairs, where pupils were asked to write down their strategies, through words, computations, using the empty number line, etc.; iii) presentation and discussion of the most significant solving strategies for the whole class; and iv) overview and identification of the most efficient strategies. A third and final problem chain was solved individually and outside the classroom by the three pupils who constituted the case studies, at the beginning of the second grade, in October 2010.

The study data were collected using video and audio recording (data from all lessons was fully transcribed), participant observation, pupils' records and field notes.

In the three problem chains there were 13 subtraction problems, covering the different subtraction problem situations. Table 1 shows the evolution of the magnitude of the numbers selected for each problem, as well as the presence of subtractions with and without regrouping, and the operations with values involving a different digit number. It is important to note that in the Portuguese curriculum there is no limit for the magnitude of numbers that should be worked in the first grade, and that, along the study, numbers were selected depending on the pupils' progress.

Problem chain	Subtraction situations	Computation	
1	<i>Compare</i> a)	20-6	subtraction
	<i>Take away</i>	15-7	subtraction
	<i>Complete</i> a)	28-16	subtraction without regrouping
	<i>Complete</i>	25-18	subtraction with regrouping
2	<i>Complete</i>	55-32	subtraction without regrouping
	<i>Take away</i>	49-26	subtraction without regrouping
	<i>Compare</i>	42-14	subtraction with regrouping
		75-48	subtraction with regrouping
	<i>Take away</i> a)	82-36	subtraction with regrouping
	<i>Complete</i>	124-47	subtraction with regrouping
3	<i>Compare</i> a)	157-43	subtraction without regrouping
	<i>Take away</i>	257-125	subtraction without regrouping
	<i>Complete</i> a)	250-135	subtraction with regrouping

a) Problems that will be described and discussed in this paper.

Table 1: Computations involved in the subtraction problems (presented by temporal order)

Content analysis was done and the categorization of computation strategies with numbers up to twenty referred by Thompson (2009) were followed, as well as the

mental computation strategies with numbers higher than twenty identified by Beishuizen (2001, 2009) and Beishuizen and Anghileri (1998).

For this paper we selected five problems (indicated in Table 1) to describe and discuss the computation strategies used by Cátia, one of the three studied pupils. Cátia is a very confident pupil that has a successful academic performance not only at Mathematics but also in other curriculum areas. The problems selection was made in order to include the different semantic situations and also regrouping/not regrouping and magnitude of the numbers.

The transcriptions that will be presented were from the audio and video recordings of the lessons. During the lessons, the teacher sometimes approached Cátia and her colleague, questioning the strategy used, like she did to the other pairs of pupils in the class.

RESULTS

Problem one, 1st chain (*compare*) – The sister of Leonor and Rita is 20 years old. How many years older is she? (Leonor and Rita are twins from the class and are 6 years old.)

This was the first problem with a *compare situation* solved in the study. Before making any notes, Cátia looked around, thoughtfully, and then said “Is 14”. Then, she used the number line to write down her strategy. She used a jumping via ten strategy, adding $6+4=10$, and then she used basic number facts to reach 20. Finally, Cátia added the partial results (Figure 1), as she explained:

Cátia: I did like this... I know that 6 plus 4 is 10. Then I did a jump of 3 that was 13.

Teacher: Why did you make a jump of 3? Why not a jump of 4 or 2...?

Cátia: Because... I decided to do one of 3 because I thought it was a good computation to do. Then I did 4 plus 3 that is 7. Then I did another jump of 3, that it was as if this 1 [from 13] didn't exist. Then I did 7 plus 3 that was 10, and then it was just plus 4 and 10 plus 4 is 14.

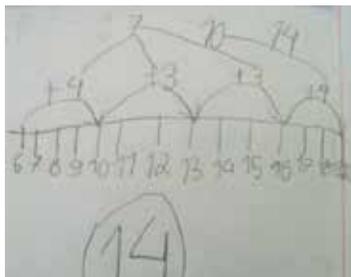

Figure 1. Cátia's solution of problem one

Problem two, 1st chain (complete) - Marta is reading a book. She has already read 16 pages and the book has 28. How many pages are left?

Cátia used an additive A10 strategy, approaching 16 to a multiple of 10, 20. Then, she added 8 ($20+8$), which is a basic number fact for her.

Cátia explained her strategy to her colleague:

Cátia: Pretend that 16 was 6, and 20 was 10. I know that 6 plus 4 is 10. Then I did a jump to 28 and saw it was a jump of 8. And 8 plus 4 is 12.

Cátia didn't feel the need to write down all the numbers in the number line, she just marked the numbers of her computations (Figure 2). As in the previous problem, Cátia solves the problem adding to the given parcel a number to reach the other parcel ($a+?=b$) and, once again, she uses the number line to show her strategy.

Figure 2. Cátia's solution of problem two

Problem three, 2nd chain (take away) - Leonor and Simão are playing a boardgame. Leonor is in house number 82. In that house she reads "How unlucky! You have to go back 36 houses." In which house is she now?

Cátia and her colleague identified easily the subtraction involved in the problem. Once again, Cátia uses a subtractive 1010 strategy and subtracted without difficulty 80 minus 50. In the subtraction 2 minus 6, she splits the 6 into 2 plus 4:

Cátia: I've splitted the 6 into 2 plus 4, and 2 minus 2 equals zero... I've already spent this 2. Then, zero minus 4 is negative 4.

She seems to overcome easily the difficulty in 2-6.

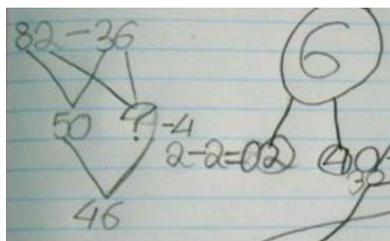

Figure 3. Cátia's solution of problem three

Cátia wrote her notes when she was talking to her colleague about what she was doing, so it is not clear if these notes were used just to show her initial strategy or if she was solving the computation as she was writing.

Problem four, 3rd chain (compare) - Miguel and Cláudia are playing the “Stop or Go” game. At the end, Cláudia got 157 points and Miguel got less 43 points than her. How many points did Miguel get?

Cátia starts to solve the problem using a subtractive 1010 strategy. She started to subtract the tens, then the units and finally the hundreds. However, Cátia did 100 minus 14. Unsure of the result, she added $86+43$ using an additive 1010 strategy, obtaining 129.

Then, she recalculated 157 minus 43, now adding the partial differences, 100 and 14 (second computation from the right, in Figure 4), explaining:

Cátia: I tried...but I didn't know if I had to add or to subtract [first computation from left, in Figure 4]. I've subtracted but it wasn't right. Now I'm doing it again and now it's right.

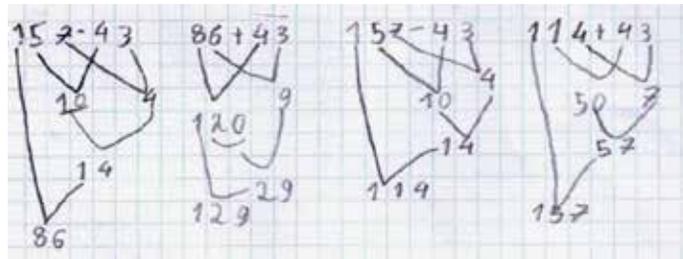

Figure 4. Cátia's attempts when solving problem four

Although Cátia reveals difficulty when rearranging the number after using a subtractive 1010 strategy, she also shows a good comprehension of the relation between addition and subtraction, using that knowledge in order to overcome her difficulty.

The role that Cátia's notes had in this problem seems unclear. As in the previous problem, it is not possible to understand if the notes were used to explicit her mental computation strategy or if she was using them to compute as she was writing.

Problem five, 3rd chain (complete) - Leonor went to a bookstore. That bookstore was doing a competition: the customer number 250 who enters the store wins a book collection of his choice! Leonor was the customer number 135. How many customers must enter the store until the prize is awarded?

Cátia uses an additive A10 strategy, adding parcels to 135, in order to approach 250 (Figure 5). In these partial additions, Cátia approximates the partial results to reference numbers, using basic fact numbers.

In this problem, her intermediate notes were important to write down the partial additions so she could add them to obtain the final result (115).

Handwritten mathematical work on grid paper showing three addition problems and a subtraction result:

$$\begin{array}{r} 135 + 5 = 140 \\ 140 + 10 = 150 \\ 150 + 100 = 250 \\ 175 \end{array}$$

Figure 5. Cátia's solution of problem five

DISCUSSION

As seen in the results described above, the *compare* and *complete* problems were usually translated by Cátia as an expression like $a + ? = b$, and solved mainly through additive A10 strategies. Generally, these strategies were also used by Cátia in the other *compare* and *complete* problems of the larger study. These results are consistent with the findings of several studies (Carpenter et al., 1998; De Corte & Verschaffel, 1987; Heirdsfield & Cooper, 1996) that identify this type of strategy as the most frequently used by children when solving this kind of subtraction problems. This probably is related to the semantic context involved in the problem, for example, in the first problem, the question was “How many years older is she?”, seems to lead to a question as “How many more years does she have?” which is usually solved through an addition operation.

The semantic context could help explain why Cátia used a subtractive 1010 strategy in a compare problem, the fourth problem analyzed. In this problem, it was said that “(...) Miguel got less 43 points than her.”, that could lead to a subtraction operation, also influencing the strategy used.

Also, in this problem it is possible to identify the weakness of 1010 strategy in subtractions with values represented with a different digit number, which led to an incorrect rearrangement of the final result. As Beishuizen (2001) stresses, this fact is due to the lost of number sense during the computation. However, Cátia overcame this difficulty through her critical analysis towards the result, using the relationship between addition and subtraction to verify the result.

In the *take away* problem, Cátia used the subtractive 1010 strategy with comprehension and without difficulty even in those situations that could cause conflict (e.g. 82-36). In the other *take away* problems, from the second and third chain, in the large study, Cátia had used this strategy with the same easiness, what seems to indicate the comprehension that she has about subtraction, particularly about the lack of commutativity of this operation. It also seems to show her understanding and mastery of negative numbers, that Thompson (2000) relates to the students with more proficiency at computation.

The notes used by Cátia had an important role in this research, as they revealed the mental computation strategy used, however, in some problems, even though all the data have been carefully analyzed, it is not clear if the use of the notes influenced the strategy actually used by the pupil.

Nevertheless, the use of notes seems to be helpful as a way of representing an inner process, as it is mental computation, and also as a way to use important supports, like the empty number line, that could help in the developing of mental computation.

Note that the mental computation strategies used by Cátia, and by the other two pupils in the large study, when solving the subtraction problems are associated in the literature to older pupils (e.g. Beishuizen, 2001; Buys, 2001; Cooper, Heirdsfield & Irons, 1995; Thompson & Smith, 1999). This aspect seems to indicate that mental computation strategies used by first grade pupils should be valued and the teacher must support their development to more complex and efficient strategies, also supporting their comprehension of numbers and operations, essential to the development of a sound number sense.

FOCUSSING STRUCTURAL RELATIONS IN THE BAR BOARD – A DESIGN RESEARCH STUDY FOR FOSTERING ALL STUDENTS’ CONCEPTUAL UNDERSTANDING OF FRACTIONS

Susanne Prediger

TU Dortmund University, Germany

For fostering conceptual understanding of fractions, connecting different representations is an often used design principle. This paper shows that this design principle is necessary but not sufficient and should be complemented by focussing structural relations. In a design research study in grade 6, different strategies for this principle were developed and empirically investigated with respect to the generated learning processes. The activities were organized around the so-called fraction bar board, a visual model that allows a comprehensive structural view on fractions, order and equivalence.

Keywords: Fractions, structural relations in pictures, design research study

Students’ difficulties with conceptual understanding of fractions have often been shown empirically (e.g., Hasemann, 1981; Behr et al, 1992; Aksu, 1997). As a consequence, fostering students’ conceptual understanding of fractions has become a central aim for many curriculum design projects all over the world (e.g., Bokhove, et al., 1996; Cramer et al., 2009; Streefland, 1991; Prediger et al., 2013). Before developing algorithmic skills, students should develop meanings for fractions and for the basic fraction concepts like order and equivalence of fractions. These curriculum projects vary in the chosen contexts and in their priorities for different fraction models: Most emphasis is usually given to the part-whole model, whereas varying priority is attributed to other important models like measure, ratio, operator, or quotient in situations of equal sharing (see Behr et al., 1992, for an overview on models). Despite of different choices of prioritized models and of contexts, nearly all curriculum projects share the design principle of *relating multiple representations*, namely graphical, symbolic, verbal and enactive representations (Lesh, 1979). Most of them also refer to the principles of *including students’ everyday experiences* by means of suitable contexts and *initiating mathematical discussions* on mathematically *rich open problems* (Freudenthal, 1983).

This paper intends to show that connecting different representations is a necessary but yet not sufficient condition for developing conceptual understanding, because especially weaker students tend not to construct the mathematically intended structural relations automatically. That is why the design principle *explicitly focussing structural relations* should complement the set of design principles. The empirical findings that support the importance of this principle and design strategies for implementing it for the topic ‘order and equivalence of fractions’ are drawn from several design experiments that were iteratively conducted within the long term design research project KOSIMA (Hußmann, Leuders, Barzel, & Prediger, 2011).

1. THEORETICAL AND EMPIRICAL STARTING POINTS

1.1 Fraction bars as important visual model

As developing conceptual understanding of mathematical objects necessitates to *relate different representations* (Lesh 1979), the concrete choice of contexts and concrete graphical representations is crucial for the mental models that students can develop. In line with many other curriculum projects (see above), our design approach starts with identifying and interpreting fractions in a variety of situations of equal sharing and part-whole situations, being graphically represented in rectangles, circles, bars and other pictures. In the second unit on order and equivalence of fractions (Prediger et al., 2013), the learning arrangement focuses on *fraction bars as the central visual model* that has to be connected to symbolic and verbal representations (bars are also used by others, e.g. van de Walle & Thompson, 1984; Cramer et al., 2009; Bokhove et al., 1996).

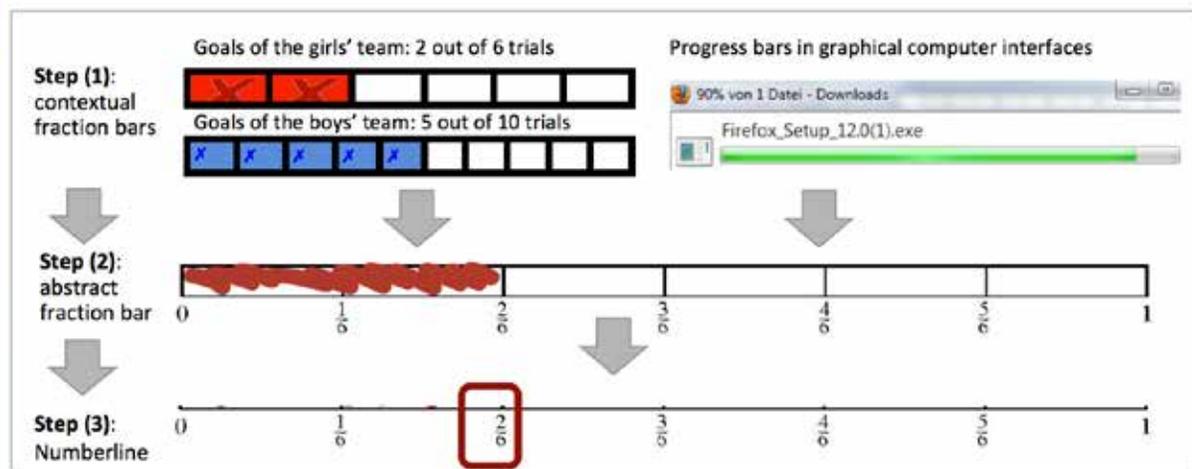

Figure 1. Three steps from contextual fraction bars to abstract fraction bars to the number line

In our curriculum, two everyday context situations support the introduction of fraction bars (Figure 1): (1a) Comparing goals for an unequal number of trials, a *situation* which provokes students to invent the mathematical concept of relative frequencies for measuring fairly, (1b) progress bars of graphical computer interfaces, showing e.g. the progress of a download. (2) From these context situations, we derive an *abstract* fraction bar as the central representation for order and equivalence. (3) In the last step (not treated in this paper), we abstract the fraction bar to the number line and use it as a bridging tool between part-whole and measure model (cf. Keijzer & Terwel, 2003, p. 288). These bridging functions are the main reason for choosing bars as main visual model.

1.2 Limits of graphical representations – a snapshot from an initial case study

Interpreting fraction bars is not evident for all students from the beginning, as could be shown in a case study on low-achieving students (Prediger, 2013). The two boys Cavit and Ismet from grade 7 followed a typical German curriculum with a focus on relating representations, but without consequent focus on meaning. In the conducted interview,

both boys easily assigned the symbolic representations $\frac{3}{4}$ and $\frac{3}{5}$ to given fraction bars. In the transcript, Cavit explains how to find $\frac{3}{5}$ in the bar:

- 9 Interviewer ... what shows you the fraction in this picture?
 10 Cavit Ehm...Ehm the ... first, you have to count the small pieces.
 These are five. And then, the three coloured ones, three fifth.

In spite of this correct answer, Ismet and Cavit compare the symbolic fractions $\frac{3}{5}$ and $\frac{3}{4}$ by commonly deciding that $\frac{3}{5}$ was bigger (in the next sequence). The interviewer asked them to use the graphical representation to validate their judgement:

- 17 Interviewer ... how can you see in the picture that this fraction (*hints to $\frac{3}{5}$*), when you say, it is greater than this (*hints to $\frac{3}{4}$*) How can you see that in the picture?

...

- 24 Ismet [...] because here (*hints to the $\frac{3}{5}$ bar*) it is five, and here are four (*hints to the $\frac{3}{4}$ bar*) then you see that this (*the $\frac{3}{5}$ bar*) is large and this (*the $\frac{3}{4}$ bar*) is small [...]

Although line 10 showed the boys' capability to switch between the graphical and the symbolic representations without mistakes, they order the fractions idiosyncratically. Ismet's explanation in line 24 shows that relating representations does not guarantee to see the *mathematically intended structural relations* in a graphical representation: Instead of comparing the length of the coloured part, Ismet counts the pieces and argues that $\frac{3}{5}$ is larger because its whole is divided into more pieces than the one for $\frac{3}{4}$. This limit of graphical representations has also been found for other arithmetical topics (Steinbring, 2005): Teaching students to draw correctly is not sufficient to guarantee that they mentally construct the intended structural relations which mathematicians see into a specific graphical or symbolic representation. Cavit and Ismet could identify the right fraction bar and described the drawing procedure. However, their linguistic expression of the *relation* between the part 3 and the whole 5 was restricted to the word "and" (line 10). Ismet's idiosyncratic interpretation of the order and this vague expression are indicators for the structural relation between part and whole not being completely mentally constructed. Hence, further support is needed (cf. Prediger 2013).

The short case study illustrates the necessity to understand 'fraction' as a relational concept (Steinbring, 2005), in the sense that it grasps the structural relation between the part and the whole. Although many students mentally construct this relation simply from dealing with graphical representations, the same can be challenging for low-achieving students (similarly Moseley, 2005). From these empirical and epistemological starting points, the following design challenge and empirical research question was concluded for a design research study aiming at overcoming the limits of graphical representations:

How can we foster all students' mental constructions of the intended structural relations between part and whole by initiating activities with fraction bars?

2. METHODOLOGY OF DIDACTICAL DESIGN RESEARCH

Mathematics education research is sometimes dichotomised by *two different aims*: 1. *designing* concrete (teaching-)learning arrangements for mathematics classrooms, and 2. *understanding* and explaining teaching-learning processes. More and more researchers aim to overcome this unfruitful dichotomy and to combine empirical research and the design of learning arrangements in order to advance *both*: practical designs and theory development (e.g. van den Akker et al., 2006). In our research group, we follow the programme of Didactical Design Research as formulated by Gravemeijer and Cobb (2006) which combines the concrete design of learning arrangements with fundamental research on the initiated learning processes. By *iterative cycles of (re-)design, design experiment and analysis of learning processes*, it focuses on both: 1. creating prototypes of learning arrangements and their underlying theoretical guidelines (design principles and strategies), and 2. elaborating on an empirically grounded *subject-specific local instruction theory* that specifies the epistemological structure of the particular learning content, students' learning pathways, typical obstacles in these pathways, and conjectured conditions and effects of specific elements of the design (Prediger & Schnell, 2013; Gravemeijer & Cobb, 2006, p. 21). For investigating processes initiated within the designed learning arrangements, design experiments have proven to be a fruitful method of *data collection* (cf. Komorek & Duit, 2004; Gravemeijer & Cobb, 2006). We usually start by laboratory settings with 2-4 students as this allows in-depth insights into individual, context-specific learning pathways, obstacles or individual prerequisites. Once the arrangements have proven suitable to initiate the intended learning processes, the experiments are widened to classroom settings with regular teachers and normal resources for investigating their robustness under varying pedagogical conditions.

For *data gathering* in the topic 'order and equivalence of fractions', we successively conducted 31 design experiment series in laboratory settings (in sum $n = 69$ students), each with 2-6 sessions. Additionally, long-term classroom experiments were conducted with six classes ($n = 123$ students) and their regular teachers, encompassing about 36 sessions for the whole fraction curriculum (on basic concepts, order and equivalence for 5 sessions, then addition, multiplication etc.) All design experiments in laboratory settings were videotaped. The data corpus includes the videos, transcripts of selected video-sequences, teaching materials and students' products. The *data analysis* of the complex process data requires interpretative qualitative methods that are specified according to the research interest in each phase of the process (Prediger & Schnell, 2013). Due to space limitations, the complex, iterative design research process cannot be reported here. Instead, some selected snapshots are presented that are chosen to illustrate three design strategies for implementing the design principle 'focussing structural relations' which do not only refer to the part-whole-relationship but also to relations between fractions that appear for order and equivalence. Each of the three strategies is illustrated by one selected activity and typical moments in the learning process. These snapshots intend to contribute to a local instruction theory for fostering all students' mental constructions of structural relations for fractions, order and equivalence.

3. DESIGN STRATEGIES FOR FOCUSING STRUCTURAL RELATIONS

3.1 Constructing relevant structural relations by contexts and systematic variation

The case of Ismet and Cavit suggests that comparing fractions might be an important activity for constructing relevant structures in the part-whole model. The *context* of computer interface progress bars (see Figure 1) was introduced into the material after analysing these initial cases. In later design experiment cycles, this connection between progress bars and the symbolic and verbal representations proved to be useful for students constructing the intended structural relations, because students activate everyday experiences and argue for example, “no, $3/5$ cannot be bigger, it has less downloaded”.

In addition to these contextual supports, we drew back on the design strategy of *systematic variation* emphasized by Duval for relating representations structurally: “It is only by investigating representation variations in the source register and representation variations in a target register, that students can at the same time realize what is mathematically relevant in a representation, achieve its conversion in another register and dissociate the represented object from the content of these representations.” (Duval 2006, p. 125).

One example for a systematic variation activity is printed in Fig. 2. It was designed to support especially low-achieving students to construct the *quasi-cardinal relation* between the systematically varied fifths: $1/5$, $2/5$, $3/5$, $4/5$ and $5/5$ (which is one aspect of measuring). Although the structure between the fifth is immediately clear for some students, our design experiments have shown that the task can allow an interesting discovery for lower achievers and help to make clear the difference between a divided whole and its parts (Prediger & Wessel, 2013).

More and more fifths

a) Now Kenan produces fifths with fraction bars. Complete his table.
 Fraction that Kenan wants to draw: Picture:

$\frac{1}{5}$		
$\frac{2}{5}$		
$\frac{3}{5}$		
$\frac{4}{5}$		
$\frac{5}{5}$		

b) Examine the table precisely and consider the following: What happens with the coloured part of the fraction stripe? Why does the coloured part change?

c) Your research: How and why does the fraction change? Write down your findings so that another student can understand what is happening with it and why it changes. ...

Figure 2. Elementary task for weaker students – example for the design strategy systematic variation

For example, Hadar (12 years old) writes, “When the numerator gets bigger, one gets more fraction.” Asim (12 years old) explains the differences with reference to a contextual situation: “Because the numerator gets always bigger, that is why Kenan gets always one [piece] more [of the chocolate bar]. And the denominators stay the same.” (citations from a case study in Prediger & Wessel, 2013).

3.2 Embedding structural relations in a comprehensive visual model: Bar board

For comparing fractions with respect to order and equivalence, students need to connect different fraction bars, e.g., not only fifths, but also fourths, thirds and eighths. Whereas higher achieving students tend to *mentally* construct the bars and their relations among each other quite quickly, weaker students profit from a comprehensive visual model that helps them to see many bars at the same time. Inspired by the prototype of the “fraction lift” which connects some bars (Bokhove et al., 1996), we have developed the fraction bar board as a comprehensive visual model for comparing fractions with respect to order and equivalence. Figure 3 sketches how to find fractions that are equivalent to $\frac{1}{3}$ by vertically positioning the ruler. The lamination of the bar board guarantees its long time usability.

The classroom design experiments have shown that most students quickly learn to use the bar board and understand the ordinal relations of fractions in the interplay of symbolic, verbal and graphical representation (Prediger, 2011). The bar board allows to embed a singular ordinal relation into a comprehensive visual model. By this, students achieve an overall orientation as the example of Lisa illustrates: Having worked with the bar board for two hours, Lisa is asked to compare $\frac{1}{10}$ with $\frac{2}{3}$. She immediately says without watching the bar board: “Imagining them, it is evident, $\frac{1}{10}$ is so much on the left.” (cited from a classroom video).

In the next step of the curriculum, the bar board serves as starting point for the process of progressive schematization (Treffers, 1987) from visually searching equivalent fractions to extending fractions by calculating: Paul explains “If you go from $\frac{2}{6}$ to the 12-bar, each sixth transforms into two twelfths, thus the denominator must be multiplied by two. The coloured pieces also transform from sixths into twelfths by one into two, so the numerator must also be multiplied by two.” (cited from a classroom video).

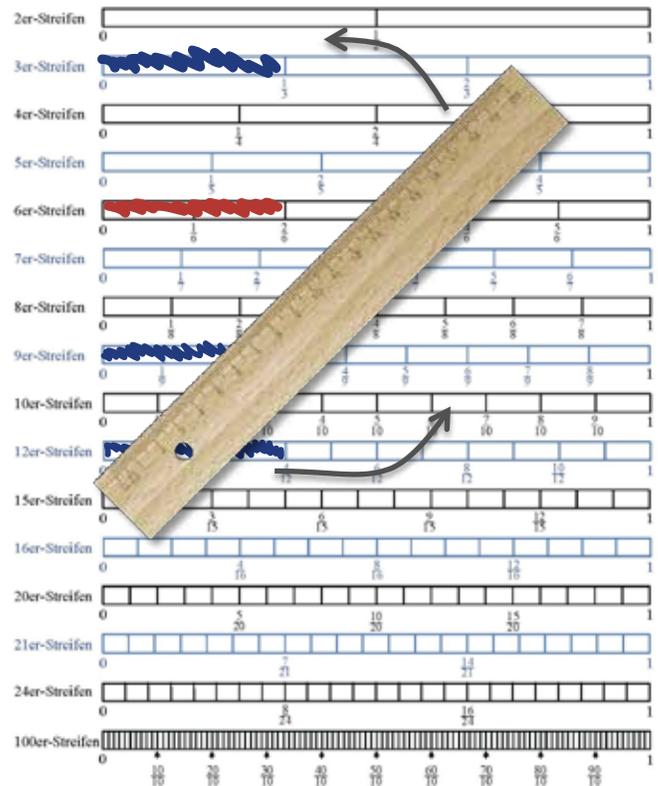

Figure 3. Extract of the fraction bar board

3.3 Internalizing structural relations by mental practices

Unlike Lisa and Paul, who quickly internalized the relational structures inherent in the bar board, other students need more help to explicitly focus the structural relations between the bars. This is illustrated by the case of Anna and Jasmin, both 11 years old (in Prediger, 2011). Both girls worked with the bar board, but treated it only empirically, which became apparent when they searched for fractions being equivalent to $3/4$:

- 230 Anna 9/12 here, isn't it? (*marks a sign on the 12-bar and draws a vertical line*)
Well, yes, that is... is 6/8, but.... it works, it seems to work! (*controls her bar board with the ruler again, during 12 seconds*)
- 232 No, it is only wrong by one millimeter.

With purely empirical methods of measuring in the bar board, Anna could not convince herself whether $9/12$ is equivalent to $6/8$ and $3/4$ or not. Whereas other children in this situation started to argue with structural relations (like Paul above), both girls only referred to the bar board as an empirical instrument (Steinbring, 2005). Even later, when they found a rule in the number patterns (multiply numerator and denominator by 2 or by 5) they could not explain the found regularity:

- 295 A Yes, denominator and numerator must always be the same. That means here, $3/5$ is the double of $6/10$. (*8 seconds break*)
- ... (*Interviewer asks for an explanation*)
- 303 A That's just how it is. Like: why is a banana called a banana (*both girls laugh*)

Thus, Anna's and Jasmin's process of progressive schematization was only partly successful due to a lack of conceptual understanding *why* their rule "take the double for denominator and numerator" applied for all fraction bars. As a consequence of these empirical findings, the redesign searched for a strategy that makes Paul's insight into structural relations more explicit for all children. For this, we developed mental practice activities (Weber, 2011) for internalizing the structure of the bar board (see Figure 4).

The bar board in your head

You can also find equivalent fractions, if you only imagine the bar board in your head. Try it!

a) Imagine how to mark $2/3$ on the 3 bar.
Go from the 3 bar to the 6 bar. Where is $2/3$ here?
How many pieces does the 6 bar have?
How many of them are coloured?

b) Pose yourself different similar tasks. ...

c) How many 25ths are $3/5$?
Explain, how you find the result even if you cannot imagine the bars.

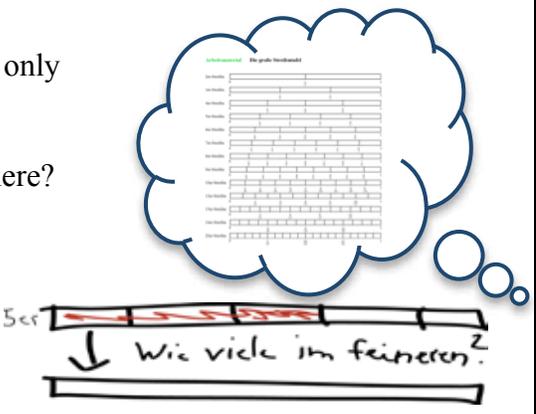

Figure 4. Mental practice for internalizing relational structures of equivalence

4. EVALUATION

Whereas laboratory design experiments and in-depth analyses offer good opportunities to understand the *situational effects* of the design (see preceding section), a quantitative evaluation of learning effects can better contribute to evaluate *the long-term efficacy* of the curriculum. That is why we conducted a first, rough assessment of effects in long-term classroom design experiments (2008-2010) with a standardized fraction test (see Table 1 for some items). We compared the performances of students in five classes (n=108) that have worked with our fraction curriculum in grades 5 to 7, with those of five neighbour classes (n=104) from the same schools that have used the usual textbook curriculum. This *pragmatic quasi-experimental sampling by neighbour classes* suggests the approximate comparability of treatment and control group with respect to general performances and socio-economic background (as these criteria were applied for composing classes in grade 5).

For comparing the long-term efficacy of two different fraction curricula, we measured students' fraction performance ten months after finalizing the curriculum with a *standardized fraction test* being adapted from Bruin-Muurling (2010) (more details in Prediger & Wessel, 2013). The test construction of 41 items tried to limit specific training effects for the intervention group by a wide coverage of different contents: e.g., identify and draw fractions in part-whole and part-group models and on the number-line, order fractions and explain order in contextual or graphical representations, find equivalent fractions and explain, part of part-tasks, subtractions, operators.

Table 1 shows the *overall results* and those items on order and equivalence with most significant intergroup differences. The treatment group was significantly better (m = 23.49) than the control group (m = 19.52) in the whole fraction test, this difference increases enormously for the items on order and equivalence. Remarkable is also the difference in standard deviations, we interpret the higher homogeneity of the treatment group as a success in giving *also weaker students* an access to conceptual understanding.

Table 1. Comparing performances of treatment / control group for overall results and selected items

	Treatment Group	Control Group	Significance
Sample size	n = 108	n = 104	
Mean of overall scores	m = 23.49	m = 19.52	T = 4.580 $\alpha < 0,001$ ***
Standard deviation	SD = 5.389	SD = 7.146	F = 4.362 $\alpha < .05$ **
Items with significant differences	Frequency of complete solutions		
Item 1a. Find fraction 3/4 from picture	99.1 %	86.5 %	
Item 5b. Compare 2/10 and 4/6	86.1 %	72.1 %	
Item 5d. Explain why 2/3 < 3/4	45.4 %	28.8 %	
Item 5f. Explain why 3/9 = 5/15	25.0 %	3.8 %	
Item 6a. Read on the number line 2/8	39.8 %	20.2 %	

5. CONCLUSION AND OUTLOOK

A design research project always aims at research results and design results: The central finding of the empirical *research* on students learning processes is that focussing on structural relations is an important condition for developing conceptual understanding of order and equivalence of fractions while relating different representations. Especially weaker students do not develop this focus automatically, but if they are fostered by suitable activities, they are able to.

Central results of the iterated *design* have been presented in three design strategies for implementing the design principle ‘focussing structural relations’, namely

1. constructing relevant structural relations by contexts and systematic variation,
2. embedding structural relations in a comprehensive visual model,
3. internalizing structural relations by mental practice.

The empirical snapshots (that could of course only show a minimal part of the large data set) illustrated how these design strategies can initiate learning processes. The qualitative insights into *situational effects* of the design were triangulated by a first rough evaluation of *efficacy* in a posttest-control-group design. The results show that the students who learned with our curriculum learned significantly more than the control group classes. However, this first rough evaluation has two important *methodological limits*: (1) the lack of fraction performance control in a pre-test in 2008 and (2) only partial control on the applied pedagogy in the long-term intervention in regular classrooms. Because of these methodological limits, we have started another evaluation study from 2012-2014. As the curriculum has further been developed, we hope to receive more robust results and perhaps even higher learning effects.

FLEXIBILITY IN MENTAL CALCULATION IN ELEMENTARY STUDENTS FROM DIFFERENT MATH CLASSES

Elisabeth Rathgeb-Schnierer / Michael Green

University of Education, Weingarten / University of North Carolina Charlotte

This paper describes a study that assesses the competence of elementary students in flexible mental calculation. Based on a specific perspective on flexibility that was derived from the relevant literature and prior research, a qualitative interview was used to field test and identify degrees of flexibility in elementary students from different classrooms in South Germany and North Carolina. This paper gives theoretical background, data analysis and a quick brief summary of early results.

Key words: Flexibility in mental calculation, recognition of number patterns and relationships, elementary arithmetic

INTRODUCTION

Flexibility in mental calculation has been considered a highly desirable ability in elementary math education for at least the last decade (e.g., Anghileri, 2001; National Council of Teachers of Mathematics, 2000; Selter, 2000). The late twentieth century saw increasing interest in students' thinking and in their techniques for performing mental addition and subtraction.

With the start of the twenty-first century, researchers have begun to explore elements of flexibility in mental addition and subtraction. In this vein different results have been reported concerning students preferences for the written computing algorithms (Selter, 2000), the negative impact of learning by examples on flexibility (Beishuizen & Klein, 1998; Heirdsfield & Cooper, 2004), various influencing factors on students' strategies (Torbeyns, De Smedt, Ghesquière, & Verschaffel, 2009; Blöte, Klein, & Beishuizen, 2000; Rathgeb-Schnierer, 2006) and approaches to math education which can enhance flexibility in mental calculation (Heinze, Marschick, & Lipowsky, 2009; Rathgeb-Schnierer, 2006).

In the context of this recent research, mental calculation means solving multidigit arithmetic problems mentally without using paper and pencil procedures. For flexibility in mental calculation a deep understanding of number and operation relationships and knowledge of basic facts and fact families is required (Heirdsfield & Cooper, 2004; Threlfall, 2002).

With the ongoing study we pursue two aims: First, we want to clarify the concept of flexibility in mental calculation based on theoretical reflections and prior research. Second, we describe a study, which investigates whether students from different classrooms show different degrees of flexibility in mental calculation. Since our theoretical framework introduces a new perspective on flexibility in mental calculation, we describe this perspective and its implications for the study's design.

THEORETICAL FRAMEWORK

Process of calculation

Results of a previous study (Rathgeb-Schnierer, 2006; 2010), in which the development of strategies of mental calculation has been investigated, suggested that it is useful to examine the process of calculation in general, before focusing on flexible mental calculation. Based on this study the following model was developed to describe the process of calculation (Rathgeb-Schnierer, 2011): Solving problems is a complex interaction between different domains that implement different functions with different degrees of explication (Fig. 1).

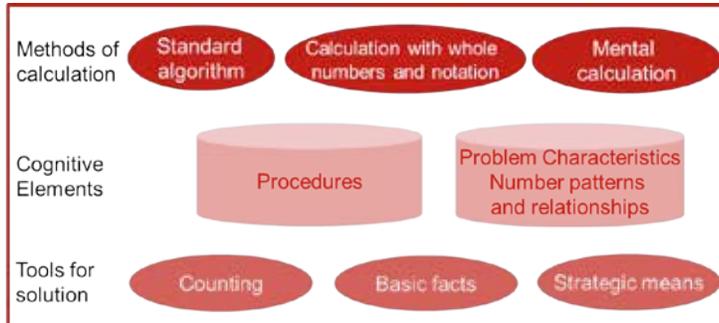

Fig. 1: Domains of calculation process (Rathgeb-Schnierer, 2011)

In our work it has been necessary to consider three distinct but interrelated domains: methods of calculation, cognitive elements, and tools for solution. Each domain is a necessary but not sufficient condition for a calculation process. Taken together, the domains allow us to examine mental flexibility independent of a problem's solution. Each domain is described more fully below.

Methods of calculation: For solving any given problem, a student can use multiple methods of calculation such as the *standard algorithm*, *partial sums*, or *mental calculation* (e.g., Selter, 2000). However, a method describes the way a solution process can be done but not how an answer is determined. For example, the standard algorithm describes a way an addition problem like $327 + 56$ can be solved. First, the terms of the sum may be written correctly, one below the other to determine the sum of each column separately. This method doesn't show the actual process for adding numbers. Looking at the example above, there are many possible tools for solution that could be used to find the answer for 6 joined with 7, like counting, drawing on basic facts, or using other adaptive strategic means. In short, obtaining a problem solution *by itself* does not shed light on the mechanism(s) used to achieve that solution.

Cognitive elements: Students' solution processes are based on specific experiences that we designate with the term "cognitive elements". Such cognitive elements that sustain a solution process can be learned *procedures* (such as computing algorithms), or they can be recognized *number characteristics* (such as number patterns and relationships) (Macintyre & Forrester, 2003; Threlfall, 2009). In reality, it is difficult

to reconstruct the basic cognitive elements that lie behind an exposed solution process as shown by Tanja, who solves the subtraction problem $46 - 19$ (data from a prior project, Rathgeb-Schnierer, 2006):

Tanja: Um. 46 (.) minus (..) 9 – no, I do now minus 6 – and then, this equals 40 and then minus 3 equals – thirty-seven and then minus 10 equals 27 .

Tanja exhibits a “Begin-With-One-Number-Method” (Fuson et al., 1997) by decomposing the subtrahend and subtracting it step by step. Whether her solution derives from a learned procedure, or from recognition and use of number patterns and relationships, or from a combination of the two cannot be determined from the information. However, for a correct assessment of Tanja’s abilities in mental calculation, it is crucial to know which cognitive elements her solution process entails. A procedure-based solution can be conducted mechanically, like following steps in a recipe, whereas a solution based on number characteristics entails dynamic use of knowledge of numbers and relationships.

Tools for solution: To find the answer to a problem, cognitive elements rely on additional *tools* that are used and combined in context. Specific tools for solution may be *counting*, referring to *basic facts*, or using other adaptive “*strategic means*”. Our sense of these “strategic means” is that they are not holistic strategies or cognitive menus that complete a solution path; rather, they are distinct devices that can be combined in flexible ways to modify complex problems to make them easier. Such strategic means include, for example, decomposing and composing ($65+28=60+20+5+5+3$), transforming a problem ($46-19=47-20$), deriving the solution from a known problem (if 7 joined with 7 equals 14 , the answer to 7 joined with 8 equals 15 , since 8 is one more than 7), and using decade analogies (if 4 joined with 5 is 9 , 40 joined with 50 must be 90) (Threlfall, 2002).

Whenever students solve a problem mentally, elements of all three domains are combined, and depending on that combination, one can identify different competencies. In judging mental flexibility, there is a meaningful difference between a student who mentally replicates a mechanically learned procedure and one who dynamically applies number sense, patterns, and problem characteristics to achieve a solution. This distinction is exemplified by the reasoning Simone shows with the subtraction problem $46-19$:

Simone: If I do add one (*points at the problem*), then I have got 20 here and 47 there, and then it is easier to calculate.

Interviewer: Which problem do you solve then?

Simone: $47-20$. This equals 26 (.) no 27 .

Interviewer: And - are you sure that you get the same answer to $47-20$ and $46-19$?

Simone: Yes, because I have added one to both numbers, and then I have more here (*points to 47*) and take away more there (*points to 20*).

Obviously Simone has solved the problem by mental calculation. First, she has transformed the actual problem into a new one that preserves the difference between the numbers. For Simone, the transformed problem is almost trivial. Her solution relies on a combination of subtraction basic facts and her knowledge of decade analogies. Simone has recognized the numerical proximity of 19 to 20, and she adapted this knowledge to the situation by transforming the problem. What we describe in the case of Simone is called “zeroing in” by Threlfall (2009, 47).

Flexibility in mental calculation

Multiple, inconsistent perspectives on the concept flexibility in mental calculation exist in the literature (Star & Newton, 2009). Depending on the definition used, different ways of operationalization are implied.

We choose to navigate through this somewhat confusing terrain by [...] defining flexibility as knowledge of multiple solutions as well as the ability and tendency to selectively choose the most appropriate ones for a given problem and a particular problem-solving goal (Star & Newton 2009, 558).

In the present article, we will, henceforth, use the dual term ‘flexibility/adaptivity’ as the overall term, ‘flexibility’ for the use of multiple strategies, and ‘adaptivity’ for making appropriate strategy choices (Verschaffel, Luwel, Torbeyns, & Van Dooren, 2009, 337/338).

First [...] we employed the definition of strategy flexibility as choosing among different strategies simply on the basis of the characteristics of the task, i.e. as using the compensation strategy on problems with a unit digit 8 or 9. Second, we also applied a more sophisticated definition wherein strategy flexibility is conceived as selecting the strategy that brings the child most quickly to an accurate answer to the problem (Torbeyns et al., 2009, 583).

All these definitions have in common the idea that flexibility in mental calculation is connected – explicit or implicit – with adaption and means an appropriate way of acting when faced with a problem. What exactly is meant by appropriate and how an appropriate way of acting can be identified is considered differently (Rechtsteiner-Merz in prep.). There is, on the one hand, the notion of choice in selecting an appropriate solution to a given problem (and perhaps including the choice of a solution deemed most appropriate). On the other hand, the appropriate way of acting when faced with a problem may not be determined by task characteristics but by the speed of obtaining a solution. In both views the focus is on mental outcomes, since researchers have typically regarded only one domain of the calculation process (Fig. 1), the tools for solution.

Similar to Threlfall (2002, 2009) and prior research (Rathgeb-Schnierer, 2006, 2010) we also define flexibility in mental calculation as a way of acting appropriately, but we have a different conception of what is meant by appropriate. Rather than the choice of the most suitable strategy or the quickest way of obtaining a solution,

appropriate acting for us means to match the combination of strategic means (see above) to the recognized number patterns and relationships of a given problem in the context of processing a problem solution. The recognition of problem characteristics, number patterns and relationships, and their use for solving a problem again depends on a student's knowledge of numbers and operations or what Threlfall (2002, 29) terms an "interaction between noticing and knowledge":

When faced with a fresh problem, the child or adult who follows different solution paths depending on the numbers does not do so by thinking about what the alternatives are and trying to decide which one to do. Rather, he or she thinks about the numbers in the problem, noticing their characteristics and what numbers they are close to, and considering possibilities for partitioning or rounding them. (Threlfall 2002, 41)

Our discussion leads us to posit a new perspective on flexible mental calculation because we are interested in mental processes that underlie the outcomes. That means, related to the model of process of calculation (Fig. 1), we focus on two different domains to identify the degree of flexibility in students: the tools for solution and the cognitive elements that support the solution processes. Only if the tools of solution are linked in a dynamic way to problem characteristics, number patterns, and relationships would we consider as evidence of flexibility in mental calculation. Hence our central questions about mental flexibility are: What problem characteristics, number patterns, and relationship do students recognize? And how do they use problem characteristics, number patterns, and relationships to solve problems?

OVERVIEW ON THE PROJECT

Questions and Assumptions

We investigated flexible mental calculation in elementary students from different classrooms in different countries. Referring to earlier research and our perspective on flexibility, the project is based on fundamental assumptions: First, there are different features in students' ways of acting when faced with an addition or subtraction problem that can be considered as indicators of flexibility. One feature is the recognition of problem characteristics, number patterns, and relationships in a given problem, and the other one is the dynamic use of recognized number patterns and relationships for solving a problem. Second, flexibility in calculation is not an all-or-none-phenomenon; it occurs in varying degrees (Rathgeb-Schnierer, 2010).

Research questions concerning the sorting task as research instrument: Does sorting problem cards into categories "easy" or "hard" help initiate mental flexibility when it is available? Do differences appear regarding sorting and reasoning, and can they be linked to different degrees of flexibility?

Research questions concerning patterns that appear in sorting, reasoning, and solving problems: Do students describe reasoning about problem characteristics, number patterns, and relationships? Do students link their tools for solution to

recognized problem characteristics, number patterns, and relationships? Can different degrees of flexibility be identified and pooled into general types?

Research questions concerning different classrooms: Do differences and tendencies show up in sorting, reasoning, and using tools for solution for students from different math classrooms? Do differences appear regarding sorting and reasoning, and can they be linked to different degrees of flexibility?

Design

Based on the theoretical model of flexibility introduced earlier, a qualitative study has been designed and carried out. Since we were interested in mental processes underlying the process of solving a problem, we decided on probing interviews as a research instrument (see following paragraph). Second graders and fourth graders from different instructional contexts in Germany (Baden-Württemberg) and USA (Charlotte, North Carolina) were selected. In total ten classrooms were sampled, 3 second grades and 2 fourth grades in each country. We chose about eight students from each classroom. Students with learning disabilities in math or with language problems were excluded in order to achieve a minimal level of understanding of number and operation. Based on the judgment of the classroom teacher, we got a sample representing predominantly middle and high achievers and carried out interviews with a total 51 second graders and 31 fourth graders.

Interviews

We developed a qualitative, problem-oriented interview that contains twelve two-digit addition and subtraction problems. Each problem was designed to show at least one special feature, sometimes more than one. Our problems incorporated features like double and half relations, same numbers at the tens and ones place, one number close to ten, both numbers close together, numbers at the ones place equal ten, reverse problems, and problems that require regrouping. These problems were displayed on small cards: $33+33$, $66-33$, $56+29$, $46-19$, $31-29$, $73+26$, $88-34$, $34+36$, $65+35$, $95-15$, $47+28$ and $63-25$.

Interviews had three parts, the first for sorting problems and talking about the sorting procedure, the second for solving problems, and the third for comparing selected problems. In the first step, cards were mixed and laid out on the table. Students were encouraged to look carefully at the numbers in each problem and sort the problems in two categories, “easy” and “hard” (these labels were placed at each side of the table). After a card was placed either to the “hard” or the “easy” side (occasionally students decided on the middle), we asked: “Why is this problem easy or hard for you?” In the second step we asked the students to choose some problems from each side, to solve one by one and to tell us what they were thinking when they solved a problem. We always started with the easy side and skipped all the problems that had already been solved during the sorting process. In the third step we focused on selected problems ($63-25$ and $88-34$; $47+28$ and $73+26$) and encouraged students to compare these in order to estimate whether one of each pair might be easier.

Students were interviewed one-on-one for 15 to 30 minutes. Video and audio recording was done for the whole interview.

Interviews were conducted by one researcher and took part in the last two months of the academic year (Germany 2010 and 2012, USA 2011). All interviews were transcribed in their original language for data analysis.

Data Analysis

Two coding systems that include both a priori and inductive meanings were used. One system was used to classify students' tools for solution; the other one was used to catalog reasoning for easy and hard problems.

The following example illustrates how a part of the coding system was developed. Data suggested that reasoning could be divided in four core categories (first level): reasoning by problem characteristics – easy (A/1), reasoning by problem characteristics – hard (A/2), reasoning by ways of solution – easy (B/1) and reasoning by ways of solution – hard (B/2).

Two different students explained why $33+33$ is an easy problem:

S 1: Because there's the same numbers in each 'um space. (A/1)

S 2: Because first I add 30 and 3, and then I add 3. (B/1)

To each core category we developed codes (second level) based on possible characteristics of numbers (e.g., Fig. 2) and theoretically described solution strategies (e.g., Selter, 2000; Threlfall, 2002). The sub-codes (third level) arose from the data again. All together we got three levels of categories/codes that were invented by combining data-based and theory-based methods. With this differentiated coding system students' utterances can be exactly assigned. See student 1 in the example above: His utterance is assigned on the first level to the core category "reasoning by characteristics – easy," on the second level to the code "special numbers", and on the third level to the sub-code "double digits".

First results and outlook on further data analyses

At the moment we have transcribed 70 interviews and categorized one third of the data using both coding systems. While we cannot yet provide definite answers to our research questions, we can report on some initial patterns we have observed. We illustrate these patterns based on a sample of 21 second grade students from three German classrooms.

Core category: reasoning by characteristic for „easy“ problems (first level)	
Codes (second level)	Sub-codes (third level)
analogies between tens and ones [5]	
size of numbers	both numbers are small [1]
numbers at the ones place	<ul style="list-style-type: none"> sum is less than ten [1] remaining or regrouping is required [1] first number smaller than second number [1] sum of ten at the ones place [8] number 5 at both ones place [14]
relationships of tasks	<ul style="list-style-type: none"> associativity [1] inverse problem [7]
relationships of numbers	<ul style="list-style-type: none"> double or half [10] number close to a ten [2] range [5]
known facts	<ul style="list-style-type: none"> parts of the problem are known by heart [18] whole problem is known by heart [10]
special digits / numbers	<ul style="list-style-type: none"> same numbers [5] number with nine [2] double digits (33) [5]

Fig. 2: Reasons for easy problems (numbers in brackets show frequency)

Overall, we have found a much larger than expected variety of patterns in students' reasoning for easy and hard problems. Already in the sample of 21 second graders various reasons for easy problems that refer to problem characteristics appeared (Fig. 2). Such variation can be considered as a hint that the sorting task encourages students to examine problems carefully; to reflect about problem characteristics, number patterns, and relationships; and to formulate solution arguments based on that recognition. In this vein, our data suggests that sorting has diagnostic value in assessing the underlying degree of flexibility in math structures.

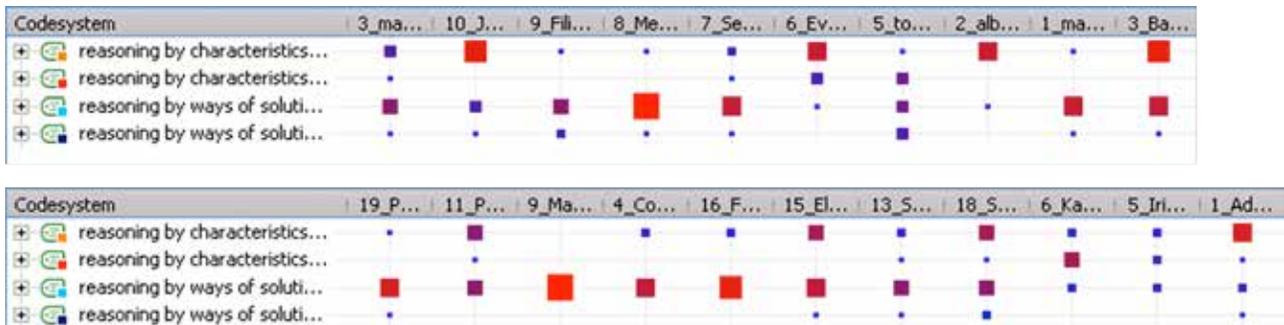

Fig. 3 Ways of reasoning

Regarding the ways of reasoning students in our sample have displayed (Fig. 3), it appears that $\frac{2}{3}^{\text{rd}}$ of the students tend to have preferences: 9 prefer reasoning by ways of solution; 5 prefer reasoning by characteristics; 7 students reason either way. Regarding the students individually, it appears that their pattern of reasoning can be described as either “dynamic” or “static.” For instance, Bartosch (3_Ba) depicted 8 different kinds of reasons (6 characteristics and 2 solutions); he would be considered as “dynamic”. In contrast, Marcel (9_Ma), who showed only two different reasons (2 solutions), would be considered as “static”.

Since this is work in progress, our current perspective on the data is only on a descriptive level. For going beyond this level, we plan on constructing types for each coding system separately (Kelle & Kluge 2010). That means, we will generate two

different typologies: one for the explicated ways of reasoning that gives information on students' recognized number patterns and relationships, and one for the utilized tools of solution that gives information on students' approach. In the next step we plan on linking and comparing both typologies with the purpose to see if students' ways of reasoning match the tools of solution they depicted. Based on our theoretical perspective on flexibility in mental calculation (see above), we will make use of this compliance to identify the degree of flexibility in each student. Then we will assign each student to a special degree of flexibility depending on characteristic patterns he or she displays in reasoning and solving. In a last step of analysis we plan on linking the degrees of flexibility we have found to the teachers' math instruction and dispositions to see if students' math experiences are associated with those degrees of flexibility.

DIFFERENT PRAXEOLOGIES FOR RATIONAL NUMBERS IN DECIMAL SYSTEM – THE $0.\bar{9}$ CASE

Benoît RITTAUD* and Laurent VIVIER**

*LAGA, Université Paris 13, France

** LDAR, Université Paris-Diderot, France

We report the results of an experiment, in which students were asked to make some computations involving the (ultimately periodic) decimal expansion of rational numbers and simple algorithms derived from the algorithms in use for decimal numbers. We show in which way these algorithms could be useful to increase the understanding of such a counterintuitive equality as $0.999\dots=1$.

Keywords: rational numbers; repeating decimals; praxeology; register of representation.

INTRODUCTION

It is well known that the understanding of the double representation of decimal numbers, in base ten system, is an important issue for students, for example for its implication in analysis. The emblem is the equality $0.\bar{9}=1$ that summarizes the situation on which teachers and searchers generally focus.

Many researchers have already investigated this inequality, among them, Tall and Scharzenberger (1978), Tall (1980), Sierpiska (1985) and Dubinsky et al. (2005) are worth to be mentioned. These studies mainly focus on the infinite character of such a representation and, more specifically, on real numbers and limits. Here, we expose an alternative viewpoint on the equality $0.\bar{9}=1$ which is essentially algebraic and emphasizes rational numbers: “are repeating numbers decimal?” and “is $0.\bar{9}$ equal to 1?” are in fact the same question. The present work derives from a recent research topic in mathematics, the notion of circular words (Rittaud & Vivier, 2012).

In this paper, we consider the comparison and the sum of repeating decimals. The register of representation (Duval, 1995, 2006) allows us to take the difference between semiotic representation (repeating decimals and fractions) and mathematical objects (rational numbers) [1] into account. We exhibit two different Mathematical Organizations (Chevallard, 1999) related to (1) repeating decimals and (2) rational numbers. The main difference between them is a technology related to the identification of the double representation of decimal numbers. These two praxeologies could explain some difficulties of students when we want them to understand why $0.\bar{9}=1$. It is our opinion that an important issue of the problem is to pass from a repeating decimals praxeology to a rational numbers praxeology. In this perspective, using an algorithm for the sum (Rittaud & Vivier, submitted work [2]) of two repeating decimals, we present a sequence of two activities that we proposed to students at the beginning of university. This relates to previous teaching at secondary school and at the very beginning of university.

THE EQUALITY $0.\overline{9}=1$: REGISTERS AND TECHNOLOGY

In this section, we present the problem of the equality of $0.\overline{9}$ and 1 with registers of representation (Duval, 2006) and praxeologies (Chevallard, 1999).

Theoretical frameworks

In the Anthropological Theory of Didactics (ATD) the mathematical activity is elaborated around types of tasks, appointed by Chevallard (1999) as mathematical organization. Generally, to perform a type of tasks T , we have at least one technique τ . Type of tasks and techniques are organized in a $[T, \tau]$ appointed block of know-how or praxis. To produce and/or justify a technique τ , it is necessary to have a theoretical look at the problem posed by T . Chevallard defines a new block $[\theta, \Theta]$, called block of knowledge or logos, made up of technology and theory. Type of tasks, techniques, technology and theory form a praxeology or mathematical organization $[T, \tau, \theta, \Theta]$.

Duval (2006) starts from signs used in the mathematical work grouped into registers of semiotic representations. The essential distinction made by Duval consists in the dichotomy between treatment and conversion. Treatment is a semiotic transformation which remains within the same register of representation. Conversion is a semiotic transformation whose result is expressed in another register. Duval stresses the essential cognitive difference between treatment and conversion. Conversion is much more complex and problematic than treatments, especially for a non-congruent conversion.

Two numerical registers of representation for rational numbers: R_f and R_d

When speaking about rational numbers, one often thinks of fractions. Fractions constitute the main way of constructing rational numbers, especially in secondary teaching because of proportionality. This is the first register of representation of rational numbers, denoted here by R_f .

Duval stressed that one needs, at least, two registers in order not to mix the object with its representation. For our purpose, the interpretation of fractions a/b by a divided by b allows, by long division, to obtain a new register written R_d related to base ten system. The result of a long division is a repeating decimal which is, traditionally, a non finite expansion for a non decimal number and a finite expansion for a decimal number [3]. As Duval pointed out, conversions between R_f and R_d are non congruent as one can see with $1/4=0.25$ or $2/7=0.\overline{285714}$.

Non congruency also appears in treatments. Obviously, the comparison of the two rational numbers above is very different in R_f and in R_d . It is also the case in terms of the four basic operations. These calculations are well known and taught at lower secondary school in France in R_f and we do not describe them. A description of algorithms for the four basic operation in R_d is one of the aim of our submitted work. We only expose in this paper the sum (see the section devoted to the sum below).

A hidden technology

Comparing two repeating decimals, a type of tasks denoted by $T_{<}$, is quite simple since one just has to compare cipher by cipher from left to right, a technique denoted by $\tau_{<}$. It is a natural generalization of the comparison of two decimal numbers. Students have no difficulty with this technique $\tau_{<}$ for the type of tasks $T_{<}$ as we will see. But are we comparing rational numbers? It is not so obvious because $\tau_{<}$ deals with semiotic representations that must be interpreted in order to have mathematical objects called numbers.

Indeed, comparing $0.\bar{9}$ and 1 leads to $0.\bar{9} < 1$ by $\tau_{<}$ technique, when computing on repeating decimals, but must lead to $0.\bar{9} = 1$ for rational numbers. We identify a new technique $\tau'_{<}$ close to $\tau_{<}$ except for decimal numbers. This shows that from the type of tasks $T_{<}$ two praxis related to two different mathematical objects arise whose writings are exactly the same: $[T_{<}, \tau_{<}]_{rd}$ for *pure* repeating decimals and $[T_{<}, \tau'_{<}]_Q$ for rational numbers – we do not speak here of fraction representation.

This distinction could be confusing because we see the same writings, the same ciphers, the same signs. The difference is in the interpretation of what is represented. Furthermore, the technology that justify technique $\tau_{<}$ and $\tau'_{<}$ are mainly identical: it is a technology that is grounded in the base ten system, denoted by θ_{bts} . Obviously, there is a lack for $\tau'_{<}$ in order to justify the equality of the two representations of decimal numbers. We denoted this *hidden* technology by $\theta_{=}$. One has to notice that, until now, there is no indication of $\theta_{=}$, it cannot appears only with the comparison and there is no indication of its nature, of its origin.

A topological technology

Actually, $\theta_{=}$ is an important technology of the real numbers theory, denoted by $\Theta_{\mathbf{R}}$, that is related to the topology of the set \mathbf{R} of real numbers [4]. Explications within the APOS theory are quite clear as Dubinsky et al. (2005, pages 261-262) wrote:

An individual who is limited to a process conception of .999... may see correctly that 1 is not directly produced by the process, but without having encapsulated the process, a conception of the "value" of the infinite decimal is meaningless. However, if an individual can see the process as a totality, and then perform an action of evaluation on the sequence .9, .99, .999, ..., then it is possible to grasp the fact that the encapsulation of the process is the transcendent object. It is equal to 1 because, once .999... is considered as an object, it is a matter of comparing two static objects, 1 and the object that comes from the encapsulation. It is then reasonable to think of the latter as a number so one can note that the two fixed numbers differ in absolute value by an amount less than any positive number, so this difference can only be zero.

At the end of this quotation, one can note a technology, that encompasses $\theta_{=}$, closely related to the topology of \mathbf{R} . But it is not so obvious, especially for students. And one has to notice that this technology does not stand in nonstandard analysis, nor in the monoid of repeating decimals we will define later.

Actually, the topology of \mathbf{Q} is enough. First, we can talk about limit in \mathbf{Q} , but it is not interesting for teaching (except for Méray-Cantor's construction of \mathbf{R}) and secondly the density of \mathbf{Q} allows concluding that $0.\bar{9}=1$ because there is no number between them, but one has to assume that $0.\bar{9}$ is a rational number, which is not obvious.

In the previous quotation, one notices that it is a question of the “value” of an infinite expansion and of “numbers”. Hence, before talking about topology of \mathbf{R} or \mathbf{Q} , we prefer to justify that we are dealing with numbers. According to (Chevallard, 1989), numbers are objects that could be, almost, compared, added, subtracted and multiplied with usual properties.

DIDACTIC UNDERSTANDING OF THE PROBLEM BY TAD THEORY

In this section, we continue the description by TAD in considering the sum type of tasks, T_+ . The aim of this section is to try to justify θ_+ by the sum according to: (1) the comparison is not sufficient to make θ_+ arise and (2) the topology technology belongs to a higher level of knowledge. Before investigating the sum type of tasks T_+ , we discuss the classical way for proving that $0.\bar{9}=1$ using calculations and an equation.

A classical way to produce and justify θ_+

A classical way to produce and justify θ_+ comes from calculations with repeating decimals, as if they were usual numbers. It is well known by all mathematics teachers that every repeating decimal could be converted into \mathbf{R}_f using an equation [5]. There are others calculations that lead to the target equality, see for example (Tall & Schwarzenberger, 1978). But all these calculations rely on the operations that are supposed to be well defined – this assumption on operations, especially on subtraction, is not so obvious and is, in fact, directly linked to the problem.

The point of view is quite natural from a mathematical perspective: after generalizing objects one wants to preserve some properties. Here, one has some new *numbers* and the properties are those of the usual operations, even if we do not know if it is possible to define these operations. Obviously, this raises the problem of the consistency of the mathematics produced. It is the same perspective for the multiplication of integers within the set \mathbf{Z} , and especially the sign of the product (Glaeser, 1981). But the consequences are not identical. Indeed, the result in \mathbf{Z} are totally new and it is not problematic since there is no opposition with an ancient knowledge – think for example at $(-2)\times(-3)=(+6)$. But in our case it is not so simple. Of course calculations *say* that $0.\bar{9}=1$, but $\tau_<$ *say* that $0.\bar{9}<1$. Hence, there is an obvious contradiction and what a student may believe? It is natural to think that the ancient knowledge is stronger, even if a student's answer is the equality because of the didactical contract. Hence, with this type of calculations the need appears of θ_+ but it also brings a contradiction and no explanation could emerge.

Four processes for the sum in \mathbf{R}_d

Here, we are describing four processes to compute the sum of two repeating decimals. Each time, we discuss the possibility to justify θ_+ .

The first process consists in performing calculations by approximations and inferring the period of the sum. This process requires two technologies: *the sum of two repeating decimals is a repeating decimal* and *the sum is continuous* (according to the usual topology of \mathbf{R}). For example, to compute $0.\bar{5} + 0.\bar{7}$, one successively writes $0.5+0.7=1.2$; $0.55+0.77=1.32$; $0.555+0.777=1.332$; and so on. It is not an algorithm since there are no criteria to stop the approximations (when do we get the period?). We do not retain it, first because it relies on the high-level technology we pointed out and second because this process causes some wrong writings to students (see below).

The second process is an algorithm that requires a conversion: calculating the addition after a conversion into \mathbf{R}_f like in $0.\bar{5} + 0.\bar{7}=5/9+7/9=12/9=1+3/9=1.\bar{3}$. The point is that the conversion of repeating decimals such as $0.\bar{9}$ requires calculations involving repeating decimals, sum and subtraction. It is close to the *doubtful* equation process (see previous section). Moreover, it is quite difficult to understand how repeating decimals could become numbers within this process since calculations are made with fractions. Hence, we also reject this process.

The third process makes an explicit use of $\theta_=\$, as in $0.\bar{5} + 0.\bar{7} = 0.\bar{9} + 0.\bar{3} = 1 + 0.\bar{3} = 1.\bar{3}$. We do not retain this algorithm since it relies strongly on $\theta_=\$ itself.

The fourth process is an algorithm we proposed in (Rittaud & Vivier, submitted work). It is quite close to the algorithm of addition of two decimal numbers in base ten system: decimal points have to be in the same row, so do the periods. In the simplest case, with no carry overlapping the periodic and aperiodic parts, we get something like in the first example of figure 1. When a carry appears at the leftmost digit of the periodic part, we have to consider it twice: the first one, as usual, at the rightmost digit of the aperiodic part (this corresponds to the exceeding part), the second one, more unusual, at the rightmost digit of the periodic part (such a unusual carry is written between parenthesis). An example is given in figure 1.

$\begin{array}{r} 1 \quad \quad 1 \\ \quad 4. 2 \quad 4 \quad 2 \\ + 1 \quad 7. 0 \quad 4 \quad 9 \\ \hline 2 \quad 1. 2 \quad 9 \quad 1 \end{array}$	$\begin{array}{r} 1 \quad (1) \\ \hline 0. 8 \quad 2 \\ + 0. 4 \quad 1 \\ \hline 1. 2 \quad \cancel{4} \end{array}$
$4.2\bar{42} + 17.0\bar{49} = 21.2\bar{91}$	$0.\bar{82} + 0.\bar{41} = 1.\bar{24}$

Figure 1: two examples of the algorithm

Of course, we also have to deal with sums in which the position of the decimal point or the length of the periods, are not the same. For example, to perform the sum $2.45\overline{38} + 13.31\overline{92}$, we first rewrite it as $2.45\overline{383838} + 13.31\overline{921921}$.

We argue that this fourth process can help making $\theta_=\$ arise and, meanwhile, to make repeating decimals become numbers. We explain in the next section.

Monoid praxeology *versus* number praxeology

The equality $0.\overline{9}=1$ is not relevant when one deals only with the comparison praxis but it is needed for calculations. Hence, we focus here on praxeologies which arise related two types of tasks: comparison, $T_{<}$, and sum, T_{+} .

We saw several techniques to solve T_{+} but, except the last one given in the previous section with our algorithm, all rely upon a technology of $\Theta_{\mathbb{R}}$ or $\Theta_{\mathbb{Q}}$ that has to be accepted without any justification. Hence, we focus on our algorithm interpreted as a technique denoted by τ_{+} . Since students may justify the technique themselves τ_{+} by θ_{bts} , the algorithm seems very interesting in order to introduce $\theta_{=}$ – this τ_{+} justification is the main difference compared to the other techniques for the sum.

We begin to build a praxeology $[T_{<}, T_{+}, \tau_{<}, \tau_{+}, \theta_{\text{bts}}]$ related to the R_d register of the repeating decimals. It is important to notice here that one works with repeating decimals, and quite easily, whether they are interpreted as rational numbers or not.

We easily get that, for any periodic expansion a with a non-zero period, we have $a+0.\overline{9} = a+1$. Hence, in the set of periodic expansions, we do not have the usual simplification property that allows to deduce from $a+c = b+c$ the equality $a = b$. To recover it, it is necessary to identify $0.\overline{9}$ and 1. Here, this is the time for the choice of $\theta_{=}$: do we accept it or not? This question is directly related to the choice between two mathematical organizations linked to the comparison, $T_{<}$, and sum, T_{+} , types of tasks:

- $\text{MO}_{\mathbb{Q}}=[T_{<}, T_{+}, \tau'_{<}, \tau_{+}, \theta_{\text{bts}}, \theta_{=}, \Theta_{\mathbb{Q}}]$ that could be extend to others operations both in R_d and R_f , that is the theory $\Theta_{\mathbb{Q}}$ of rational numbers.
- $\text{MO}_m=[T_{<}, T_{+}, \tau_{<}, \tau_{+}, \theta_{\text{bts}}, \Theta_m]$ that could not be extend to fractions nor to other operations. Here, we only have a non regular monoid (it is not a semi-group).

The aim of our investigation is to use this opportunity to show students where the problem is, in order to make them understand that only one of these two possible choices leads to the convenient notion of rational numbers.

AT THE BEGINNING OF UNIVERSITY

A test was given to 29 students in mathematics in the first year of university. It was presented in two steps: first an individual test (see annex 1), then, two days later, a team test (see annex 2) with three students in each group. The first step was diagnostic: understanding of the coding (questions E1 and E2), comparison (questions C1 to C4), sum (questions S1 to S6) and difference (questions D1 to D3). The team test showed the algorithm, asked for an explanation and then proposed an activity with the intent of presenting the $\theta_{=}$ alternative.

Students knew the two representations of rational numbers since grade 10 because of the ancient French mathematics secondary syllabus (before 2009), and heard of it again in their first semester of university. The case of $0.\overline{9}=1$ was taught as well.

This investigation follows a previous test in grade 10 and in the first year of university (Vivier, 2011): in grade 10 many of the 113 students were able to use the

algorithm, but they were not able to explain it probably because the base ten system (θ_{bts}) is not understood well enough. Hence, we think that *good level* for this kind of experiment in France is at the transition between secondary and university level.

Individual and diagnostic test

The coding (E1 and E2) caused some problems to 6 students and, obviously, they did not succeed the test (they were subsequently dispatched over 6 different teams).

Comparison of the three non problematic cases was successful for all students. They wrote the numbers in extension and used $\tau_{<}$ for comparing them. As we expected it, $\tau_{<}$ is not problematic at all since it is the same technique for MO_Q and MO_m .

But, for the case of $0.\bar{9}$ and 1, only 8 students stated the equality and 21 the inequality, a ratio close to Tall(1980) where it was 14 over 36 students. Among the first ones, two students wrote that this case was seen before, one of them qualifying this case as “strange”. One other student stated both the equality and the inequality, arguing for the equality that it is “because it is not a real number”, and for the inequality by comparing the unit cipher of $0.\bar{9}$ and 1 (she used $\tau_{<}$). One can see here the gap between MO_Q and MO_m .

Unsurprisingly, 25 students computed the sums and differences by approximation. Some students used sometimes a conversion into R_f and also the equality $0.\bar{9}=1$ (see the third process above). As expected, 14 students gave *infinitesimal answers* (Margolinas, 1988) such as $0.\bar{5} + 0.\bar{7} = 1.\bar{3}2$.

Finally, 7 students concluded that $2 - 1.\bar{9}=0$. All of them having previously declared that $0.\bar{9}=1$. 11 students gave $0.\bar{0}1$ as a result (infinitesimal answer again), 6 gave $0.\bar{1}$, 2 gave 0.0001 (with a finite number of 0) and one gave $0.\bar{10}$ as an answer. More generally, no student who affirmed $0.\bar{9}=1$ wrote an infinitesimal answer.

The equality $0.\bar{9}=1$ seems to point a more general knowledge on repeating decimals related to MO_Q . Even if repeating decimals are written in extension for treatments, the interpretation and control of results show a difference between the two mathematical organizations MO_Q and MO_m beyond the $\theta_{=}$ understanding.

Despite the frequent appearance of rational numbers written in base ten, in secondary teaching as well as in the university, most of the students do not agree with the equality $0.\bar{9}=1$ and about half of them write infinitesimal answers for the sum. Hence, it seems reasonable to say that previous teaching neither gave them sufficient control nor understanding of rational numbers in decimal writings, even if our experiment involved only mathematics students. MO_Q seems to provide more control and a better understanding for the sum than MO_m , even for tasks not involving $\theta_{=}$.

The team test

The justifications of the algorithm were quite good for 4 teams: in terms of anticipation of the carry coming from the right, existence of two carries (“local” and “inherited”), periodicity of the periods and some mentions of the stability of the

periods lengths. Two other groups proposed some partial justifications, three did not write any justification and one team did not understand the algorithm.

Apart from team I in which the algorithm was not understood, teams gave the answer 1 in the third line of the table (see annex 2). Hence, the activity is adequate to set the problem that $x=0.\bar{9}+a$ even if $x-a=1$. Only the four groups in which there was at least one student who wrote $0.\bar{9}=1$ in individual test made the remark $0.\bar{9}=1$. Groups A, B and E expressed the apparent contradiction between an algebraic calculation (such as $0.\bar{9}+a-a$ is equal to 1) but concluded, as group J, that there are some approximations. Group F wrote: “if one uses the algorithm then $0.\bar{9}=1$ ” leading us thinking that the validity of the algorithm is quite suspicious for that group.

Hence, in spite of the opposition that emerged, our objective is not fully attained since $\theta_$ not arose but only some contradictions related to $\theta_$. A first explanation is that the short time at our disposal was probably not sufficient. Second, the fact that the test was given after recalling the students that $0.\bar{9}=1$ was obviously a bias that might have inhibited remarks and reflexions. It would therefore be interesting to make a comparison with secondary students (grades 11 or 12), students at the very beginning of university, and student-professors of primary education.

CONCLUSION

It appears clearly, and it is not very surprising, that both secondary and first year university teaching are not suited to understand the problem of the double representations of decimal numbers in base ten system. However, from the individual test, one may think that the understanding of the equality $0.\bar{9}=1$ is important for a general understanding of MO_Q that seems to give a powerful control on calculations.

We pointed out the following alternative: do we take $\theta_$ or not? Besides the fact that the objective of the team session was not fully attained, overall because of a too little working time on the algorithm, we think that the use of comparison and addition could help in exhibiting and understanding this necessary choice. Indeed, from this working session, the opposition linked to the alternative arises.

Our position is close to the investigation of Weller et al (2009): they shown that working on comparison, sum and difference of rational numbers written in the decimal system – they used a software which makes calculations with fractions, hidden for the students – is important in order to understand the equality $0.\bar{9}=1$.

We intend to pursue our investigations in order to understand if and how our algorithm could foster students’ understanding of the double representation of decimals. We think that another point has to be considered: conversion into fraction by long division is interesting for validation and control of the addition algorithm.

NOTES

1. In this paper we only consider numerical registers.
2. A simplified French version is available at <<http://hal.archives-ouvertes.fr/hal-00593413>>.

3. When dividing a by b , one has just to replace the usual condition on remainders, $0 \leq r < b$, by the new one $0 < r \leq b$ in order to obtain the alternative representation of decimal numbers, with an infinite sequence of 9. Moreover, the fact that, in \mathbf{R}_d , two different sequences of digits could represent the same number constitute a gap with the case of decimal numbers.

4. Without identifying the double representation of decimal numbers, the obtained set is not \mathbf{R} but a Cantor set.

5. This kind of exercises appears in some French textbooks at grade 10. The meaning of the equation is quite unusual since the unknown is not the number but one of its representations: for $a=0.\bar{9}$, one has $10a-a=9$ and therefore $a=1$.

ANNEX 1: THE INDIVIDUAL TEST

CONVENTION : In the decimal writing of a rational number, we write the period by a bar above it. Hence, the number $0.127272727\dots$ with period 27 could be written as $0.12\overline{7}$.

E1) Circle the number which is different from the other ones:

$$5.\overline{00100} \quad 5.001\overline{0001} \quad 5.\overline{001000100} \quad 5.\overline{00101} \quad 5.001\overline{000}$$

E2) Write in four different ways the number $14,\overline{121}$.

Circle the right answer and then justify your choice:

C1) $8.13 < 8.\overline{13}$ $8.13 = 8.\overline{13}$ $8.13 > 8.\overline{13}$

C2) $3.\overline{4} < 3.\overline{40}$ $3.\overline{4} = 3.\overline{40}$ $3.\overline{4} > 3.\overline{40}$

C3) $0.\overline{9} < 1$ $0.\overline{9} = 1$ $0.\overline{9} > 1$

C4) $45.\overline{101} < 45.1\overline{01}$ $45.\overline{101} = 45.1\overline{01}$ $45.\overline{101} > 45.1\overline{01}$

Compute the following sums:

S1) $0.\overline{24} + 0.\overline{57}$ S2) $6,7\overline{1} + 1,8\overline{5}$ S3) $0.\overline{5} + 0.\overline{7}$

S4) $0.0\overline{8} + 0.\overline{2}$ S5) $0.\overline{9} + 0.\overline{4}$ S6) $0.\overline{5} + 0.\overline{72}$

Compute the following differences:

D1) $2,1\overline{7} - 0.\overline{7}$ D2) $2 - 1,\overline{9}$ D3) $1,\overline{28} - 0.\overline{72}$

(Two different individual tests, of equal difficulty, was given to avoid cribbing.)

ANNEX 2: GROUP TEST

Q1) We propose to discover a new algorithm to compute the sum of two rational numbers in decimal writing. In your opinion, is this algorithm give the good result? Justify your answer. (The two examples of figure 1 was given.)

Q2) In trying to find all the cases, give at least five other sums involving two rational numbers in decimal writing and compute these sums with the proposed algorithm. Note that, whether the case you consider, some adaptations of the algorithm are required.

Q3) Chose, each of you, a number a with a period. One defines, for each number a chosen, the number $x = 0.\overline{9} + a$. Fill the following table:

	Student 1	Student 2	Student 3
a			
$x = 0.\overline{9} + a$			
$x - a$			

Which remark(s) this table may suggest?

ABOUT STUDENTS' INDIVIDUAL CONCEPTS OF NEGATIVE INTEGERS – IN TERMS OF THE ORDER RELATION

Maike Schindler, Stephan Hußmann

IEEM, Technische Universität Dortmund

In the presented study we investigated sixth graders' individual concepts of negative integers right before they were introduced to the "world" of the negatives. In order to investigate students' first ideas of negative numbers, we initially investigated their ideas concerning the order relation of integers. With a qualitative data analysis utilizing a theoretical lens concerning individual concept formation, we gained insight into the students' individual procedures and conceptions as well as into how the procedures are linked to the students' previous knowledge.

Keywords: Negative number, integer, order relation, concept formation, previous knowledge.

INTRODUCTION

In mathematics education there are many studies dealing with the development of specific content areas (i.e. algebra, fractions and functions) and other studies analyzing learners' perspectives. Many of these empirical works focus on the outcomes of students' learning, but not on the learning *processes* themselves. Furthermore the misconceptions and difficulties in individual learning processes are analyzed with respect to an ideal learning trajectory, whereas the productive potential of these individual processes is not taken into account. In our contribution the aim is to structure and understand students' learning processes in mathematics. Thereby we use a theoretical approach, which enables us to reveal key points of misunderstandings as well as main influencing factors. These constitute the basis for an adaptive structuring of the mathematical content and hence for the development of instructional designs.

THE RESEARCH OBJECTIVE

Negative integers constitute a significant topic in mathematics teaching and learning. The concept of negative integer is relevant for both, the handling of inner mathematical situations such as solving the equation $x+3=1$, as well as the handling of real-world situations. Although negative numbers have not been subject of research as often as e.g. fractions or other topics for a time (cf. Bruno & Martínón 1996), the number of studies and papers is increasing. With the presented study, we want to make a contribution to the current state of research by investigating one aspect, which has not been subject of research sufficiently. The aim of the presented study is to investigate the very beginning with negative numbers in mathematics class: It is our special interest to investigate the students' levels of knowledge when being introduced to negative integers in school and to analyze which parts of their previous knowledge students take into account (cf. Bruno & Martínón 1996). We focus especially on the students' understanding related to the *order relation* of

integers, which constitutes – followed by addition, subtraction etc. – one of the first topics when learning about the negatives. The suitable continuous ordering (in terms of the formula $a < b$ ($a, b \in \mathbb{IN}$) $\Rightarrow -b < -a$) is not self-explanatory for students, who may order the numbers as well by focusing on magnitudes (in terms of the formula $a < b$ ($a, b \in \mathbb{IN}$) $\Rightarrow -a < -b$). “Ordering negative numbers is complex because there are two possible orderings that are supported by thinking about common contexts – the standard ordering and ordering by magnitude (absolute value)” (Widjaja, Stacey & Steinle 2011, 81). While there are already some findings about the ordering of negative integers (see Bruno & Cabrera 2005, Thomaidis & Tzanakis 2007, Widjaja et al. 2011), an access to the *interplay of concepts* is still missing: In order to learn more about the very beginning with negative integers, there has to be gained more insight into the parts of the students’ *previous knowledge* taken into account while ordering integers, and to the reasons *why* students use the one or the other ordering.

This perspective constitutes the basis for our investigation. The expected findings are assumed to serve for a structuring and organization of the mathematical content of the introduction of negative integers, especially of ordering integers.

The research issues of the present study are the following.

- (1) Which *procedures* do students have for ordering integers? Which concepts and which assumptions are interwoven in these strategies? Which difficulties do students have?
- (2) Which *previous knowledge* is taken into account? Which reasons can be reconstructed for the students’ approaches to order integers? Which previous-built concepts are taken into account?

In our research project we pursue these questions with regard to two main issues: *Firstly* we want to figure out, how students handle situations just shortly *before* they get to know negative integers in school in order to bring their previous knowledge to light. We intend to assess how students perform due to this previous knowledge without having had any introduction to the topic of negative integers before. *Secondly* we intend to focus on *concept formation processes*. It is our aim to investigate these processes on the one hand in a short-term perspective – to analyze how difficulties and misconceptions can be overcome and which impetus is helpful. On the other hand we focus on a long-term development over a lecture series and intend to find out how procedures and utilized concepts change. Because of the limited space, we have to restrict ourselves to the first issue, i.e. the previous knowledge, in the presented paper.

METHOD

For the purpose of our investigation, half-structured, task-orientated clinical interviews (cf. Selter & Spiegel 1997) were undertaken with eight sixth graders in German schools. The interviews were followed by a lecture series to introduce negative integers by means of a suitable learning environment, which again was

followed by interviews. The qualitative analysis of video sequences and transcripts was taken as a basis for evaluating the data.

For the purpose of this study, students got different pairs of integers and had to determine the “greater” one. As negative numbers are in a way ‘fictive’ as they are not physically perceptible on their own, representations have a pivotal importance for the teaching and learning of negative integers. There are most notably four kinds of representation, which seem to be meaningful for getting to know the negatives (expanded from Bruno & Martínón 1999): These are (a) the representation on the number line or other ordinal arrangements regarding the order of integers (like ... -3 -2 -1 0 1 ...) (b) a quantity representation, which students mostly know from natural numbers (like e.g. “3 means three spots”), (b) the representation in a real-world context (e.g. temperatures, debts-and-assets) as well as (c) the symbolic representation (e.g. -6 or “minus six“). These kinds of representation and their interplay are of great importance for the learning of negative integers (cf. Bruno & Martínón 1999).

Whereas the results of some studies (e.g. Malle 1988) indicate that most of the students seem to know the symbolic representation of negative integers from the very start of the introduction to negative integers, the aim of our investigation was to find out if the students in our study also knew the symbolic representation *before* having had an introduction to negative numbers. Beyond that, we intended to find out if students are able to utilize the number line or other ordinal arrangements, and in what way they fall back on real-world contexts. Therefore, the integers were presented in a symbolic way and the use and change of representations was investigated.

Naturally, by displaying integers in a symbolic way, the knowledge students are able to activate, is limited: If integers were for example given in a contextual way, students would surely be able to handle situations more competently, using real-life knowledge more easily. But in our study, we wanted to figure out which knowledge students are able to activate when regarding numbers such as 12 or -15: if they alter the kind of representation for their reasoning, if they activate contextual knowledge etc. In the interviews students first compared a positive with a negative integer, then two negatives, followed by the comparison of a negative and a positive integer each with zero. In doing so, students received two small cards each of them displaying an integer in a symbolic representation (e.g. 12 and -15).

A GLIMPSE OF THE THEORETICAL AND ANALYTICAL FRAMEWORK

For the concern to analyze students’ individual concepts and their development we use a theoretical approach (Hußmann & Schacht 2009, Schacht 2012), which serves as a theoretical lens for analyzing concepts and from which appropriate analytical tools can be deduced. The theoretical approach is based on different influences: For the epistemological framework, Robert Brandom’s semantic Inferentialism (e.g. Brandom 1994) constitutes a basis and an essential factor from a philosophical perspective. Gérard Vergnaud’s Theory of Conceptual Fields (e.g. Vergnaud 1996)

replenishes the theoretical framework from a rather psychogenetic and mathematics-didactical point of view. The background theory will be briefly outlined in the following by giving a short overview of the crucial ideas. The arising building blocks of our analytical scheme (commitments, inferences, focuses (see below)) will be illustrated and explained in detail afterwards.

In the underlying *theoretical framework*, the individual's responsibility for his or her actions and utterances is regarded as essential for the conceptual. For the contemplation of the individual's personal responsibility, the idea of the *language game*, which can be attributed to the late Wittgenstein, plays an important role. The ability to give reasons and to ask for them in the language game is regarded as substantial for the individual's responsibility: In the language game, individuals show responsibility for their utterances and actions by being able to give reasons for them. For the analysis of the conceptual, individual commitments and individual judgments are essential: Individual *judgments* are the smallest units individuals can take responsibility for. They have propositional content, such as the judgment "Negative numbers are below zero". *Commitments* are those individual judgments, which are made explicit by the student as propositions (e.g. "Zero is the freezing point.").

Within our analysis, we investigate *commitments* as well as the *relations*, which exist between commitments in terms of the students' individual reasonings: the individual *inferences*. There is an *inferential relationship* between commitments if one commitment entitles the student to affirm another one (e.g. "Negative numbers are below zero *because* positive numbers are above zero.") and if the student accepts this inference as true. Practical reasoning discloses such inferential relationships.

Furthermore, we analyze students' individual *focuses* in terms of individual categories that are used to structure situations and to select the given information (cf. Vergnaud 1996, 225). *Focuses* are categories, which are used to handle and select the information of a given situation (e.g. 'the minus sign' or 'subtraction' or 'the number line' or 'changes in temperatures'). Individual commitments, inferences and focuses form students' individual *inferential webs*.

Beyond that, it is our aim to investigate if students use commitments (respectively judgments) and focuses *across situations* – to what extent they are *invariant* (cf. Vergnaud 1996). By analyzing the invariant focuses and commitments we can investigate which situations belong together in the students' eyes, which situations belong – according to the students – into the same class of situations and much more.

To sum up, the kernel of our theoretical framework signifies that understanding a concept means understanding the use of a concept with its reasons and its inferences.

In the following, the main building blocks of our *analytical scheme* (focus, commitment, inference) are illustrated and explained by giving a glimpse of the analysis of one student's way of proceeding during the pre-interview. The case of the student Nicole was chosen to be presented here. While working on the task to name the greater of a positive and a negative integer in the pre-interview she proceeds in a

way, which is interesting as she seems to subtract the two integers and compare them by using the difference. In the following, an excerpt of the transcript of the pre-interview is presented in order to illustrate the analytical scheme. The scene took place in the very beginning of the interview.

Interviewer: I brought along two numbers and I want you to tell me which one of them is greater (gives two small cards to the student, displaying 12 and -15)

Nicole: (looking at the cards) (6sec) The fifteen. (6sec) No the twelve, because there at- in front of the fifteen there is- minus fifteen is displayed there- then it has to be the twelve.

Our approach is based on the assumption that concept formation takes place within situational conditions and that a strong interrelationship exists between situated action and conceptualization. For the understanding of students' concept formation it is indispensable to investigate the situations in which it takes place and the aspects on which students focus. By setting *focuses* in situations, students on the one hand deal with the situation at hand and on the other hand they simultaneously deal with the concepts they possess. While trying to handle available situations, students use individual concepts, relationships, properties etc. as categories that they developed before and that enable them to select the diverse information embodied in the given situation. In the given interview sequence Nicole seems to focus on the *minus sign*.

Besides individual focuses the student makes assumptions concerning the situation, about relationships of the properties etc. They are interwoven with the focuses since focuses give the orientation for the assumptions to be made. In our approach, we are looking at these assumptions by examining individual *commitments*. In the above-mentioned case of Nicole, there can be assigned the following commitments to her utterances: Firstly, she seems to commit to “Among (-)15 and 12, (-)15 is greater.” (cm01) At this point in time, it is not yet reconstructable whether she means that 15 or minus 15 is greater. But she seems to reject this commitment by uttering “no” and committing to another, contrary commitment: she commits to “Among (-)15 and 12, 12 is greater.”(cm02) and obviously tries to entitle this commitment by giving a reason for it. In other words, the latter commitment (cm02) constitutes a conclusion and she is trying to give a premise for it. In our theoretical approach these entitlings have a pivotal importance for reconstructing *inferences* as they concern the reasons, which students give for their commitments and focuses and finally for their approaches. In Nicole's case, she seems to entitle the commitment “Among (-)15 and 12, 12 is greater.”(cm02) by committing to the fact that there is a minus (sign) in front of 15. The commitment “There is a minus sign in front of 15.”(cm03) is assigned to her utterance. The inferential relationship between the commitments is assigned as an inference: “Among (-)15 and 12, 12 is greater, because there is a minus in front of 15.”

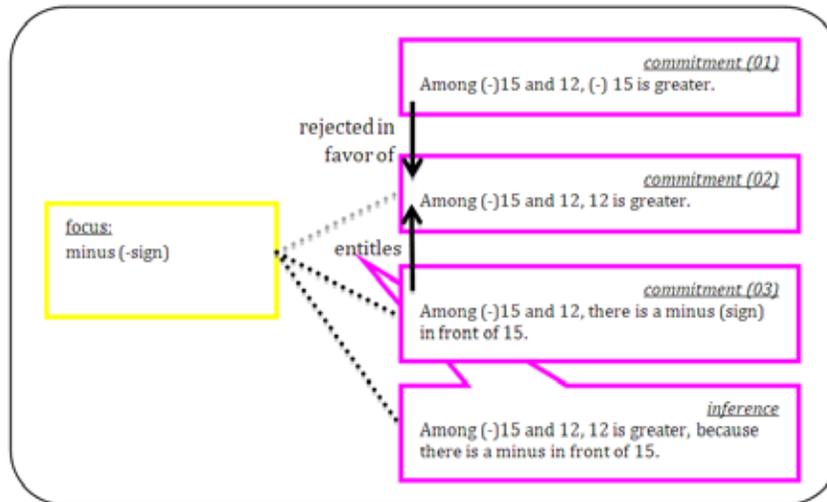

Figure 1 Nicole's focus, commitments and inference

Focuses, commitments and inferences form inferential webs. Understanding the concept of integer means to be endowed with an *inferential web* in which the concept of integer itself and other related concepts are involved. By analyzing the students' individual inferential webs it is possible to get an insight into the above-mentioned research issues: It enables us to uncover the students' individual approaches in detail as well as their difficulties (research issue 1) and they make it possible to focus on the previous knowledge that the individual approaches rely on (research issue 2).

The outcomes of the analysis concern the above-mentioned research perspectives as they give a detailed insight into individual procedures, into difficulties and possible reasons especially for the point in time when getting to know negative integers. By examining inferential webs, it can be investigated which previous concepts are taken into account and how the inferential structures change during the learning process. This constitutes the basis for structuring the mathematical content as well as for the optimization of the developed learning environment.

Nicole's strategy of subtraction

At a later time, the analysis unfolds *why* the focus on the minus sign leads Nicole to the inference "Among 12 and -15, 12 is greater because there is a minus in front of 15" (see above). The commitments "In order to determine the greater number among -15 and 12, I can subtract." with the focus on *subtraction* as well as "The numbers 12 and -15 form a mathematical task." with the focus *mathematical task* that can be assigned to her utterances seem to have a pivotal importance. It appears that she perceives the situation as a mathematical task, which prompts her to subtract the two numbers. It also becomes clear *why* she seems to focus this way:

Interviewer: How did you get the idea of making a mathematical task out of it?

Nicole: Because there, well (putting the cards side by side: 12 -15), it is, let me say, cut out. Because the twelve is a number (pointing to 12) and then, the minus

is already there (pointing to the minus sign), and then f- m- f- minus fifteen and then it is actually a mathematical task.

There are three commitments and corresponding focuses, which point out why Nicole is thinking about a mathematical task and – as a consequence – subtracts. These are (a) “12 is a number“, (b) “I have got the minus of the mathematical task from the -15“, (c) “I subtract 15“. While regarding the numbers 12 and -15, she pays attention to what she already knows: She first focuses on the ‘normal’ *number* 12 as the first part of a mathematical task. Then she focuses on the *minus sign*, which is required for a mathematical task. For her, the ‘minus’ is linked to the focusing of *subtraction* – it indicates a subtraction in terms of a binary use of the minus sign (Bofferding 2010) as an operative sign (Vlassis 2004) – and *not* to the focusing of a signed number, where the minus-sign is a predicative and unary one (ibid.). By means of the further analysis of Nicole’s inferential web, her approach concerning the comparison of the two integers as well as the influence of her previous knowledge can be increasingly detailed. In case of a negative and a positive integer the inferential web likewise shows that she uses a conspicuous strategy of first subtracting, then replacing the minuend with the result of the task und comparing the re-placed minuend (the result) with the subtrahend subsequently.

By analyzing the invariance of focuses and commitments resp. judgments we found the *individual classes of situations* that Nicole differentiates. As she does not seem to interpret the minus sign as a predictive sign, it is not surprising that the classes, which she differentiates individually, differ from classes that can be determined from a theoretical point of view. Nevertheless, it is interesting and partially surprising, which classes she is making a distinction between: Slightly different focuses, commitments and inferences, which she uses according to the absolute values of the given numbers, indicate that she differentiates, for instance, between the classes in which she compares two integers in the form a and $-b$ ($a, b \in \mathbb{N}$, $|a| < |b|$) or in the form a and $-b$ ($a, b \in \mathbb{N}$, $|a| > |b|$): In the latter class, she seems e.g. to focus on natural numbers as amounts and she claims that she cannot subtract in the way used before (see above). Irrespective of the differences in these individual classes, there are also many invariant commitments and focuses as the student is trying to adapt her procedures to different classes of situations. The inferential webs of other classes of situations (e.g. comparing two negative integers) show, that she uses partly the same focuses but adapted commitments according to the situations. The case of Nicole shows that she seems not yet to know the minus sign as a predictive sign. Because of that she naturally is not able to interpret the integer as negative integer, but she proceeds in a comprehensible way, which makes sense from her individual perspective.

Tom and his recourse to a real-life context

In order to give a glimpse of the broad range of the students’ previous knowledge, Tom’s way of comparing the numbers 12 and -15 is mentioned in the following.

Interviewer: I brought along some cards, and on the cards there are displayed two numbers. And I want you to tell me which one of them is greater (gives two small cards to the student, displaying 12 and -15)

Tom: (receiving the cards) May I -

Interviewer: Mhm (affirmative), you can take them.

Tom: (looking at the cards, holding them in his hands) The twelve is greater.

Interviewer: Mhm? (quietly)

Tom: Because (slowly) minus is below zero and the twelve is just normal, the twelve.

Interviewer: Okay. How do you imagine that?

Tom: Well at the thermometer you sometimes also see minus numbers and then, if there, er, is no minus there, then there is simply just the number. Twelve degrees or so.

When regarding the cards briefly, Tom at once seems to commit to “*Among -15 and 12, 12 is greater*”. In order to justify this commitment, he gives two reasons, which he combines. The inference “*Among -15 and 12, 12 is greater because minus numbers are below zero and 12 is a normal number.*” can be assigned to his utterances. Asked how he imagines that, he mentions the real-life situation of negative numbers on the *thermometer*. Commitments like “At the thermometer there are minus numbers.” and many more can be assigned to his utterances in this excerpt of the transcript and the following ones. For him, the real-life context of temperatures, especially the *thermometer*, the concept of *natural number* (‘normal number’) and the concept of *negative number* (‘minus number’) seem to constitute important focuses, which characterize his way of proceeding when trying to determine the greater of these two integers. Later in the interview it transpires that the real-life context of *temperatures* seems to serve as a solid basis for Tom’s inferential web including negatives. Tom’s experiences concerning rises and falls in temperature seem to serve as basis for his concept of integer.

THE OUTCOMES OF THE STUDY – AN OVERVIEW

The presented findings were deduced from two case studies (Nicole and Tom). The analysis of the students’ inferential webs gives insight into the broad spectrum of the students’ levels of knowledge before having had an introduction to negative integers. In the following, some of the main findings are outlined and reflected. They concern students’ procedures and difficulties as well as the involved previous knowledge.

Concept of natural number By the analysis of Nicole’s pre-interview we found that there *are* sixth graders whose inferential webs, which are activated when regarding symbolic represented integers like -12, mainly affect natural numbers. The analysis shows that Nicole does not yet seem to know about negative numbers. Consequently, she is not yet able to interpret the minus sign as a predicative sign. Instead, she

activates previous knowledge in terms of arithmetic problems, which makes sense from her perspective: She knows “normal” numbers and she knows about the minus sign as indicator of subtraction which leads her to subtract the two numbers and compare them consequently. She develops a subtraction scheme with its own rules, and she tries to activate and adapt it to new situations. She seems not to know that there are negative integers beneath positive ones. Our findings seem to support the suggestion, that some of the students have to overcome (mis-)conceptions from elementary school, e.g. that there are no numbers below zero (cf. Bruno 2001, 415). The finding that students partially seem not to be able to interpret the minus sign as predictive sign, indicates that an introduction of negative integers in mathematics class should not purely be based on a symbolic representation, but probably should resume experiences in real-life contexts.

Concept of negative integer On the contrary, the case of Tom shows that there *are* students, who already have a substantial and sophisticated inferential web including negative integers at their disposal – even before they received an introduction to negative integers in school. Tom’s inferential web seems to be relatively stable and to a great extent tenable from a mathematical point of view. It is interesting to have a look at the previous knowledge that Tom is activating: He utilizes contextual knowledge from the context *temperatures* (see above). This shows how powerful real-life experiences may be for conceptual development. We also found that the assigned inferential web in Tom’s preliminary interview indicates an **order relation**, which focuses on magnitudes in terms of a “divided number line” model (Mukhopadhyay 1997). The individual *focus* on the *absolute value* of integers (“the value of the number”) is of vital importance for this order relation, which seems to be related to his previous knowledge in terms of natural numbers. The findings indicate that a continuous order relation for integers can not be deduced easily from real-life experiences by students on their own, but it needs educational attention and support.

In summary, it can be noted that the presented study contributes in some respects to the state of research in terms of negative numbers. We found that the students’ previous knowledge is widely spread: some students were already able to interpret the symbolic representation of negative numbers before being introduced to this topic, whilst others – like Nicole – were not. Beyond that, by using our theoretical and analytical framework we gained a detailed insight of the activated knowledge, the causes of misconceptions, the interplay of activated concepts etc. Concerning the order relation, we got a detailed insight into which individual focuses the investigated students chose and how they influence students’ procedures and their sustainability.

REPRESENTATIONS AND REASONING STRATEGIES OF GRADE 3 STUDENTS IN PROBLEM SOLVING

Isabel Velez

Unidade de Investigação do Instituto de
Educação, Universidade de Lisboa

João Pedro da Ponte

Instituto de Educação,
Universidade de Lisboa

In this communication we analyse the representations used by grade 3 students and how they relate to mathematics reasoning on a mathematical problem. Data were collected through audio and video recording in the classroom as well as students' written productions. Students that use schematic representations are those who have more success in solving the problem, in contrast with those that use pictorial and symbolic representations. The reasoning of some students shows interesting instances of making generalizations and working in a systematic way.

INTRODUCTION

The use of mathematical representations plays a fundamental role in students' learning of this subject, which is underlined by curriculum documents in many countries (e.g., NCTM, 2000). Reasoning, another important mathematics process, is highly dependent on the use of representations (Ponte, Mata-Pereira & Henriques, 2012). However, how students use these processes is an issue under-researched, in particular at elementary school level. This communication analyses the representations used by grade 3 students and how they relate to mathematics reasoning when they work on a mathematical problem.

MATHEMATICAL REPRESENTATIONS AND REASONING

In their mathematical work, students use a variety of external representations. Webb, Boswinkel and Dekker (2008) mention three key kinds of representations: informal (produced by students themselves, closely related to the context), preformal (still connected to the context, but including some abstract and formal aspects) and formal (with mathematical notations and language). In their perspective, students begin by using informal representations and gradually move on towards formalization. Some investigations describe the difficulties of students with specific representations. For example, Deizman and English (2001) refer the difficulties that students have in using and understanding diagrams, an important visual representation. The authors consider that these difficulties are related to misunderstanding the notion of diagram (not knowing the structure of the representation and overvaluing superficial characteristics), to incapacity to elaborate adequate diagrams (choosing the diagram that represents the situation or being unable to structure in a diagram the information provided) and to incapacity of reasoning in an proper way with diagrams (making valid inferences regarding the problem).

Reasoning is the process of making proper inferences from given information (Ponte, Mata-Pereira & Henriques, 2012). Mathematics reasoning is thought of as essentially deductive, deriving statements in a logical way from given propositions, but it also

may be seen as having an experimental side, making conjectures from specific cases and testing them (Pólya, 1990). Induction is the process of making a generalization by abstracting common features in a number of cases. Abduction is the process of establishing a general hypothesis that may explain a phenomenon from which only some elements are known. Rivera and Becker (2009) present in the following way the relations between abduction, induction and deduction:

Abductive reasoning involves forming a reasonable hypothesis about the phenomenon. To form that hypothesis, we verify and test the abduced hypothesis several times to see whether it makes sense. (...). Following Peirce, abduction as a concept exists and is used only in relation to induction. Thus, a complete pattern generalization involves complementary acts of abduction and induction and, of course, justification. (p. 217)

According to Lannin, Ellis and Elliot (2011) mathematics reasoning involves processes such as conjecturing, generalizing, investigating why and developing and evaluating arguments. From these, we give especial attention to generalizing (the key process of inductive and abductive reasoning) and justifying (the key process of deductive reasoning). Teachers may understand their students' reasoning from the representations that they use, since these yield a record of their efforts to grapple with mathematics (NCTM, 2000). Mathematical reasoning takes place in solving mathematics problems. As Wickelgren (1974) indicates, solving a problem may be regarded as achieving a goal using certain operations on certain givens. In any problem, besides the explicit information provided, there is always the need to use also implicit information regarding goals, givens and operations. Solving a problem is making inferences (or reasoning) from the available explicit and implicit information in order to reach the stated goal. The global approach to solving a problem is a reasoning strategy. As this author indicates, random trial and error is the "first thing that most people do when confronted with a problem" (p. 46). A most desirable strategy to solve problems is systematic trial and error, that is a "method that automatically [produce] a mutually exclusive and exhaustive listing of all sequences of actions up to some maximum length" (pp. 46-47). As this author points out, between random and completely systematic trial and error "there can be different degrees of systematicness" (p. 47)

RESEARCH METHODOLOGY

This study follows a qualitative approach and was undertaken in a school near Lisbon with the first author as a non-participant observer (Bogdan & Biklen, 1994). The participants are the teacher Fernanda and her 19 grade 3 students (teacher and student names are pseudonyms) who have been together since grade 1. The teacher has been working in this school for the last 10 years and has tenure. She indicated that the students were used to solve problems similar to the one reported on this paper. In this communication we analyse the students' work in one task (during about 40 minutes) that we choose because we found it particularly appropriate to study students' representations and reasoning strategies.

We made content analysis (Bardin, 1977, Laville & Dionne, 1999) of the students' productions and of audio and video recorded interaction among students and between teachers and students. In the content analysis, we followed the three steps defined by Bardin (1977): Pre-analysis, material exploration and processing of results. In the first phase, we defined categories through an open model (Laville & Dionne, 1999), in the second phase, we defined the registration units by subject (Bardin, 1977) and, in the third phase, we made a qualitative approach of iterative construction of an explanation (Laville & Dionne, 1999). We chose this approach because we wanted to develop, through the data, step by step, an explanation of the phenomenon observed. In analysing students' representations we noticed two main categories (pictorial and schematic) which we further subdivided into finer categories (pictorial detailed/simplified, scheme with dashes/letters). In pictorial representations students made drawings to depict figurative images of the animals; these drawings could be detailed (showing the whole animal) or partial (showing an animal part – heads or hands). In schematic representations, students used more abstract representations like dashes or letters. Some students used drawings as decoration, but reasoned based on schemes so, we considered this as cases of schematic representations. In analysing the participants' discourse by subjects (Bardin, 1977), with a focus on students' reasoning, we came up with two main categories of strategies (working on a random way and on a systematic way) and we further subdivided the second category (working in a systematic way with a single animal first/taking into account the two animals). We come up with these categories working inductively from the data as we explain ahead in the paper. As in the previous analysis, these categories were built by observing regularities in data. In a second level of analysis, we sought to connect the information provided by both kinds of analyses – regarding representations and reasoning strategies. To understand the students' reasoning strategies we also analysed the explanations that they gave to their teacher and to their colleagues in different moments. The teacher intervention during class was not a problem as she was helping them by questioning and not telling them the solution right away. The importance of the interventions from the teacher are clear in our analysis.

STUDENTS' REPRESENTATIONS AND REASONING

Fernanda began by writing on the board the problem for the students to solve it in pairs (one student just worked by herself), providing their response in an A3 paper sheet to be latter collectively discussed by the whole class: “In a farm there are 21 ducks and rabbits. If we count the hands we know that there are 54 in total. How many ducks and how many rabbits are there?” The teacher did a brief explanation about what was intended and the students begun working. When a student pair asked for help, the teacher recalled them the statement of the problem.

Choice of representation

Some students used (informal) pictorial representations but with two levels of detail, representing the whole animal with many features or just representing parts of an animal such as hands or heads. Other students used (pre-formal) schematic

representations, either with dashes (to represent hands) or with the first letter of the name of the animal.

Kind of representation	Representations used	Students
Pictorial representation	Detailed drawing of the animals	(1) Maria and Tiago, (2) Vanessa and Eloísa, (3) Joaquim and Francisco
	Simplified drawing of the animals (head or hands)	(1) Renata and Rui, (2) Guida and Júlio, (3) Núria and Daniel
Schematic representation	Scheme with dashes	(1) Dário and Kátia, (2) Ernesto and Patrick, (3) Bruna
	Scheme with letters	(1) Patrício and Sandro

Table 1. Representations used by students in their final work

For example, Maria and Tiago used pictorial representations, drawing successive animals in great detail (figure 1). At some point they begun changing an animal by another. They did not realize that this type of representation does not allow them to get the right answer on time and distract them with too many details, paying attention to irrelevant aspects and not focusing in the important issues at stake.

Figure 1. Representation of Maria and Tiago

On the other hand, Guida and Júlio and Daniel and Núria began by making detailed pictorial representations but they concluded that this was not appropriate and made a new schema, just representing animal hands. Daniel and Núria justified their change: “We were already doing drawings, but then [Núria] said: ‘Let us erase all because this way we are going to take a long time!’ And then we made the hands!” They showed to understand the need to find an adequate representation to solve the task.

Patrício and Sandro made a symbolic representation (vertical computation), that does not represent the givens of the problem (figure 2a). They found a number that added to 21 gives 54, but 54 is the total number of hands, not the number of animals. These two students seem to assume that symbolic representations are the most adequate and allow more efficient reasoning to solve the problem. They use sophisticated representations in an improper way and with which they could not solve the problem.

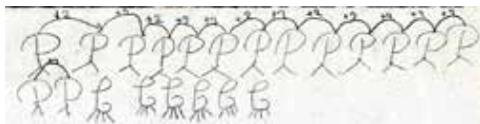

Figure 2. Representations of Patrício e Sandro: (a) First attempt; (b) Second attempt

Ernesto and Patrick presented a quite elaborated representation, with circled dashes, 2 for ducks (*pato*) and 4 for rabbits (*coelho*) (Figure 3). In this way, as we shall see, they were able to count efficiently the number of hands and the number of animals.

Figure 3. Representation of Ernesto and Patrick

Reasoning strategies and representations

All student pairs solved the problem by trial and error but used two kinds of reasoning strategies: (i) working on a random way (5 pairs); and striving to work on a systematic way, either (ii) taking into account simultaneously the two animals (3 pairs) or (iii) considering a single animal first and then striving to combine the information regarding two animals (2 pairs) (Table 2). We considered that the students used random strategies when they began to solve the problem drawing animals randomly until they meet one of the conditions of the problem. A second group of students strived to work on a more systematic way. They began assuming that they could solve the problem with only one type of animal and drew 21 animals of a particular type. Then, counting the hands, they realized that they had too much (if they drew rabbits) or too less (if they drew ducks) and started to replace some of the animals drawn by the other animal. A third group of students, assumed that the amount of ducks and rabbits was similar and began to draw them in pairs, one of each kind, until they reached the desired number of animals, and, at the same time, they were counting the hands.

Reasoning	Random strategy	Single animal first, then combining two animals	Taking into account simultaneously the two animals
Student pairs	Patrício and Sandro Joaquim and Francisco Maria and Tiago Daniel and Núria Bruna	Guida and Júlio Vanessa and Eloísa	Renata and Rui Ernesto and Patrício Dário and Kátia

Table 2. Reasoning strategies used by students in solving the problem

i) Random strategy. About a half of the student pairs solved the problem in a random way. For example, Núria and Daniel draw ducks and rabbits for a long time. As we mentioned above, at some point they realized that too much detail was not necessary and began to represent the animals in a more simplified way. They searched the solution by trial and error, but in a completely random way. They represented different combinations of animals and counted the number of hands. They were lucky

Teacher: You put more rabbits? But if you draw more rabbits, there will be more than 21 animals, or not? How shall we do that? (...)

Renata: I will erase two ducks and draw one rabbit!

The statement that two ducks are equivalent (in the number of hands) to one rabbit is an important generalization. The idea that this inference (drawn from the givens of the problem in a deductive way) may be used to solve this problem is an important insight. Having done that, the students further conjecture that they would not need to do great changes and they would just need to replace 4 ducks by 2 rabbits. That was close to what was required, but still not the solution of the problem. Supported by the questions of the teacher, the students finally concluded what animals they still needed to draw to solve the problem:

Teacher: So?

Renata: We erased 4 ducks and made 2 rabbits!

Teacher: Yes... And now? How many hands we have and how many animals we have? Rui?

Rui: Now we have... 1, 2, 6 (counts hands one animal by one) 50!

Teacher: 50 hands... I want 54! We are almost there! How many animals we have?

Students (Count one by one and answer): 19.

Teacher: And how many animals we must have?

Renata: 21...

Teacher: You have 19... (...) How many animals are missing?

Renata: We need 2 animals more!

Teacher: And how many hands?

Renata: 50... 54, so we need to draw 2 ducks!!

Teacher: Why?

Renata: Because... 2 more 2 is 4 and we have 50 [hands] and we need 2 more animals and the ducks have 2 hands... I think it will work!

The drawing with the 19 animals that allows for the counting of the 54 hands provides the justification that this is a solution to the problem. It is a solution by exhibition, since the students constructed an object that satisfies the conditions of the problem. Later on, Renata provides a very explicit explanation of the relationship between the hands of ducks and rabbits, which may be regarded as the key generalization in this task:

Renata: If two ducks have four legs and one rabbit has four legs... And we had too much animals... We erased two rabbits... Oh! No! [We erased] two ducks and we draw one rabbit!

Ernesto and Patrick had an elaborated representation with circles and dashes (figure 3) and explained to the teacher their strategy to solve the problem: “We have made schemes by a trial strategy (...) We though 10 ducks and 11 rabbits. But then we saw that does not give us 54 hands and we did it again” (Patrick). They also used an inductive approach, trying out cases, and figured out the equivalence between two ducks and one rabbit.

iii) Systematic strategy beginning with one animal. Other students followed a different strategy, seeking first to fulfill one of the conditions of the problem and then doing attempts to replace some animals by the other. For example, Guida and Júlio began by drawing just ducks:

Guida: We were doing... 2 [Two hands – a duck] up to 19 [animals], but then it doesn't give us 54 hands!

They concluded that if they kept drawing only ducks they would have more animals than required. By realizing the key generalization that one rabbit is equivalent to two ducks they quickly figured out how to solve the problem replacing two ducks by one rabbit or vice-versa until they had the right number of animals and hands. Therefore, they began by representing only one kind of animal, but at some point, they evaluated the situation and they understood that they needed to combine the two kinds of animals and to use a systematic strategy of replacing an animal by another until they got the correct solution.

Vanessa and Eloísa began by drawing just rabbits, until they got 21 animals but they realized that they had much more hands than required. They randomly erased several rabbits and started drawing ducks (but not replacing one by one). They did this several times, until they got 54 hands. At this moment they realized that they had only 19 animals. With the help of the teacher, they finally found the solution:

Teacher: (counts animals with fingers one by one) 19! (...) But you need 21! And the 54 hands? (the students shake their heads meaning yes)

Teacher: What are you going to do?

Vanessa: We need to replace...

Teacher: To replace why? And by what?

Eloísa: Rabbits by ducks...

Teacher: Huuummm... How many rabbits by how many ducks?

Vanessa: I am going to take... I am going to take a rabbit and then I will put... (looks at the duck) I am going to put two, because they have two hands!

After working at random for some time, these students finally noticed that a rabbit and two ducks have the same number of hands (the key generalization) and that they may change two ducks for one rabbit, keeping constant the number of hands.

In this way, the student pairs that define a systematic working strategy, either considering one or two animals, and that at some point evaluate their work and discover relationships among different elements (especially the generalization that two ducks have as many hands as one rabbit) are those who more quickly solve the task.

CONCLUSION

Solving this problem involves understanding and representing the conditions, defining a reasoning strategy, and applying and monitoring that strategy. First, the students have to understand the problem conditions and make a suitable representation. To understand the statement of the problem it is not easy for some of the students at this level. Some use pictorial (informal) representations, drawing animals in detail, a very slow, distractive and inefficient representation process. Other students use schematic representations such as dashes and hands (pre-formal), without spending time on details, what makes the solution quicker and allows them to focus their attention in important elements of the problem. Some represent ducks and rabbits in different lines or blocks, or sequences of duck-rabbit pairs, for easier counting. Others, to make sure that the number of animals is equal or easily comparable, draw them alternatively. Still some students use symbolic (formal) representations that do not represent well the problem, naturally with no success.

Based on an initial representation, the students define a solving strategy. The problem may be solved algebraically with a system of four equations and four unknowns ($h=4R$; $k=2D$; $h+k=54$; $R+D=21$, with h and k being the number of hands of rabbits and ducks and R and D the number of rabbits and ducks) but grade 3 students cannot do it this way. They have to use trial and error, following an abductive/inductive approach, trying out different combinations of animals. The key to reach to a solution is to work in a systematic way, either taking into account simultaneously the two animals, or considering a single animal first and then combining the information regarding the two animals. However, to solve the problem the students need to recognize the four relations above. Starting with both animals means to take into account the equation $R+D=21$, then changing the value of one variable (the other just follows from that) and seeing what happens to the sum $h+k$. Starting just with one animal is similar, except that we begin with $R=0$ or $D=0$. In both cases, it is critical to notice that in replacing one rabbit by two ducks $h+k$ remains constant (which is the key generalization in the problem) whereas $R+D$ increases 1 unit. This may lead to formulate a hypothesis that replacing one rabbit by two ducks or vice-versa will solve the problem. All steps done by students may be justified by the givens of the problem and the allowed operations. The justification why 6 rabbits and 15 ducks is the solution is done by exhibition, counting the corresponding number of hands.

The students that use pictorial representations tend to follow a random strategy. The students that use symbolic representations also have trouble because the representations that they choose are not adequate to consider the problem conditions. The students that use schematic pre-formal representations (Webb et al., 2008) that

salient important aspects of the problem (number of hands of each animal) and omit irrelevant features (e.g., the physical aspect of the animals), are those who formulate the most efficient solution strategies. The fact that students used a wide variety of representations with distinct potential for solving the problem, shows that the teacher may assume an important role, helping the students to use increasingly sophisticated representations with understanding. The difficulty of the students in keeping track of the conditions of the problem and in reasoning in a systematic way also suggests the critical role of the teacher in dialoging with students. This underlines the need to further study how teachers may support their students in learning to use mathematical representations and to develop their reasoning processes.

THE CONSISTENCY OF STUDENTS' ERROR PATTERNS IN SOLVING COMPUTATIONAL PROBLEMS WITH FRACTIONS

Gerald Wittmann

University of Education Freiburg

Error patterns in solving computational problems with fractions are well known. However, the question whether these patterns are consistent or not is still unanswered. This paper presents the design and results of an empirical study focussing on this question in the case of computational problems with fractions. It shows that a considerable part of error patterns and furthermore of approaches is not consistent. This implies that the concerning students do not have any strategies when dealing with computational problems. Instead, their solutions are not rationally chosen but emerge while treating the problem.

Key words: adding fractions, multiplying fractions, students' errors, empirical study

1 ERROR PATTERNS AND THE CONSISTENCY OF ERROR PATTERNS

Learning fractions in secondary mathematics education has two aspects: The students should build up conceptual knowledge (e.g. the interpretation of a fraction as part of a whole) as well as procedural knowledge (e.g. computational skills like adding or multiplying two fractions). This paper focuses on the second aspect. It investigates the consistency of students' error patterns in solving computational problems with fractions.

In that regard, a *computational problem* is a problem that can predominantly be solved by using procedural knowledge as there exist specific algorithms to solve the problem (e.g. adding two fractions by converting to a common denominator). Therefore, neither conceptual knowledge nor heuristic strategies are necessary. Beyond that, a computational problem can be solved in another manner as well: By recalling (e.g. knowing that $\frac{1}{2} + \frac{1}{4} = \frac{3}{4}$), by “seeing” the result without any calculation (e.g. $6\frac{5}{7}$ as result of $6 + \frac{5}{7}$) or by using conceptual knowledge (e.g. realizing $\frac{2}{9}$ as half of $\frac{4}{9}$ and thus $\frac{2}{9}$ as result of $\frac{4}{9} \cdot \frac{1}{2}$). However, the relationship between conceptual and procedural knowledge and their interdependency still needs further research (Hallet, Nunes & Bryant, 2010).

The *research on students' errors* concerning computational problems with fractions has a long tradition. Frequently appearing errors are well-known and comprehensively documented over many years (Carpenter, Fennema & Romberg, 1993; Kerslake, 1986; Eichelmann, Narciss, Schnaubert & Melis, 2012). An *error pattern* can be identified when identically structured errors appear in the solution of two or more identically structured problems (Prediger & Wittmann, 2009).

The error patterns relevant for this study are given in table 1. Nearly all of them can be characterised as a combination of well-known steps of solution processes being inappropriate for the underlying problem. A common model to explain this fact is the “bug-repair-theory” (Brown & VanLehn, 1980).

<p>Multiplication of two fractions with a common denominator: $\frac{a}{b} \cdot \frac{c}{b} = \frac{a \cdot c}{b}$</p> <p>Addition or subtraction of two fractions: $\frac{a}{b} \pm \frac{c}{d} = \frac{a \pm c}{b \pm d}$</p> <p>Addition of a fraction and an integer: $\frac{a}{b} + c = \frac{a+c}{b}$, $\frac{a}{b} + c = \frac{a}{b+c}$, $\frac{a}{b} + c = \frac{a+c}{b+c}$</p>

Table 1: Main error patterns

An error pattern is called *consistent* referred to a student if the student deals with two or more identically structured problems within a short period of time and produces the same error pattern in each (or nearly each) of the underlying solution processes. For example, if a student deals with several computational problems of adding fractions within a test, the common error pattern ‘adding the numerators and adding the denominators’ may occur in all of his or her solutions – in this case it is consistent. But it may occur that only some solutions show the error pattern and the other solutions are correct – then the error pattern is not consistent. Therefore, the consistency of an error pattern has to be investigated at an individual level.

The question *whether error patterns concerning computational problems with fractions are consistent or not* still lacks research. In literature there is little evidence. Earlier studies always consider the entire test population as they aim primarily at the identification of error patterns or the frequency of their occurrence (e.g. Hart, 1981; Padberg, 1986). Solely Padberg (1986) differs between ‘typical errors’ (error patterns occurring frequently in the whole population) and ‘systematic errors’ (error patterns occurring consistently at an individual level). However, he does not provide any data answering the question if error patterns are consistent.

Recent studies concerning computational problems with fractions show a broad range of (correct or incorrect) individual solutions (Hennecke, 1999, using methods of graph theory) or demonstrate that students’ procedural knowledge about fractions falls apart into several incoherent classes of problems, even the addition and the subtraction of fractions (Herden & Pallack, 2000, by means of cluster and factor analyses). Beyond that, studies on solutions of linear equations in algebra lead to the hypothesis that error patterns are often not consistent (Tietze, 1988; Stahl, 2000).

Regarding the question whether error patterns are consistent or not, a special view on students’ solutions is very helpful. This study gathers students’ *approaches* to computational problems with fractions. An approach is a general form of solving the problem, including many individual solutions. Taking the addition of fractions as an example, two approaches can be distinguished: first, converting both fractions to a

common denominator; second, adding the numerators and the denominators separately.

Though the presented study can be seen in the long tradition of research on students' errors, the research question is formulated more generally, regarding not only errors but also correct solutions: *Are approaches to computational problems with fractions consistent?* The answer to this question can be seen as one step to understand and model the way in which students solve computational problems.

2 DESIGN OF THE EMPIRICAL STUDY

In order to examine the consistency of error patterns empirically, four sets of six problems were developed (table 2).

Multiplication of two fractions:	$\frac{4}{9} \cdot \frac{1}{2}$	$\frac{8}{5} \cdot \frac{3}{7}$	$\frac{4}{5} \cdot \frac{3}{5}$	$\frac{5}{13} \cdot \frac{3}{13}$	$\frac{5}{2} \cdot \frac{5}{2}$	$\frac{4}{15} \cdot \frac{4}{15}$
Addition of two fractions:	$\frac{1}{2} + \frac{1}{4}$	$\frac{2}{7} + \frac{4}{5}$	$\frac{2}{13} + \frac{4}{9}$	$\frac{1}{9} + \frac{1}{8}$	$\frac{2}{5} + \frac{2}{5}$	$\frac{6}{11} + \frac{6}{11}$
Subtraction of two fractions:	$\frac{3}{4} - \frac{1}{2}$	$\frac{6}{7} - \frac{2}{5}$	$\frac{7}{10} - \frac{8}{15}$	$\frac{2}{3} - \frac{2}{7}$	$\frac{13}{8} - \frac{11}{8}$	$\frac{7}{13} - \frac{7}{13}$
Addition of a fraction and an integer:	$\frac{1}{4} + 1$	$\frac{2}{3} + 7$	$\frac{2}{13} + 6$	$4 + \frac{2}{3}$	$6 + \frac{5}{7}$	$7 + \frac{1}{13}$

Table 2: Four sets of computational problems

The problems within a set differ from each other in the given numbers. For example, the set of problems for multiplication of two fractions contains three pairs of problems: (1) with different denominators, (2) with the same denominator but different numerators and (3) with equal fractions. Each of the pairs contains a problem with large numbers and a problem with small numbers.

Each test sheet comprises 18 tasks in three of the four sets of problems which are arranged in nine variants in a random order to avoid serial effects. Thus there are 36 different test sheets. Three more problems without any relevance were inserted to scatter a series of problems of one set caused by the random order.

The students' working time was 40 min and they were allowed to solve the problems in a free way, e.g. calculate mentally or in a written form but not with a calculator. 428 students participated in the test in July 2011. As the students only worked on three of the four sets of problems (due to the construction of the test), the number of solutions to each problem is lower. The students were 6th- and 7th-graders of Real- and Werkrealschule in Baden-Württemberg, a federal state in south-west Germany. A considerable number of low-achievers attend these schools.

Unlike traditional research on students' errors, the coding of the data focuses on approaches rather than on correct or incorrect solutions. For this reason, simple computational errors are ignored, e.g. errors concerning the multiplication tables like $7 \cdot 9 = 61$. In order to answer the question whether an error pattern is consistent or not, these errors do not matter. This way of transforming the data reduces the data to

a necessary extent and features the required precision at the same time. However, in some cases the transformation of the data is an interpretation of written calculations and hence vulnerable to artefacts. A crucial prerequisite is that different approaches can be separated clearly. In the presented study concerning fractions this succeeds very well. Table 3 shows the coding manual taking the example of multiplication.

0	Missing.
1	Correct approach (whether calculated mentally or in a written form; the solution itself may be correct or incorrect).
3	Main error pattern ‘denominator maintained’ (in the case of fractions with different denominators after converting to a common denominator); further errors might be encountered, e.g. errors concerning the multiplication tables.
9	Other (rare error patterns e.g. multiplication with the reciprocal or performing an operation or incomprehensible solutions).

Table 3: Coding manual taking the example of multiplication

Afterwards the data is analysed with methods of descriptive statistics: frequency tables, cross tables (supplemented by a significance test) and tables of ordered tuples of codes.

3 SELECTED RESULTS

Some results of three areas are given: multiplication of two fractions, addition of two fractions and addition of a fraction and an integer. Thereby the process of data analysis is illustrated.

3.1 Multiplication of two fractions

Table 4 shows the frequencies of the approaches concerning the six multiplication problems (N = 315).

Coding	$\frac{4}{9} \cdot \frac{1}{2}$	$\frac{8}{5} \cdot \frac{3}{7}$	$\frac{4}{5} \cdot \frac{3}{5}$	$\frac{5}{13} \cdot \frac{3}{13}$	$\frac{5}{2} \cdot \frac{5}{2}$	$\frac{4}{15} \cdot \frac{4}{15}$
0 Missing	24	31	14	21	13	21
1 Correct approach	226	228	199	167	207	176
3 ‘Denominator maintained’	30	25	74	102	53	91
9 Others	35	31	28	25	42	27

Table 4: Multiplication of two fractions – Frequency of approaches

A correct approach occurs more often in problems with different denominators than in problems with a common denominator while the main error pattern ‘denominator maintained’ pertains the opposite. Besides, some students act consistently in an extreme way: They convert fractions to a common denominator and subsequently

deal with the multiplication according to the main error pattern ‘denominator maintained’. So do 30 students at the first problem and 25 at the second (among them 17 at both problems).

Considering the problems with a common denominator, the main error pattern is in each of the two pairs of problems obviously more frequent when the denominator is larger. Table 5 shows a detailed analysis of this effect in the case of multiplying two equal fractions: 235 of 315 students solve both tasks by the same approach while 80 generate different approaches. Notably, 31 students performed a correct approach with the denominator 2 (‘small denominator’) while they maintained the denominator 15 (‘large denominator’). The McNemar-Bowker-test confirms that the asymmetry of the cross table is significant ($\chi^2 = 39,015$; $df = 5$; $\alpha < 0,001$). This test checks against the null hypothesis that the cross table is symmetrical along the main diagonal.

		$\frac{4}{15} \cdot \frac{4}{15}$ (‘large denominators’)				
		0	1	3	9	
$\frac{5}{2} \cdot \frac{5}{2}$	(‘small denominators’) 0	11	1	0	1	13
	1	7	159	31	10	207
	3	0	2	50	1	53
	9	3	14	10	15	42
		21	176	91	27	315

Table 5: Multiplication of two equal fractions – cross table

Table 6 focuses on the approaches to the four multiplication problems with a common denominator that can be estimated/regarded as identically structured.

	So many students performed x -times ...				
	0	1	2	3	4
Correct approach	79	28	38	35	135
‘denominator maintained’	199	20	28	28	40

Table 6: Multiplication of two fractions with the same denominator – frequency of approaches

When multiplying two fractions with a common denominator, 135 of 315 students treated all four problems according to a correct approach, while e.g. 38 did so at only two out of four problems and behaved differently at the other two problems. 199 students never followed the approach ‘denominator maintained’ and 40 students used

it each time while 20 students generated this error pattern only at one out of four problems and dealt with the remaining three problems in another way.

In addition to table 6, further interesting facts can be outlined: 11 out of 40 students who maintained the denominator at all four problems worked on the two problems with different denominators in the same way, after converting the denominators. Therefore, the error pattern is consistent regarding all six multiplication problems. Another 11 students who maintained the denominator at all four problems solved the two problems with different denominators according to the correct approach – the approaches are consistent only within the cases of common or different denominators.

3.2 Addition of two fractions

Regarding the addition of two fractions, the frequency of the main error pattern ‘separate addition of numerators and denominators’ varies little across all six problems, as table 7 shows (N = 347).

Category	$\frac{1}{2} + \frac{1}{4}$	$\frac{2}{7} + \frac{4}{5}$	$\frac{2}{13} + \frac{4}{9}$	$\frac{1}{9} + \frac{1}{8}$	$\frac{2}{5} + \frac{2}{5}$	$\frac{6}{11} + \frac{6}{11}$
0 Missing	19	41	116	62	16	16
1 Correct approach	227	205	116	167	224	230
3 Main error pattern	73	79	84	78	92	78
9 Others	28	22	31	40	15	23

Table 7: Addition of two fractions – frequency of the approaches

However, another effect is striking: the larger the two denominators are, the less often the right approach occurs and the less often students work on the problem (but skip it), with a range of 19 to 116 students. This can be interpreted as follows: to leave out a problem is a reaction to ‘large’ denominators when finding a common denominator affords a higher level of mental calculation. This reaction gives the hint that the regarding students neither have the result of the underlying multiplication problem as a retrievable fact nor can expand it briefly. It is not possible to decide if the students cannot find a common denominator or if they do not want to work on it, perhaps due to a lack of motivation or effort or a low level of frustration tolerance.

Table 8 shows the students’ approaches across the six addition problems as ordered 6-tuples. For example, 110111 in the second line means that the first two and the last three problems are solved correctly whereas the third problem was not done at all. Among 347 students there are 126 different tuples: 18 of them can be found at least three times (these are shown in table 8), another 13 tuples occur only twice and 95 only once.

6-Tupel	Frequency	Percentage	Cumulative percentage
111111	83	23,9	23,9
110111	34	9,8	33,7
333333	32	9,2	42,9
110011	21	6,1	49,0
111133	7	2,0	51,0
333311	7	2,0	53,0
000000	6	1,7	54,8
110131	6	1,7	56,5
333331	5	1,4	57,9
111131	4	1,2	59,1
100011	3	0,9	59,9
110113	3	0,9	60,8
111311	3	0,9	61,7
113333	3	0,9	62,5
119911	3	0,9	63,4
199911	3	0,9	64,3
333313	3	0,9	65,1
999911	3	0,9	66,0

Table 8: Addition of two fractions – processing of six problems

The tuples 111111 and 333333 indicate consistent approaches: 83 students always have a right approach and 32 students show the main error pattern ‘separate addition of numerator and denominator’ in all six tasks. This means that a third of the approaches can be explained by the assumption of consistent approaches whereas two-thirds of the approaches are seen as non-consistent.

Amongst these two-thirds there are two very interesting tuples: Both 111133 and 333311 occur seven times. The first characterises these students who approach the four additions of fractions with two different denominators in a correct way and the two additions of fractions with common denominators according to the main error pattern. The second describes the reverse of the phenomenon. In other words, there are students who ‘fall into’ the error pattern in case of common denominators but there are also students who ‘fall into’ the error pattern in case of different denominators.

3.3 Addition of a fraction and an integer

This section briefly describes two interesting results without showing the full data.

Concerning the addition of a fraction and an integer a more detailed translation of data into code is appropriate (even though there are naturally some borderline cases): First, a mental solution is classified as a category of its own because it refers to conceptual knowledge. In fact, about a quarter to a third of the problems is solved mentally. Regarding the approaches, no differences can be seen between problems of the structure ‘fraction plus integer’ and ‘integer plus fraction’ (table 2). The hypothesis that in the case of ‘integer plus fraction’ the solution is ‘seen’ more often than in the case of ‘fraction plus integer’ (cf. Padberg, 1986) cannot be approved. On the contrary, the problem $\frac{1}{4}+1$ is solved slightly more frequently mentally than the other five. In consequence, the fact whether the denominator is ‘large’ or not has more influence on the solution process than the question whether the problem is of the form ‘integer plus fraction’ or of the form ‘fraction plus integer’.

Second, the addition of a fraction and an integer does not show only one main error pattern but several error patterns (table 1) which all occur in the test. The approaches of 28 out of 313 students show at least two different error patterns. In conclusion, these students do not possess retrievable stable algorithms but only some fragments of algorithms which they apply and combine haphazardly. Furthermore, they lack conceptual knowledge to check their results or the used algorithms.

4 DISCUSSION

The study shows that the numbers given in computational problems with fractions (especially as denominators) have an effect on (1) whether students work on the problem or skip it and (2) what kind of approaches occur. Especially the last finding is astonishing. It was clear in advance that the percentage of correct *solutions* decreases when the denominators get larger as more errors occur. But the fact that the given numbers even have an effect on the *approach* could not have been expected. Concerning error patterns, this can be interpreted as following: Problems which are identically structured in a mathematical point of view (and differing only in the given numbers) are not necessarily identically structured regarding a student’s individual approach to solve these problems. For example, in terms of multiplying fractions this is well known for fractions with a common denominator vs. fractions with different denominators. The presented study shows the same effect for the size of the given numbers. However, there is the hypothesis that not only and not primarily the size of the numbers is relevant but the question if necessary multiplication tables are known by heart or can be calculated mentally without any difficulties. This hypothesis is an aim of further research.

With regard to the consistency of approaches *four groups of students* can be distinguished for each of the four operations. *Group 1* includes the students who

solve all problems of one operation according to a correct approach. About a fourth to a third of the tested population belong to this group. Within this group, two subgroups can be found: students who treat the problems in a very flexible way, adequate to the given numbers (e.g. if the numbers are small, the solution is ‘seen’ or solved mentally), and students with an extreme commitment to a certain approach regardless whether it is appropriate for the posed problem or not (‘always convert the denominators before adding two fractions’). *Group 2* contains students whose solutions show the main error pattern without exception. These students may have internalized an incorrect procedure while performing automation exercises. This group is quite small.

The first two groups can be distinguished clearly. Together they comprise those students whose approaches are absolutely consistent. Two other groups include those students whose approaches are not consistent. These two groups cannot be separated clearly but merge into each other.

Group 3 contains the students who show mainly correct approaches but occasionally proceed otherwise. Due to this small amount of different approaches this group is different to group 1. One possible explanation may be careless mistakes that are possibly fostered by the intuitive form of error patterns, by the random arrangement of problems in the test sheet and by the given numbers when they ‘fit’ into an error pattern.

Group 4 accumulates the students whose approaches are not consistent at all. Even within one set of problems there are two or more different approaches. Presumably, the influence of given numbers is dominant because no stable methods are available. Therefore, special cases (e.g. fractions with a common denominator) are treated differently than general problems. The approaches of group 4 can be interpreted as ‘calculating with digits’ and as a widely unconsidered processing of numbers given in the problem according to known elements of algorithms. The concerning students do not have any strategies when dealing with computational problems.

As a result, students’ work on computational problems quite often appears as a barely controlled and only partly aware process. This is very astonishing as all of the students attended a systematic course in fractions. The approaches are in some cases rather rationally chosen but emerge over time while treating the problem (according to Threlfall, 2009). Especially the approaches of low achievers can be described as manipulating given numbers and combining fragments of algorithms without reflecting these processes. In consequence, at least some of the students’ errors emerge, too. They are not consistent referred to a student but their appearance varies from task to task depending on the given numbers (and perhaps some other parameters). Therefore, error patterns can not be regarded as an individual phenomenon but as a phenomenon appearing in written tests which are run in larger populations.

TRANSFORMATIONS VIA FRACTIONS, DECIMALS, AND PERCENTS

Regina Reinup

Tallinn University

Keywords: Secondary school mathematics, mathematical transformations

SUMMARY

The topic of percentages in the school mathematics is usually taught in the age of 12-13, i.e. on the 6th and 7th grade of the secondary school. In the phase of learning this topic the students must be able to conceive transformations from decimals to percents, from fractions to percents, from fractions to decimals, and vice versa. At this phase many students face problems. This poster presentation will describe the background of these transformations, and introduce some results of a study, carried out in fall 2008.

Many teachers and researchers (e.g. Moss, 2005; Adjage & Pluvillage, 2007; Hallett, 2008) have mentioned that teaching and learning of fractions, ratio, and proportionality is a complex process. The difficulties are caused (1) by the ambiguousness of fractions and decimals (Moss 2005; Charalambos & Pitta-Pantazi, 2007) and the necessity to change from one semiotic system to another (Duval, 2006), and (2) by students' poor skills in transformations (Hallett, 2008; Moss 2005).

It is quite common that in case the students cannot do transformations correctly, they begin to construct answers by using the numbers that they see. Hallett (2008) found that 55% of the 13-year-olds answer to the question "Which of the following numbers: 1, 2, 19 and 21 are the closest to the sum of $12/13 + 7/8$ " either 19 or 21. It can be assumed that some types of transformations are simpler for students. In order to better understand students' skills and preferences in transformations, I carried out a group interview with students (aged 13 – 14) from the 7th grade. (This interview is a part of a bigger study.) The results showed that transformations from percents to decimals, and vice versa, are simpler than others. The most difficult is transformation from fractions to percents, because it needs two sequential transformations: first from fraction to decimal, and then from decimal to percent.

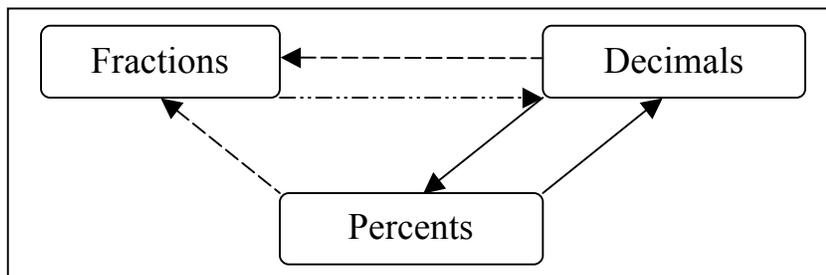

Figure 1: Strength via different transformations

THE WAY OF PRESENTING

The central part of the poster will be Figure 1, which visually presents the main conclusions from an empirical study, and illustrates the differing strengths of the skills in the transformations.

Additional visual material will be organised around this figure, e.g. tables with data from (1) students' answers (right/wrong), and (2) students' preferences in transformations, when the order of the transformations was chosen free. I have also students' written answers, which will be used as illustrating material.

The textual data in the poster will be organized in short sections: (1) Introduction, (2) Methods, (3) Results, (4) Summary, and (5) References.

TO MEASURE WITH A BROKEN RULER TO UNDERSTAND THE COMMON TECHNIQUE OF THE SUBTRACTION

Anne-Marie Rinaldi

Paris Diderot Paris 7 Université, France

Laboratoire de Didactique André Revuz (L.D.A.R)

Keywords: Subtraction, technology, semiotic mediation

INTRODUCTION

The research that I am conducting as a PhD candidate focuses on the teaching and learning of calculus subtractive at primary school. With the poster that I am presenting, I am showing the interest to teach the notion of difference/distance and after the property of the conservation of differences for understand the usual technique subtraction in France. I suggest a sequence of learning, using as artefact a broken ruler and I have studied its potential. I am using as theoretical part of the anthropological theory of the didactic and of the semiotic mediation.

CONTENT OF THE POSTER

The poster is organised in four parts:

First box: Scientific context and motivation

I initially observed that the put-down subtractions with numbers of carry over are not mastered by pupils of the fourth year (CE2) or of the fifth year (CM1). At the first level (technical), the carried out calculations are wrong because the algorithm learned during the class is badly applied. At the second level (technological), the calculation is right, but the pupils don't know what mathematical meaning they have to give to the numbers to carry over. Should we then conclude that students do not know the differences conservation property?

The study of different manuals would lead us to believe, that one day, they have been in a situation where the property of conservation of the differences has been used but that this theoretical element is not reused in several contexts and linked up to others knowledge's.

Convinced of this lack, I think about a mathematical organisation, where the kind of proposed task will be linked up to another by a technological speech, or by the successive development of techniques. It is with this ambition that I have conceived this situation. Probably she will become an key element of the engineering that I will suggest at the end of my thesis. The fact of measuring with a ruler broken suggests that the distance between "a" and "b" is the difference between "b" and "a". ($a < b$). After it's more easy to integrate the notion of invariant difference by translation on the numerical line so the differences conservation property.

Second box: aims

To have the notion of difference between two numbers, of distance between two dots, the ruler is broken in order to not permit a direct reading of the measure. On the poster, the situation of learning will be described in its entirety. I will expose the conditions of the testing led in 2010. Finally, I will be explained the different techniques of measurement, adopted by the pupils, and exchanges between students in a group. I will show what are the techniques which have been validated or invalidated and how each pupil have could think on their own experience with the artefact and to compare some different utilisations of the same broken ruler. The last phase of the session, « the discussion of class » to resume the term of Mariotti and Maracci (2010) is also interesting for the mathematical signs. To conclude, I will present a extension of the session which will allow to introduce the property of preservation of difference by translation on the line.

Third box: Methods and results

The method is based on the confrontation between a priori analysis and a posteriori analysis. It allows establishing that the situation « to measure with a broken ruler » has a potential, under some conditions that I going to enumerate. Pupils after learning a subtraction calculation technique can take ownership, a mathematical property, which allows to justify this technique, and which also can be used in mental calculation.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG3: ALGEBRAIC THINKING

María C. Cañadas^a, Thérèse Dooley^b, Jeremy Hodgen^c, Reinhard Oldenburg^d

^aUniversity of Granada, ^b St. Patrick's College, Dublin

^cKing's College London, ^d Goethe University Frankfurt

Keywords: *Early algebra; generalized arithmetic; equivalence; equals sign; generalization; semantic; syntactic; teaching and learning algebra; mental algebra; functions*

In CERME-8, as a long-standing group, Working Group 3 “Algebraic thinking” continued the work carried out in previous CERME conferences (Cañadas, Dooley, Hodgen & Oldenburg, 2011).

THE PAPERS AND THEMES

A total of 16 papers and 5 posters with a total of 25 group participants representing 14 countries, Canada, France, Germany, Ireland, Italy, Netherlands, Norway, Portugal, Spain, Sweden, Tunisia, Turkey, UK, USA / Romania. We considered the papers in the following themes (although, of course, there are many overlaps across the themes):

Entry to algebra

Several studies focused on the relation between algebra and arithmetic. These continue and extend discussions from previous CERME conferences (e.g., Ainley, Bagni, Hefendehl-Hebeker, & Lagrange, 2009). We note that the focus is on ‘early algebra’ in both primary and secondary education. Working in Portugal, where an ‘early algebra’ focused curriculum has been introduced, Mestre and Oliveira describe and analyse a teaching experiment in which Grade 4 children are introduced to the use of informal symbols as quasi-variables. They find that such an approach has benefits for the development of algebraic thinking, particularly in moving from equations involving specific unknowns to equations expressing generalisations about arithmetic. In contrast, Gerhard examines how a generalised number approach may hinder the development of algebraic thinking. Using her own interdependence analysis tool she examines how new patterns of action are related to old patterns of action. In particular, she argues that poorly developed patterns of action relating to multiplication (such as an over-reliance on repeated addition) may be overcome by Davydov’s more geometrically-based approach. Mellone, Romano & Tortora report research with older students (Grade 10) and examine how the students tackle the problem $10^{38}+10^{37}$. They argue that, in making sense of the problem, students draw on a ‘social’ rationality in addition to purely mathematical reasoning and that this has implications for the relationship between arithmetic and algebra. Mata-Pereira & da Ponte’s poster examines how Portuguese secondary students’ reasoning about real numbers and generalized arithmetic.

Equivalence

Several papers addressed issues relating to equivalence, perhaps reflected a general resurgence of interest in the field. Drawing on Frege, Pilet argues that the French curriculum places little explicit attention to the issues of equivalence and that this exacerbates students' conceptual difficulties. She analyses a learning situation designed to do this. Zwetschler & Prediger argue that, whilst previous research has examined the learning of equivalence in transformational situations, little attention has been devoted to the equivalence of expressions in generational activities. In a case study designed to address this gap, they find two conceptual barriers to understanding: an over-emphasis on operational rather than relational meanings, and difficulties relating to the generality of variables and figures. Vieira, Palhares & Gimenez report the findings of a pilot study that investigated Portuguese primary children's understanding of equality and the equal sign following the introduction of a new curriculum. Although the children in their study performed better than in previous studies of the equal sign, they suggest that their understanding of relational meanings and equivalence are nevertheless poor.

Structural generalisation

Unsurprisingly, generalization continues to be a theme of interest for WG3 participants. Måsøval analyses how two student teachers struggle to find an explicit general formula for a sequence. Using Brousseau, she shows how the milieu for algebraic generalisation is constrained both by the design of the task and by the teacher educator's (incorrect) presupposition of prior knowledge. Dooley examines the strategies that primary children (aged 9-10) in Ireland used when solving a quadratic problem and analyses how mediation by the teacher (and the children themselves) can enable young children to tackle relatively sophisticated algebraic problems. Postelnicu reports the results of two surveys examining secondary school and college students' difficulties with Cartesian representations of linear functions. She argues that the difficulties she finds are due to epistemological, rather than simply procedural, obstacles and these in turn relate to an overemphasis on geometric rather than analytic perspectives on slope and gradient. Rolfes, Roth & Schnotz's poster presents the early results of a teaching experiment aimed at improving secondary understanding of covariation of functions.

The relationship between semantic and syntactic understandings

Two papers focus on the relationship between syntactic and semantic understandings of algebra. Focusing on equations and inequations, Kouki & Chellougui discuss the difficulties that students encounter in mastering the syntactic rules of algebra and argue that both syntactic and semantic understanding is necessary for such mastery. Oldenburg, Hodgen & Küchemann examine whether these two aspects of algebraic thinking, syntactic and semantic, can be distinguished empirically using test items. Although there are considerable difficulties in operationalizing the distinction using test items, their exploratory analysis suggests a fruitful line of analysis may be

to treat the semantic aspect as consisting of two sub-dimensions, based on whether one or many meanings or interpretations appear to be required.

Teachers and teaching

Several papers and posters address issues relating to teachers and the teaching of algebra. Kilhamn examines how two teachers enact the same teaching materials and finds that outwardly similar content is addressed differently. Although these differences at first appear subtle, the two teachers approaches tackle issues such as variable in radically different ways. Çelikdemir & Erbaş analyse TIMSS 2007 data on Turkish mathematics teachers' self-reported preparedness to teach school algebra, finding that they reported that they were less well prepared to teach algebra than their counterparts around the world. Sari & Özdemir report on the effects of a teaching intervention supporting metacognitive strategy use on improving Turkish seventh grade students' conceptual and procedural knowledge on algebraic expressions and equations. They find a significant difference between experimental and control groups in terms of gain scores on conceptual and procedural knowledge in favor of experimental group. Two posters, by Wathne and Røj-Lindberg, present the methodology and early findings of the VIDEOMAT, a video study of mathematics lessons in Finland, Norway, Sweden and the USA on the introduction to algebra.

New directions

Several papers address new directions for the Algebraic Thinking Working Group at CERME. Proulx reports on an exploratory study examining mental algebra. He argues that too little attention has been devoted to understanding mental mathematics activities with objects other than numbers and discusses its potential for algebra teaching and learning. In the only paper to directly address issues involving technology, Lagrange discusses the limitations of an exclusively functional approach to algebra. He argues that both experiencing covariation and bodily activity are crucial for students' understanding of functions, showing how this can be facilitated through the Casyopée environment. Kop's poster presents early data from a study of how expert mathematicians sketch graphs of functions.

GENERAL REFLECTIONS

As we observed in our CERME7 report, algebraic thinking is a “mature” sub-domain within mathematics education research (Cañadas et al., 2011). As a result, our group discussions touched on many familiar themes, including the recontextualisation of existing research, the need for both ‘young’ researchers and less developed communities to ‘make it their own’, the relationship between different theoretical approaches and the nature of algebra / algebraic thinking / algebra as an activity. But it was also exciting to revisit epistemological debates and the implications of these for the teaching and learning of algebra.

LOOKING FORWARD TO CERME-9

Finally, in looking forward to CERME-9, the group hope that future research will address advanced as well as early algebra, the nature and design of paradigmatic tasks, the extent to which (research on) algebraic thinking is influenced by context and culture and the tensions between rigorous research and classroom practice and students' difficulties and misconceptions. We also hope to engage in continuing discussions about the nature and utility of the familiar dualities in algebra (syntactic / semantic, procedural / conceptual etc). We were surprised to have only one paper addressing digital technologies and hope that this omission will be rectified at CERME9.

AN ANALYSIS OF TURKISH MATHEMATICS TEACHERS' SELF-REPORTED PREPAREDNESS TO TEACH ALGEBRA IN TIMSS 2007

Kübra Çelikdemir¹ & Ayhan Kürşat Erbaş²

¹*Middle East Technical University, Department of Elementary Education*

²*Middle East Technical University, Department of Secondary Science and Mathematics Education*

The purpose of the study was to investigate Turkish mathematics teachers' self-reported preparedness to teach some particular topics in school algebra and determine possible differences among groups of teachers with different teaching experience. For this purpose, the data collected from 146 Turkish mathematics teachers in TIMSS 2007 were analyzed. First of all, teachers' self-reported preparedness in each topic was analyzed using descriptive methods. Then, one-way MANOVA was run. According to the descriptive results, although majority of the Turkish teachers reported that they were very well prepared to teach the stated algebra topics, they reported that they were less well prepared to teach algebra than their counterparts around the world. On the other hand, MANOVA analysis was nonsignificant.

INTRODUCTION

Several studies have pointed out that cognitive and affective domains are related (e.g., see Ma & Kishor, 1997; Mandler, 1989; McLeod, 1992). Therefore, current reforms in mathematics education (e.g., National Council of Teachers of Mathematics [NCTM], 1989, 1990, 2000) emphasize the incorporation of affective and cognitive factors in mathematics education. However, the literature suggests that researchers place more emphasis on the cognitive domain than on the affective domain. Thompson (1992) attributes this neglect to the effect of behaviorism in mathematics education for a certain period of time.

It is obvious that trends in mathematics education are changing and developing over time and these developments guide the trends in mathematics education research. Like the neglect of affective domain in the past, teachers, compared to students, have been ignored as focus of studies (Even, 2008). There remains relatively few studies about mathematics teachers' cognitions and conceptions and the effect of these on their teaching.

There are similar gaps in research in the field of algebra, which is one of the subdomains of mathematics. Doerr (2004) noted that while there are several studies that investigated students' understanding in algebra, research on teachers' algebraic knowledge and practices is less prevalent.

Notwithstanding this, there has been a considerable effort to eliminate such shortcomings in the related literature in recent years. Even large scale international studies like TIMSS (Trends in Mathematics and Science Study) and PISA (Programme for International Student Assessment) collect data on (mathematics) teachers' perceptions. These studies provide comparative data among the participated countries and enable researchers to understand certain issue in a broad perspective. For example, TIMSS 2007 measured mathematics teachers' perceived preparedness in teaching particular topics and provided rich data for national and international evaluations. For this reason, the data gathered from TIMSS 2007 were used in this study. Its purpose was to investigate Turkish mathematics teachers' self-reported preparedness to teach particular topics in school algebra and algebra in general compared to their counterparts and to determine if there is any statistically significant difference among group of teachers with different teaching experience. The following research questions guided the study:

- 1) How do eighth grade Turkish mathematics teachers perceive their preparation to teach algebra in general and in predetermined topics, compared with the international average?
- 2) Does teaching experience affect teachers' perceptions about their preparation to teach algebra?

The significance of this study lies not only in yielding a better understanding of (Turkish) teachers' perceived preparedness in algebra but, also, in providing a clear picture of a possible significant relationship between preparation and experience. On the other hand, the study can provide an account of the influence of the present mathematics curriculum that developed in 2004 after Turkish students' failures in TIMSS 1999 and PIRLS 2001 (Progress in International Reading Literacy Study) and PISA 2003.

METHODS

Data Source and Sample

This study utilizes the TIMSS 2007 Turkish data collected from 146 mathematics teachers each of whom was teaching Grade 8 mathematics in a different elementary school chosen by using a two-stage cluster sampling design. Schools were determined at the first stage and one class from each school was chosen randomly at the second stage. Since the number of schools were determined using probability proportional to the size of each country, the target population was all mathematics teachers teaching eighth grade mathematics in Turkey.

Instrumentation

TIMSS 2007 used achievement tests and background questionnaires to measure students' learning in mathematics and science topics and to explain the educational context behind the scores. In the present study, data from the questionnaire that related to eighth grade mathematics teacher background were used (Erberber, Arora,

& Preuschoff, 2008). The questionnaire included 33 questions on information from mathematics teachers about their demographics, experience, attitudes, pedagogical information, instruction load, resources related to teaching mathematics, mathematics course content, and comments on the teaching of mathematics.

In particular, teachers were asked about their perceived preparedness in 18 topics in total, including 5 topics in number, 4 topics in algebra, 6 topics in geometry, and 3 topics in data and chance. For the present study, the following four topics in algebra were considered:

- numeric, algebraic, and geometric patterns or sequences (extension, missing terms, generalization of patterns),
- simplifying and evaluating algebraic expressions,
- simple linear equations and inequalities, and simultaneous (two variable) equations,
- equivalent representations of functions as ordered pairs, tables, graphs, words, or equations.

Teachers were asked to mark one of the alternatives in the four-point scale: “not applicable”, “very well prepared”, “somewhat prepared” and “not well prepared” which were coded as 1, 2, 3, and 4 respectively.

Variables and Statistical Analysis

As fit for the purpose of the study, teaching experience and teachers’ perceived preparedness to teach algebra topics stated above were taken into consideration. While teaching experience was considered as the independent variable, teachers’ preparations in specific topics in algebra were taken as dependent variables in the analysis of possible mean differences in perceived preparedness among the group of teachers and differences in teaching experience.

Since the teachers wrote their exact year of teaching experience in the questionnaire, this variable was not a categorical variable. Therefore, for the purposes of statistical analysis, data were split into four categories and coded as “1” for having less than three years of teaching experience, “2” for 3-5 years, “3” for 6-10 years, and “4” for more than 10 years. Table 1 shows the frequencies, percentages, means, standard deviations and minimum and maximum values of teaching experience in each category.

Number of years	Ω	%	M	SD	Min	Max
Less than three years	25	17.1	1.3	.5	1	2
3-5 years	35	24.0	4.3	.8	3	5
6 -10 years	31	21.2	8.0	1.2	6	10
More than 10 years	44	30.1	22.8	6.2	11	37
OMITTED	11	7.5				
Total	146	100.0				

Table 1: Teaching experience of eighth grade Turkish mathematics teachers

In order to address the first research question, percentages of teachers who perceived themselves to be very well prepared on algebra are provided and compared with the international average.

Furthermore, to answer whether the more experienced teachers perceived themselves as more prepared to teach the stated algebra topics, mean differences between the groups of teachers with different teaching experience were analyzed using a one-way multiple analysis of variance (MANOVA). Since there was one categorical independent variable and four continuous dependent variables, one-way MANOVA was chosen for the analysis. In addition, one-way MANOVA was preferred because it considers four dependent variables in combination and protects against inflated Type I errors due to multiple tests of likely correlated dependent variables (Tabachnick & Fidell, 1996). All statistical analyses were carried out using the software SPSS.

The listwise deletion method was used on data that was omitted or not administered. Accordingly, MANOVA analysis was run for 130 teachers out of 146 teachers.

RESULTS

Descriptive Results

In TIMSS 2007 (Martin, Mullis & Foy, 2008), the percentages of teachers who perceived themselves as “very well prepared” to teach four algebra topics were given for each participating country. Based on the obtained results of four algebra topics, preparedness to algebra in general was computed. In addition, the international averages for each topic and algebra in general were also calculated.

Accordingly, while the international average of teachers who perceived themselves as “very well prepared” to teach algebra is 82%, only 66% of Turkish mathematics teachers perceived themselves to be so. Comparisons of Turkish teachers and international average for each algebra topic are reported in Table 2. It is important to note that the percentages for Turkey reported in this study differ from percentages in the figures in the TIMSS 2007 International Mathematics Report (Martin et al., 2008). The standard errors in TIMSS 2007 published figures or the errors in Turkey row data can be the possible explanations for this difference.

	Patterns or Sequences	Algebraic Expressions	Linear Equations and Inequalities	Equivalent Representations of Functions
Turkey	52	81	77	40
International Avg.	70	89	88	80

Table 2: Percentage of teachers who reported very well prepared to teach algebra topics

It can be seen that although the majority of the Turkish teachers perceived themselves to be very well prepared to teach algebra topics, the percentages are considerably lower than the international averages. The highest percentages were for “Algebraic expressions” (81%) followed by “Linear equations and Inequalities” (77%) and the lowest were for ‘Patterns or Sequences’ (52%) followed by ‘Equivalent Representations of Functions’ (40%) for Turkish teachers. Similar patterns exist in the international averages. However, while the lowest percentage for Turkish teachers was for ‘Equivalent Representations of Functions’, the lowest percentage of the international average was for ‘Patterns or Sequences’.

On the other hand, the percentages of Turkish teachers who perceived themselves as “not well prepared” or “somewhat prepared” to teach should not be ignored. Therefore, the percentages of alternative answers are given in Table 3. For the topics of ‘Patterns or Sequences’ and ‘Equivalent Representations of Functions’, the percentage of teachers who reported that they were “somewhat prepared” or “not well prepared” cannot be underestimated.

	Patterns or Sequences	Algebraic Expressions	Linear Equations and Inequalities	Equivalent Representations of Functions
Not Applicable	10	-	-	28
Very Well Prepared	52	81	77	40
Somewhat Prepared	28	11	16	24
Not Well Prepared	10	8	7	8
Total	100	100	100.0	100

Table 3: Percentages of Turkish mathematics teachers’ perceived preparedness to teach the algebra topics.

MANOVA Results

Before conducting a one-way MANOVA, the following assumptions are made:

- a) independent random sampling: since TIMSS used a random sampling technique, the observations are independent of each other.
- b) level and measurement of the variables: while the independent variable in this study, teaching experience, was categorical, the four dependent variables were scale variables.
- c) linearity of dependent variables: to examine multicollinearity, correlations between all of the four dependent variables were checked with Pearson product-moment correlations. According to Tabachnick and Fidell (1996), problems occur at higher correlations (.90 and higher). Since the highest correlation between the four dependent variables is .70, the problem was not detected.
- d) Normality: all of the dependent variables are normally distributed. ($p > .05$)
- e) Homogeneity of variances: the results of Box's Test ($F(30, 31082) = 1.37, p = .08$) were nonsignificant which means that the group variance-covariance matrices were equal.

A one-way MANOVA was conducted to explore the effect of difference in teaching experience on perceived preparedness to teach the algebra topics stated above. The results for the MANOVA were statistically nonsignificant for the teaching experience main effect, Wilks's $\Lambda = .93$ $F(12, 326) = .77, p = .68$. In other words, there were no statistically significant differences among group of teachers with different teaching experience on teachers' perceived preparedness in teaching algebra topics.

CONCLUSION

Based on the descriptive data, it is clear that Turkish teachers perceived themselves as less well prepared to teach all of the stated algebra topics and algebra in general compared to their counterparts around the world. This is an important observation as it may be the reason for Turkish students' low scores in algebra since research shows that teachers' confidence in their teaching affects their teaching efficacy and effective teaching affects students' achievement (Ingvarson, Beavis, Bishop, Peck, & Elsworth, 2004; Richardson, 2011; Vanek, Snyder, Hull, & Hekelman, 1996)

On the other hand, while the percentage of teachers who perceived themselves as very well prepared to teach 'Algebraic Expressions and Linear Equations' is high, the percentages of teachers who perceived themselves as very well prepared to teach 'Patterns or Sequences' and 'Equivalent Representations of Functions' are considerably lower. One possible explanation for this is the emphasis in the Turkish elementary mathematics curriculum (Talim ve Terbiye Kurulu [TTKB], 2009). Compared with patterns and sequences and functions, algebraic expressions and linear equations are given more weight in the curriculum. For this reason, teachers spend more time and energy teaching those topics. It is possible that their engagement in the topics influenced their understandings of and perceptions about

teaching them (Lee, Baldassari & Leblang, 2005). Similarly, in teacher education programs, elementary mathematics teachers might have not been well prepared to teach patterns and sequences or functions in elementary school level. Moreover, pure content courses in these topics are found to be ineffective in teachers' confidence in their teaching (Beswick, 2011).

Before analyzing the data, it was expected that teachers who have more experience in teaching would perceive themselves as significantly more prepared to teach algebra topics. Although there is much research reporting the positive effect of experience on teachers' confidence in teaching (Adams, Hutchinson & Martray, 1980; Griffin, 1983), a few studies (e.g., Wessels & Nieuwoudt, 2010) have found no significant effect of experience on teachers' confidence to teach, as was the case in this study. Since there is not a consensus on this issue in the literature, it needs to be further investigated. However, this result may indicate that Turkish mathematics teachers have not been able to upgrade their understanding of algebra topics over time. In order to reach such a conclusion, further research is needed.

The findings of the study imply that regardless of their teaching experience, Turkish mathematics teachers require additional support to improve their understanding in algebra topics, especially in patterns and sequences and functions and efficacy to teach them. Therefore, professional development programs that strengthen teachers' understandings in algebra and enrich their teaching by providing multiple materials should be organized. This may influence their perceptions about teaching algebra and, in turn, may develop students' algebraic understandings.

YOUNG PUPILS' GENERALISATION STRATEGIES FOR THE 'HANDSHAKES' PROBLEM

Thérèse Dooley, St. Patrick's College, Dublin

In describing the strategies that young pupils employ for algebraic generalisation, most research focuses on linear rather than quadratic problem situations. The strategies identified by Lannin, Barker and Townsend (2006) for the cube sticker (linear) problem include counting, recursion, chunking and development of an explicit formula. However, erroneous solutions are often given for 'high' numbers because of the tendency by students to use inappropriate proportional reasoning in such instances. In this paper I describe the strategies that pupils aged 9 – 10 years used in whole-class conversation to solve the 'handshakes' problem, an example of a quadratic generalising situation. They used many (but not all) of the strategies that apply to linear problems and were able to verify the explicit formula that they developed with reference to the structural elements of the problem.

INTRODUCTION

The capacity of children to engage in sophisticated generalisation activities is at the core of the inclusion of the strand of algebra in primary mathematics curricula (e.g., Kaput, Blanton, & Moreno, 2008). In this regard, previous discussions at the Algebra working group of the Congress of European Research in Mathematics Education (CERME) have called for students to engage in problems the purpose of which is to express generality (e.g., Puig, Ainley, Arcavi, & Bagni, 2007). In this paper I describe the strategies that pupils aged 9 – 10 years used to solve the well-known 'handshakes' problem. It builds, in particular, on a recommendation made by Barbosa (2011, p.427) at CERME 7 that students be provided with "tasks which allow the application of a diversity of [generalisation] strategies". However central to the development of these strategies are (a) the role of the teacher and (b) task design.

GENERALISATION STRATEGIES

In early years classrooms, the emphasis in algebra is usually on the exploration of simple repeating and growing patterns. Since any variation usually occurs within the pattern itself, the focus is on single variational thinking (for example, finding relationships between y values rather than between x and y values). As pupils move through the primary school system, greater emphasis is placed on the formation of functional relationships and the generalisation of patterns. Functional thinking is described by Smith (2008, p.143) as follows:

... representational thinking that focuses on the relationship between two (or more) varying quantities, specifically the kinds of thinking that lead from specific relationships (individual incidences) to generalizations of relationships across instances.

Functional thinking is intrinsic to algebraic reasoning because it allows for the generalisation of a relationship between two varying quantities. Furthermore, it lays a firm foundation for more formal algebra work in later years (Blanton & Kaput, 2011).

Although young children are capable of thinking functionally (Blanton & Kaput, 2004; Warren, 2005), there is evidence that, throughout the primary years, they focus on pattern spotting in one data set rather than on the relationship between an element of a pattern and its position. Warren (2005) suggests that this is the case either because it is cognitively easier for children or is so engrained from school experience that there is a tendency to revert to it.

Most of the research on the generalisation strategies used by pupils is based on linear problems (e.g., Lannin, Barker, & Townsend, 2006b; Rivera & Becker, 2008). An example of one such problem is the Square Matchstick Problem:

Figure 1: ‘Square Matchstick’ pattern

The number of matchsticks required to form the n th element of this sequence is $3n + 1$ (for example, 13 matchsticks are required to build the fourth element).

Lannin, Barker and Townsend (2006a) developed a framework of generalisation strategies for linear problems as follows:

- **Counting:** Student draws a picture or constructs a model to represent the situation and then counts the desired attribute.
- **Recursive:** Student describes a relationship that occurs in the situation between consecutive values of the dependent variable.
- **Chunking:** Student builds on a recursive pattern by building a unit onto known values of the desired attribute. In the matchsticks problem, if a student knows that ten matchsticks are required for the third element, s/he might calculate the number required for the fifth element by using a strategy such as $10 + 2(3)$ (because the number increases by 3 each time).
- **Whole-object:** Student uses a portion as a unit to construct a larger unit using multiples of the unit. For example, the fifth element requires 16 matchsticks and therefore the tenth element requires $32 - 1$ (where the 1 is subtracted to take account of the first matchstick used in the first element).
- **Explicit:** Student constructs a rule that allows for immediate calculation of any output value.

According to Lannin et al. (2006b), recursive rules involve “recognising and using the change from term-to-term in the dependent variable” (p. 300) while explicit rules use “index-to-term reasoning that relates the independent variable to the dependent variable(s), allowing for the immediate calculation of any output variable” (ibid). For example, in the square matchsticks problem above, an example of the recursive rule is that the difference between the number of matchstick required is 3 (‘going up in threes’) whereas an explicit rule is ‘ $3n + 1$ ’. The ‘chunking’ and ‘whole object strategies’ are similar and represent attempts by students to calculate values

immediately. However, they are strategies that often lead to erroneous calculations. A student using a chunking strategy might add the fifth output value (16 in the matchsticks problem) to the tenth output value (31) to find the fifteenth output value (thus finding a solution of 47 instead of 46). A false ‘whole-object’ technique that is prevalently used by students is the application of direct proportion or linearity (for example, doubling the number of matchsticks required for ten to find that for 20 and failing to take account of the ‘first’ matchstick in the pattern). Stacey (1989) suggests that this tends to be evoked when ‘far generalisation’ (an input value that renders the step by step approach unfeasible for example, finding the number of matchsticks required in the 50th element) is required. She found this to be the case even when students have made correct use of counting or a functional rule for smaller input values. This inappropriate proportional reasoning (or the ‘illusion of linearity’) has been found to exist among students of different ages and in a variety of mathematical domains (De Bock, Van Dooren, Janssens, & Verschaffel, 2002).

While the strategies outlined here represent increasingly sophisticated means of generating solutions for any n , Lannin et al (2006a) recognise the need not only for students to formulate rules but also to engage in explanation and justification of these rules. In this regard, Rowland (1999) makes a distinction between empirical generalisation - which is achieved by considering the form of the results - and structural generalisation which is made by investigation of the underlying meanings, structures or procedures of the problem at hand. For example in the ‘square matchstick’ problem, a student might notice the ‘going up in threes’ pattern (empirical) or be able to verify the pattern in terms of the need to add three sticks in order to make a new square (structural).

There is little research on the kind of generalisation strategies that pupils might use for non-linear patterns. In research on how primary school pupils abstract mathematical entities in the context of teacher-led discussion, I taught a series of lessons in three different primary schools in Ireland (Dooley, 2010). My research design – a teaching experiment – entailed the development of a hypothetical learning trajectory in advance of each lesson (Cobb, 2000). The one that I formed in advance of a lesson on a non-linear problem (the ‘handshakes’ problem) was based on Lannin et al’s framework. I used it in conjunction with the RBC (recognising – building with – constructing) model of abstraction (Schwartz, Dreyfus, & Hershkowitz, 2009) for analysis purposes; however, in this paper I report only on the suitability of the framework as a learning trajectory in this particular situation and not on the RBC aspect.

HYPOTHETICAL LEARNING TRAJECTORY

The lesson which is the subject of this paper is Chess (the ‘handshakes’ problem) a task that supports children’s development of functional thinking (Blanton & Kaput, 2005). It reads as follows:

In a chess league each participant plays a game of chess with all other participants. How many games will there be if there are 3 participants? 10 participants? 20? Is there a way to find the number of games for any number of participants?

While the ‘Chess’ problem is a quadratic problem situation and therefore could be expected to be more cognitively challenging than linear problems for pupils, there are many ways that the problem might be solved. I refer here to those that are most likely to emerge in a primary school setting. This is not to exclude the possibility that a primary student might notice or use others. One way, as shown in table 1, is to make a list and look for a pattern:

Number of People (x)	Number of Games (y)	Difference (d)
1	0	
2	1	1
3	3	2
4	6	3
5	10	4

Table 1: Table of values for ‘Chess Problem’

The differences, d , between consecutive values y form the sequence of natural numbers. A related observation is that a number in the y column might be found by adding x and y values in the previous row (e.g., $4 + 6 = 10$, referred to in future as the $x + y$ method). These patterns are contingent on writing x and y values in consecutive order.

The function mapping x to y is $y = \frac{x(x-1)}{2}$. This might emerge from inspection of the relationship between the x and y values. The same formula emerges if one gives consideration to the symmetric nature of the activity, that is, there is one game for each ‘pair’ (Rowland, 2003).

Another way to solve this problem is to consider the number of games played by each person, that is, the first person plays a Chess game with seven others, the second with six more, the third with five more and so on. The solution for eight people then is $7 + 6 + 5 + 4 + 3 + 2 + 1$ giving a total of 28 games. Although this method (referred to in future as ‘summation’) generalises for all numbers it becomes cumbersome for larger numbers, especially if the numbers are added in consecutive order.

While the lesson took place over two consecutive days, a related lesson that took place a month earlier with this class was one entitled Friendship Notes and which reads:

As part of Friendship Week in Greenville School, each pupil writes a short note to each other pupil in his/her class. Each pupil is given one sheet of paper for each note. How many sheets of paper are needed if there are 5 pupils in a class? 10 pupils? What would be the number [of sheets] for any number of pupils?

Both Friendship Notes and Chess are characterised by non-reflexivity (that is, no element of a set relates to itself). The main difference between the activities lies in the property of symmetry. ‘Chess’ is symmetrical because if A relates to (‘competes with’) B, then it follows that B relates to A. However, in ‘Friendship Notes’, if A relates to (‘writes to’) B, the reciprocal relationship is not implied. For this reason the function mapping x (the number of people) to y (the number of notes) in the Friendships Notes is $y = x(x-1)$ while in Chess, $y = \frac{1}{2} x(x-1)$ where x represents the number of people and y the number of games. Of relevance to this paper is that pupils had developed a ‘rule’ – expressed verbally – for the solution of any x in Friendship Notes.

As previously mentioned the Chess lesson took place over two consecutive days (the daily sessions will be referred to hereafter as Chess 1 and Chess 2). The format of both Chess 1 and Chess 2 was introductory whole-class discussion and small group work followed by whole-class discussion. In group work pupils worked in self-selecting pairs or triads. In Chess 1, there was a whole class lesson in which consideration was given to the number of games that would apply to 1 – 5 players. Pupils then worked in groups to consider cases of 1 – 10 players – for this part of the lesson they filled in a table similar to that shown in Table 1 above (without the ‘difference’ column). At the end of the lesson there was a plenary discussion on the number for 20 players. In Chess 2, there was a review of the previous day’s lesson. During the group-work phase they were asked to fill in a table for 11 – 20 players and during the final discussion the focus was on the generation of a rule for *any* number of players. There were 31 pupils in the class and the school was located in an area of middle socio-economic status¹. Data collected included audiotapes of whole-class and small-group conversations, pupils written artefacts, field notes and digital photographs of activities. Video data were not collected due to ethical constraints. In this paper I report only on interactions that occurred in whole-class discussion as this was the main site for growing sophistication in solution strategies, a point to which I will return in the discussion section.

PUPILS’ SOLUTION STRATEGIES

There was a total of 712 turns in the whole-class discussion phases of both lessons. Up to turn 196, the count strategy was employed. For example, when considering the number of games for four competitors, Killian erroneously suggested five games but used a counting procedure²:

- 136 Killian: Five.
 137 TD: Why do you think five?
 138 Killian: Cos Enda plays three and then Barry plays two, then David plays Colin, that’s ()
 139 TD: So just say that, explain that to me again ... you’ve got ...?
 140 Killian: So David plays the other three.
 141 TD: So how many games is that?

- 142 Killian: Three.
 143 TD: Right, go on.
 144 Killian: And then Barry plays the other two and then Colin plays Barry...six.

In turn 196, Anne used an incorrect recursive strategy and suggested that nine games would be played by four competitors:

- 196 Anne: Em, nine.
 197 TD: Why are you thinking nine?
 198 Anne: Because it's going up in threes.

The first time that there was any allusion to an explicit rule was in turn 206 when Fiona used the summation rule. She first counted the five pupils at the top of the room but then stated a way of working in which no mention of pupils was made:

- 202 Fiona: Well, if Enda would play four people and then Barry would have to play eh ... three people ...
 203 TD: Yeah.
 204 Fiona: ... and then Colin would have to play two people and then David would have to play one.
 205 TD: So what do you think it would be? How would you find out the answer? ... What would you do to find out the answer?
 206 Fiona: Eh, four, three, two and one.

During group work, most pupils used the $x + y$ recursion method to find solutions for seven, eight, nine and ten competitors. However, when having a whole-class discussion at the end of the first session about a larger number of competitors (i.e., 20), there was evidence of inappropriate linear reasoning on the part of some pupils. For example, Desmond doubled the number of games for ten competitors to find the solution for 20:

- 357 Desmond: Ninety.
 358 TD: Getting ninety, why do you think it's ninety for twenty people?
 359 Desmond: Eh ten is forty-five.

The explicit rule that was being expressed towards the conclusion of the lesson related to 'summation'. For example, Fiona used the formula she had developed for five competitors to find the solution for 20 competitors:

- 402 Fiona: Well you could em you could do em add one, two, three, four, five, six, seven, eight, nine, ten, eleven, twelve, thirteen, fourteen, fifteen, sixteen up to nineteen.

Brenda, Myles and David articulated a similar strategy. Anne suggested multiplying 20 by 19 to find the solution and a short while later, David tentatively suggested a formula:

- 432 David: Em, well, it might not work all the time but twenty nineteens is three hundred and eighty and half that is one hundred and ninety ...

However, he did not justify his conjecture structurally.

In Chess 2, the algebraic strategies most often used were ‘recursion’ and ‘explicit rule’. The counting strategy was not evident. In the lesson introduction, Liam used the $x + y$ method recursively:

447 Liam: Just really one plus zero is one, two plus one is three, three plus three is six, four plus six is ten, five plus ten is fifteen, ... eh six plus fifteen is twenty-one, eh seven plus twenty-one is twenty-eight, nine eh eight plus twenty-eight is thirty-six, nine plus thirty-six is forty-five.

During group work, pupils were given a worksheet in which they were asked to give consideration to the number of games of chess that would be played in the case of 11 to 20 competitors and thereafter to 40 competitors. The majority of them used the $x + y$ strategy to complete the worksheets for 11 to 20 competitors. However, in the follow-up discussion on the number of games for large numbers of competitors, David reiterated the rule he had found on day 1:

635 David: Multiply it by the number less ...

636 TD: Hm, hm.

637 David: ... and then half it.

Shortly after this, Enda observed the similarity between Chess and Friendship Notes.

639 Enda: It looks like ... it’s pretty much the very same as the friendship cards, it seems kind of like that.

Barry reflected on the non-reflective nature of both activities, that is,

641 Barry: It’s kind of the same thing as, eh, you wouldn’t have to do themselves so there’s going to be one less.

Both Myles and Colin gave consideration to the structural difference between the two activities. Colin gave the following description:

651 Colin: Em, well cos in the friendship notes you have to give two because if there were three you would have to give one to each person ...

652 TD: Hm, hm.

653 Colin: ... and everyone has to give one to each person, so it’s the same as three by two

654 TD: Hm, hm.

655 Colin: Eh, and in chess you only have to play them once even if they challenge you

656 TD: Hm, hm.

On foot of these ‘structural’ deliberations, Enda announced that

662 Enda: Eh well, I actually definitely agree with David’s way by doing the friendship notes, the same way as the friendship notes and halving it ...

It would seem that the justification offered by Barry, Myles and Colin was sufficient to convince him that the explicit formula was indeed appropriate. In follow-up reflective accounts most pupils aligned themselves with ‘David’s method’, although it is unclear if they took account of the structural verification of his formula.

DISCUSSION

The strategies that were used by this group of pupils to solve the Chess problem included counting, recursion, whole object (incorrectly) and formation of an explicit rule. They did not appear to use the ‘chunking’ strategy. The explicit rules included both summation and a more general formula. Towards the conclusion of the lesson some pupils were able to verify the explicit rule (formula) with reference to the structure of the problem. Although most pupils aligned themselves with the formula at the end of the lesson, it is not clear that all had fully understood the structural dimension. What this paper shows, however, is the variety of strategies that pupils can use to solve complex problems. It could be argued that the format of the lesson (that is the use of consecutive lower numbers initially and later ‘higher’ numbers) lent itself to a progression from count through recursion and eventually to the use of a formula. In this regard, Warren, Cooper, and Lamb (2006) have alluded to the consecutive listing of x , y values as a factor that inhibits the development of relational or functional thinking. What seems to be the case in this lesson was that, in general, pupils’ choice of strategy was based on that which seemed to be most efficient for the task at hand. However, the dominance of the $x + y$ method can be attributed to the use of a table and it would be interesting to see what kind of strategies would emerge if the lesson were designed differently.

In the lesson described in this chapter, the pupils used natural language to express the relationship between the number of players and the number of games. For David’s statement in turns 635 and 637 (“Multiply it by the number less ... and then half it”) could be described in conventional algebraic terms as $\frac{1}{2} n (n-1)$. While there well might be concern about the lack of rigor in children’s use of terms, I would argue that pupils need to have the opportunity to speak thus before embarking on more conventional symbolic terms and that it is perhaps the lack of opportunity to do so that has contributed to the ‘Algebra Problem’ (Kaput, 2008). This resonates with an argument, made by Caspi and Sfard at CERME 7, that pupils’ informal discourse can serve as a powerful resource for the development of more formal algebraic ideas (Caspi & Sfard, 2011).

Lannin (2005) found that students rarely justify their generalisations in small group situations and acknowledged the role played by a teacher in pressing for such justification. It was similar in the lesson described here and, in fact, in the plenary phase at the end of each session, probes by the teacher led to students justifying their choices and building on each other’s thinking (e.g., in turn 641 Barry built on Enda’s conjecture). This was a significant factor in developing algebraic thinking. Furthermore, the use of an activity with some variation a month previously laid the ground for structural verification of the formula. It is likely that were it not for the Friendship Notes lesson, pupils’ thinking would not have progressed beyond the empirical level. To this end, the sequencing of activities by teachers is an important element in stimulating and developing pupils’ generalisation strategies.

NOTES

1. In the Republic of Ireland, indicators such as unemployment levels, housing, number of medical card holders and information on basic literacy and numeracy are used to determine socio-economic status of schools.
2. Transcript conventions (related to this paper) are: TD: the researcher/teacher (myself); ... : a short pause; (): inaudible input.

HOW ARITHMETIC EDUCATION INFLUENCES THE LEARNING OF SYMBOLIC ALGEBRA

Sandra Gerhard

Goethe-University Frankfurt, Germany

***Abstract** In line with a design science project aiming at designing a theory-driven learning environment for teaching symbolic algebra by comparing geometric quantities, this paper presents first results of an investigation on how students' previous experience with arithmetic and new learned (geometrical) knowledge about symbolic algebra are intertwined.*

***Keywords:** Symbolic Algebra, Didactical Contract, Algebra History*

INTRODUCTION

Various international researchers work on questions concerning problems of students' approach to school algebra (see e.g. Kieran, 2007). Hence, there is detailed knowledge about which difficulties exist and many ideas concerning how to face these difficulties. The idea of early algebra (see e.g. Carraher & Schliemann, 2007) is to introduce algebra in earlier grades. There are different reasons for following this approach. An important reason for teaching early algebra is that there is evidence for arithmetic, as it is taught in school, negatively affecting children's algebra learning ability (see McNeil, 2004). But there is little research regarding *how* exactly arithmetical education influences the learning of algebra.

THEORETICAL FRAMEWORK

Algebra as generalised arithmetic?

“When we look at school tradition in different countries [...] algebra is generalised arithmetic.” (Lins & Kaput, 2004, p.50) But to tie algebra to children's experience with natural numbers provokes multifaceted difficulties. McNeil (2004) emphasised the relevance of the change-resistance account. “More specifically, the account posits that children construct knowledge on the basis of their early experiences with arithmetic operations and that this knowledge contributes to children's difficulties with more complex equations.” (McNeil, 2004, p.938) She refers to three knowledge structures that are hindering a good approach to algebraic equations: solving math problems means acting out operations, the structure of maths problems is “operations=answer” and the equal sign is followed by the result. Carraher & Schliemann (2007, p. 670) point up similar findings.

A reason for these difficulties may be the focus on natural numbers, especially the number sense concerning these numbers, and the lack of concentration on a more generalised idea of number in the early years of mathematics education. But field reports from early algebra classrooms show that arithmetic can be taught effectually as part of algebra. This leads to the conjecture that not arithmetical knowledge itself, but the way of dealing with mathematics that students acquire in traditional

arithmetic education is the source of these difficulties. And because this kind of handling of mathematics is acquired in arithmetic education it may be triggered whenever numbers come into play. In this paper the concept “patterns of action” is used for these ways of dealing with mathematics.

The concept “pattern of action” is based on Brousseau’s didactical contract (see Hersant & Perrin-Glorian, 2005). “Situating a problem within a certain mathematical field guarantees that certain techniques will appear natural and will be favoured whereas others will be improbable.” (Hersant & Perrin-Glorian 2005, p.118). Patterns of actions are defined as this certain techniques which are bound to the *domain* in which students believe themselves to be. Patterns of actions depend on the *didactic status of knowledge*. Usually patterns of actions connected with old knowledge are rooted deeper than patterns of actions connected with new, recently taught knowledge.

There are several ideas to counter the problem caused by unwanted patterns of action that are induced by arithmetic education and hinder a good approach to algebra. One idea is to change curricula, train teachers and in doing so trying to teach arithmetic in a more algebraic way. Research literature on early algebra shows the gains from such approaches (see Carraher & Schliemann, 2007). However, changes in primary mathematics classrooms are slow and “mathematics equals calculating” is deep-seated in our society. Hence, there is also a need for research about how to teach algebra to students who have already acquired patterns of action that hinder their algebra learning.

Teaching algebra without arithmetic?

In traditional school algebra the introduction of algebra is characterised by a syntactic way of using symbolic algebra. The consequence is that students focus on the symbols and have problems to give variables meaning (see e.g. Malle, 1993). In order to give symbolic algebra meaning it is necessary to connect it with a mathematical subject students are already familiar with, like numbers and arithmetic. However, using arithmetic as base for symbolic algebra brings in the undesired patterns of action described above. As the patterns of action are bound to a domain, in this case arithmetic, a way to face this problem may be introducing symbolic algebra within a different domain and link algebra with arithmetic later, when the desired algebraic patterns of action are consolidated.

A historical point of view

To learn more about the learning of symbolic algebra an additional look at the development of symbolic algebra from a historical point of view may be helpful. The reason for looking at the history of algebra is not that the ontogenesis of students’ understanding of symbolic algebra has to follow the phylogeny of symbolic algebra (see Harper, 1987). Rather a look at the history of the development of symbolic algebra can help to identify specific problems with and chances for learning to deal with symbolic algebra. Rhetoric and syncopated algebra were used over centuries

before symbolic algebra emerged. Hence it is not surprising that introducing symbolic algebra is likewise challenging for students.

History shows that the development of algebra is closely connected to geometry, the so called geometric algebra. One may reason that geometric algebra was an obstacle for symbolic algebra because in order to work with symbolic algebra one has to detach oneself from the graphic power of geometry (Krämer, 1988), which is not easy. However, whilst geometric algebra supports a holistic, object-oriented view on algebra (Sfard, 1995), the introduction of symbolic algebra allowed a new view on geometry, namely analytical geometry.

Geometric algebra as an alternative entry point to algebra

This historical situation cannot be transferred one-to-one to school curriculum, because the students do not have an extensive education in geometry prior to the introduction of algebra. They only have an extensive education in arithmetic. If the (possible) roles of geometry and arithmetic for school algebra are contrasted (see Figure 1) a possible alternative route into algebra becomes apparent.

Introducing symbolic algebra with...	
Geometry	Arithmetic
Advantage	
A graphic basis for working with variables allows a holistic view on the task, the operations and relations.	A numerical basis for working with variables allows a pool of abstract examples for operations and relations.
Disadvantage	
“Graphic power” ties symbolic algebra to concrete geometry.	Patterns of action hinder the view on operations and relations.
Perspective	
Analytical geometry gives new insight into geometry.	“Algebraic arithmetic” gives new insight in arithmetical operations.

Figure 1: Relation between symbolic algebra and geometry respectively arithmetic

The idea is to use the graphic basis of geometry to teach students a holistic view of operations and relations. Because geometry is used, the already acquired patterns of action that may obstruct students view on operations and relations may not be triggered. Later, when students have achieved the desired algebraic patterns of action, algebra can be connected with arithmetic. Then the rich arithmetic pool of abstract examples for relations and operations can be used to untie algebra from concrete geometry. Additionally the new “algebraic arithmetic” may give new insight in arithmetical operations.

The crucial point of this approach towards algebra does not appear to be the teaching of algebra in a geometric way. In fact the fundamental question is what will happen when geometric algebra meets arithmetic? Will arithmetic patterns of action still dominate? How sustainable will be geometric-algebraic patterns of action? Which patterns of action will be applied if the arithmetic and the geometric-algebraic

domain converge? In the following will be presented how these questions have been investigated and as well as the discussion of first results

METHODOLOGY

The aim of the design research project (see The Design-Based Research Collective, 2003) that is underlying this paper is the development of a theory-driven learning environment for introducing symbolic algebra after primary school, based on geometry. After several pre-studies (see Gerhard, 2009) a teaching experiment with 10-11 years old students of a 5th grade of a grammar school was conducted. The learning environment is based on ideas of the El'konin-Davydov-Curriculum, which was developed in Russia and refined during teaching experiments by the Measure-Up-Program at the University of Hawaii. For a detailed description of the teaching experiments see Dougherty (2008) and Davydov (1975).

The teaching experiment took place at the end of the school year. During the school year arithmetic lessons contained repeating basic arithmetic operations, place value system, calculating with decimals and prime numbers. Topics of geometry lessons were the coordinate system and basic ideas about circles and angles. The topics length, area and volume had not been taught at the time of the teaching experiment. Hence, for the teaching experiment, a key consideration was that student would need to use intuitive ideas of area and volume without using multiplication. Figure 2 shows the basic principles of the learning environment and a sample task.

Basic principles	Sample task
<ul style="list-style-type: none"> • Comparing geometric quantities of unknown size • Calculation with letters that characterise unknown sizes of geometric quantities • Visualisation with auxiliary drawings. • Analytical idea: choosing letter variables for unknown values • Finding as many relations as possible. • Write down relations as equations and inequations. • Use basic transformation rules (Malle, 1993, e.g. $a+b=c \Leftrightarrow b = c-a \Leftrightarrow a = c-b$) 	<p>A piece of land has area p. The piece of land contains of two parts. One part is grassland, the other part is farmland. The grassland has area g. How big is the area of the farmland?</p> <ol style="list-style-type: none"> 1) Make a drawing which should be as simple as possible. 2) Write down all equations and inequations you can think of the diagram. 3) Which equations and in-equations tell you how big the farmland is?

Figure 2: Learning Environment

The research focus of this paper is on the question how new patterns of action about symbolic algebra acquired in the teaching experiment might interact with old patterns of action acquired in previous arithmetic education. The approach to this question is explorative and therefore hypothesis generating. To allow for an investigation of the long-term effects, additional problem-centred, semi-standardised interviews were conducted 6-7 months after the teaching experiment. During the interviews students were confronted with arithmetic story problems that were modified by using letters instead of numbers. The transcripts of the interviews together with the students'

written products were analysed using an analysis tool which was designed for this purpose (see Gerhard, 2011 and Figure 3).

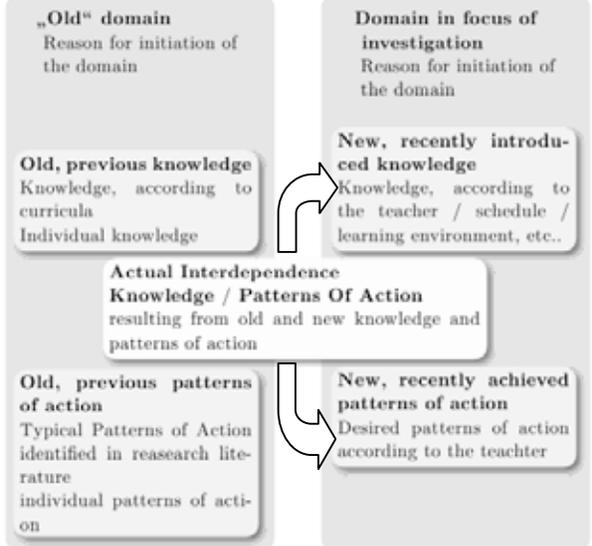

Sample interview problem	Interdependence Analysis Tool (revised 2012)
<p>Running for a good cause Mrs. Gunther takes part in a run in stages. The more kilometres she runs the more donations are paid to the organizer.</p> <p>The run lasts from Monday to Saturday. From Monday she runs a hours per day. On Saturday she only runs half of the time. If she makes b kilometres per hour, how many kilometres does she run altogether?</p> <p>(Structure of the task: $5 \cdot a \cdot b + (a:2) \cdot b = L$)</p>	 <p>The diagram illustrates the Interdependence Analysis Tool. It features two main columns. The left column represents the '„Old“ domain' and includes 'Old, previous knowledge' (Knowledge, according to curricula, Individual knowledge) and 'Old, previous patterns of action' (Typical Patterns of Action identified in reasearch literature, individual patterns of action). The right column represents the 'Domain in focus of investigation' and includes 'New, recently introduced knowledge' (Knowledge, according to the teacher / schedule / learning environment, etc..) and 'New, recently achieved patterns of action' (Desired patterns of action according to the teacher). A central box labeled 'Actual Interdependence Knowledge / Patterns Of Action resulting from old and new knowledge and patterns of action' is connected to the four surrounding boxes by curved arrows, indicating the integration and interdependence of these elements.</p>

Figure 3: Interview design and revised interdependence analysis tool

There was a need for a new analysis tool because for the analysis two dimensions have to be considered. First, students previous experience that has its origin in previous arithmetic education has to be contrasted with their understanding of algebra that stems from the geometric-algebraic teaching intervention. Second, beyond the patterns of action the students' arithmetical and geometric-algebraic knowledge have to be investigated as well. In fact the patterns of action supposedly play a key role, but this does not mean that the domain-specific knowledge can be neglected.

The analysis tool is used as follows: The starting point is an interpretation concerning the reasons for how the student acts in the actual situation. These reasons are classified according to domain, knowledge and patterns of action, both old and new. The analysis starts with expected patterns of actions and knowledge in both domains and ends with the student's supposable actual algebraic patterns of action and knowledge influenced by previous arithmetic patterns of action knowledge.

THE STUDENTS

The performance of two students, Dorian and Christina, on the sample task is used to illustrate the findings. The analysis is part of case studies with twelve students, which differ in performance on arithmetic and algebra. Dorian is an outstanding student in arithmetic, while Christina is low-achieving. Both students did well in the tasks of the teaching intervention.

Dorian read the task and immediately started to write down and explain a solution of the task (see Figure 4), using letters and numbers.

1	Hm- well, than is that here, then she runs Monday to Friday, that are 5 days every day a hours,
---	---

2	that means a plus a plus a plus a plus a - (writes ',a+a+a+a+a') and then she runs only half as many and
3	that means she also runs only half as many, that means again once more plus a divided by 2 (writes
4	' $+a:2$ ') [...] And that is then- only the time (writes ',=T'). If we now, if we, if now a hours are 2 hours,
5	then she would walk there always 2. (points to the first a , writes ' $2+2+2+2+2$ ') and here always
6	1 (writes '+1') and that would be then two four six eight ten (writes '=11') eleven hours. And then
7	she makes 3 Kilometres per hour, well in 2 hours then 6 plus 6 plus 6 plus 6 plus 6 plus 3 (writes
8	' $6+6+6+6+6+3$ '), that would be one two three four five- thirty three (writes '=33'). And that is so a
9	while, that is the same as this (points one after another at the first and second written number
10	equation). Then I could her, you already see, that looks nearly the same, b plus b plus b plus b plus b
11	plus b divided by 2 (writes ' $b+b+b+b+b+b:2$ ') and that would be kilometres (writes '=K').

Figure 4: Dorian solving the task “Running for a good cause”

Christina (see Figure 5) begins with an auxiliary drawing. Then she solves the task with invented numbers, while at the same time working on the letters (line 21-25). Finally she solves the task with letters (line 31-32).

Solution with numbers	Solution with letters
21	And the, erm, has to be from Monday till Friday, erm, every day, erm, a hours. Well, you could maybe
22	a - a equals 2 (writes ' $a=2$ Stunden' ($a=2$ hours)). [...] well write down. Every day she (writes 'Jeden
23	Tag läuft sie a Stunden' (<i>Every day she runs a hours</i>) under the line) runs a hours. And then, if she
24	from, erm, on Saturday runs only half of the time, erm, this has to be so 1 hour. Well here, if you, if
25	you (incomprehensible) b , no (writes b under the line and cancels it out) c , c is the one hour?
...	
31	Well, for my part 5 times a ? [...] 5 times a equals- Then you shall invent letters for the result? [...]
32	5 times a equals d , for my part- and yes then d plus c equals for my part f .

Figure 5: Christina solving the task “Running for a good cause” with illustrating notes

RESULTS AND DISCUSSION

Dorian's and Christina's transcripts illustrate the following patterns of action: *Keyword-Strategy*, *Inventing-Letters-Strategy*, *Inventing-Numbers-Strategy*, *Letters-As-Quantities* and *Use of Auxiliary-Drawings*.

Keyword-Strategy

Using keywords to find out which operation to conduct is an old *pattern of action* rooted in previous mathematics education. For example the keyword “remove” leads to subtraction. Because keywords will not change when letters are used this strategy still work with letters. Dorian may have chosen the operation “:2” because of the keyword “half” (line 2-4). Keywords have a positive effect, if the calculation

strategies they invoke are explicitly available. For Christina, the keyword “half” did not invoke “:2”. Instead she wrote c (line 25) and defined, that c is half of a (line 24). She is not doing this explicitly but via *Inventing-Number-Strategy* (see later). This may be a sign that she lacks *old arithmetic knowledge*, that she has an *insufficient operational understanding*

Students adopt the Keyword-Strategy for the use in the *new algebraic domain*, but they will only have a positive effect, if the calculation strategies they invoke are compatible with the corresponding symbolic description. In another task the students had to find out how often a distance x fits into a distance y . Transcripts of several students working on that task show that another keyword that cannot easily be expressed in symbolic language is “how often fits in”. The students learned in previous arithmetic education the *old pattern of action* that if x and y are natural numbers and y is a multiple of x it is possible to calculate the solution L with the help of repeated addition or multiplication, instead of division. But repeated addition without knowing how many addends there are is difficult to express with symbolic algebra. The corresponding symbolic description for multiplication is: $L \cdot x = y$. As the solution L of the problem is not identical with the “result” y of the equation, this equation is not compatible with *Process-Oriented* (see later), an *old pattern of action* which draws the student’s attention to results instead of relations.

Inventing-Letters-Strategy

Inventing letters directly results from a fundamental algebraic idea, the *Analytical Idea*, which was taught as *new algebraic knowledge* as part of our algebraic learning environment. It results in the *new pattern of action*, that if a value is unknown you can write a letter that can be used like a number. Thus one is able to work with the unknown value like an actual number assumed this *new algebraic knowledge* exists. Dorian is combining the analytical idea with an *old pattern of action*, *Process-Oriented*. He is allowed to use letters for unknown values and the result of his letter calculations (line 2-4 and 11) is unknown. So he concludes that he is allowed to invent letters for results, T for time and K for kilometres. Of course an algebra teacher might welcome Dorian’s expressions $a+a+a+a+a+a:2$ and $b+b+b+b+b:2$ as result. But these expressions lack closure and students who are tied to process-orientation will hardly accept this. However, inventing a letter as result may be a good *new pattern of action* for a start.

Christina also uses this strategy as *new pattern of action* (line 25 and 31). At first she uses b for half of the time but realised properly that b is already given away (line 24-25). Instead she uses c . The difficulty with inventing letters for unknown numbers is that students have to relate every new letters symbolically with the variables already in use. Christina is not able to relate c with a symbolically, most likely because of *insufficient operational understanding*. However if she gains more experience with the use of variables this may help her to identify insufficient operational understanding and make explicit her *implicit old knowledge* about operations. Here it

is possible that her *old arithmetical knowledge* may benefit from *new algebraic knowledge*.

Inventing-Numbers-Strategy

Dorian replaces letters by invented numbers, conducts the calculations and translates the conducted calculations back in letter expressions. Later Dorian will say that he has used the numbers as aid for thinking.

Old knowledge about *setting up and manipulating number expressions* as well as *number operations* can support *new knowledge* about *setting up and manipulating letter expressions* as well as *letter operations*. But *patterns of action* like choosing inappropriate numbers, replacing the wrong letters or inventing numbers for unknown values without keeping in mind the relations to other values, which are deeply connected with *old knowledge* may cause problems.

Christina is inventing the numbers for the hours per day and hours for half of the time considering the relation between the variables (line 22-24). But she does not explain that c is half of a . Instead she uses the numbers to make this relation explicit by explaining that a equals 2 hours, 1 is half this time and c equals 1 hours. Probably the *pattern of action* of choosing easy numbers is inappropriate to put in her mind that the half can be calculated explicitly by “:2”.

Letters-as-Quantities

Dorian was taught the *new knowledge* *letters signify unknown numerical values of quantities*. Earlier in the interview he explained that letters stand for numerical values, but he consequently refers to the quantities as if he is talking about the value of the quantities. Therefore he uses Letter-as-Quantities as *new pattern of action*. He calls T time (line 4) and K kilometres (line 12). At first this seemed to be a metonymy because it is easier to talk about kilometres instead of the number of kilometres. Especially in geometry this double meaning is widely accepted, e.g. talking about the side s if actually meaning the length s of the side. But using multiple meanings as *old geometric pattern of action* may cause problems.

At the end of the task (line 10-11) Dorian is using b for both kilometres per hour and kilometres per day, but not for all kind of kilometres as the kilometres in total are signified as K . One reason may be that due to using the *Inventing-Number-Strategy* and consequently calculating the kilometres per day with mental arithmetic, for him the relation between hours and kilometres does not become explicit. Thus he may not realize that the status of the kilometres has changed. Christina does not clarify the relation between hours and kilometres, too, and mixes up the letters that signify the quantities. Again *new algebraic knowledge* may be a chance, here for making explicit the students' *implicit old knowledge* about relations

Using auxiliary drawings

Christina encountered the problem in beginning to solve the task and needed first to convince herself that she could use a drawing, with lines to represent the quantities.

While she was working she comprised the drawing many times (line 22-25). In the end she translates the drawing into equations (line 31-32). This suggests that using auxiliary drawings is an important *new pattern of action* for her. Dorian does without using a drawing but he later refers to the ‘graphic power’ of the equations by stating “you already see, that looks nearly the same” (line 10). He seems to be able to ‘see’ the explicit relations in equations without using drawings. Dorian’s new algebraic knowledge benefits from this *old knowledge*. But unfortunately this *old knowledge* is not self-evident for students.

The problem with auxiliary drawings is that students can only see in the drawings what they have put into it. Christina’s drawing does not contain enough information about the relation between hours and kilometres and hence she is not able to gain equations that represent the relations of the task, although the equations represent the relations of the drawing correctly. Indeed, the *old pattern of action of concentrating on numbers instead of relations*, reinforced by a *Process-Oriented* and an inappropriate *Keyword-Strategy* may be the reason for inadequate drawings.

PERSPECTIVE

The influence of previous arithmetical education on the learning of algebra is complex. The examples of Christina and Dorian reveal that in particular the lack of explicit knowledge about operations and relations hinder a good approach to algebra. Patterns of action and knowledge about proportions of numbers, both achieved in previous arithmetic education account for clouding this knowledge. Giving algebra a graphic basis may help to make operations and relations explicit. Christina’s example shows that the drawings help her finding equations that represent the relations of the drawing. However, it also shows that teaching students to transform texts into drawings is a challenge that should not be underestimated. It remains open if a graphic basis of algebra is an effective corrective for patterns of action acquired in previous arithmetic education.

HIDDEN DIFFERENCES IN TEACHERS' APPROACH TO ALGEBRA – A COMPARATIVE CASE STUDY OF TWO LESSONS

Cecilia Kilhamn

University of Gothenburg, Sweden

Algebra is a multi-dimensional content of school mathematics. In this study a fine-grained analysis was made of two lessons on introduction of variables in two Swedish classes with teachers who followed the same curriculum. When comparing the two lessons subtle differences were found in the approach to algebra and the meaning of variable in what at first seemed to be lessons about the same content. Findings indicate that teachers shape the opportunities of learning by the approach they take.

INTRODUCTION

Introduction to algebra is known to be a problematic topics in school mathematics, and recent research claims that the problems are more related to learning conditions than to cognitive limitations (e.g. Cai & Knuth, 2011; Kaput, Carragher, & Blanton, 2008). Algebra is a large content area and can be approached from many different perspectives. There is a considerable variation between different countries concerning approaches to algebra and content for algebra teaching, and naturally these differences may lead to differences in learning outcomes (Kendal & Stacey, 2004). Differences found in curricula documents and textbooks can make comparisons of teaching and learning algebra difficult due to a lack of consensus about how they define algebra. Research on teachers' use of curriculum (Remillard, 2005) has highlighted the teacher's role in the enactment and meaning making of curriculum. The enacted curriculum is influenced by variables such as teacher's mathematical knowledge, beliefs, goals and traditions. Some such variables may be clearly outspoken, others may stay hidden and surface only in the enacted curriculum. The question raised in this comparative case study is whether two teachers who follow the same curriculum and textbook teach the same algebra, or if differences can be found on a subtle classroom level that may influence students' opportunities for learning. A fine-grained analysis of the given instruction shows that two different approaches to algebra are made although both teachers follow the same national curricula syllabus and plan the lesson influenced by the same textbook task. The specific content in the lessons is introduction to the concept of variable. When learning about variables six different ways that children interpret and use letters have been described by Küchemann (1981), of which only one is the interpretation of a letter as a variable in its proper sense: as representing a range of unspecified values. The other categories are: letter evaluated, not used, as an object, as a specific unknown and as a generalised number i.e. representing several (specific) values rather than just one.

DIFFERENT APPROACHES TO SCHOOL ALGEBRA

The discussion of how to define algebra is as multifaceted as are people's experiences of algebra and views on how to teach it. In the 1990's reports showed that school algebra was predominantly rule based and procedural (Kieran, 1992) whereas researchers suggested a broader approach including a generalisation, modelling, problem-solving and functional perspective (Bednarz, Kieran, & Lee, 1996). Although algebra is an indispensable linguistic support in the development of mathematics (Rojano, 1996), history warns us of approaching algebra as a language emphasising its syntax and "placing symbolic manipulation as an object of knowledge in advance of situations which can give rise to it" (ibid, p 61). Today algebra is described as a branch of mathematics that deals with symbolizing general numerical relationships and mathematical structures. The learning of algebra can thus be seen as both *learning to see and reason* about relationships and structures, and *learning the formal symbolic language* used to express these relationships and structures. The former is often called algebraic reasoning and is prominent in literature about early algebra (Cai & Knuth, 2011; Kaput et al., 2008). According to Kieran (2004) school algebra is constituted by three types of activities; *generational activities* such as forming expressions and equations using variables and unknowns, *transformational activities* such as simplifying, substituting or solving equations, and *global meta-level activities* where algebra is used as a tool, including problem solving, modelling, noticing structure or change and analysing relationships. In a linguistic approach generational and transformational activities dominate instruction, whereas a generalisation (Mason, 1996) or a problem-solving (Bednarz & Janvier, 1996) approach to algebra involve more global meta-level activities. The current state of school algebra varies from country to country but tend to follow either a traditional or reform-oriented program (Kieran, 2007). A traditional program has a strong symbolic orientation and approaches algebra as a language, whereas a reformist program deals more with functional situations through modelling and problem-solving activities. Using the term *curriculum* to describe the resources and guides used by teachers (Remillard, 2005), this study investigates if two lessons following the same curriculum give the same perspective on algebra or if different approaches to algebra surface through the teachers' transposition of the curricula documents.

METHOD

As part of data collected in an international comparative video study called VIDEOMAT (Kilhamn & Røj-Lindberg, 2013) two Swedish grade 6 classrooms were videotaped during a lesson on introduction to the concept of variable. Data was collected *in situ* using three cameras during a sequence of four lessons when the teachers planned to introduce algebra. Both schools were public schools, following the national curriculum (Lgr11) and using the same textbook (Carlsson, Liljegren, & Picetti, 2004). Both teachers were trained as generalist teachers for grades 1-7 with approximately 10 years of teaching experience. Explorative analyses were made of the videos and of verbatim transcripts (in Swedish and translated into English).

Similarities and differences of the two lessons were sought, particularly in relation to different approaches to algebra as described in research literature.

CURRICULA DOCUMENTS AND TEXTBOOK TASK

Before presenting the classroom analysis the curriculum that serves as a common point of departure for both teachers is described. When planning the algebra unit both teachers refer to the National Curriculum (Lgr11) and the textbook (Carlsson et al., 2004), including its teacher guide, as the foundation of their instruction. Lgr11 includes a mathematics syllabus consisting of general aims and core content in mathematics (Lgr11, pp. 59-46). Algebra is a core content, including for grades 4-6:

“Unknown numbers and their properties and also situations where there is a need to represent an unknown number by a symbol; simple algebraic expressions and equations in situations that are relevant for pupils; methods of solving simple equations; and how patterns in number sequences and geometrical patterns can be constructed, described and expressed.”

The two lessons analysed is, in both classes, the very first lesson in which the concept of variable is introduced. The textbook unit on algebra starts on pages 94-99 dealing with the meaning of the equality sign and simple equations with one unknown. On page 100, labelled ‘*Variables can vary*’, the concept of variable is introduced using age differences with the following information given (all translations made by the author of this paper):

“We can call Amer’s age a . Sama is 4 years older than Amer. That makes Sama’s age $a + 4$. The value of a changes when Amer’s age changes. The value of a can vary, a is a variable.” (Carlsson et al., 2004, p. 100).

This introduction is followed by a task on the same topic (fig 1), and is commented in the teacher guide in a short paragraph (*italics added*):

“The word *variable* is another new word for the students. A variable is a quantity that can *vary*. On page 100 we have ages as an example of variables. All students understand that ages vary – when my sibling is one year older I am one year older. To work with variables is *very useful* in mathematics, for example all *formulas* are based on the fact that you can vary the value of the variable. Formulas are *valid for a range of values*.”

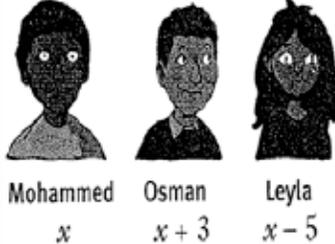

<p>Osmond is 3 years older than Mohammed. Leyla is 5 years younger than Mohammed.</p> <p>How old is Osman when Mohammed is a) 10 years b) 15 years c) 30 years</p> <p>How old is Leyla when Mohammed is a) 10 years b) 15 years c) 30 years</p>	 <p>Mohammed Osman Leyla x $x + 3$ $x - 5$</p>

Figure 1: First task on introduction to variables (Carlsson et al., 2004, p. 100)

RESULTS

The results presented here focus similarities and differences concerning the content matter taught by the two teachers, Ms B and Ms C. Undoubtedly there are demographic differences as well as differences in classroom organization that have an impact on learning outcomes which are not in focus in this study, and no comparisons of actual learning outcomes is possible from the collected data. Instead the intent is to look closely at the art of the content matter taught and the approach taken to algebra in each lesson, highlighting similarities and differences in the first classroom activity in the lesson on *introducing variables* that surfaced in the analysis.

Ms B's lesson

Ms B starts her lesson by referring to previous tasks where a variety of symbols were used in place of a number, and asks the students to find a more simple, convenient way of writing the mathematical statement “some number added to 2”. Ms B emphasises many times that the point of algebra is to write something in an efficient way. “And maths is very much about actually finding convenient ways of doing things” The term *variable* is said to be related to *varying* illustrated by the statement that “ x varies [in $x+2=5$ and $x+2=7$] because it does not represent the same value”.

The age relation task from the textbook (fig 1) is projected onto the whiteboard and students are asked to work with it in small groups. Later their solutions are projected onto the board and discussed in class. Ms B particularly points out that she expects them to explain how they worked out the answer: “I want you to fill in how you have reasoned using a variable” She points out that they need to know what x means “what is it that you– in the problem so to speak what is it that you have found out? It might be good to know then what, this symbolises. Because x is a symbol for something.”

When Ms B discusses the students' solutions in class, much time is spent going back and forth between different representations; words \Leftrightarrow symbols. On the whiteboard Ms B first shows answers without any variable, asking if the calculations are correct, which they all agree to. One example of such an answer is:

- a) 13 years. Osman is 3 years older than Mohammed so when Mohammed is 10 years Osman is 13 years.

Then Ms B highlights answers where x is present in the explanation, ending with the student focus group (FG) who wrote:

- a) $10+x+3=13$
 b) $15+x+3=18$
 c) $30+x+3=33$ $x=0$ Osman is always 3 years older than Mohammed.

In this example the students have added Mohammed's age and Osman's age ($x+3$) and the difficulty does not lie in getting the correct answer but in understanding the meaning of x . Excerpt 1 shows how the group discussed the problem. One student has solved the problem of finding the sought ages straight away [1], but then the group spends another 10 minutes discussing how to write it down. They include an x

because they know it is supposed to be there [2]. They try adding the symbolic expressions of the ages of Osman and Mohammed [2-4], but the discussion of what x symbolises continues until the third student finally suggests that $x=0$ [5-6].

Excerpt 1: FG discussing the age task, extracts from a 10 minutes long interaction.

- [1] S1 it is just 13, 18 and 33
 S3 so we can start working out how old they are now, how old they are.
 S2 Osman is 3 years older than Mohammed
 (...)
- [2] S4 Shall I work it out in an algebra way?
 S1 no (protests and wants to go on)
 S4 okay. Well then this is what we do. That is x plus x plus 3.
 (...)
- [3] S4 (pointing to where she has written $10 + x + 3$) That is Osman's age
 [10] and that is someone else's age [$x + 3$]. It is Mohammed's age
 (...)
- [4] S2 We know Osman is 3 years older than Mohammed all the time.
 S1 So it has to be 13
 S2 yes 18, and then 33
 S1 yes. I said so all along. That's how easy it is.
 S2 because I tried, we tried to work out how old they are now. But that is
 impossible. (S4 writes $10+x+3=13$, $15+x+3=18$, $33+x+3=33$)
- [5] S3 but eh, how about the x ?
 S4 but x , they, here it is an age
 S3 well but
 S4 it's one of them. It's 3
 S3 but you can't have just x there? If it's there you think it means
 something () write something
 S4 write x plus 3 is equal to, eh, 3
 (...)
- [6] S3 (writes $x=0$) Do you think this is, do you think this is correct?
 S2 x is equal to zero?
 S3 yes because x is nothing it is just what his age is called.

In the following whole class discussion (excerpt 2), Ms B directs attention to the information given in the task, particularly the algebraic expressions under the picture. She wants the students to express the ages in the algebraic way; however, this is not easy since they all agree that the answer is already given in the text.

Excerpt 2: Extracts of Ms B's whole class discussion of the age task.

- Ms B: What information did you use, to arrive at what Osman was? What
 does Peter say?
- Student: How old the others were.
- Ms B: And how did you find that out? Marcus?
- Student: It's in the text.
- (...) (Ms B returns to the task and points at the algebraic expressions under the picture)
- Ms B: Was there any group who explained the ages this way? When you
 tried to find out, how old Osman was?
- (...)

Student: Eh, we, we checked what the x :s meant and put it together.

Ms C's lesson

Ms C starts the lesson reminding the students of equations and introducing the term variable as being “reminiscent of variation for example. Thus it is something that varies”. The introduction is centred on a description of the ages of Ms C's own family members, and ways of describing those ages in relation to her. She writes ages and age differences on the whiteboard (see fig 2). Ms C uses the first letter of each name to represent that person's age. Then she relates all the members' ages to her own, “describe our ages based on a variable then. I will describe it with a, a, with letters and numbers. And I will base it on myself all the time”. When describing relations Ms C introduces *formulas* (in Swedish: *formel*) as illustrated in figure 2 and says:

“Eh, for me to describe dad's age I'll take my age and then I'll add years, because he's older than me. This— my— since J means 36 right now. Mm, eh, so I add 27 there. That means that one can calculate via this formula, if one knows that I'm 36, then, that dad is 36 plus 27, which is 63. And we can also by looking at this understand how old my dad will be when I'm 40. When I'm 40, then the same formula holds, he's always 27 years older. Eh, so then you get 40 in there. How old is my dad when I'm 40, Alex?”

$M = J + 27$	<u>M</u> ark	<u>A</u> nn- <u>C</u> hristin	<u>J</u> enny	<u>E</u> mma	<u>A</u> нна	<u>L</u> otta
$L = J - 13$	63 yrs	60 yrs	36 yrs	32 yrs	29 yrs	23 yrs

Figure 2: What Ms C wrote on the board during the introduction.

By asking the students to calculate the father's age at different points in time (when J is 36 and when J is 40), Ms C illustrates the idea of a constant relationship involving a variable that can take different values. Students are then asked to describe their own families in a similar fashion. When the students have represented their families they are asked to “write down a variable and start from your family. For example: mom's age, equals, my age, plus ...” See figure 3 for an example of a student's work.

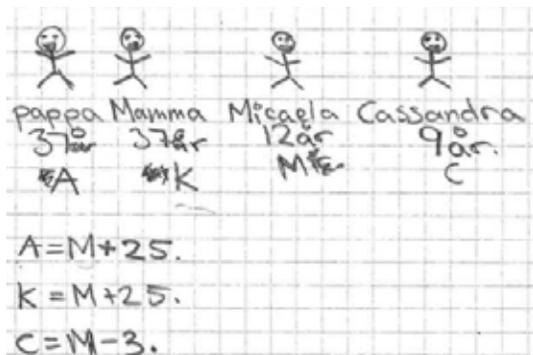

Figure 3: example of student work from Ms C's class.

Since they have all written several variables (one for each family member), what Ms C means is probably that they should decide which variable to relate to and then write

down formulas that show the other members' ages in relation to the chosen one. During the following whole-class discussion of the student's results (see excerpt 3) Ms C asks: "What have you chosen as a variable", meaning which variable they have chosen as independent.

Excerpt 3: Extract from Ms C's whole class discussion on the family age relation task.

- Ms C: Then you'll tell us first about your family.
 Student E: Eh, okay, dad ()
 Ms C: Dad, he is...
 Student E: Eh, 48.
 Ms C: 48? Mm. Mom?
 Student E: Eh, 44
 Ms C: 44 years old. And then you?
 Student E: Eh, I'm 12. (Ms C writes P 48, M 44, E 12).
 Ms C: You're 12. Eh, and what have you chosen as a variable?
 Student E: Eh...
 Ms C: Sh!
 Student E: I've chosen, A... Or, dad...
 Ms C: Yes.
 Student E: ...equals me plus... should I say what it makes?

After some negotiation they work out $48-12=36$. Ms C writes on the board: $P=E+36$. Here the independent variable is E (student's age) and the fathers age (P) is expressed by a formula using the variable E.

ANALYSIS OF SIMILARITIES AND DIFFERENCES

When comparing these two introductions to the concept of variable some similar features can be noticed:

- The concept of variable is introduced using age relations as suggested by the textbook, involving the use of symbolic language to represent age relations.
- A letter or other symbol for an unknown in an equation has been introduced before the concept of variable.
- Variable is described as something that varies and there is an underlying but unclear distinction between a specific unknown and a variable.

Some differences between the two lessons concerning the algebra content and the approach to algebra were found and will be described in terms of i) the framing of the algebra task, ii) the meaning of algebra, and iii) the meaning of variable.

Framing of the age relation task

Ms B starts her lesson with group discussions based on the textbook task. In this task all relations are given both in words and symbolically and students are asked to interpret them to calculate ages in different scenarios. Only one variable is used. It is easy for the students to find the ages. The task gives the general case (the relation)

and students are asked to calculate specific cases. Students *interpret and try to understand the language of algebra*. The activity is *transformational*.

Ms C asks her students to describe their own families. In that setting all specific ages are known and the task is to find a way of describing their relations, both with words and symbolically using a formula. More than one variable is used. It is a question of choosing an independent variable, of assigning symbols and of describing relations. The task gives specific cases and students are asked to express a generality. Students *use the language of algebra* as a tool to model a situation, and the activity could be characterised as *generational* and *global meta-level*.

The meaning of algebra

Ms B tells her students that algebra is a simpler, quicker, more convenient way of writing down mathematical statements. The task itself is easily solved without algebra so the introduction of algebra in the activity does not make it more simple or convenient. The meaning of algebra conveyed in this lesson is “algebra as (an efficient) language”. Students first solve the task by calculating specific values and then try to express what they already know in the new language.

Ms C introduces the concept of *formula* along with the term *variable* so that relationships can be modelled. Algebra is used as a tool to model age relations and as a result formulas can be used to predict different scenarios. The meaning of algebra conveyed is “algebra as generalisation” and “algebra as a problem solving tool”.

The meaning of variable:

In Ms B’s lesson expressions with only one variable are used. It is implicit that the variable stands for a range of values (Osman’s age as $x+3$), but the students are asked to calculate specific values. In the students’ equations x does not vary ($10+3=13$; $10+x+3=13$). Moreover, in Ms B’s examples of a variable in the two equations $x+2=5$ and $x+2=7$, x represents a specific unknown in each case rather than a range of values. Ms B pointed out that “ x is a symbol for something”, but in the students talk it is unclear to them what x symbolises: “If it’s there you think it means something”, “ x is nothing it is just what his age is called”. The meaning of variable is a letter that symbolises something, unclear what, or a symbol for specific unknown numbers.

In Ms C’s lesson students are asked to write formulas including two variables resulting in equations that are true for a range of unspecified values. There is some confusion as to what in the task is a variable: “write down a variable and start from your family”. When Ms C says “what have you chosen for a variable” the information she seeks is actually threefold: independent variable (E), dependent variable (P) and formula describing the relation ($P=E+36$). For Ms C the variable is a point of departure, it is what you relate to in a formula. “describe our ages based on a variable then. I will describe it with a, a, with letters and numbers. And I will base it on myself all the time”. Her use of the terms *variable* and *formula* is a bit fuzzy, but she has situated the idea of variable in the context of expressing relations. Through

the activity of generating formulas with two variables, the meaning of variable is a letter that represents a range of unspecified values.

DISCUSSION

The results indicate that the two teachers approached algebra in different ways. Ms B approached algebra as if it were a language of symbols that students need to learn through activities of interpretation and translation. Eventually this new language will prove to be efficient and facilitate mathematics. The learning process involved interpreting a general statement in specific cases. Only one variable was used and students were given the opportunity to experience letters as specific unknown or generalised numbers or to solve the task sufficiently without using the letter.

Ms C approached algebra as if it were a problem-solving tool, useful to model, generalise and express relations. The learning process involved taking a specific case to a general level. Several variables were used modelling one variable as a function of another and incorporating the concept of formula. Students were given the opportunity to experience letters as representing a range of unspecified values describing a relationship between two sets of values. The description of *algebra* and *variable* given in the curriculum follow a more traditional that reformist-oriented program for school algebra, and Ms B complies with this and with the textbook task to a larger extent than Ms C, who creates a new task inspired by the curriculum but with a slightly different approach. Ms B tried to teach her students the meaning of the word variable in line with how the teachers' guide introduces it: "The word variable is another new word for the students". In contrast, Ms C lets the last part of the teachers' guide inspire her where it says: "all formulas are based on the fact that you can vary the value of the variable. Formulas are valid for a range of values". The differences in how these two teachers interpret and enact the curriculum is subtle but results in different learning opportunities for the students. An awareness of the effects of such differences may influence textbook and syllabus writers to be more specific in the choice of examples and more explicit in explanations of the intended learning.

Conjectures about differences that are made in this paper do not take into account what happened after the introductory lesson, it is not ruled out that a teacher may approach algebra differently at different points in time or consciously use different approaches separately. The intention was to illustrate differences in what *may seem* to be similar introductions to the concept of variable based on the same curriculum. It can be argued that these differences may influence opportunities of learning offered in the lesson. It might well be that the teachers themselves are unaware of these differences and that their learning goals are the same. An implication of this study is that comparative research can be useful to detect hidden differences in teaching.

LIMIT OF THE SYNTACTICAL METHOD IN SECONDARY SCHOOL ALGEBRA

*Rahim Kouki & **Faïza Chellougui

*LAMSIN ENIT de Tunis, Université de Tunis El Manar, Tunisia, **Faculté des Sciences de Bizerte, Université de Carthage, Tunisia

One of the main difficulties that secondary school students have to face in Algebra is insufficient mastering of syntactic rules as often pointed out both by teachers as well as researchers. In this paper, we adopt a logical point of view on equations and inequations and we support the hypothesis that for an adequate appropriation of these two notions, it is necessary to be able to articulate syntax and semantics. We start by explaining what is meant by “a logical point of view”. Then, we examine in which respect the dialectic between syntax and semantics appears in Tunisian textbooks, through an analysis relying on both the dialectic between syntax and semantics as well as mathematical praxeology. Finally, we provide an example enlightening the paramount importance, in some cases, of the semantic point of view in order to solve (in)equations.

INTRODUCTION

One could think that the main challenge in the teaching and learning of the resolution of (in)equations in high school concerns algebraic rules. However, it is not always the case that applying such rules ensures effectiveness, as we will see in the example presented.

In this paper, we adopt a logical point of view on (in)equation, and we support the hypothesis that, for an adequate appropriation of (in)equations, it is necessary to be able to articulate both syntactic and semantic aspect. We first briefly present this approach referring to predicate calculus. Then, we examine in which respect the dialectic between syntax and semantics appears in Tunisian textbooks, by analysis relying on both the dialectic between syntax and semantics aspect as well as mathematical praxeology (Chevallard 1998). Finally, we provide an example enlightening the fact that, in some cases, the lack of mobilization of the semantic point of view may prevent students of successfully solving (in)equations.

A LOGICAL POINT OF VIEW ON EQUATIONS AND INEQUATIONS

Chevallard (1989) emphasizes the essential dialectic between arithmetic and algebraic calculations that he interprets as a link between syntax and semantics. Indeed the author explains that “when, in the sixth class, the teacher moves from $2 + 3 = 5$ and $3 + 2 = 5$ to the general relationship $a + b = b + a$, he moves from computing on numbers (integer) to an algebraic calculation (integer coefficient). In other words, an algebraic calculation, that we do not define more precisely here,

makes a clear syntax to which the associated computational domain provides a semantic” [1] (Chevallard, 1989, p. 51). Moreover, the author shows that the students' understanding of algebraic calculation doesn't incorporate the idea of a dialectic between manipulation of algebraic expressions and substitution of numerical values in these expressions.

Furthermore, authors such as Selden & Selden (1995), Durand-Guerrier (2003) Durand-Guerrier et al. (2000), Durand-Guerrier & Arsac (2003, 2005), Chellougui (2009), Weber & Alcock (2004) and Iannone & Nardi (2007) have pointed out the relevance of the logical point of view for the analysis of mathematical reasoning in an educational perspective, mainly in calculus. As for us, we consider that the issue of linking both perspectives, i.e, semantics and syntax, has not been extensively addressed in research, neither in research on the teaching of mathematics in general, nor in the teaching of algebra in high school.

In our research program, the main question concerns the possibility of identifying, phenomena related to the dialectical syntax / semantic in the development of concepts of equation and inequation. In order to address this issue, following Durand-Guerrier (2008), we make the assumption that the semantic conception of the truth developed by Tarski (1936, 1944) through the notion of satisfaction of an open sentence by an element of the domain of interpretation, provides a relevant framework.

In formalised languages, as predicate calculus, a formula which is neither a logical theorem nor a contradiction is neither true nor false. In order to provide a truth-value, it is necessary to choose an interpretation, namely a domain of objects, properties and/or a relation. Furthermore, it is an important fact that such a formula may be regarded as a true statement in one interpretation, and as a false statement in another one. In the case of a logical theorem, it is true whatever the interpretation, while in the case of a contradiction, it is false whatever the interpretation.

For example, let us consider the formula “ $\forall x \exists y F(x, y) \Rightarrow \exists y \forall x F(x, y)$ ” and the following interpretation: the domain of objects is the real number set; F is interpreted by the relationship “ \leq ” the statement that interprets the formula is “ $\forall_R x \exists_R y, x \leq y \Leftrightarrow \exists_R y \forall_R x, x \leq y$ ”; the antecedent of the implication is true, and the consequent is false, so the statement is false. Nevertheless, if the domain of objects that is considered is an upper-bounded part of the real number set, then the corresponding statement is true.

In introducing the notion of satisfaction of a formula, Tarski explicitly refers to the notion of mathematical equation. From this perspective, an equation is an open sentence; given a domain, it may be true for some elements of the domain, but not all, or true for every element of the domain, or false for every element. Solving an (in)equation means determining the elements satisfying this open sentence. In addition, it is possible that, given an equation, no solution fits in the domain, or that there there is one or more than one solution in another domain. For example

“ $x^2 + 1 = 0$ ” has no solution in the real number set, but two solutions in the complex number set.

On the other hand, in formalised languages, syntax is the term used in logic in a broad sense including:

1. The study of the rules of well-formedness of expressions of a given language (the grammar);
2. The set of rules of derivation in an established theory of demonstration in the formal sense of the term, opposed to the semantics which takes into account the interpretations.

For example, two equations are equivalent if and only if:

1. They are satisfied by exactly the same elements (semantic point of view);
2. It is possible to transform one equation into another one if algebraic rules preserving equivalence are applied (syntactical point of view). It is important to notice that some algebraic rules do not preserve equivalence, so that, in some cases, it is necessary to come back to the involved domain for a semantic control.

For example, let us consider the equation “ $x^2 - 2 = |3x + 2|$ ” whose set of solutions in the real number set is $\{-3, 4\}$. By applying syntactic rules and transformations without a semantic control, the set $\{-3, -1, 0, 4\}$ could be considered as the set of solutions although it contains elements that do not satisfy the equation.

Finally, logical semantics allow us to give precise definitions of (in)equations on the one hand, and supports our claim of the relevance of taking into account both semantic and syntactic aspects in mathematical reasoning.

CROSSING MATHEMATICAL PRAXEOLOGY AND LOGICAL SEMANTICS FOR A STUDY OF TUNISIAN SYLLABUS AND TEXTBOOKS

Following Chevallard (1989)’s perspective on didactic transposition, and in order to identify the institutional prescription concerning the knowledge to be taught on (in)equations, we have analysed the Tunisian syllabus and textbooks, through mathematical praxeology (Chevallard 1992).

According to Chevallard, all human activities, and namely, mathematical activity, can be described through praxeology. A praxeology is composed of two blocks. The first block is named the *praxis*. It refers to the practice, and has two components: *Type of the task*, what is to be done (e.g., solve a quadratic equation in complex numbers set) and *Techniques*, the ways to achieve a certain type of task (e.g., to compute discriminator; to study its sign; to apply the relevant formula to get both solutions). The second block is named the *logos*. It refers to the theory, and also has two components: the *Technology* that is, a discourse that enables justification of a technique (i.e. write down and factorize the canonical decomposition of the quadratic

trinomial) and the *Theory*, which provides a justification for a technology (e.g., the axioms and properties of the complex numbers field).

However, we consider that this theoretical perspective is not sufficient to grasp the dialectics between syntax and semantics. Thus, we have enriched the categorisation by crossing praxeology (namely the praxis [2]) with the dialectics between syntax and semantics. In addition, we take into account the registers of semiotic representation (Duval, 1991) that play a crucial role in algebra and, following Robert (1998), we consider the way in which students work on notions in exercises or problems (merely applying them or being able to mobilize them when required or on their own). This led us to elaborate the bi-dimensional grid sketched by Table 1.

<i>Technique /Task</i> [3]	<i>Semantic</i>	<i>Syntactic</i>	<i>Mixed</i> [5]
NMFK [4]			
Elementary	Verify / numerical-graphic	Factorize / algebraic	Solve/numerical-algebraic
Mobilized	Interpret/graphic-algebraic	Demonstrate/Analytic	Study and represent / algebraic-analytic-graphic
Available	Existence/analytic-graphic	Discuss/algebraic	Conjectur/numerical-algebraic-graphic

Table 1: Bi-dimensional grid for analysing program and textbooks

From reading this table we can say that several types of techniques, that can be semantic, syntactic or mixed, apply to a given type of task. This type of work requires a level of knowledge that can be assumed to be elementary, mobilizable or available, depending on the level of education of the student.

At a glance, our study of the Tunisian textbooks of the secondary school showed that:

- The treatment of (in)equations, in exercises and in problems of synthesis, requires mostly the use of syntactic techniques, whereas, introductory activities, that are often modelings of problem or graphic situations, take significant account of the articulation between syntax and semantics.
- The relationship between a Cartesian equation of a curve (e.g., a conic given by a not necessarily functional relation “ $R(x,y) = 0$ ”) and a graphical representation of a function (e.g., quadratics) $y = f(x)$ is not clearly stated, the conics appearing mainly, if not exclusively, as a graphic representation of functions.
- Introduction of functions mainly relies on semantic techniques: substitution values to variables, interpretation, etc. (Chevallard, 1989)

DIDACTIC INVESTIGATION

As part of a research conducted in our PhD, we submitted a questionnaire to 111 students in secondary school and 32 students in the first year of the university. [6] (cf. Kouki 2008). Through this survey we were interested in assessing which point of

view (semantic and / or syntax) was preferably mobilized by the students in solving (in)equations. In addition, we tried to identify students' ability to smoothly move from one or more registers of semiotic representation to another one. [7]

The mathematical and didactic analysis of different strategies of resolution in the treatment of the various tasks were based on theoretical frameworks crossing the logical semantic perspective and the didactical anthropology of the didactics (Chevallard 1992), and took account of the system of semiotic representation and registers, for analysing students' production consisting in signs, graphics and algebraic writings (cf. Duval 1991).

For this analysis, we refer to the grid (cf. Table 1). We assigned a code to each type of technique the questionnaire: each type of technique has been denoted by t_{a-b} , indexes a , and b stand respectively for:

- a : The logical categorization of the technique in terms of syntactic, semantic or mixed respectively denoted "se", "sy" and "M".
- b : the classification of a technique in a register of semiotic representation of the type - graph, numerical, algebraic, analytical or functional, etc. respectively denoted grph, num, alg, and anl, etc.

The overall results of the questionnaire analysis lead to the conclusion that students showed a preference for syntactical techniques, even in cases where intermediate questions involving semantics treatments in numerical or graphical register were introduced. On the other hand, we have observed a fairly high percentage of pupils and students who use semantics as tools of resolution only in cases where such tools are explicitly required by the given task. Moreover, it is worth mentioning the difference between the type of procedures (syntactic/semantics) for the resolution of exercises of the questionnaire utilized by students at the same level which makes us think that it could be linked to the practice of classroom. This accords with Alcock's (2009) results at the tertiary level. Further research is required to explore this issue.

We chose to present here the results provided by the analysis of an exercise from our questionnaire. They point to the fact that, in some cases, the use of purely syntactic methods hampers solution of the given task. Indeed, the task requires adopting a semantic point of view for articulating (in)equation and curves.

In the exercise all the solutions of the "product inequation" in two real variables $(y-x)(y-x^2+3x) > 0$ are sought. The difference in age-levels of the students led us to propose the exercise in two different ways. For the second group of students, i.e., those in second and third year, the exercise that was proposed is as follows:

Let f and g functions defined over IR by: $f(x) = x$ and $g(x) = x^2 - 3x$.

Let Γ_f and Γ_g the graphs of f and g live in an orthonormal (O, \vec{i}, \vec{j}) .

- 1) Representing Γ_f and Γ_g in Cartesian coordinates system (O, \vec{i}, \vec{j}) .
- 2) Determine the sign of $h(x, y) = (y - x)(y - x^2 + 3x)$ in each of the following pairs:
 - $(x, y) = (2, 1)$
 - $(x, y) = (1, 3)$
 - $(x, y) = (5, 4)$
 - $(x, y) = (-2, -1)$
 - $(x, y) = (-1, -2)$
 - $(x, y) = (6, 7)$
- 1) Place in (O, \vec{i}, \vec{j}) , points A, B, C, D and F respective coordinates of: $(2, 1)$, $(1, 3)$, $(5, 4)$, $(-2, -1)$, $(-1, -2)$ et $(6, 7)$.
- 2) Determine by calculation or graphically, all solutions of the inequation $(y - x)(y - x^2 + 3x) > 0$.

The first three questions were proposed to provide indicators that could lead students to move to the register of algebraic graph, to represent the different parts of the plane determined by the two graphic representations Γ_f and Γ_g , and to make a correspondence between the sign of each values of the function h in different points A, B, C and D in each region, on the other side.

Regarding the students of “Preparatory Classes for engineering schools”, we have considered that they had acquired sufficient ability to solve the inequation based solely on graphs Γ_f and Γ_g .

Consequently, we have chosen to propose the exercise as follows:

Let f and g functions defined over IR by: $f(x) = x$ and $g(x) = x^2 - 3x$.

Let Γ_f and Γ_g the graphs of f and g live in an orthonormal (O, \vec{i}, \vec{j}) .

- 1) Representing Γ_f and Γ_g landmarks in (O, \vec{i}, \vec{j}) .
- 2) Determine by calculation or graphically, all solutions of the inequation $(y - x)(y - x^2 + 3x) > 0$.

The *a posteriori* analysis of the first three issues has shown that students can mobilize different types of technical records, articulating different algebraic, numerical and analytical graphics to meet the intermediate targets.

In this paper, we focus on the resolution of the inequation $(y - x)(y - x^2 + 3x) > 0$, which can be solved, straightforwardly, by the technique of a change of register: from the register of algebraic equations involving the straight line $y - x = 0$ and the parabola $y - x^2 + 3x = 0$ to graphs Γ_f and Γ_g which intersect at the origin of the orthonormal coordinate system (O, \vec{i}, \vec{j}) and the point of coordinates $(4, 4)$. The line divides the plane into two half planes with open upper half plane is the points

$M(x,y)$ as far as $y - x > 0$ and the interior of the parabola is the set of points $M(x,y)$ as $y - x^2 + 3x > 0$. The sign of the algebraic expression $(y - x)(y - x^2 + 3x)$ is determined by Figure 1..

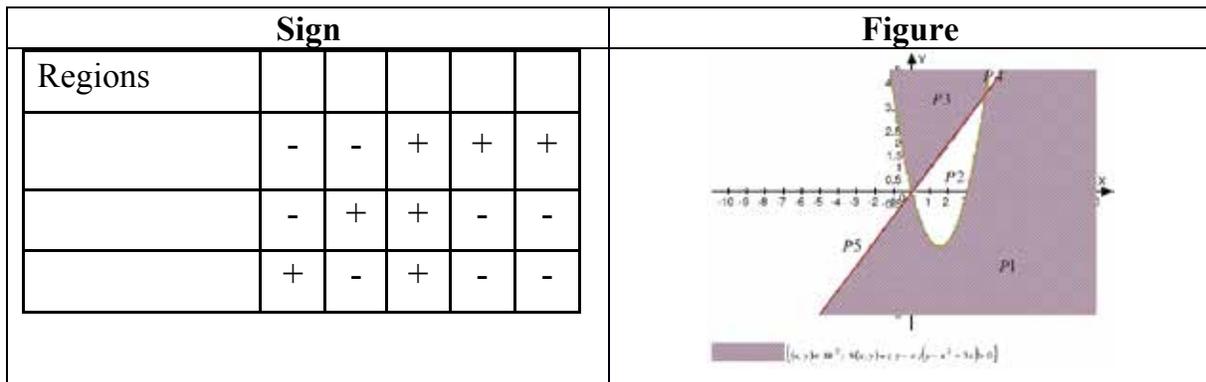

Figure 1: Sign of the “algebraic expression” in different parts of the plan

In conclusion, the set of the solutions of the inequation is the set of pairs that exactly correspond to the coordinates of the points in the region $P_1 \cup P_3$.

The *a priori* analysis of this question showed that three types of techniques could be used by students; we respectively denote these techniques T_1 , T_2 and T_3 .

The first technique T_1 is of type “Mixed”; it consists of interpreting graphically the sign of the two algebraic expressions “ $y - x$ ” and “ $y - x^2 + 3x$ ” and then concluding that the product is strictly positive in the region $P_1 \cup P_3$.

The second technique T_2 is of type “semantics”; it consists of linking graphic and algebraic register, affecting the sign of the factors for each point according to its position in the Cartesian plane, and then deducing which are the points in the region.

The third technique T_3 is a purely syntactic one in algebraic register that consists of attempts in order to transform the inequation $(y - x)(y - x^2 + 3x) > 0$. This technique appears to be inoperative at the considered level.

For methodological reasons, we denote the group of students of the second year of secondary school G1 and the group of third year students mathematics section G2 and the group of students of the first year of the university G3. Concerning the last question, more than 50% (76 among 143[8]), did not give an answer, while students answering these questions have mobilized different techniques. The syntactic techniques T_3 of the algebraic register appeared in 28 answers of 67 and contained no exact answer (7 of G1, 7 of G2 and 14 of G3). The semantic techniques T_2 of the graphic register appeared in 18 copies (8 of G1, 6 of G2 and 4 of G3), among them 4 correct answers were found (2 of G2 and 2 of G3). The mixed technique T_1 was mobilized in two answers that they were correct (1 of G1 and 1 of G3). The other answers had no connection with the exercise; they were classified in “Other types of responses”. We can add that for the types of tasks that require mobilized and available levels of knowledge, only students who were able to articulate semantic and

syntactic aspects and to coordinate the registers of semiotic representations succeeded in this task.

The results on the three exercises highlight that pupils use the syntactic technique of resolution as soon as they are available even if intermediate questions should call for semantic treatments (graphic or numerical). On the other hand, we pointed out that a rather large percentage of pupils and students use the semantic tool of resolution only if the type of task requires it. Moreover, we observed rather remarkable differences between the procedures of resolution of the exercises of the questionnaire between students of the same level. In this respect, we think that such differences could be linked to differences in the practice of the teachers in class with respect to the dialectics between syntax and semantics.

CONCLUSION

The semantics logical approach, referring to the notion of satisfaction of an open sentence, has permitted us to identify difficulties that pupils could face when working with (in)equation and function. In particular, when students solve the expression $y = f(x)$ our investigation shows that the logical status of the variable y and the term $f(x)$ are not clear for students. A deeper investigation will be needed in order to better understand this point.

The necessity for semantics, something that is largely neglected in the Tunisian programs and textbooks is highlighted if account is taken of the relationship between equations, curves and functions. Combining the approach we have developed with the study of effective teaching practices could provide paths for examining the extent to which the syntactic or the semantics preferences that we have observed are or are not linked to teachers' preferences. Our experimental investigations have pointed out the relevance of using semantics when syntactic techniques have been shown to be ineffective. In addition, we have shown that many students fail to take account of the relationship between the equation, curves and function, in line with the fact that, as evidenced by our analysis, this relationship is not made explicit in the textbooks.

Finally, we think that the investigation of the same notions of (in)equation and function in domains others than numerical domains, which appear in advanced mathematics, would be promising for the didactic analyses in higher education. We actually investigate the interest of our logical point of view in reference to Predicate calculus for studying in an educational perspective (in)equations in various domains (matrix, vector, functions etc.) Indeed, the notion of open sentences and satisfaction by an element provides a very general frame for the concepts of (in)equation that we suspect to be fruitful.

NOTES

1. Our translation.

2. We have chosen in our work not to consider the second block in praxeology (the logos) due to the fact that in Tunisian program and textbooks, there are very few references to technology and theory.
3. By this, we mean type of technique corresponding to a definite type of task.
4. Level of operating knowledge.
5. Techniques are expected to mobilize when both syntactic and semantic techniques are mixed in the treatment of mathematical objects.
6. They were students with high achievement attending « Classes préparatoires aux grandes écoles », that prepare them to the competitive examinations for entry into Engineering Schools.
7. The different types of techniques articulating different registers are detailed in Kouki ((2008).
8. Three classes of second year secondary science section composed of 88 students, one class of third grade of secondary school of the mathematics section composed of 23 students and a preparatory class in technology specialty.

COVARIATION, EMBODIED COGNITION, SYMBOLISM AND SOFTWARE DESIGN IN TEACHING/LEARNING ABOUT FUNCTIONS: THE CASE OF CASYOPÉE

Jean-Baptiste Lagrange

LDAR, University Paris Diderot, France

From the early nineties, most reformed curricula at upper secondary level chose to give functions a major position. The goal of this paper is to introduce key elements of a successful approach to the teaching of functions and to show how functions can influence research work including the design of a software environment and the evaluation of classroom situation. We will discuss how experiencing covariation and using references to body activity are crucial for students' understanding of functions. An example of a situation based on the use of the Casyopée environment is proposed as an illustration.

INTRODUCTION

The functional perspective on the teaching of algebra is seen by curricula reformers as an effective approach to consolidate post middle school students' algebraic knowledge and to prepare them to undertake courses in calculus. The use of technology, especially graphical and dynamic geometry software, is encouraged in an exploratory approach to functions. However, the topic of functions is complex and Kieran (2007, p. 710) notes that the reform gives way to “hybrid versions of programs of study that can create additional difficulties for algebra learners”. She depicts these programs of study as oriented towards the solution of realistic problems and multi-representational activity, with the aid of technological tools, resulting in algebraic content that is less manipulation oriented and an approach in which there is a shift away from traditional algebraic skills. Among the objections Kieran raises, I am particularly sensitive to the strong presumption, that, in these programs, symbolic forms will be interpreted graphically, rather than dealt with, as the use of technology prioritises screen (graphical) interpretations of functions. Clearly, there is a risk that, through these programs, students will have no access to understanding symbolic forms which are at the core of algebra and will be deprived of the power they offer for solving problems and more generally “for understanding the world”.

In a first part of the paper I review some issues regarding the teaching/learning of functions. Then I question the use of “standard” computer algebra in this domain, taking the example of a non-differentiable function. This is starting point for reporting on the work of the Casyopée research group that, for more than ten years, worked in France in order to promote an approach to functions encouraging students' multi-representational exploration together with work on algebraic symbolism and that designed a CAS software environment with this aim.

TEACHING/LEARNING ABOUT FUNCTIONS, KEY QUESTIONS

Within the general concern expressed above, the functional approach to algebra raises several issues documented by literature. Here I will consider three: (1) the necessity for students to understand covariation as a foundation for functions, (2) the interest in using references to body activity for students' understanding of functions (3) the understanding of the structure of the algebraic formula in a function. I will then discuss, using an example, the potentialities and limitation of a software tool.

From process-object to covariation and embodied cognition

From the early nineties most of the studies concerning students' conceptions of functions were based on the distinction between the two major stances that students adopt towards functions: the *process view* and the *object view* (Sfard, 1991). With regard to the process–object duality in students' understanding of functions, mathematics educators suggested that students' understanding of functions can be considered as moving from an initial focus on actions and processes to more object-oriented views characterized by a gradual focus on structure, incorporation of properties and reification of mathematical objects. In this vein, from the middle nineties, a number of approaches developed to describe object-oriented views of function that emphasized the covariation aspect of function (Thompson, 1994). Covariational reasoning consists in coordinating two varying quantities while attending to the ways in which they change in relation to each other. This involves a shift in understanding an expression from a single input-output view to a more dynamic way which can be described “as ‘running through’ a continuum of numbers, letting an expression evaluate itself (very rapidly!) at each number” (Thompson, 1994, p. 26). However, this dynamic conception of variation does not seem to be obvious for students since it is essential to take into account simultaneous variation between magnitudes at different levels emerging in an ordered succession. Furthermore, there is a need for situations that provide students with opportunities to think about the covariational nature of functions in modelling dynamic events.

The hypothesis is then that students' understanding of covariation can be built following interaction with a dynamic physical device. Researchers like Rasmussen et al. (2004) and Botzer & Yerushalmy (2008) refer to embodied cognition to characterise the sense of a mathematical notion that students can get via interaction with a physical device. A central assumption of embodied cognition is that students' reference to bodily activity in physical settings and to emotions experienced in this activity, can be a basis for deeper understanding of functional notions, compared with a pure formal approach of these notions. Covariational characteristics of functions are experienced through feelings and emotions. Moreover, elements of language used to reflect on the experience, especially gestures and words describing covariation, give students a semiotic means of expression complementing formal approaches. Rasmussen et al. (2004) give the example of a university student who knew the formal definition of acceleration, but did not fully understand this notion.

Experimenting with a rotating unbalanced wheel she identified herself with the wheel and became “friends with the acceleration”.

The role of symbolism

There is evidence in the literature that the symbolism of functions is a major difficulty for students. Students’ view of symbolic expressions can be of a pure input-output correspondence. In other circumstances, it can be pseudo-structural, the expressions being understood as an object in itself, not connected to functional understanding (Sfard, 1991). Slavit (1997) indicates the critical role of symbolism “confronted in very different forms (such as graphs and equations)” (p. 277) in the development of the function concept and suggests the need for students’ investigation of algebraic and functional ideas in different contexts such as the geometric one. Even when students have access to basic proficiencies in algebraic symbolism, coordinating these proficiencies with an understanding of the structure of the algebraic formula in a function is critical and is particularly at stake when the function comes from a problem context. Most students fail in this coordination. Evidence of failure is given in the context of equation. For instance, van der Kooij (2010, p.122) notes that most students in a vocational high school “were able to do calculation on the pendulum equation $T = 2\pi\sqrt{\frac{l}{g}}$ while they gave no sense to an “abstract” equation $y = 2\sqrt{x}$ ”.

Potentialities and limitation of a software tool: The case of Computer Algebra

With regard to software tools that might contribute to a functional approach to algebra, the preceding review of issues, and particularly the critical question of symbolism focus attention on Computer Algebra Systems (CAS) because these systems were created to help mathematicians to go beyond mere numerical experimentation. Used in the classroom, computer algebra might help students concentrate on the sense of transformations. The reason for this is that in paper/pencil transformational activities, algebraic manipulations and transformational skills are necessary to get a given form, possibly detracting attention from how the outcome compares with the initial form. CAS generally include graphing and tabulating capabilities, then allowing graphic and numerical exploration, as well as symbolic approaches to problem solving.

However, standard CAS are tools for mathematicians, and the representation of mathematical objects often behave differently compared to mathematical objects as defined in secondary curricula. The following example comes from a French experimentation of the TI-92 CAS calculator in the years 1990 (figure 1).

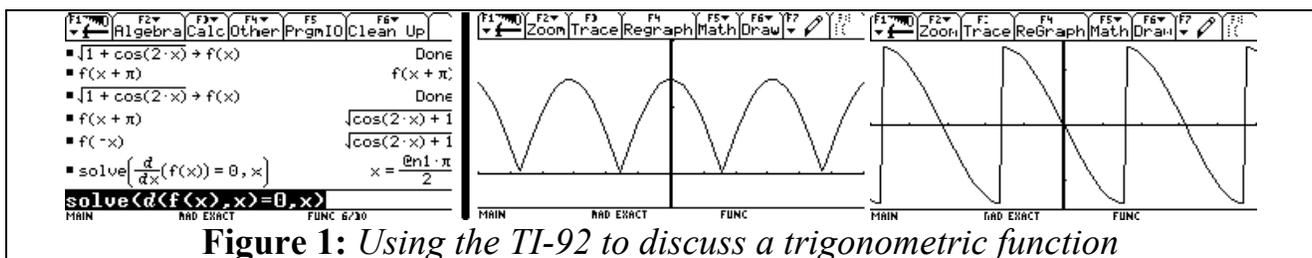

Figure 1: Using the TI-92 to discuss a trigonometric function

The task was to study the function $f(x) = \sqrt{1 + \cos(2 \cdot x)}$. It was set to 11th graders at the end of the year. The students used a TI-92 CAS calculator throughout the year within a research project (Lagrange 1999). We expected that students, by observing that the curve has different non-zero gradients approaching these points from the right and from the left, would detect that the derivative is not defined at the points where the curve reaches the x-axis. Observation showed that the accurate interpretation of the behaviour of the function at the points where the curve reaches the x-axis was not possible. Students persisted in thinking of an 'ordinary minimum', wondering why repeated 'zooming in' did not show a null gradient. This idea was reinforced by the false solution of the equation $f'(x) = 0$ by the symbolic module, where zeros of the derivative were given for every $k\pi/2$. Even the graph of the derivative (figure 1, right) was misleading because of the irrelevant line across the discontinuity. The reason for this behaviour was that in the TI-92, like other symbolic systems, functions are not defined on a domain and, in solving the equation, consideration is given to zeros of the numerators and not to possible zeros of the denominator.

Observations like this drew attention towards the importance of a careful design of software tools and of the associated classroom situations, taking into account the multiple constraints of classroom use. It was the starting point of the work of the Casyopée group, presented below.

DESIGNING CASYOPÉE: OBJECTIVES AND SITUATIONS OF USE

The genesis of the Casyopée [1] group was in the years 1995-2000 with the above mentioned experimentation of the TI-92 calculator. The group was concerned with the instrumental difficulties and epistemological problems inherent in Computer Algebra Software (CAS) designed for advanced users. The group started to build a CAS tool that could be really used in the classroom. A central aim was to ensure consistency with current notations and practices at secondary level. We wanted also to avoid any command language by designing a menu and button driven interface as in Dynamic Geometry, because keywords are always difficult to handle for beginners and they create confusions with mathematical notations. These choices helped to create an innovative algebraic tool contributing to a better appreciation of CAS by teachers. The group saw the potential of this tool for students to explore and solve problems involving modelling geometrical dependencies, for instance, an area against a length. However the group was concerned that geometrical exploration and modelling had to be done separately from the work of Casyopée.

In the years 2006-2009, the group was involved in the ReMath [2] project that focused on multi-representation of mathematical objects. This was an opportunity to extend the representations in Casyopée by adding a dynamic geometry window and representations of measures and of their covariation. This extension enabled covariations between couples of geometric magnitudes to be explored and couples

that are in functional dependency to be exported into the symbolic window. The outcome of this exportation is an algebraic function modelling the dependency, likely to be treated with all the available tools. In order to help students in modelling dependencies, this exportation can be done automatically. I will refer to this functionality as “automatic modelling” below. After the ReMath project, the group worked to build a conceptual framework about functions and algebra (Lagrange & Artigue 2009). It is based on the idea that students approach the notion of functions by working on dependencies at three levels (1) activity in a physical system where dependencies are “sensually” experienced; (2) activity on magnitudes, expected to provide a fruitful domain that enhances the consideration of functions as models of physical dependencies; and (3) activity on mathematical functions, with formulas, graphs, tables and other possible algebraic representations.

Designing classroom situations: the modelling cycle

The outcome of the above reflection is that the Casyopée group favours classroom situations where students have to build and use a function as a model of a relationship between variables in a dynamic system. Starting from a problem relative to a dynamic system, we expect that students progress through the steps of a “functional modelling cycle” (figure 2).

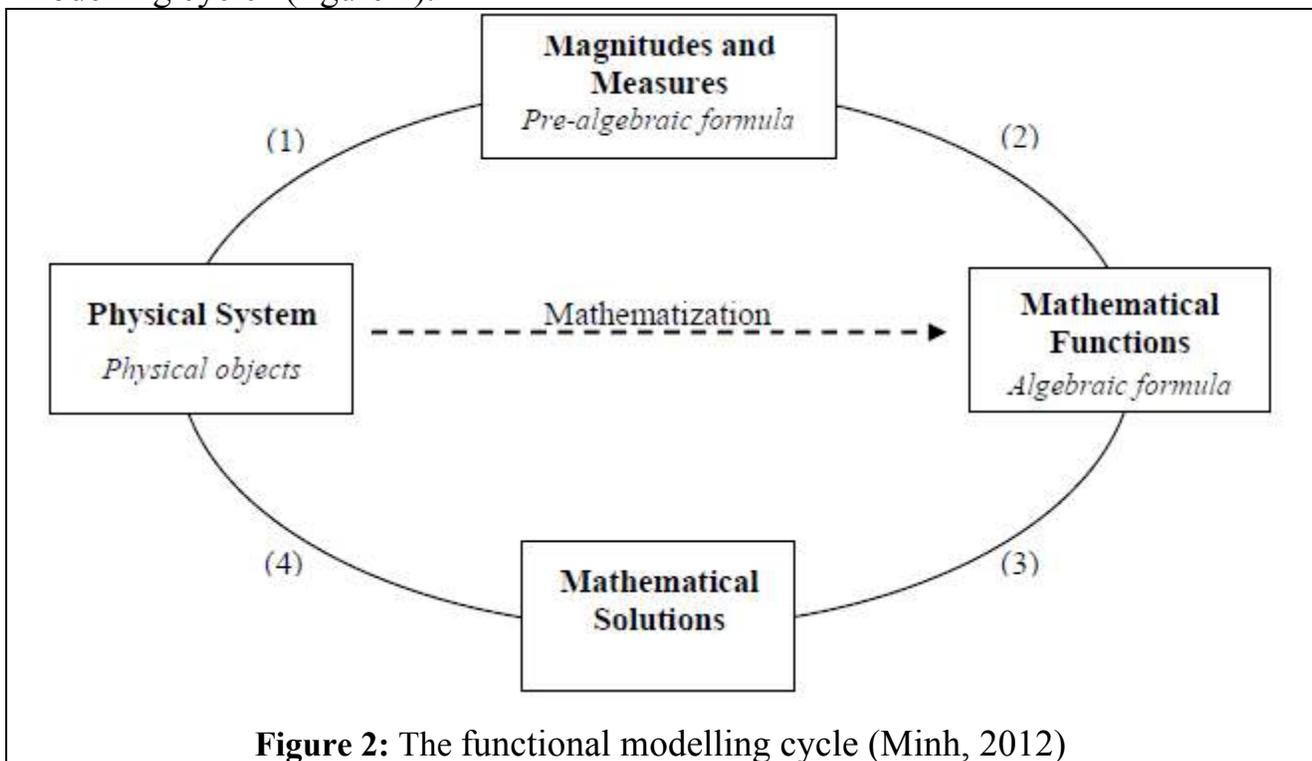

Figure 2: The functional modelling cycle (Minh, 2012)

In the physical system, students can observe, explore and perceive dependency relations between objects (step 1). Generally the problem that they have to solve (for instance, a problem of optimisation) involves quantifying the observations, and then students have to identify magnitudes whose covariation model the behaviour of the physical system. As explained above, the choice has been made in Casyopée to implement covariations between geometric magnitudes (areas, lengths, angles...)

involving geometrical objects existing in the dynamic geometry window. The consequence is that a dynamic geometry figure representing the system has to be built, followed by the determination of the magnitudes in covariation. This is far from obvious for students, and an important step in the understanding of functions. Step 2 consists of calculating a domain and a formula for a function expressing the covariation identified in step 1. The actual calculation is generally technically difficult and for the Casyopée group it is not insightful. In contrast, we favour the possibility of students exploring several covariations in order to find one which could be adequate for solving the problem. That is why the students can use the “automatic modelling” feature presented above. Step 3 consists of manipulations and transformations of the formula and algebraic proofs, helped by Casyopée’s symbolic capabilities, in order to find a mathematical result that could help to solve the problem. Step 4 is the interpretation phase. Students go back to the physical system to interpret the mathematical result and get a solution. In the next section I present a classroom situation designed on this basis.

A CLASSROOM SITUATION: THE AMUSEMENT PARK RIDE

This classroom situation was designed to take up two challenges. The first one was the necessity for students to consider “irregular” functions before entering the university level. This is so because situations involving modelling dependencies generally deal with infinitely differentiable functions not questioning understanding of irregularities like discontinuities or non-differentiability. The second challenge was to test with Casyopée the above mentioned embodied cognition assumption regarding the role of bodily activity in physical settings. More precisely here the situation was designed in order that students connect properties of an irregular function with a sensual experience of movements, in order to get a deeper understanding. Another feature of the situation is that the function involved is similar to the function whose study was at stake in the task with the TI-92 calculator observed above, allowing a comparison of students’ achievements in two different settings.

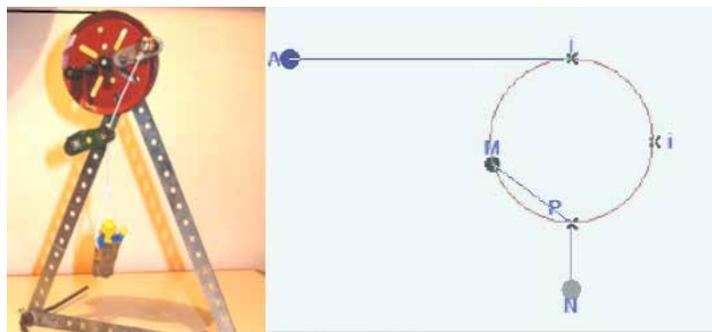

Figure 3: The Amusement Park Ride Problem

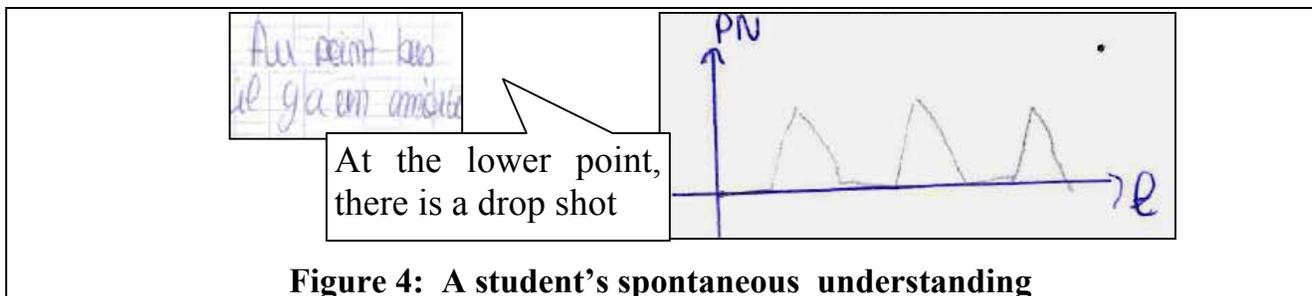

The problem was the following: a wheel rotates with uniform motion around its horizontal axis. A rope is attached at a point on the circumference and passes through a fixed guide. A car is hanging at the other end. The motion is chosen in order that a

person placed in the car feels differently the transition at high and low point. It was expected that students would identify the difference, associate this with different properties of the function (non-differentiability and differentiability) after modelling the movement. The problem is given in “real life” settings, the students being able to manipulate a scaled device, and then the first step of modelling consists in building a dynamic geometry figure replicating the device (figure 3).

The following indications are given to the students: the rope is attached to the wheel in a mobile point M and the guide is on the fixed point P. The car is in N (figure 3). Step 1 implies a not trivial geometric modelling: construction of a point M in order that the circular distance IM is equal to the linear distance Aj, and of a point N in order that $MP+PN$ is constant.

In this situation, we did not want especially to emphasize the choice of variables (step 2) because students already met this aspect of functions in previous situations. The real focus was on the properties of the function (step 3) and the interpretation (step 4). In order to ease step 2, and because working on covariation between lengths is easier for students, compared with covariation involving a variable angle, we asked students to consider that the wheel is put into rotation by pulling on a horizontal rope jA. At step 3, the focus is placed on the algebraic formula of the function. The students have to use Casyopée to get the derivative and should notice and identify precisely the points of non-differentiability. The lesson was carried out with a 12th grade class in a 90 minute session. I report first on students’ spontaneous model of the physical situation, and then on how they performed in the four steps presented above and how their understanding of the physical situation progressed after working on the algebraic function.

Students’ spontaneous understanding of the physical situation

Starting the session and demonstrating by animating a scaled model, the teacher asked the students to describe what was happening at the lower point and whether it was different to the high point. Figure 4 illustrates a typical answer. Students said that, at the high point, the car stopped and they had some difficulties explaining what was happening at the lower point. Some students tried to mimic the movement by getting up and down. The most commonly used expression, ‘drop shot’, is not accurate because it means that the car is arriving at a certain speed, stops and starts up again at a lower speed. Students illustrated with a graph of a piecewise linear

function. Actually they thought that because the wheel rotates uniformly, the car's movement should be piecewise uniform.

Building a dynamic geometry model

This was a difficult part. Students' poor practical knowledge in trigonometry explains why they needed help in defining M in order that the circular distance IM equalled the linear distance A_j . It seems more surprising that they found it difficult to define N in order to make $MP+PN=2$ (the length of the rope). After the teacher indicated that PN is known when MP is known, some students used a circle centred in P with a radius of $2-MP$ and defined N as an intersection point with the y -axis, and others directly defined N with the coordinates $(0; y_p-(2-MP))$.

Choosing the dependent and independent variables

Generally the students had no difficulties in making this choice appropriately with the software. However, their explanations for this choice were not always clear. For instance a pair of students wrote in the report: "We choose distance A_j as the (independent) variable" and added " A_j is a function of the coordinates of N ".

Working on the algebraic function obtained via Casyopée's automatic modelling

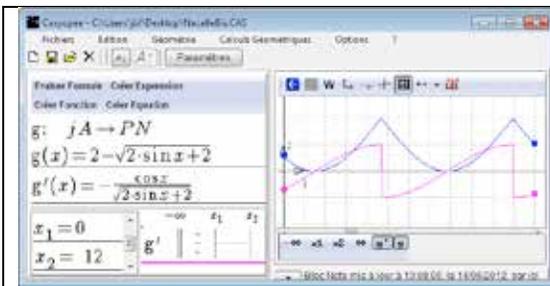

Figure 5: A graph of the derivative with wrong vertical segments

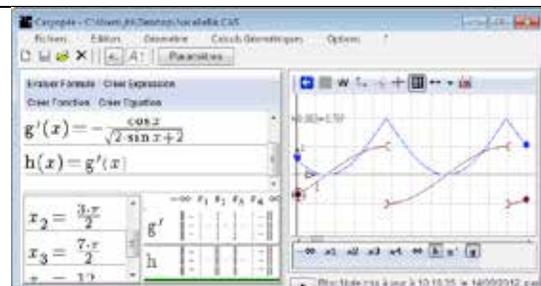

Figure 6: A correct graph of the derivative

The students obtained the derivative by using Casyopée under the form $x \rightarrow \frac{-\cos x}{\sqrt{2} \cdot \sin x + 2}$. Casyopée issued warnings because this function is not defined everywhere. Students ignored the warnings and obtained a graph with incorrect vertical segments (figure 5). The teacher drew students' attention to these segments and asked them to make a connection with Casyopée's warning. Students recognised that there should be discontinuities of the derivative corresponding to the low points. The teacher asked them to compute the position of these discontinuities. No students did this from the formal definition of the derivative. Rather they came back to the geometrical figure or the physical device, looking for the value of A_j corresponding to the lower point of the car. After they found these values and excluded them from the definition of the derivative, they got a correct graph (figure 6).

Students' understanding of the situation after working on the algebraic function

Students' understanding was much better after working on the algebraic function. They identified the derivative and the car's speed, saying that the speed was null at

the high point corresponding to a horizontal tangent on the graph of the movement. Implicitly, they recognised that at the lower point the car starts up again briskly at the same speed, speaking of “rebound” corresponding to non-differentiability points, rather than of “drop shot” implying softer stop and restart (Figure 7).

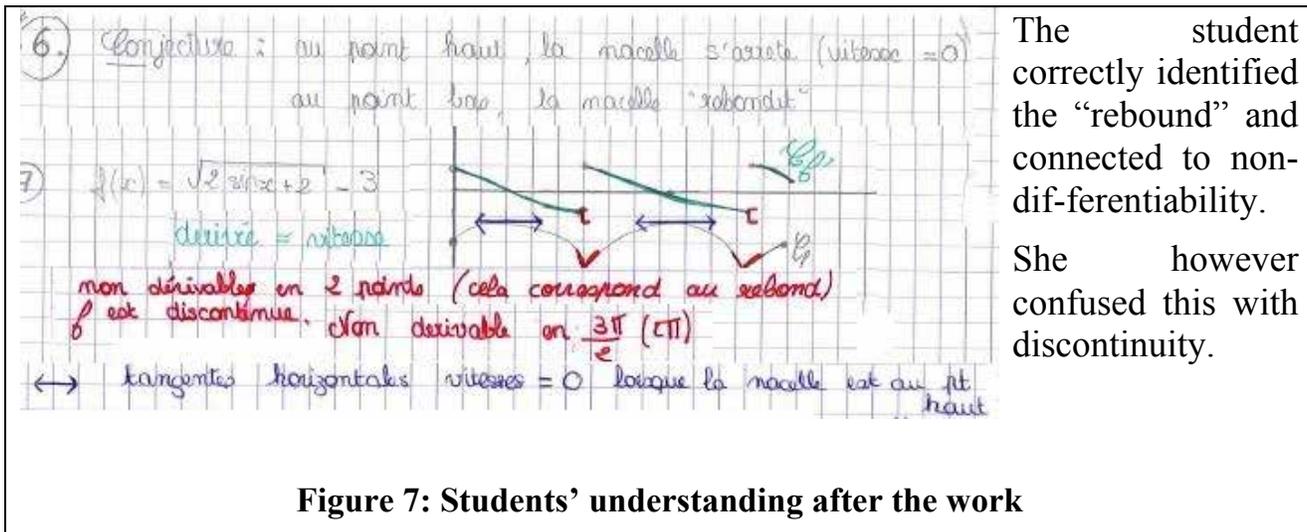

Figure 7: Students’ understanding after the work

CONCLUSION AND DISCUSSION

This paper started by identifying key questions about the teaching and learning of functions: experiencing covariation and using references to bodily activity is crucial for students’ conceptualisation of functions, and understanding of the structure of the algebraic formula in a function is critical.

An example of a situation was presented, based on the “embodied cognition” hypothesis and on the use of Casyopée’s functionalities, especially the fact that it builds a link between a geometrical dependency and a function modelling this dependency, and the consideration of a domain for the definition of a function. The comparison with the observation of students using a TI-92 to explore the properties of a similar function is insightful: (1) in the TI-92 situation, the formula and the graph do not allow students distinguishing between the two kinds of extrema, while in the “amusement park” situation students can link the behaviour of the function with “embodied” sensations helping them to progressively grasp the different nature of the extrema (2) Casyopée’s functionalities helped students to get an accurate view of the function’s behaviour, while the TI-92, like other CAS, delivers confusing messages. These functionalities are the result of ten years of reflection and development.

Regarding Kieran’s concern mentioned in the introduction that, in recent curricula, symbolic forms will be interpreted graphically, rather than dealt with, the example shows how students can work on symbolic forms of the function at stake and are able to establish links with the magnitudes whose covariation the function models. The capacity to deal with symbolism and of the associated situations of use is a distinct design feature of Casyopée, with the aim to reconcile symbolic forms and dynamic manipulation of mathematical objects and relationships. This is at least the beginning of an answer to Kieran’s objection.

FROM RECURSIVE TO EXPLICIT FORMULA FOR THE N -TH MEMBER OF A SEQUENCE MAPPED FROM A SHAPE PATTERN

Heidi Strømskag Måsøval

Sør-Trøndelag University College, Norway

This paper presents how two student teachers struggle to find an explicit formula for the general member of a sequence mapped from a shape pattern which they have successfully generalised in terms of a recursive formula. The paper shows how the milieu for algebraic generalisation in the observed episode is constrained in two senses: first, by the design of the task; second, by the teacher educator's intervention which presupposes prior knowledge that the student teachers do not have. It is indicated how manipulations on the geometrical configurations might enhance the milieu for algebraic generalisation of shape patterns and provide a link between recursive and explicit formulae.

Keywords: Recursive and explicit formulae, shape pattern, growth of sequence, decomposition, milieu, didactical situation.

INTRODUCTION

There is a two-fold purpose of tasks on algebraic generalisation of shape patterns (Måsøval, 2011): One is to provide a physical or iconic context for algebraic generalisation where the aim is to promote students' algebraic thinking and justification. Here, algebra is approached through pattern generalisation. The other is to lead students to experience patterns as mathematical structures as an aim in itself. Here, algebra is a mediational means to represent invariant structures in the patterns. However, it is rather common that shape patterns are used only to produce a sequence of numbers which subsequently is generalised in terms of an algebraic formula without references to the elements of the pattern (Lannin, Barker & Townsend, 2006). Strategies of "guess-and-check" that involve superficial pattern spotting are frequently used with the consequence that students do not detect the generality of the formulae they find (Lannin et al., 2006).

THEORETICAL FRAMEWORK

In Brousseau's (1997) theory of didactical situations in mathematics, an *adidactical situation* is a situation in which the student takes a mathematical problem as his own and solves it on the basis of its internal logic without the teacher's guidance and without trying to interpret the teacher's intention with the problem. The *devolution* of an adidactical learning situation is the act by which the teacher encourages the student to accept the responsibility for an adidactical learning situation or for a problem, and the teacher accepts the consequences of the transfer of this responsibility (Brousseau, 1997). The student cannot engage in any adidactical situation; the teacher attempts to arrange an adidactical situation that the student can handle.

In the devolution process, which is part of the broader (didactical) situation, the teacher is faced with a system that consists of the student and a *milieu* “that lacks any didactical intentions with regard to the student” (Brousseau, 1997, p. 40). The milieu is a subset of the students’ environment with only those features that are relevant with respect to the knowledge aimed at by the teacher in the didactical situation. The concept of milieu models the elements of the material or intellectual reality on which the students act and which may be an obstacle to their actions and reasoning (Laborde & Perrin-Glorian, 2005). That is, the milieu of a didactical situation is the part of the environment that can bring feedback to students’ actions to accomplish a task.

An adidactical situation is part of the didactical situation that is the broader situation with the system of interaction of the students with the milieu arranged with the purpose of the students’ appropriation of the target knowledge without the teacher’s intervention (Brousseau, 1997). The teacher can act on the milieu by providing new information or new equipment, for example by asking a question or directing students’ attention to certain factors in the classroom situation. When the teacher acts on the milieu, she changes the knowledge needed to solve the problem (Perrin-Glorian, Deblois & Robert, 2008). Whether the student can handle an adidactical situation depends upon two conditions: first, that the student has prior knowledge that enables him to engage with the situation; second, that the milieu created by the teacher provides the student with personal knowledge that enable him to develop the knowledge aimed at (by the teacher).

METHODOLOGY

The reported research is derived from the author’s PhD project (Måsøval, 2011). In the rest of the paper, “students” is used to refer to the student teachers, and “teacher” is used to refer to the teacher educator. The research question addressed in the paper is: *How do the mathematical task and the teacher’s intervention constrain students’ appropriation of algebraic generality in a shape pattern?* The task with which the paper deals (Figure 1) was the first of four tasks (during eight lessons) on algebraic generalisation of shape patterns. There had been a short whole-class introduction to figurate numbers (illustrated by triangular numbers) before the observed small-group lesson.

The data is a video-recorded observation of two students’ collaborative engagement with Task 1 (with teacher intervention). The students are Alice and Ida, who were in their first academic year on a four-year undergraduate teacher education programme for primary and lower secondary school in Norway. The teacher is Erik, who was responsible for teaching algebra to the class of which Alice and Ida were members. The observed students worked on the same task as the rest of the class (ca. 60 students). My role during data collection was to be a non-participant observer while video-recording the interaction between the students and the teacher. The video-recorded episode has been transcribed and analysed through a process of open coding (using an adapted grounded theory approach, Strauss & Corbin, 1998) where concepts from Brousseau’s (1997) theory have been used to answer the research

question. For a discussion of the legitimacy of the theory of didactical situations in the analysis of the data, I refer to (Måsøval, 2011, Chapter 2.5).

An *a priori* analysis of the shape pattern in the mathematical task

Task 1 (Figure 1) has been designed by Erik for collaborative work in small groups. According to Erik, the aim of Task 1 was twofold: first, to express the regularity of the shape pattern in natural language; second, to transform the natural language expression into algebraic symbolism.

Below you see the development of the first two shapes in a pattern.

a) Draw the third and fourth shapes in this pattern. You may use the squared paper.

b) Count the number of stars in each of the shapes you have now, and put the results into a table. Explain how the number of stars increases from one shape to the next. Use this to calculate how many stars there are in the fifth shape.

c) What you have found in task b is called a recursive (or indirect) formula. Can you express it in terms of mathematical symbols?

d) Try to find a connection between the position of a shape and the number of stars in that shape. This is called an explicit formula. Can you express such a formula in terms of mathematical symbols?

Figure 1. Task 1 given to the class for work in small groups

There are several possible ways to continue the pattern in Task 1 of which the first two geometrical configurations (elements) are given. In the *a priori* analysis I concentrate on the alternative identified by Alice and Ida (Figure 2), and relate it to the teacher's intention with the task.

Figure 2. A possible continuation of the shape pattern in Task 1

A figural approach to algebraic generality in shape patterns might involve an analysis of the invariant structure of the shape pattern by *decomposition* of its geometrical configurations according to an algorithmic rule (e.g., to isolate diagrammatically by encircling, or to paint with different colours). Below I present two possible decompositions of the actual pattern (shown in Figure 3 and Figure 4). In Figure 3 the first four elements are partitioned to illustrate that the differences of the sequence mapped from the shape pattern are multiples of four. Moreover, it is possible to see how the next element (with five dots on each side) can be made by the same rule:

Adding a line with four dots on each side of the fourth element (the same way as the other lines are placed) will complete the fifth element.

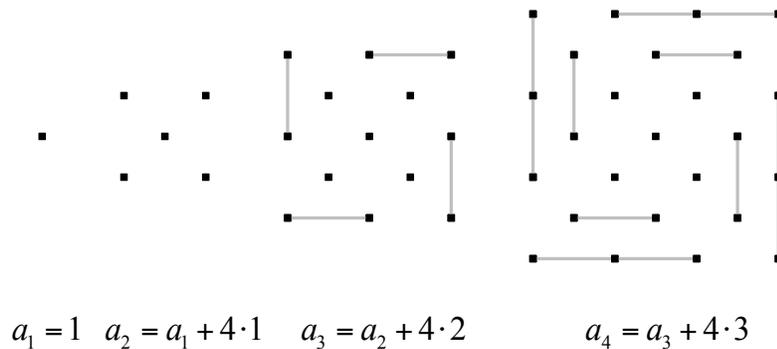

Figure 3. The first four elements illustrating that the differences are multiples of four
 The arithmetic relations presented in Figure 3 ($a_1 = 1$, $a_2 = a_1 + 4 \cdot 1$, $a_3 = a_2 + 4 \cdot 2$, $a_4 = a_3 + 4 \cdot 3$) have references in the partitions: It is visible how each element is composed by the previous element plus four lines, each line with one dot less than the position of the current element.

Based on this, the n -th member of the sequence mapped from the shape pattern can be generalised by algebraic thinking (Mason, 1996) as the recursive formula $a_n = a_{n-1} + 4(n-1)$, with $a_1 = 1$. It can be noticed that the decomposition presented in Figure 3 can also serve as reference for the representation of the sequence shown in Table 1, where the n -th member is given in terms of an explicit formula:

$$b_n = 1 + \sum_{i=1}^{n-1} 4i.$$

Table 1. Sequence originating from a decomposition in terms of multiples of four

Position	1	2	3	L	n
Number of dots	1	$1 + 4 \cdot 1$	$1 + 4 \cdot 1 + 4 \cdot 2$	L	$1 + \sum_{i=1}^{n-1} 4i$

A second decomposition is shown in Figure 4, where the components of the first four elements are drawn with different colours to illustrate that each element is a sum of consecutive squares. The arithmetic relations presented in Figure 4 ($c_1 = 1^2$, $c_2 = 2^2 + 1^2$, $c_3 = 3^2 + 2^2$, $c_4 = 4^2 + 3^2$) can be used to identify a relationship between the position of a member of the sequence and the rank of the squares to be added: The n -th member can be generalised by algebraic thinking as $c_n = n^2 + (n-1)^2$. This is an explicit formula for the n -th member of the sequence at stake. It is equivalent to b_n , but syntactically and semantically different (because it has been developed from a different route). The formula for the n -th partial sum of an arithmetic series can now be used to establish that $b_n = 1 + 4 \frac{n}{2}(n-1) = 2n^2 - 2n + 1 = n^2 + (n-1)^2 = c_n$. This

provides a connection between the different formulae with references to the partitions of the alternative decompositions presented.

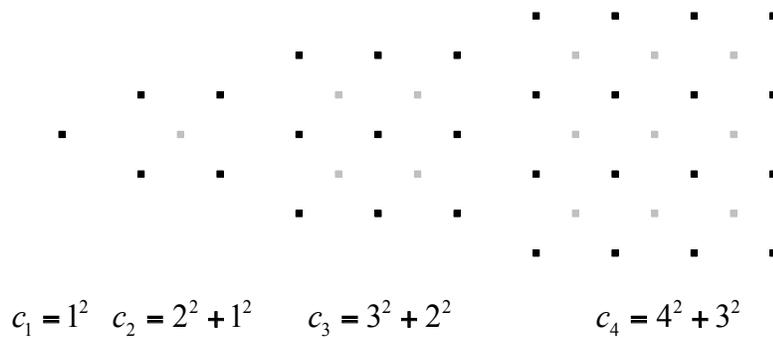

Figure 4. The first four elements illustrating nested squares

Different decompositions developed by students provide opportunities to import different meanings for the algebraic symbols in formulae (corresponding to the structure of the different partitions). Moreover, it provides opportunities to engage students in meaningful manipulations of (equivalent) algebraic expressions when students show that formulae that are syntactically different can be transformed into the same expression.

ANALYSIS OF THE EPISODE

A formula for the general member of a sequence – isolated from the regularity of the shape pattern from which it is arising

The students have written the numbers mapped from the first four elements of the shape pattern down in a table where differences between successive members are written in the bottom row. Alice notices that “it is indeed the four-times table”, and Ida says that “it must be sixteen and then twenty the next time.” They use this to extend their table which becomes like the one shown in Table 2.

Table 2

Shape	1	2	3	4	5	6
Number of stars	1	5	13	25	41	61
		+4	+8	+12	+16	+20

Then they reflect further on how the number of stars increases from one shape to the next (Task 1b):

- 28 Alice: You increase by the four-times table in a way. Each time [Pause 1-3 s] it increases by four and four each time.
- 29 Ida: Yes, for each new shape it increases by four.
- 30 Alice: Then it increases by [Pause 1-3 s] the previous [increment] plus four.

Their observations of the growth, as manifested in turns 28-30, describe properties of a pattern with quadratic growth: The first differences follow a pattern of linear growth; that is, the second differences are constant (Kalman, 1997). Alice and Ida, however, do not use the terms “linear”, “quadratic”, “difference”, or “second

difference”. After they have written the first eight, and then the 19th, 42nd and 99th members of the sequence as the sum of the previous member and the difference, they arrive at the following recursive formula: $(n - 1)4 + s_{n-1} = s_n$. This formula is similar to a_n presented above, except that it does not display the initial condition ($a_1 = 1$).

Alice and Ida have in the above used a numerical approach to generality. This is not surprising, given the design of the task; the focus is on counting components and putting the numbers into a table (Task 1a). Further, the students have decomposed particular numbers mapped from the shape pattern in terms of arithmetic relations, where the numbers are written as a sum of their predecessor and the difference. Algebraic thinking is then used to establish the formula $(n - 1)4 + s_{n-1} = s_n$. This is based on the students’ observation (of the particular members) that the difference between successive members is equal to the product of the number four and the position of the least member.

In the numerical approach employed by the students, the geometrical configurations are important only as a context to produce a sequence of numbers that subsequently is generalised in terms of a formula in algebraic symbols. However, the shape pattern in the task is a *real milieu* (Brousseau, 1997) in the sense that it can be manipulated. The students draw the next elements and count their components, but they do not decompose the geometrical configurations to analyse the invariant structure of the pattern: There is no feedback in the didactical situation that makes a structural analysis of the elements necessary.

The teacher’s intention with the task (to express the regularity of the shape pattern) might have been handled by making the students create references (as suggested in the *a priori* analysis) between partitions (resulting from decomposition) of the elements on the one hand, and the symbols in the formula on the other. These two objects, partition and symbol, would be the outcomes of the situations of *action* and *formulation* (Brousseau, 1997), respectively. To express the regularity of the pattern in natural language (based on a decomposition) would correspond to an informal model of the regularity of the pattern in the situation of action, whereas the algebraic formula would correspond to a formal model of the regularity in the situation of formulation.

Alice and Ida do not make references between the iconic context and the arithmetic relations they have written down. In this way, when they generalise the arithmetic relations by algebraic thinking, it is likely that they do not experience the pattern as a mathematical structure to be an aim in itself, where algebra is a mediational means to represent the invariant structure in the pattern.

An attempt to make a connection between a recursive formula and an explicit formula does not succeed

When the students subsequently (without the teacher present) worked together to find an explicit formula for the n -th member of the same sequence, they use an analogue

approach: In search for an explicit relationship, explained in Task 1d as “a connection between the position of a shape and the number of building blocks in that shape”, they calculate the *differences* between the members of the actual sequence and their respective positions. This method I interpret as the students’ erroneous application (“overgeneralisation”) of the features of a recursive approach in an explicit approach to the general member of the sequence.

An explicit formula for the general member of a sequence mapped from a shape pattern can be defined as the numerical value of the n -th element expressed as a function of n . The method employed by the students is inappropriate because they establish an arithmetic relation (difference) between member and position, $f(n) - n$, instead of a functional relationship between member and position. Based on their calculation of the differences, $f(n) - n$, I infer that they have interpreted the word “connection” used in the task to mean “difference”. Alice and Ida’s construal is possibly influenced by their engagement with a recursive formula (Task 1c, in the same session), where they had calculated the differences between successive numbers of the sequence at stake. In search for an explicit formula (Task 1d), they produce the diagram shown in Table 3, where the commentary column (where R refers to “row”) is made by me to explain how the numbers are derived. To distinguish differences from other elements of the table, differences are written in grey.

Table 3: Diagram produced by the students in search for an explicit formula

						Commentary	
1	2	3	4	5	6	R 1	n
0	3	10	21	36	55	R 2	$f(n) - n$
1	5	13	25	41	61	R 3	$f(n)$
	3	7	11	15	19	R 4	$(R 2)_{i+1} - (R 2)_i$
	+4	+4	+4	+4		R 5	$(R 4)_{i+1} - (R 4)_i$

The second row of Table 3 (in the commentary column symbolised by $f(n) - n$) consists of differences between members of the sequence mapped from the shape pattern (third row) and their position (first row). In constructing the numbers in the second row, the students have not focused on coordinating the referents (components and position) for the variables. If referents were added for numbers in the second row, the resulting number sentence would be: 5 [components] - 2 [position?] = 3 [components]. This is problematic since the operation of difference is not referent transforming. Further, the fourth row of Table 3 consists of first differences of $f(n) - n$, and the fifth row consists of second differences of $f(n) - n$.

When teacher Erik, who has designed the task, enters the room (on his own initiative), the students ask him if they are on the right track with respect to an explicit formula. The teacher responds by asking them what the characteristic of the recursive formula is. The students answer by describing the general nature of a

recursive formula, but the teacher says that he means the particular recursive formula in Task 1. The conversation continues like this:

374 Teacher E: It is not so easy, you know, the explicit one [laughs]. There is something, there is something about the recursive [relationship] which makes it complicated. [Pause 1-3 s] How is it if you look at the increase from one shape to the next?

375 Alice: Ehm [Pause 1-3 s] you take the previous one and multiply. No, you take the previous increase and add four to it.

376 Teacher E: Yes, exactly, right. You take the previous increase and add four.

When the teacher in turn 374 suggests that there is something that makes the sought explicit relationship complicated, I interpret that he attempts to explain the complexity by the *type* of growth of the sequence arising from the shape pattern. This is indicated in the same turn by the teacher's attention to the (first) differences of the sequence when he asks the students to describe "the increase from one shape to the next." He reinforces that the growth is non-constant by repeating Alice's description of the increase (turn 376). I find it plausible that his claim about the complexity of the sought explicit relationship and his attention to the fact that the first differences are non-constant, are attempts to make the students work analytically and thereby potentially deduce properties of the syntax of the explicit formula searched for. This interpretation has been approved by teacher Erik in a conversation I had with him after the observed lesson. It is consistent with a later utterance (from the transcript), where it appears that the teacher understands the numbers in the fourth row to represent the first differences of the sequence mapped from the shape pattern:

455 Teacher E: It's just that, that [Pause 1-3 s] life would have been much easier with respect to a formula, if we had a pattern where *this* row had been a constant number [points at the fourth row in Table 3].

This interpretation by the teacher of the fourth row is possibly influenced by a comment by Alice (turn 377) about the same row of Table 3, where she claims to refer to the difference $f(6) - f(5)$ (which is equal to 20), whereas she actually refers to the difference $f(6) - 6$ (which is equal to 55). Erik's interpretation of the fourth row of Table 3 as consisting of (first) differences would be in agreement with the second differences in the fifth row (which are constantly four). I interpret the teacher's intervention described in the above as an attempt to make a connection between the recursive properties of the sequence at stake (that it has *quadratic* growth) and the syntax of the desired explicit formula (that it is a polynomial of order *two*). This is however non-trivial, and there is no indication in the students' reasoning which suggests that they are able to utilise the teacher's hint: When the teacher later asks the students: "Do you have a kind of feeling which type of formulaic expressions that may emerge?" (turn 474), this is succeeded by 16 seconds of silence.

Given the school curriculum, I believe that it is most likely that Alice and Ida have no previous knowledge about different types of growth of sequences. Teacher Erik's intervention in this episode I interpret as an instance of a *metamathematical shift*

(Brousseau, 1997): It is characterised by the phenomenon that the teacher has substituted for the mathematical task (to find an explicit formula in algebraic notation) a discussion of the logic of its solution (what can be inferred about the syntax of the explicit formula from the observations about the growth of the sequence at stake). The teacher has tried to help the students improve their proficiency in establishing an explicit formula for the general member of a sequence, but the chosen method did not bring about the desired results. The unprompted utterances below indicate that the focus on a connection between recursive properties and the syntax of an explicit formula has not been helpful for the students:

- 611 Ida: I'm supposed to come up with that one [explicit] [Pause 1-3 s] I'm all the time confused by the [recursive] one we figured out here.
- 612 Alice: I don't see a clear distinction between recursive and explicit (Ida: no). I don't know what the different formulae are, and then I can't just shift from one to the other.

DISCUSSION

The milieu in the observed episode does not provide any feedback that requires that they analyse the pattern structurally (e.g. by decomposition) to make references between the elements of the pattern and the syntax of a formula. Quite the contrary, Task 1a focuses on counting components and putting the numbers into a table. This is in opposition to the teacher's intention, which is to express the invariant structure of the pattern. The feedback provided by the milieu with respect to an explicit formula is the concept "connection" between member and position. "Connection" is a vague (everyday) notion used instead of the mathematical concept "functional relationship" between member and position. It constitutes a weakness in the milieu because it contributes to confusion for the students in that they do not distinguish between a recursive approach (which involves *difference* between successive members) and an explicit approach (which involves member as a *function* of position).

When teacher Erik intervenes during Alice and Ida's struggle to find an explicit formula, he acts on the milieu by directing attention to a relationship between the recursive and the explicit formulae through the concept of type of growth of the sequence at stake. He thereby changes the knowledge needed to solve the problem. The analysis of the episode shows that the students cannot handle the new didactical situation: They do not have knowledge of type of growth of sequences, neither does the milieu provide feedback that enables them to develop the knowledge necessary to utilise the teacher's intervention. However, encouraging students to connect recursive and explicit formulae is by Lannin et al. (2006) claimed to be important. Further, they recommend that tasks on generalisation of shape pattern be designed so as to promote students to remain connected to the figural representation (see also Steele, 2008). This is in line with Hewitt (1994) who warns against using contexts only to produce tables and spotting patterns in number sequences, because it does not give students insights into the structure of the original situation.

The *a priori* analysis of the actual shape pattern indicates how the process of decomposition might be used to provide feedback that could help the students remain connected to the figural representation, and hence discover and express the invariant structure of the pattern. Further, the decomposition presented in Figure 3 shows how a recursive formula and an explicit formula for the general member of the derived sequence are connected (in the way Figure 3 displays how an explicit formula is the sum of the first member and the first differences).

DIFFERENT WAYS OF GRASPING STRUCTURE IN ARITHMETICAL TASKS, AS STEPS TOWARD ALGEBRA

Maria Mellone*, Piera Romano** & Roberto Tortora*

*Dipartimento di Matematica e Applicazioni - Università Federico II, Napoli (Italy)

**Liceo Scientifico Statale “Mons. B. Mangino” - Pagani, Salerno (Italy)

In this study we propose an analysis of some interesting solving processes of 9-grade students engaged in an arithmetical task. It originates as an item of a national test that has proven to be very critical for Italian students. By changing the way of administering the task, and also by virtue of some interviews, we got the opportunity to observe interesting students' behaviours, some of which throw, in our opinion, new light on students' sense-making processes in the borderline between arithmetic and algebra.

KEYWORDS: *arithmetic-algebra, sense-making*

INTRODUCTION

In these last years new perspectives about the teaching and learning of algebra are emerging, due, among other things, to the impact of educational technologies (see e. g. De Vries & Mottier, 2006) and to the achievements of Early Algebra (for a wide overview, see Cai & Knuth, 2011). Moreover, interesting hypotheses about the presence of a sort of algebraic discourse within the daily life media have been advanced: “*It is possible that these days algebra is simply ‘in the air’ [...]. With the help of media, algebraic forms of expression may even be infiltrating colloquial discourses*” (Caspi & Sfard, 2012, p. 64).

Our research group has been working for several years on the teaching and learning of algebra with particular care to motivational aspects and sense-making processes (see e. g. Guidoni, Iannece & Tortora, 2005). We have been studying these processes mainly adopting a Vygotskian research perspective, that is arranging suitable class settings, where social interaction and immersion in culturally relevant activities are enhanced, at a secondary school level (Iannece & Romano, 2008), as well as at a primary one (Mellone, 2011), where we share the basic claims of Early Algebra.

This paper originates from a didactic activity, devised for understanding and analysing the poor performances realized in some items of the annual Italian national assessment for 10-grade students organized by INVALSI (*Istituto Nazionale per la VALutazione del Sistema educativo di Istruzione e di formazione*) in the year 2010-2011 (a complete account of the test, together with an analysis of students' difficulties can be found in http://www.invalsi.it/snv1011/documenti/Rapporto_SNV%202010-11_e_Prova_nazionale_2011.pdf).

Some poor results of the test come as no surprise, rather they confirm some of the most frequently observed difficulties met by students.

The following (D16) is one of the INVALSI test items, where the Italian students encountered major difficulties, as shown in the table below:

D16. The expression $10^{37} + 10^{38}$ is also equal to:

- A. 20^{75}
- B. 10^7
- C. $11 \cdot 10^{37}$
- D. $10^{37,38}$

A (%)	B (%)	C (%)	D (%)	No answer (%)
35.0	1.9	22.0 (correct)	38.7	2.4

This result, together with the results to the whole test, acted on us as a stimulus for trying to understand more deeply their causes. Therefore, we have arranged several slightly different modalities for administrating the questions to different students. Moreover, in a second phase, a selected sample of them have been briefly interviewed. We have collected several data and are now just interpreting them, as the object of a deep study.

In this paper, of an exploratory character, we do not intend to analyze the causes of students' errors. Instead, our aim is to focus on a few episodes occurring in students' answers to item D16, mainly to underline how, when the students are (more) free to select and to express their own strategies, the spectrum of their behaviours considerably enlarge and often goes beyond any simplified classification attempt. In particular we notice that some of their arguments on the borderline between arithmetic and algebra may even suggest new reflections and ideas on the usual meaning of the algebraic notions and procedures.

THEORETICAL FRAMEWORK

Algebra is a mathematical domain in which the search for meaning is very problematic. Indeed, many meanings can be given to the algebraic symbols and to the word 'Algebra' itself in 'official' Mathematics just as much as in mathematics education. For instance, we contend that in Bourbaki's work we can find the ultimate roots of the emphasis given in the last decades by all world school curricula to the syntactical aspects of algebra and of the corresponding tendency to leave meanings in the shadow.

However, it is widely acknowledged that from a didactic point of view the link between arithmetic and algebra is the high road to support and justify the introduction and the development of algebraic skills. Therefore, the problem becomes rather to understand the different aspects of this link and to suitably

manage them by means of an effective didactic mediation, in order to avoid the common and well known difficulties met by students.

In this direction, many research lines suggest that the link arithmetic-algebra cannot be reduced to a simple one-way path (see, for instance, the study Iannece, Mellone & Tortora, 2010 inspired to Davydov's, 1982, ideas). In a recent study (2011), Subramaniam and Banerjee document that as early as in the twelfth century famous Indian text 'Bhaskara', the role of algebra is explicitly viewed as a foundation rather than as a mere generalization for arithmetic, along a typical two-ways relationship: algebra "*was viewed both as a domain where the rationales for computations were grasped and as a furnace where new computational techniques were forged*" (Subramaniam & Banerjee, 2011, p. 95).

Turning to students' behaviours, the international literature about the solution of algebraic exercises and word problems offers several examples that suggest an apparent 'suspension of sense-making' (see, for example, Schoenfeld, 1991). On the other hand, according to wide evidence coming from neuroscience (see, for example, Rizzolatti & Sinigaglia, 2006), there doesn't exist in our brain an absolute *absence of meaning*, but instead the brain's way of working is always subjected to an automatic and sometimes unconscious dynamics of search for meaning. In particular, whenever the time at our disposal is quite short, what often happens is a suspension of the meanings that come from mature knowledge in favour of an appeal to previous more basic resources or to rapid analogical reasoning.

So, along a solving process, students' making-sense could be genuinely a search for solutions plausible and coherent with the text of the exercise, typically *inside* the discipline. Or, students can also look for a, so to say, *outside* sense, basing their interpretation of the task on the fact that who assigns it is an adult bearing an authority, and so trying to interpret this adult's behaviour too: "[...] *there is a gross mismatch between the goals that the teacher thinks he or she is getting for students and the goals that students actually seek to achieve. In other words, the teacher believes that the students are operating in a mathematical context when their overall goals are primarily social rather than mathematical in nature*" (Cobb, 1986, p. 8). For example, during the solving process of an algebraic exercise, it can happen that its sense be identified with the mechanical use of formulas or algorithms, because students' perception is often that the meaning of such an exercise is exactly to show that some rules have been well memorized. This is also the effect of the belief that the success in mathematics strongly depends from the ability to execute a task in a brief time, belief that often comes from the first grades of school and is supported by the many test that students meet during their lives. As claimed by Arcavi (2005), the kind of sense making followed by students in their solving processes is strongly linked to the classroom culture. Therefore, the classroom culture has a central role in behaviour or habit of the learners and this has important implications in the

didactic practice. Arcavi gives some advice as to the direction that didactic practice could move, suggesting *“asking students to develop the habit not to jump to symbols right away, but to make sense of the problem, to draw a graph or a picture, to encourage them to describe what they see and to reason about it”* (Arcavi, 2005, p. 45).

METHODOLOGY AND CONTEXT

The INVALSI test for grade 10 lasts 90 minutes and contains 30 questions, in most cases multiple-choice questions, and some consisting of several items. The test is administered to all the Italian students and, as we have already noted, some of the questions were answered very poorly. So, we decided to involve a group of teachers in a research study in order to examine the reasons behind this poor performance. We are convinced that the formats of the questions (multiple-choice, above all) and the short time have strongly contributed to students' failure, triggering a sense-making oriented to a “social survival” (Cobb, 1986) more than one genuinely linked to the discipline. By social survival, we refer to a general problem facing complex human interaction within constraints formed by a variety of intentions and goals, many of which are not mathematical.

As a first step of our work, each question and the corresponding national results has been carefully studied. Then we decided to modify the way of administering some selected critical items, one of which is the D16 item, and to test them in several classes of different grades. The teachers inserted the selected questions in their monthly written tests, which usually include about 15 exercises of several kinds (open questions, closed questions, problem solving) and the students were asked to justify their answers, including those for multiple-choice questions. The time allowed for answers is generally longer than in INVALSI test. In a few cases a student has been interviewed, after the correction of the classwork, in order to better understand some passages in her/his text or to realize to what extent (s)he was aware of the legitimacy of the procedure employed. The general purpose was to reflect on students' solution processes and, possibly, to link them with the didactic strategies of the teachers. In fact, it is worth noticing that the educational approach of the teachers of our team is inspired by Vygotsky's ideas about the social and semiotic nature of learning. In particular, they often approach algebra by means of numerical problems organized around the cycle Conjecture-Argumentation-Proof: firstly, students are asked to search for regularities and to make conjectures, later they are encouraged to discuss and finally to provide a mathematical proof or a counter-example to the conjectures. Often proofs need new algebraic techniques that, in this way, aren't proposed as mere theoretical notions but rather as suitable tools to make generalizations, tools that only afterward will be stabilized as standard procedures to be used in similar problems.

In this paper we report an analysis of students' answers to the D16 item. As the item involves tasks usually faced in the 9th grade, we decided to administer it in

May 2012 to 43 students of two 9th grade classes. This was after the students were formally taught the rules of calculation with powers.

D16 is very interesting for many reasons. First of all, it is a context-free task that can be approached through different solving strategies: for example, a) it can be solved comparing the magnitudes of the numbers; b) the particular base 10 of the powers could induce students to perform arithmetical computations; c) the sum of two powers with the same base can wrongly induce students to apply powers properties, as suggested by the two distractors A and D (38% of Italian students chose D); d) the expression can be manipulated as an algebraic one, using a symbolic rule like factorization to facilitate a complex arithmetical computation, becoming in this way a good example of interplay between algebra and arithmetic. Moreover, D16 requires a transformation of an arithmetical expression: according with (Subramaniam & Banerjee, 2011), working with the operational composition of numbers is one of the key ideas marking the transition from arithmetic to algebra.

The following table contains the answers to question D16 in the two classes:

Choice	A	B	C	D	No answer
Number of students	4	0	28	11	0

Although our sample is not representative and of sufficient size to show statistical significance, we note that the percentage of correct answers is considerably higher than the national one ($28/45 \cong 62\%$ vs. 22%). We suggest that this may be largely due to two factors: the extra time allowed to them (with respect to the official test), and to the teacher's care in giving sense to the transition arithmetic-algebra. In the next section we will analyse a few protocols, which can be seen, in a sense, as alternative to the usual arithmetical/algebraic procedures.

ANALYSIS OF SOME PROTOCOLS

Many correct answers employ standard algebraic procedures (which are also those expected by the authors of INVALSI test), as well exemplified in Lucia's protocol (Fig. 1), where the result is obtained using a factorization step, carefully expressed in algebraic terms and applied to the numerical case.

$$10^{37} + 10^{38} = 10^{37}(1+10) = 10^{37} \cdot 11$$

inoltre $x^{37} + x^{38} = x^{37}(1+x) = \dots$

Fig. 1 - Lucia's protocol

$10^{37} + 10^{38}$ è uguale a 10^{75} perché vedo addizioni delle potenze con denominatore uguale e sommo le potenze 37 e 38.

Fig. 2 - Susy's protocol. She says: “ $10^{37} + 10^{38}$ is equal to $= 10^{75}$ because when we add powers with the same denominators [*sic*] the powers [*sic*] 37 and 38 are added”.

There are several incorrect answers mainly due to confusions about the rules for powers. See Susy's protocol, fig. 2. Note also that, although she selects option A, she writes 10^{75} instead of 20^{75} in her justification). Also there are cases where the correct answer is achieved via incorrect procedures. See Emanuela's protocol, fig. 3, where all the passages are pure inventions but magically lead to the right conclusion $11 \cdot 10^{37}$. But what is more interesting for us is to try to understand some less normal, although still reasonable, ways followed by other students, both in the cases where they do and do not succeed.

$$10^{37} + 10^{38} =$$

$$= 10^{37} + 100^{37} =$$

$$= 110^{37} = 11 \cdot 10^{37}$$

Fig. 3 - Emanuela's protocol

$$\begin{array}{r} 100 \dots 00 \\ + 20 \dots 00 \\ \hline 110 \dots 00 \end{array} \Rightarrow 10^{38} + 10^{37} = 11 \cdot 10^{37}$$

Fig. 4 - Ciro's protocol

Ciro's (Fig. 4), Rosanna's (Fig. 5) and Giuseppe's (Fig. 6) excerpts are similar, in that they catch the right answer using procedures that have some algebraic features, but do not abandon the arithmetical domain. Another common characteristic is that their results are, from a strictly logical point of view, just likely, maybe strongly likely, but not safely proved. Or, at least, it can be said that possible refinements of their reasonings, to get rigorous proofs, are not a priority for them.

Ciro's way of avoiding heavy computations is as easy as an Egg of Columbus and reveals a strong confidence with place value and related algorithms. The use of ellipsis in his decimal writing of powers of ten is a clever shortcut, which may be considered as a kind of algebraic attitude, although Ciro's focus is on structure rather than generalization. In fact, Ciro is able to recognize his result as the product $11 \cdot 10^{37}$. Moreover, we guess that the path toward forms of generalizations is wide open for Ciro. One can simply replace the numbers 37 and 38 on the braces to begin to generalise to other similar problems.

The right answer is C. In fact, if for example we figure $10^2 + 10^3$ out, we get $100 + 1000 = 1100$. The other options are wrong, since they look as if the properties of powers had been applied to the expression $10^{37} + 10^{38}$, whereas they can only be applied to multiplications or divisions.

Fig. 5 - Rosanna's protocol (our translation)

Rosanna's strategy is not so different, but she prefers a simplified numerical example to justify her choice. She notices that the numbers 37 and 38 are consecutive and is quite aware of the importance of this fact: again a structural aspect underlying the specific numerical case. And she is able to substitute two simpler numbers, that is 2 and 3, to see and to explain the result for the larger ones using the numbers chosen as a so called *generic* example. Moreover she skilfully detects the deceiving role of the distractors, even if we wonder whether she uses her metacognitive attitude to rely more firmly on her result or to provide a more complete answer.

Giuseppe's protocol is quite complex, and perhaps even more interesting. He renounces to the advantages of decimal representation of numbers and prefers to rely on smaller numbers and on his familiarity with operations on them. The choice made by Giuseppe brings him farther from the arithmetical reasoning, requiring a quite rich algebraic treatment of the problem. But, as a matter of fact, he succeeds in the task of controlling two simultaneous substitutions (the base 2 for the base 10 and the exponents 2 and 3 for 37 and 38), grasping the essential (structural) relationships, and succeeds in correctly applying the obtained results to the original numerical case. Here Giuseppe, like Rosanna, apparently uses a *generic* example. But his direct jump from a single case to another one without the interposed support of a general argument turns out to be a bit reckless. A deeper insight on his way of reasoning comes from the interview, whose essential passages are reported here.

Interviewer: Why did you change 10^{37} and 10^{38} into 2^3 and 2^4 , instead of computing the two powers of ten?

Giuseppe: I chose smaller numbers to make easier calculations.

I.: But how just 3 and 4 as exponents?

G.: Since 37 and 38 are consecutive numbers, so I selected two consecutive numbers, but very small.

I.: Ok, and then?

Fig. 6 - Giuseppe's protocol. He says: "Since operating with 2... then I have made..."

- G.: Well, $2^3 + 2^4$ is 24, then I noticed that, in the answer C, 10^{38} becomes 11 [sic], therefore I transformed 2^4 into 3, computed $3 \cdot 2^3 = 24$, and since the results turn out to be the same, I chose C.
- I.: Oh, but you certainly remember what you have heard several times, that one example doesn't make a proof! How could you be sure of your answer, after only one example?
- G.: Because I controlled the other answers.
- I.: What do you mean?
- G.: I computed 4^7 [Giuseppe points on the option A on his sheet], 2^7 [on B] and 2^{12} [on D] and none of them resulted in 24, then I guessed that if only the option C works for 2, then the same must hold true for 10.

As can be seen, Giuseppe's justifications of his procedure confirm what has already been deduced from his protocol, that is a solid grasping of the structural features of the numerical expression. Indeed he handles the arithmetical expressions occurring in the various answers as algebraic ones, substituting time after time the numbers of his example. But what is more interesting is the intertwining between his reasoning toward the right result and the way he uses the distractors, in particular the hypothesis that only one of the answers is correct. His mathematical (or better logical) argument is frankly convincing although quite complex, to the point that we confess some difficulty of ours in transforming it in a safe logical argument. In other words, we could say that Giuseppe's argument is not certain, but nevertheless a strongly reliable one.

Mariarosaria's protocol (Fig. 7) shows a typical example of a wrong choice: she is attracted by the option D, the most preferred by Italian students.

$10^{37} + 10^{38}$ can be written as $10^{37 \cdot 38}$ since the exponents aren't equal, therefore we cannot concentrate on equal bases, there isn't a multiplication, so we can't add the exponents, but with equal bases we multiply the exponents even if there is a sum of the bases.

Fig. 7 - Mariarosaria's protocol (our translation)

Also M. was interviewed, to better understand her strategy and in particular why she completely disregarded the right answer C.

- I.: Why didn't you consider C, when you realized that something didn't work with the power properties?
- M.: Well, the other options looked as more likely; C was too strange.

Perhaps there is not so much to comment on this: the distractor hit. But something can still be deepened and some 'reasonable' insights identified in Mariarosaria's words. First, the word "concentrate" belongs to the class

language and therefore to classroom norms and practices, in the sense of Cobb (1986), as witnessed by the teacher; when she gives instructions about products or divisions of powers, she usually says: “when the exponents are equal, you must concentrate on bases, when bases are equal, on exponents”. Apparently, teacher’s message was received, but the emphasis on the two possible cases caused neglecting that only the multiplicative structure is involved. Anyway, it can be said that Mariarosaria views the exercise as concerning just calculation techniques of powers (she calls “strange” the option C) to the extent that she dares to invent a new rule to justify her choice.

CONCLUSION

First of all, we want to emphasize that the Vygotskian methodology used by the teacher and in particular the continuous attention devoted to students’ reasoning is the invaluable condition that allows, here as well as in general, the students to freely express their views and the teachers and researchers to observe them and to achieve new insights about students’ behaviours and their sense-making processes.

In our case, the various students’ attempts to solve the task appear to us difficult to classify using existing tools. This raises, in our opinion, a lot of didactic and research questions regarding the kind of rationality which lies behind these solving processes. Indeed, we hypothesise that some kind of ‘social’ rationality (Cobb, 1986) is active and intertwined with the more pure mathematical reasoning. As a consequence, a new question arises, namely if it is better to encourage or to discourage this kind of arguments, and moreover if we are disposed to consider them genuine mathematics.

Of course, we have no definite answer to these questions, but are convinced that they are more and more urgent, since multiple choice tests are just examples of problematic situations very frequent in today life. Technological advances mean that modern society requires a great capacity to take rapid decisions. To face these problems is, in our opinion, one of the biggest challenges of tomorrow educators.

Finally, we want to point out that the variations in the way of administrating the task were also used by teachers involved in this research as a tool to reflect on their own didactic practice. For this reason we are convinced that this kind of experience could provide suggestions for a possible wide scale work with teachers, both to support them in facing the national test, and as a good hint for in-service training.

GENERALISING THROUGH QUASI-VARIABLE THINKING: A STUDY WITH GRADE 4 STUDENTS

Célia Mestre & Hélia Oliveira

Unidade de Investigação do Instituto de Educação, Universidade de Lisboa, Portugal

This paper presents a study from the beginning of a teaching experiment to promote grade 4 students' algebraic thinking. It aims to analyse how quasi-variable thinking contributed to the development of generalisation and to the first uses of symbolisation by the students. The data were collected from two mathematical tasks that explored computation strategies. The lessons were taught by the researcher (the first author), the data were collected using video recordings, and the collective discussion moments in the classroom were analysed. The results show how the teacher conducted the exploration of some particular numerical expressions to lead students to generalise the relationships underlying the structure of the calculation strategies. Thereby, using quasi-variable thinking, some students express the generalisation in natural language and start making a pathway to symbolisation.

Key-words: algebraic thinking, generalization, symbolization, quasi-variable thinking

INTRODUCTION

The development of algebraic thinking from the first years of schooling should be understood as a way of thinking that brings meaning, depth and coherence to the learning of other topics and has the potential of unifying the existing mathematics curriculum (NCTM, 2000). The recent Portuguese curriculum (Ministério de Educação, 2007) assumes that students should start to develop the algebraic thinking by using arithmetic as an entry point, as they work with generalizable regularities in numbers and operations and also by the study of figurative sequences.

The present paper aims to discuss how the use of quasi-variable thinking can contribute to the development of generalisation and to the beginning of symbolization process in grade 4 students. [1] Namely, we seek to understand: (i) How the exploration of computation strategies from particular numerical expressions leads the students to express generalisation?; and ii) How is generalisation starting to be expressed into symbolic mathematical language?

THEORETICAL BACKGROUND

According to Blanton and Kaput (2005), algebraic thinking can be regarded as “a process in which students generalise mathematical ideas from a set of particular instances, establish those generalisations through the discourse of argumentation, and express them in increasingly formal and age-appropriate ways” (p. 413). Considering the potentially algebraic character of arithmetic as one of the possible approaches for the development of algebraic thinking, the construction of the generalisation can be promoted through the exploration of numerical relationships and arithmetical

operations and their properties and, also, by developing the notion of equivalence related to the equal sign (Carpenter, Franke & Levi, 2003).

Rivera (2006) suggests that numerical systems should be taught in a way that students understand the numerical relationships and proprieties of individual objects and progressively realise that those are invariant independently from the considered objects. The regularities that students find on arithmetical operations can be the basis for the exploration of generalisation about numbers and operations and also to practices as the formulation, test and proof of the produced generalisations. In this way, particular numerical expressions can be used to work general relationships. Fujii (2003) uses the expression of *quasi-variable* to describe a “number sentence or group of number sentences that indicate an underlying mathematical relationship which remains true whatever the numbers used are” (p. 59). Within this perspective numbers, in generalizable numerical expressions, act themselves as variables that allow students to focus their attention in the expressions’ structure, and in identifying and discussing the algebraic generalisation before being introduced to formal algebraic symbology. This kind of quasi-variable thinking can provide an important bridge between arithmetic and algebraic thinking and, also, a gateway to the concept of variable (Fujii, 2003).

Britt and Irwin (2011) consider that algebraic thinking should provide opportunities for all students to work with several layers of awareness of generalisation. These authors suggest that a pathway for algebraic thinking develop in such a way that “students use three semiotic systems to express that generalisation: first they should work with numbers as quasi-variables, then with words and finally with the literal symbols of algebra” (p. 154). Similarly, Russell, Schiffer and Bastable (2011) advocate the introduction of algebraic notation when students already express their ideas into words and images allowing them to access the meaning of symbols. These authors contend that this new form of representation, not only provides a concise expression of students’ ideas, but also offers new ways of perceiving mathematical relationships.

In this paper, we also assume the conception of generalisation as a dynamic and social situated process that can evolve through collaborative acts (Ellis, 2011). In this perspective, the classroom situations are seen as multiple process of interaction “in which the students and the teacher co-contribute to the development of meaning through their talk, shared activity, and engagement with artefacts” (p. 311). This interactionist perspective includes both teacher-student and student-student interaction and allows researchers to take into account how shared ways of interacting promote the development of generalisation.

Cobb, Boufi, McClain and Whitenack (1997) designate *reflective discourse* as a kind of a classroom discourse in which mathematical activity is objectified and becomes an explicit topic of conversation. When students engage in a collective act of reflective discourse, they have the required circumstances for mathematical learning, and their individual contributions develop the discourse that supports and sustains

collective reflection. In that kind of activity, the teacher's role is very important because he "can proactively support students mathematical development" (p. 269). The relation between individual and collective learning is not a simple one, as the students' mathematical development emerges from the interactions and the cultural practices in the classroom but, it is "the individual child who has to do the reflecting and reorganising while participating" (p. 266) in the discourse. So, that reflexive discourse must support both individual and collective learning, and the teacher's role must respect these two dimensions.

METHODOLOGY

The results presented in this paper are part of a broader study, which focuses on the implementation of a year-long teaching experiment (Gravemeijer & Cobb, 2006) aiming to promote the development of algebraic thinking in one grade 4 class. The teaching experiment took place in the school year of 2010/11 and the mathematical tasks proposed to the class drew on the mathematical topics defined by the annual plan made by the school teacher. However, these tasks were innovative considering the usual teacher's practice as they accommodated the prospect of conceiving the algebraic thinking as guiding the syllabus (NCTM, 2000) through a logic of curricular integration. Focusing on some insufficiencies detected on students' number sense, we developed a sequence of tasks, aimed at the exploration of numerical relations and operations properties with the intention of promoting generalisation through natural language, and the beginning of a way towards mathematical symbolisation. The use of some informal symbolism was introduced in the tenth task, when the teacher-researcher proposed the use of the symbol "?" to express "what is the number that..." in expressions like "?x5=100".

In this paper, we focus on the moments of collective discussions in the classroom, after the students' work in pairs on two of the mathematical tasks in the teaching experiment (the 12th and the 14th). These tasks explored computation strategies with the goal of leading students to express the generalisation in natural language and to begin to express it in mathematical language. These were the first tasks where the teacher-researcher intentionally promoted the expression of generalisation into mathematical symbolic language. The lessons were videotaped, and from the analyses of the videos we choose the episodes that show how the teacher conducted the exploration of particular numerical expressions to foster the generalisation of the computation strategies involved in each of the tasks. These episodes show how some students are starting to use symbolic mathematical language in the sequence of the teacher-researcher's challenge.

RESULTS

The first task analysed in this paper - *Calculation using double* - explores the double and half relationships between the four times table and the eight times table. The

teacher's intention is that students explain the relationships and generalise the strategy in natural language, and then translate it to mathematical language.

“Calculating using doubles”

In Sara's class, students were calculating products:

I want to calculate 6×8 , but I can't remember 8 times table! Ah! But I know the 4 times table and I know that 6×4 is 24. So $6 \times 8 = 2 \times 24 = 48$

I want to calculate 12×8 and I know that 12×4 equals 48, so $12 \times 8 = 2 \times 48 = 96$

These students used the same strategy to calculate different products.

1. Explain their strategy.

Figure 1 - Task “Calculating using the double”.

In the collective discussion of the task, it was evident that the students understood the strategy, as they were able to provide some particular cases. Then, the teacher conducts the discussion with the goal of making the students extend the strategy beyond those cases in order to induce them to express it in a generalised way.

Teacher: Okay. We have three examples, but does this strategy only fit those examples?

Students: No.

Fábio: The strategy we used is good for all computations.

Teacher: And how can we synthesise that strategy in a clear way? What strategy was that?

Diogo: We made the double computation.

Teacher: The double of what?

Diogo: Double of the result. (...)

Teacher: Which multiplication table do we want to work on?

Students: The 8 one.

Teacher: And to work with the 8 times table, we used which multiplication table?

Students: The 4's.

Rita: We can use the halves.

Teacher: And what did we find out? I can construct the 8 times table using which one?

Students: The 4's.

In this episode, these students reveal that they understand that there is a property involved in the numerical equalities present in the task. But in this moment they still refer it as a procedure they can apply to all numbers. After that, a student, Rita, was able to express the computation strategy of generalisation beyond the particular cases, but still using a confusing and repetitive language. Having this in mind, the teacher asks if the expression should be simpler and clear, but still the students answer with examples: “To know 25×8 we do from 25×4 ” (Carolina). Then, she asks: “To know the 8 times table, what do I do?” and the students answer: “Double the 4 times table”.

From this moment on, one student proposes the generalisation of the computation strategy in natural language and writes it on the board: “To find out the 8 times table, we do the double ($\times 2$) of the 4 times table” (João). Several students show that they identify the underlying relationship between these two multiplication tables. After that, the collective discussion was conducted to enable students to express the generalisation in mathematical language. As this was the first time that students were confronted with this issue, the teacher attempts to make them understand what it means to write the generalisation in “mathematical language”.

Teacher: Now I want that you think about the sentence João wrote on the board and try to write it in mathematical language. How can we use mathematical language?

Students: With operations.

Teacher: So, how can I write that? But pay attention because I don't want particular cases like 6×8 , 12×8 or 25×8 , I want that to all numbers of the 8 times table and 4 times table.

Rita: We can do it to 7×8 .

Teacher: But that is a particular case. I want it to all cases.

Rita: How is that?

Teacher: To all cases in the 8 times table. What happens in the 8 times table?

Fábio: It is always plus 8.

Teacher: Ok, it's always plus 8. But if we use multiplication, what are we doing?

Students: We are always multiplying by 8.

Teacher: How can I write that?

Rita: We can use a question mark.

Fábio: Times 8.

The expression of generalisation in mathematical language was not immediate. First, the students tried to use particular examples. Then, the teacher conducted the class to use the structure of the computation strategy of the multiplication by eight to all cases. When Rita mentions the “question mark”, she uses the symbol that she knows

from the tenth task, briefly described before. Then, Rita went to the board and wrote the expression shown hereafter:

$$? \times 8 = 2 \times (? \times 4) = ?$$

Figure 2 – Generalising expression in mathematical language, made by Rita.

Instead of saying something about the correctness of the expression, the teacher suggests the substitution of the symbol by a specific number. In this way, she tries that students attach the meaning of that symbol and find out if the expression written by Rita was correct. Some students suggest the use of number 6 and then others numbers, and therefore, they find out that the expression was not correct. As a result most students express that they agree that the correct expression should not have the question mark at the end.

The *second task* analysed in this paper - *Afonso's strategy* - concerns the inverse computation strategy of the previous one: multiplying by five is equivalent to the half of the multiplication by ten. The particular case of 36×5 is proposed in the task as it follows:

“Afonso’s strategy”

Afonso wants to calculate this product:

$36 \times 5 =$

It's easy!
The answer is 180.
If I do 36×10 , I get 360, as 5 is half of 10, 36×5 is half of 360.

1. Is Afonso's answer correct? Explain his strategy.
2. Use Afonso's strategy to multiply other numbers by five.

Figure 3 - Task “Afonso’s strategy”.

In the beginning of the collective discussion of the task, the teacher asked the students to express that strategy in natural language. Several students did it without difficulty, expressing it in the following way: “To find out the 5 times table we make half of the 10 times table”. In spite of this, when the teacher requested the students to write the computation strategy in mathematical language, they still used particular cases. As in the first task, she stresses that she is not asking for particular cases but for a computation strategy that can be applied to “any number”. At that point, some students suggest the use of the question mark at the beginning of the sentence, and others a few other non-numerical symbols. The difficulties they face then have to do

with the representation of “half of any number”. Henrique suggests a creative representation by drawing a flower divided by half of it.

Figure 4 – Henrique’s attempt to express the generalisation in mathematical language.

But as this seems an odd representation to students, the teacher focused the students’ attention in the exploration of the particular case presented in the statement of task, 36×5 , revising the strategy previously discussed. As it was not expressed in mathematical language, but only in natural language, the teacher forwards the students to do it.

- Teacher: We had 36×5 ... What did we do?
 Rita: 35 times 10.
 Teacher: And then?
 Rita: We divided by 2.
 Teacher: So, how can we do it? Any number times 5 is equal to...
 Fábio: Is equal to half.
 Teacher: What did we do first?
 Gonçalo: We multiply by 10.
 Teacher: We multiply by 10... But is $36 \times 5 = 36 \times 10$ correct or not?
 Students: No.
 Gonçalo: No, then we made the half.
 Teacher: (...) And how can we represent half of it?
 Rita: Dividing by 2.

The teacher writes the expression $36 \times 5 = (36 \times 10) : 2$ on the blackboard, and then compels the students to write it for “any number, and not particularly for 36”, using Rita’s former representation: “ $? \times 5$ ”. In that moment, Rita says that now she knows how to do it and writes the expression in a symbolic way (fig. 5, left side). As the teacher asks for other possible representations for the question mark with the meaning of “any number”, Fabio proposes the use of a flower in the expression (fig. 5, right side).

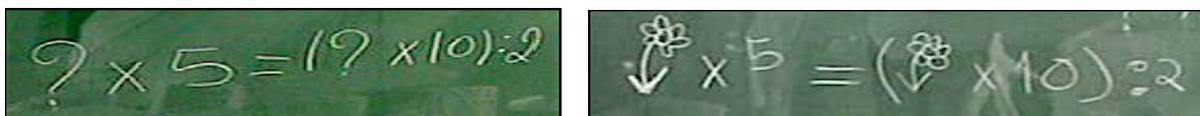

Figure 5 - Expressions of generalisation in mathematical language.

The teacher stresses that those symbols may represent any number and, at that point, Fabio mentions that: “This also works with others numbers. If you do flower times three equals six dividing by two. And also to four and eight, and to one and two”, showing that he can extend the computation strategies to others multiplication tables. This is an evidence of the student’s understanding of the structural property of the depicted strategy, and of the use of quasi-variable thinking in a general way.

FINAL REMARKS

This study shows that when students used particular numerical sentences regarding computation strategies they were able to identify the structure of those strategies and to express them in a more general way, as the teacher conducted the collective discussion with that intention. Actually, the computation strategies were explored in order to make explicit the underlying structure and to apply it to other numbers besides those used in the task’s statement, in the meaning of quasi-variable thinking (Fujii, 2003). In this way, representing the generalisation of the computation strategy in natural language was not difficult for students because they easily identified the operation involved and translated it in words, like when one student said “to find out the 8 times table we do the double of the 4 times table”.

However, when compelled by the teacher to generalise that relation in symbolic language, students had to create a new way to represent “any number” in order to represent all the numbers that satisfy the condition of the computation strategies, even in the restricted context of the multiplication tables. In a previous task, the teacher proposed the “question mark” to represent an unknown, but in the tasks analysed in this paper, she does not propose any symbol. It was one student, Rita, who suggested the “question mark”. In the second task, some students created other symbols to represent their idea of “any number”, using figurative representations like flowers. For instance, when they were first confronted with the need to represent “half of any number” in a symbolic way, one student shows some creativity by drawing half of a flower. This initial pathway in the use of symbols to express the idea of a general number shows that students were starting to construct their own sense and personal meaning for symbols, and were not simply reproducing rigidly the symbolism used by the teacher. In this initial phase it is important to give students the time to explore and create their own conceptions of the symbol. Although the results reported in this paper concern a very early stage of the teaching experiment, the later development of the study shows how that these initial tasks contributed to the development of the students’ ability to generalise and to use meaningfully symbolic mathematical language (Mestre, 2011).

It is clear from the collective discussion in the classroom that two students had a leading role in the discourse: Fabio and Rita. As we could see, when they participate in the discourse they contribute to raise the level of the collective discussion. As Cobb, Boufi, McClain and Whitenack (1997) argue as long as these students engage in discussions, they reflect and reorganize their action and their development was

explicit during the interaction with the teacher and other students. However, according to those authors, and in line with the conception of the generalisation as a collective process (Ellis, 2011), its expression in the classroom resulted from the engagement of several other students during the collective discussion. The teacher's role was crucial in this process as she promoted opportunities for students to express and to explore their ideas and conducted them to analyse the arithmetical expressions in a more algebraic way, allowing the construction of the generalisation.

The teacher's intention to have the students using symbols to express the generalisation of the depicted numerical strategies may not only contribute to assist them in expressing their ideas in a more concise way but also to foster new ways of perceiving mathematical relationships (Russell, Schiffer and Bastable, 2011). At the time of writing, we are still analysing the data from the teaching experiment and investigating this possibility, but in this paper we observe, for instance, that Fabio expands the arithmetic strategy explored from the written symbolic expression.

This study shows an alternative way to the traditional approach of arithmetic, in the Portuguese context, with the implementation of a new mathematics curriculum, which assumes the importance of algebraic thinking in the early years of schooling. By focusing the students' attention in the numerical relationships and in the study of properties of numbers and operations, they start to deal with algebraic ideas, developing also a deeper understanding of arithmetic. In this perspective, the use of quasi-variable thinking (Fujii, 2003), as it was evidenced in this study, can be a potential pathway for algebraic thinking since it can provide opportunities to work with several layers of awareness of generalisation (Britt & Irwin, 2011) starting from the arithmetic context which is familiar to students. The broader research from where this study emerges intends to add to the research on early algebra by showing that the exploration of quasi-variable thinking is a potential avenue to introduce algebraic symbols in young students even when their previous experiences with the mathematical generalization process were very restricted.

SYNTACTIC AND SEMANTIC ITEMS IN ALGEBRA TESTS – A CONCEPTUAL AND EMPIRICAL VIEW

Reinhard Oldenburg,^{*} Jeremy Hodgen,^{**} Dietmar Küchemann^{**}

^{*}Goethe University Frankfurt, ^{**}King's College London

In this paper, we draw a distinction between syntactic and semantic aspects of algebraic thinking. We examine the hypothesis that these two aspects can be distinguished empirically using test items. We present exploratory analysis of a test of algebra based on a large sample of students aged 11-14 in England and contrast this to a previous analysis of older German students (Oldenburg, 2009). This analysis indicates that there are considerable difficulties in operationalizing the distinction using test items, but suggests a potentially fruitful line of analysis may be to treat the semantic aspect as consisting of two sub-dimensions, based on whether one or many meanings or interpretations appear to be required.

INTRODUCTION

Although research on algebra education is now at a mature stage, many aspects of student progression and learning remain poorly understood. Of particular interest, is the relationship between the syntactic understanding of the rules and procedures involved in the manipulation of symbols and the semantic understanding required to interpret and attach meaning to symbols and rules. In a previous study, Oldenburg (2009) argued that test items could be constructed to measure and distinguish these two aspects of algebraic thinking. Using this distinction, he found that students can gain some level of proficiency in one aspect while being weak in the other, but that both aspects were necessary for a sophisticated understanding to develop. Whilst accepting the utility and validity of the syntactic / semantic distinction both to describe algebraic thinking and to inform pedagogy, the other two authors of this paper were sceptical about whether this distinction could be applied to items and whether such thinking could be measured using test instruments. The present paper is a result of the authors' subsequent debates and explores the meaning, usability and limitation of this pair of constructs. To do this, we analyse the performance of different items in an algebra test administered to a nationally representative sample of students in England.

THEORY: DISTINGUISHING SYNTACTIC AND SEMANTIC TASKS

If we consider algebra as a language, then, as with any other language, algebra can be thought of as having syntax and semantics, which must be applied to any use of the algebraic language, e.g. in communication and problem solving. Since thinking is to a large extent based on language, syntax and semantics can be viewed as aspects of thinking and understanding in general. In general, any algebraic thinking involves both aspects and hence distinguishing the two is not straightforward. Nevertheless, we contend that some algebraic tasks are more amenable to syntactic approaches,

whilst others are more amenable to semantic approaches. For the purposes of the present paper, we give the following working definition:

A syntactic task, or assessment item is one that can be solved by actions triggered by the syntactic structure of the expression alone without involving a mental model for interpretation, i.e. without having mental objects referred to by the symbols. For example, it is possible to solve the expansion of $(x+y)^2$ by purely syntactic thinking, because the pure lexical structure may activate the schema of the binomial theorem.

A semantic task, or assessment item is one in which the need for the interpretation of symbols (i.e. the construction of a mental model of objects denoted by symbols) is dominant in successful solutions. For example, in order to give a general expression that allows one to calculate the number of wheels a certain number of cars have, one has to activate semantic thinking to symbolize the number of cars by a letter and relate this letter in its domain of interpretation with the wheel number.

Syntactic tasks by this definition are those that can be successfully carried out by “term rewriting systems” as defined in computer science (Baader & Nipkow, 1999). Such systems cannot carry out tasks that require students to link the algebraic language with objects and concepts from outside mathematics. We contend that tasks that require at least a complete sentence in natural language are very likely to be semantic. We note that this definition is based on the anticipated processes that will be used when solving the items. Thus, in order to classify tasks as mainly syntactic or mainly semantic, one needs to anticipate the way that students tackle it.

We do not claim that our distinction between syntax and semantics is entirely unique, although other researchers’ definitions differ in some key respects. Most recently, the distinction has been used to analyse different approaches to, and aspects of, the production of proof (Weber & Alcock, 2004; see also, Iannone & Nardi, 2007). Weber and Alcock distinguish between “syntactic proof production”, by which they mean “one which is written solely by manipulating correctly stated definitions and other relevant facts in a logically permissible way”, and “semantic proof production”, by which they mean “a proof of a statement in which the prover uses instantiation(s) of the mathematical object(s) to which the statement applies to suggest and guide the formal inferences that he or she draws” (p. 210). One problem with this definition is that the precise meaning of both “stated definition” and “permissible way” is rather vague. However, Weber and Alcock’s approach shares with ours a concern for the importance of the domain of reference.

Kieran (1996) draws a distinction between ‘transformational’, or rule-based, activity, ‘generational’ activity in which the objects of algebra, expressions and equations, are formed, and ‘global, meta-level’ activity, which includes problem-solving and modelling. Whilst she argues that transformational activities are more often based on syntactic rules, she notes that they can in certain cases be legitimated by semantic arguments (e.g., transforming $1/(1-v/c)$ to $1-v/c$ in special relativity incorporates some physical assumptions). Further, although Kieran argues that much of the “meaning-

building” for algebraic objects takes place through generational activity, some generational activity can be largely rule-based (e.g., the generation of the polynomial sequence, $(x-1)^n$). Engelbrecht, Harding and Potgieter (2005) used the distinction between procedural and conceptual knowledge and found medium correlation. Note that this distinction is different from ours, as is explained in table 1. Neubrand and Neubrand (2004) draw a distinction between technical, or procedural, tasks and modeling tasks, which often require semantic, or meaning-based, constructions. However, they note that technical calculation tasks may require some meaning-based activity, particularly those involving longer algorithms. Similarly, modelling requires students to operate on symbols as well as constructing meaning for the symbols. Although neither Kieran’s nor Neubrand and Neubrand’s dichotomies are completely identical to the syntactic/semantic distinction, their analyses do serve to remind us that the distinction between syntactic and semantic tasks is somewhat blurred, specifically:

- Some items can be tackled both syntactically and semantically. For example, expanding $5 \cdot (x+2)$ may be done either by syntactic matching to the pattern of the distributive law $a \cdot (b+c)$ or by applying the semantic way of interpreting the expression as the area of a rectangle.
- A semantic approach may be helpful to help a learner self-correct the misapplication of syntactic rules. In the case of the expansion of $(x+y)^2$ referred to above, semantic thinking (by, for example, substituting some numbers for the symbols) can help avoid the common expansion error of x^2+y^2 .
- Even items that are mainly semantic in nature (e.g. “Explain the meaning of $2g+4r$ in some context”) involve at least the syntactic ability to read the expression. Here, one needs the semantic understanding that $2g+4r$ is a legitimate (set of) numbers/answer not just that the expression can be read as “2 times g added to 4 times r ”.
- Modelling tasks (i.e. generating an expression or equation to describe a situation or relation) require at least the minimal syntactic competence to write down the expression. So, while a mental distinction may be possible, it can be blurred as soon as the communication processes are required.

<i>Knowledge</i>	syntactic	semantic
procedural	Distribute $2 \cdot (x+y)$	Substitute values and calculate [1]
conceptual	Number of opening and closing bracket must be the same	Upon substitution for both x in $x+x$ must be replaced by the same value

Table 1: A comparison of syntactic/semantic and conceptual/procedural dimensions

One could argue that the entanglement of syntactic and semantic aspects within the domain of algebraic thinking is clear from the outset, e.g. one could read Lins and Kaput’s (2004) definition of algebraic thinking that way: “First, [algebraic thinking] involves acts of deliberate generalisation and expression of generality. Second, it

involves, usually a separate endeavour, reasoning based on the *forms* of syntactically-structured generalisations, including syntactically and semantically guided actions” (Lins & Kaput, 2004, p. 48). In fact, certain algebraic actions may be justified from semantic or from a syntactic perspective. Indeed we even more assume that this effect may depend on the development of algebraic thinking, i.e., we suggest that, as students’ algebraic thinking becomes more sophisticated, the thinking evoked may change and tasks that previously required semantic approaches may be solved using purely syntactic approaches. Moreover, the hypothesis that items (and not a particular student’s way of doing an item) can (at least to some extent) be classified as either syntactic or semantic assumes that typical students have a preferred way of tackling these problems. We note also that it is possible a students’ preferred approach may be strongly influenced by the teaching approaches adopted by their teachers. Hence, whilst it is possible theoretically to distinguish between syntactic and semantic aspects of algebraic thinking, it is not clear whether these aspects can be reliably distinguished empirically through test items. If the distinction can be used successfully at all, it must be applied to small focussed test items, not to larger problems as substantial mathematical activities usually span syntactic and semantic aspects.

METHODS

In this paper, we analyse the performance of different items on an algebra test originally developed in the 1970s as part of the Concepts in Secondary Mathematics and Science (CSMS) study (Hart et al., 1981). In 2008 and 2009, these tests were administered to a nationally representative sample of 5115 students in England aged 11-14 as part of the Increasing Competence and Confidence in Algebra and Multiplicative Structures (ICCAMS) study (Hodgen, Küchemann, Brown & Coe, 2009). These data were collected as part of a larger study and not specifically designed for the study reported here.

The focus of the CSMS/ICCAMS algebra test is on generalized arithmetic (Küchemann, 1981). Drawing on, and extending, Collis’s (1975) analysis of the different ways in which pronumerals can be interpreted, items were devised to bring out the following six categories (Küchemann, 1981): Letter evaluated, Letter not used, Letter as object, Letter as specific unknown, Letter as generalised number, and Letter as variable. We note that the test items were not developed specifically to address the syntactic / semantic distinction. Indeed, items in a category may involve syntactic or semantic approaches, although items in the two categories, ‘letter as generalised number’ and ‘letter as variable’, are more likely to be semantic.

The items were independently coded as syntactic, semantic or mixed by the three authors of this paper using only the definition of the categories given in the Theory section above, with mixed used for items felt to involve both aspect. Examples of classifications are given in figure 1 and 2. We assume that the classification in figure 1 can be easily agreed on, figure 2 presents items that are potentially difficult to classify. One may say that all of them have a syntactic appeal if attacked by replacing

one sub-expression by a part that is known to be equal. This is what puts 5a,5b into the mixed category (as there are references to concrete numbers as well which constitute the semantic aspect). In the case of 5c, however, we assume that plugging 8 for $e+f$ in the second equation is different from tasks the student may have met before, so that according to the above definition (“A syntactic task is one that can be solved by actions triggered by the syntactic structure of the expression alone.”) we miss the triggering effect to take place in the student that we assume to do the item.

The results of this initial coding exercise reflect the problematic nature of applying the syntactic/semantic distinction to items. The overall inter-rater reliability (3 rater, 3 categories) measured by Cohen’s kappa =0.54 which can, according to Landis and Koch (1977), be judged as moderate agreement. Inspection shows that this is mainly due to one rater who used the mixed classification a lot. Between the other two raters we find $\kappa=0.70$ which is a good inter-rater reliability. A final agreed classification was developed through discussion. In this final classification, of the 51 items in total, 18 were coded as syntactic, 25 as semantic, and only 8 as mixed.

13. $a + 3a$ can be written more simply as $4a$.

Write these more simply, where possible:

$$2a + 5a = \dots\dots\dots$$

$$2a + 5b = \dots\dots\dots$$

$$(a + b) + a = \dots\dots\dots$$

$$2a + 5b + a = \dots\dots\dots$$

$$(a - b) + b = \dots\dots\dots$$

$$3a - (b + a) = \dots\dots\dots$$

$$a + 4 + a - 4 = \dots\dots\dots$$

$$3a - b + a = \dots\dots\dots$$

$$(a + b) + (a - b) = \dots\dots\dots$$

Figure 1: All nine items in Question 13 were coded as syntactic

$$5. \text{ If } a + b = 43$$

$$\text{If } n - 246 = 762$$

$$\text{If } e + f = 8$$

$$a + b + 2 = \dots\dots\dots$$

$$n - 247 = \dots\dots\dots$$

$$e + f + g = \dots\dots\dots$$

Figure 2: The first two items in Question 5 were coded as mixed; the third item ($e+f+g=$) was coded as semantic.

REVISITING OLDENBURG’S ORIGINAL FINDINGS

Oldenburg’s (2009) original paper reports findings from a different algebra test performed with 11th graders (aged 16) in Germany. This test included many items from the ICCAMS test together with items on more advanced symbolic manipulation (e.g. simplifying square roots) and on real world applications (e.g. translating between real world contexts and algebra). The test data from 2008 indicated a rather low correlation of $r=0.33$ between syntactic and semantic items. In the meantime this test has been conducted with many more students and higher correlations in different

groups up to $r=0.54$ have been found. From comparing these various groups one can deduce the rule that the correlation is higher in higher achieving schools. This result cannot be explained by a ceiling effect as even in the weakest group facility (i.e. the fraction of correct answers) on syntactic and semantic items has been 33% resp. 53% so that no ceiling effects that would reduce the correlation have to be anticipated.

One potential explanation for these low correlations is that it may be that any arbitrarily chosen groups of items of similar facilities would tend to have a similarly low correlation. In order to test this hypothesis, we performed a bootstrapping process on the data from Oldenburg (2009). [2] This produced a large set of randomly chosen scales with a higher average correlation of 0.64 (standard deviation 0.062). We conclude that the selection of syntactic items is not arbitrary.

EXAMINING THE PERFORMANCE OF SYNTACTIC AND SEMANTIC ITEMS

We now consider our analysis of the 2008/9 ICCAMS dataset. The scales or item groups for both syntactic and semantic groups were found to have good internal reliability: Cronbach's alpha was 0.87 for the syntactic scale and 0.86 for the semantic scale. However, in sharp contrast to the original study, the correlation between the two scales was $r=0.75$ rising to $r=0.78$ (when blank responses are treated as incorrect rather than missing).

First, the difference may indicate some sample dependence. For example, the relationship between syntactic and semantic approaches may be influenced by the different curricula and pedagogic approaches in England and Germany. Second, as described above, we aimed to code as many items as possible. It is clear that this approach may tend to classify 'mixed' items as either syntactic or semantic. This may be reflected in the difficulties that we encountered in the coding process. Third, unlike Oldenburg's (2009) study, the ICCAMS test items were not specifically designed to assess the syntactic / semantic distinction. In fact, the ICCAMS test was not specifically designed to examine the syntactic/semantic distinction but sought to use items that use "problems which were recognizably connected to the mathematics curriculum but which would require the child to use methods which were not obviously 'rules'." (Hart & Johnson, 1983, p.2). As a result, the test items may be biased towards syntactic items that require some semantic thinking.

To investigate the second and third of these points, we reduced the syntactic scale to a core of 9 syntactic items originally coded as syntactic by all three authors. This reduces the correlations to 0.66 (or 0.69 with missing values treated as incorrect). However, a similar process of elimination from the semantic scale does not bring the value further down, so that still the explanation is not satisfactory. We propose an explanation that is related but not identical to aspects and uses of letters as symbols.

In mathematical logic (cf. Turlakis 2003, p. 53) semantics is defined using interpretations. An interpretation of a set of formulae of predicate calculus is given by a set S (the domain of the interpretation) and an assignment that gives an element of

S for every occurrence of an unbound variable in the formula, and functions and predicates over S for every function and predicate symbol in the formulae. After applying all these assignments the formulae reduce to statements in the domain with no unbound variables remaining. For working with specific numbers it is thus enough to consider one interpretation, but to prove that a formula is a tautology one has to show that it is true in all interpretations. This distinction is crucial for learners. Küchemann (1981) has carefully drawn the distinction between an understanding of letters as specific unknowns and a more sophisticated understanding of letters as generalized numbers or variables. We suggest that the former, although semantic, requires the learner to consider only one possible interpretation or meaning, while the latter requires one to consider multiple interpretations. This suggests that treating the semantic scale as one-dimensional may not be justified. Thus we split up the semantic scale into two:

- **SES – *Semantics with single interpretation***: These are items that require only one interpretation to be considered. Thus they can be solved by mentally replacing the x by one number. A key example is the item: Write down the smallest and the largest of these: $n + 1, n + 4, n - 3, n, n - 7$
- **SEM – *Semantics with multiple interpretations***: These items can only be solved if multiple interpretations of the variable are considered. A key item is: Which is larger, $2n$ or $n + 2$?

This gives the following correlations:

<i>r</i>	SYN	SES	SEM
SYN	1	0.87	0.50
SES		1	0.55

Table 1: Correlations between syntactic and two kind of semantic items

If one replaces SYN by the core of transformational items then the correlation SYN-SEM goes down to 0.45 and of SYN-SES to 0.71. Again with the standard definition of SYN, one observes an interesting dependency of the correlation SYN-SEM which is for students aged 12, 13 and 14, respectively, 0.45, 0.47, 0.54. This is consistent with the observation made above that the test from Oldenburg (2009) shows higher correlations in better performing schools. Our interpretation of this is that it is possible to gain a certain level of facility with either syntactic or semantic items without understanding the complementary aspect, but that higher achievement levels (as typically reached by older students) require a tighter integration of both aspects.

This suggests – although one should keep in mind that this claim has no broader base than the one presented – that a simple dichotomy between semantic and syntactic item may be useful as a first approximation but blurs some important distinctions. The three scales defined above seem to better model the cognitive structure of students.

In order to examine this hypothesis further, we performed a structural equation modeling of the situation with SYN, SES and SEM as latent variables. Fitting such a

model enables the identification of items that do not fit well into a scale. [3] The resulting model showed a good model fit (RMSEA=0.047, CFI=0.37). See Figure 3.

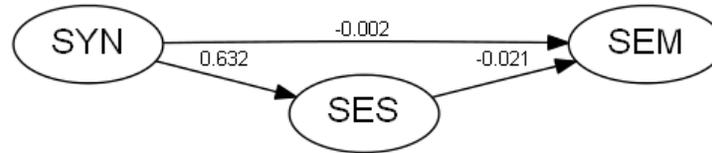

Figure 3: The structural model of three latent variables

The model equations were as follows:

$$\text{SES} = 0.63 * \text{SYN} + \text{error (1)}$$

$$\text{SEM} = -0.002 * \text{SYN} - 0.011 * \text{SES} + \text{error (2)}$$

Equation (1) suggests that there may be a bridge from understanding the syntax of expressions to the ability to use it with specific (although unknown) numbers in one interpretation. One might conjecture that applying the interpretation (of letter as a specific but unknown number) requires at least the syntactic ability to plug in values for letters and evaluate the result. Equation (2), on the other hand, suggests that a fuller semantic understanding may develop relatively independently of syntactic and semantics with a single interpretation. [4]

CONCLUSION

As we have seen, there are considerable methodological issues in operationalizing the distinction between syntactic and semantic modes of thinking in existing test items. We found the process of coding the items to be problematic. This difficulty is reflected in the theoretical literature where the two modes are not treated as entirely distinct. Our initial approach was to attempt to code as many items as possible as either syntactic or semantic. On this basis, our analysis of the English data suggested that these data do not show the same pronounced distinction between syntactic and semantic items as was previously reported for the German data (Oldenburg, 2009). We have hypothesised possible reasons for this, such as some interdependence with different country curricula. In addition, the two samples were of different ages and it may be that the classification of items as syntactic or semantic may be age-related. Our analysis also suggests that the semantic scale may not be uni-dimensional. By classifying the semantic aspect into two sub-dimensions, based on whether one or many meanings or interpretations appear to be required, we found a relationship between syntactic and semantic items based on a single meaning, but not between either and semantic items requiring multiple interpretations. We emphasise, however, that this is exploratory analysis and further studies are needed to explore these questions deeper. Nevertheless, our analysis suggests that it may be possible to identify syntactic and semantic abilities using test items. We note, however, that this may require items designed specifically for this purpose.

NOTES

1. We are emphasising that the choice of numbers to substitute involves semantic processes.

2. The bootstrapping was conducted as follows. We drew 10,000 samples of groups of seven and 30 items, exactly the same size as the syntactic and semantic groups in Oldenburg's (2009) study. Samples were retained if the average facility was within 15% of the average facility in the syntactic (33%) and semantic (53%) item groups and otherwise discarded. The average correlation was calculated on the basis of all the retained samples.
3. We used the R package lavaan using a polychoric covariance matrix (calculated with the R package polycor) in order to compensate for the binary indicator variable used here. The binary coded items were used as indicator variables with free weights that the three latent variables load on. The variance of the latent constructs was fixed to be 1.
4. The fact that both weights are negative is not important because both numbers are very small and don't differ from 0 significantly (standard errors are 0.026 and 0.021 for the first and second coefficient, respectively).

IMPLICIT LEARNING IN THE TEACHING OF ALGEBRA: DESIGNING A TASK TO ADDRESS THE EQUIVALENCE OF EXPRESSIONS

Julia Pilet

Laboratoire de Didactique André Revuz, Paris-Diderot University, France

Laboratoire Education et Apprentissages, Paris-Descartes University, France

In this paper, I assume that, in addition to the conceptual difficulties, some difficulties encountered by students, especially in elementary algebra, are generated by learning needs left implicit or unknown, inasmuch as they are not addressed within the learning institution. According to (Pilet, 2012), the equivalence of algebraic expressions, which plays an important part in managing, checking and anticipating algebraic transformations, is one type of learning left implicit in the French curriculum. After situating my work around the equivalence of algebraic expressions, I present a learning situation to address this notion which seems to be absent in curricula, then I analyze the implementation of this situation in a classroom.

Keywords: implicit learning, equivalence of algebraic expressions, school algebra

ORIGIN OF THE STUDY

My question about the existence of implicit learning needs which is left out in the teaching of algebra in France stems from a larger line of questioning addressed in my PhD thesis (Pilet 2012): what learning materials should be given to teachers to help them manage difficulties encountered by students in school algebra, and develop the students' personal relationships with algebra? I made the following assumption: in addition to the conceptual difficulties, *some difficulties encountered by students* in algebra may be intensified by the fact that students learn within institutions (Chevallard, 1999) where learning needs are left implicit or unknown, inasmuch as they are not addressed within the learning institution (Bosch, Fonseca, Gascon, 2004; Castela, 2008). Using an epistemological, cognitive and anthropological approach, I have shown in my thesis that the equivalence of expressions is one of these implicit learning needs in the French secondary school curriculum. However, a number of students seldom refer to the possibility of describing the same mathematical object using several algebraic expressions. Hence my question in this paper: What learning situation should be designed in order to allow students to tackle the equivalence of expressions? In this paper, I consider polynomial algebraic expressions.

After situating my work around the equivalence of algebraic expressions, I describe a learning situation¹ that I have designed to address this notion to students of a grade 9 class (14 year-olds) in France. Then, I analyze the classroom experiment of this situation. Finally, I use these analyses to reconsider my conceptual choices and

question the necessary conditions under which this situation can exist in a regular classroom.

EQUIVALENCE OF ALGEBRAIC EXPRESSIONS

The notion of equivalence of expressions is present in several studies. In this section, I develop the approaches of Frege (1971) and Kieran (2007).

Frege: *sense and reference*

Equivalence of algebraic expressions refers to the distinction established by Frege (1971) between *Sinn* and *Bedeutung*, usually translated, respectively, as *sense* and *reference*. This distinction was re-used in didactics of algebra works for example by Drouhard (1992). A mathematical object has a unique denotation but may have different senses. For example, the expression $4(x-1)$ can be transformed as $x^2-(x-2)^2$ or as $4x-4$. These expressions have different *senses* (for example, they have different structures or they have different interpretations in geometry). They have the same *reference*, that is to say, they *refer* to same object (for example, evaluated for the same numerical values, they have the same values). Algebraic transformation is a subtle process of shifting between *sense* and *reference*. The choice of transformations of expressions is checked by *sense* (the final goal, for example, choosing the expression that can be best used for an equation) but respecting the written *reference* is an indispensable criteria. When one expression is transformed into another, we obtain two equivalent expressions. They are equal for all values, they have the same *reference*.

For many students, however, the conservation of *reference* during the transformation of an expression is unknown or absent. For instance, when a teacher addresses a common error $(x+4)^2=x^2+16$ and uses a numerical counter-example (for $x=1$, $(1+4)^2=25$ is different from $1^2+16=17$), students may not be convinced because the argument used (implicitly) refers to the conservation of *reference*. Similarly, when a teacher suggests the identity $(a+b)^2=a^2+2ab+b^2$ to replace the student's $(a+b)^2=a^2+b^2$, there can be a misunderstanding. The teacher is referring to *reference*, while for students it may seem to be a "choice" made by the teacher.

Kieran: equivalence of expressions as a theoretical control

From an international synthesis of research related to the learning of algebra, Kieran (2007) puts the equivalence of expressions at the core of the theoretical elements of transformational activity (factorization, expansion of products, rules for solving equations and inequalities, etc.).

"One resource of algebra is a rich plurality of symbolic forms; one core notion, that of equivalence. Equivalence and transformation are linked notions, indicating sameness perceived in difference for some purposes, or indifference with respect to others? The existence of multiple expressions "for the same thing" can suggest the very possibility of transforming expressions directly to get from one to another." (Kieran 2007, p.722)

According to Kieran, equivalence of expressions has a fundamental role in theoretical control, ensuring that the transformed expression is equivalent to the second. This verification can theoretically be done in two ways: either by reference to the properties of algebra used or by linking with numerical and substituting numerical values for letters. However, students have a great deal of difficulty in identifying the properties they use when they transform algebraic expressions (Kieran, 2007). Moreover, in France, students have difficulty making the link between transformation of expressions and substitution of numerical values. Students have difficulty making connections between the arithmetical and the algebraic world.

The equivalence of expressions appears in these studies as an indispensable theoretical element of the conduct and checking of algebraic calculations. This point of view is adopted in several research works. For example, in the computing environments *Algebrista* of Cerulli and Mariotti (2009) and *APLUSIX* of Nicaud (1994), the equivalence intervenes to theoretically control algebraic transformations. Alternative points of view on equivalence are developed in other works for example (Zwetschler and Prediger, 2013).

EQUIVALENCE OF ALGEBRAIC EXPRESSIONS: AN IMPLICIT LEARNING IN THE FRENCH CURRICULUM

In Pilet (2012), I analyzed the curriculum and several secondary school textbooks in France (for 14-15 year-olds) in order to identify the presence of equivalent expressions as a theoretical element of the transformation of expressions. The French secondary school curriculum addresses in a formal setting how to develop, factorize and simplify expressions as a goal in itself. The ideas of getting students to perceive the fact that two different expressions may represent the same object, and the idea of checking calculations, are not included in the curriculum and very rarely appear in textbooks. The equivalence of algebraic expressions is one type of learning left implicit in the French curriculum, inasmuch as its teaching is not addressed within the learning institution. Nevertheless, students are powerless when conducting and checking algebraic transformations, as they do not refer to the possibility of describing the same mathematical object using several algebraic expressions. Hence, I have designed a learning situation which aims at leading students towards understanding the fact that two expressions may denote the same mathematical object. This learning situation is presented in the next section.

DESIGN OF A LEARNING SITUATION

Context and methodology

This study is part of a larger research project, the project PépiMeP², which consists in developing resources (assessment, learning situation, interactive exercises) for diagnosis and differentiation of teaching about the learning of algebra towards the end of compulsory education the learning situation presented in this paper has been designed in this context. We present two components.

To start with, in this project learning situations are developed for a differentiated teaching. Teaching is differentiated in the following way: the learning objective is the same for the whole classroom—all students work on the same type of tasks—but the task is adapted to students' learning needs as identified by the diagnostic assessment *Pépité*² developed in PépiMeP project. In this article, the described situation focuses on the goal "Study of equivalent expressions". It is differentiated according to the specific student groups B and C established by Pépité. The differentiation in the learning situation presented in this paper is about the complexity of the algebraic expressions. Since differentiation of teaching is not of main interest in this article, I will not go further into our choices here. For more information, please see (Delozanne and al., 2008; Pilet, 2012; Grugeon and al. 2012; Pilet and al., 2013).

Secondly, I worked throughout the 2011-2012 school year in collaboration with several secondary school teachers to test the viability of our proposals in ordinary classrooms. The situation presented here was designed with these teachers. The choice of algebraic expressions, the tasks' decomposition and the predicted teaching scenario were discussed. Each situation was analyzed a priori and then tested in class by these teachers. Each experiment was analyzed a posteriori to retrace our design choices. The experiment that I present in the next section was conducted by one of these teachers.

The learning situation

The situation is shown in Figure 1. It is designed for students in a *grade nine* class (14 year-olds) in France. The learning situation focuses on the fundamental question: What are equivalent expressions? Given that the curriculum doesn't deal with the notion of equivalence, I ask students the following question: "Are these expressions equal for any value of x ?"

We would like to know if the following three expressions are equal for all x :

B Group				C Group			
<ul style="list-style-type: none"> • A: $(x-1)^2-4$ • B: $(x+1)(x-3)$ • C: $x(x-2)-x^2-2$ 				<ul style="list-style-type: none"> • A: $(x+2)^2-4$ • B: $x(x+4)$ • C: $9x-6$ 			
x	$(x-1)^2-4$	$(x+1)(x-3)$	$x(x-2)-x^2-2$	x	$(x+2)^2-4$	$x(x+4)$	$9x-6$
1				2			
-1				3			
0				0			

- 1) Complete the first two rows in the above table. What can you guess about the equality of these expressions?
- 2) Complete the third row in the above table. Does this confirm your conjecture? Otherwise makes a new guess.
- 3) Are the three expressions equal for any x ? Justify. Does your guess hold up?

Figure 1. A learning situation "Study equivalent expressions"

In order to lead students towards understanding the fact that two equivalent expressions have the same reference, two changes of frame ("cadre" in French) (Douady, 1986) are possible: a change from the algebraic to the numerical frame and a change from the algebraic to the functional frame. The first consists of

implementing a numerical framework to evaluate the equivalent expressions for the same numerical values. The second consists of using a graphical framework to compare the representative curves of functions defined by algebraic expressions. In accordance with the French curriculum of grade 9, we chose the numerical framework.

Given that the students in groups B and C take little into account the equivalence of expressions to guide and control the algebraic transformations, the first challenge is to make sense of the fact that two expressions can be equal to any value of the letter. Therefore, the equivalence of expressions is first conjectured from numerical substitutions and proven from algebra. I now present the *a priori* analysis of the situation.

***A priori* analysis**

The learning situation consists of three questions. Three expressions are given. Expressions A and B are equivalent but not C.

The first two questions require students to make a conjecture about the equality of the expressions for any value. This step is absolutely necessary in order to bring students to understand that two different expressions can be equal to any value. In question 1, students test expressions for two numerical values chosen so that they return the same number. This leads them to formulate an initial hypothesis: the expressions are equal for any value of the letter. Then, in question 2, a third test provides a counterexample of the equivalence of expression C with A and B. A new conjecture about the equality of any value of expressions A and B can be formulated. The use of numerical tests aims to highlight the fact that the expressions either do or do not produce the same number. The layout of these tests in a table of values is a vital aspect of the task. It emphasizes the fact that two expressions can have the same *reference*. Question 3 requires students to prove this conjecture. It involves algebraic proof and the use of a numerical counterexample. In fact, students are expected to use a counterexample to prove that expression C is not equivalent to A and B. To prove the equivalence of A and B, a development is expected. In order to do this, students must detect the structure of the expressions and choose the correct rule to apply.

This task is unusual in the current curriculum. First of all, the link with numbers in order to test the expressions is seldom used. In addition, students are responsible for recognizing which properties to use and for deciding to transform expressions A and B so as to prove their equivalence. The proof task forces students to finalize the algebraic transformations and to justify them, which they do not do in the technical exercises.

The teacher plays an important role in helping students understand the limitations of numerical calculation and to prove the equivalence algebraically. After noticing that expressions A and B are equal for several values, some students may suggest an incorrect technique, such as “the expressions are equal for one or two values so they all are equal”. The teacher is expected to rely on quantification in order to counter

them: “we want a proof for any value”. The use of quantification can help students understand the necessity of proof and use algebraic calculations. The teacher may highlight that it is impossible to numerically test every possible value. Although requiring formalism is obviously not one of the task’s goals, it remains a key component of students’ being able to master the notion of equivalence of expressions.

The predicted teaching scenario involves individual work phases and collective debate phases. The fact that groups are working on different expressions is an opportunity to decontextualize the task. At the end, the institutionalization focuses on reference of algebraic expressions with the fact that two algebraic expressions can be equal for any values and the transformation of one into the other is controlled by the rules of algebra. In the next section, we discuss the implementation of this learning situation in a classroom.

EXPERIMENT

Data gathering in experiment

This learning situation was experimented in a *grade 9* class (14 year-olds) in France. The experiment’s protocol was specific to the PepiMeP research project. The teacher first had her students take the *Pépîte* diagnostic assessment. Her class was divided into two groups: the C group (15 students) and the B group (6 students). She covered content related to algebra by introducing a new property of the calculation ($(a \pm b)^2 = a^2 \pm 2ab + b^2$ and $(a+b)(a-b) = a^2 - b^2$) and by developing several generalizations and proof problems. The learning situation illustrated in Figure 1 is found at the end of the chapter on algebraic expressions. It was completed during a 50-minute class period. I filmed, recorded and translated³ individual and collective discussions between the teacher and her students.

Data analysis

The data analysis is based on the a priori analysis. Therefore, I analyze the data in several ways. First, I study the verbal exchanges about questions 1 and 2 in light of the following question: to what extent does the learning situation and its management by the teacher allow students to approach the fact that two different expressions evaluated for any number can have the same value? Then, I study the talks verbal exchanges about question 3 in light the following question: how does the teacher lead students towards understanding the limitations of numerical tests and producing an algebraic proof for the equivalence of A and B? These analyses are presented in the next section.

***A posteriori* analysis**

Questions 1 and 2: Conjecture and reference of expressions

At the beginning, the teacher quickly informed students of the lesson’s goal: “We’ll be working on equal expressions.” She emphasized substitution with numerical values, but did not reveal the goal of this substitution. This may explain why at the beginning students focused on the simple and isolated task of substitution by a

numerical value. Errors appeared such as ignoring rules for parentheses and the order of operation. Hence, the teacher allowed the use of calculators. It spared students some of the numerical calculations work. As illustrated in the following extract, students focused more on the task's ultimate goal: conjecture about the equivalence of expressions.

This is an extract from an exchange between the teacher and a pair of students in group C about question 1. Students have completed the table of values (Figure 1). They found 12 for the first line and 21 for the second for A, B and C.

Chloé: But **in fact, it should give the same results everywhere?**

Teacher: Well, sometimes it... ? [to Yann] Ok. So, what did you get, here? 12, 12, 12. And here, 21, 21, 21. So, in theory, what should we say, then?

Yann: That they... they... they are all equal.

Teacher: Yeah. The expressions are equal.

Yann: But I don't know.

Students were surprised by the fact that different expressions can have the same value when they are evaluated for the same number. The teacher leads them to conjecture the equivalence of the three expressions and to change this conjecture with question 2. Thus, the choice of appropriate numerical values and the presence of a table of values are sufficiently robust to allow students to approach the reference of expressions. However, in group exchanges in the classroom, the teacher does not return to the fact that the expressions A and B have the same numerical values when evaluated for the same number. We may wonder if this has been sufficient for students to reinvest in other cases.

Question 3: From conjecture to algebraic proof

To lead students towards understanding the limitations of numerical tests and the necessity of algebraic proof of the equivalence of A and B, the teacher used, as expected, the quantification. Here is an extract to illustrate.

Teacher: No, we don't know, do we? We just showed that it was true for two values. It doesn't necessarily mean **that it was true for all values**. So, now, you calculate for x equal to zero. [...] Here we are. So, let's go, explain that! And so, your third expression, what is it? You will have to prove **that all of those expressions are equal for any value**. So, what are you going to use to be able to prove that these expressions are...?

In addition, quantification has played an important role in an attempt to show students the limits of their own technique: "it is true for two values so it must be true for all values".

Teacher: How did you manage, Ina, to prove...? Does the table allows us to assert that the expressions are equal?

Students: No.

Ina: Well, yes, because...

Théodule: No. Because we didn't use the distributive property.

Teacher: I do agree with you. Here, we find out that these are the three same values. But if you find out that both expressions are equal for three values can you assert that **they are equal for any value**?

Students: No.

Teacher: No. So, how can you manage to prove that your expressions **are equal for any value**?

Ina: Well... we calculate again.

Teacher: We should calculate again for another value?

Ina: Well, yes. Well...

Teacher : If you calculate again for another value, **it will mean that they are equal for four values. You, you want to prove that they are equal for any value.**

After several individual or collective exchanges, the teacher led her students to understand the necessity of the algebraic proof. However, students have a quite difficult time recognizing the structure of the expressions and the properties to be applied which leads to many errors in algebraic transformations.

DISCUSSION AND PERSPECTIVES

To conclude with, I return to the goal of the learning situation. Did it successfully lead students to understand the *reference* of algebraic expressions, and thus recognize equivalent expressions? Given that our analysis is only a case study, the conclusions to be drawn from it should be limited.

The choice of appropriate numerical values—the table of values—allowed students to understand the fact that expressions can produce the same number. I believe, however, that presenting a table of values with infinitely many numbers when the teacher asks students how they approached the problem could have reinforced students' understanding of the situation. The use of a spreadsheet in collective phases could play an important role in emphasizing the *reference* but differs too much from teachers' current practices. The analysis of discussions shows that the *reference* and the equivalence of expressions could be due to numerical conjecture, but the teacher did not suggest it again in question 3 or during the institutionalization. The institutionalization dealt with part of this content. The technique of numerical conjecture and algebraic proof, aiming to prove that two algebraic expressions are equal (or unequal) for any value of the letter, was presented. But the teacher did not add anything that might help students draw conclusions about the *reference* of

expressions. The fact that algebraic expressions with two different written forms give the same number for any value was not presented.

This experiment shows the real potential of the designed task, as long as work has been done beforehand with teachers emphasizing their role and the task's goals. Readers should keep in mind that the designed task involves very few aspects of the current French curriculum (equivalence, links with numerical or quantification) and is quite different from teachers' current practice. The implicit learning that is essential to educational algebra needs a long period of preparation with teachers regarding two points: on one hand they must be aware of the links between implicit or ignored learning and students' difficulties in algebra and, on the other hand, they must develop their algebraic teaching practices. For this reason, I continue to work collaboratively with teachers to accompany the task with a discussion of the didactical issues at hand and their management in the classroom.

NOTES

¹ The term of “learning situation” is taken in this paper in a common sense.

² At present, the *Pépîte* software is developed in PepiMeP project which consists of implementing computer resources in *LaboMep* platform, which has been developed by *Sésamath* to help teachers to differentiate students' learning in elementary algebra. Ile-de-France Region supports the project. *Sésamath* (<http://www.sesamath.net/>) is a French mathematics teachers' association, which has a central place in French online database systems. More information is given in a paper in working group 15 (Pilet et al., 2013).

³ In this paper, I translated transcripts from French to English.

ACKNOWLEDGMENT

I wish to thank my PhD supervisor, Ms. B. Grugeon-Allys, I would also like to thank the Ile-de-France region and the L.D.A.R. for funding my contribution to CERME.

STUDENTS' DIFFICULTIES WITH THE CARTESIAN CONNECTION

Valentina Postelnicu

Arizona State University

The purpose of the study was to gain insight into students' difficulties with linear functions, particularly epistemological obstacles with the Cartesian connection, the connection between the symbolic and graphic representation. Two cross-sectional studies were conducted, one with secondary school students (Grades 8-10), and the other with college students. Participants completed several tasks and commented on their difficulties and successful algorithms. Interviews were conducted with some of the participants. Data analysis revealed that students performed poorly on tasks referring to the Cartesian connection. Moreover, findings suggest that even the few students who were successful at solving the tasks did not have the necessary mathematical principles and coherence to organize and advance their structures of knowledge.

Keywords: Epistemological obstacles, Cartesian connection, linear functions

SIGNIFICANCE AND PURPOSE

Among the key algebraic concepts are linear functions (National Mathematics Advisory Panel, 2008). During the last two decades, student difficulties with linear functions have been studied by many researchers (Knuth, 2000; Lobato & Siebert, 2002; Schoenfeld, Smith III & Arcavi, 1993; Stump, 2001; Zaslavsky, Sela, & Leron, 2002). Despite their efforts to gain insight into student difficulties and assist mathematics educators in implementing curricular and instructional changes, American students' difficulties with linear functions persist (American Diploma Project, 2010). Previous studies showed the importance of the Cartesian connection for student understanding of linear functions. The Cartesian connection states that a point (x_0, y_0) is on the graph of the line l if and only if its coordinates satisfy the equation of l , $y = mx + b$ (Schoenfeld et al., 1993), given that all the mathematical conventions associated with graphing in a Cartesian system of coordinates are respected.

The purpose of the studies reported here was to identify students' difficulties with the Cartesian connection, of interest being the “epistemological obstacles which occur because of the nature of the mathematical concepts themselves” (Cornu, 1991; Sierpinska, 1992), or those difficulties with knowledge that works satisfactory in old contexts but fails in new contexts (Brousseau, 1983). Results from two cross-sectional studies are used.

OVERVIEW OF THE FIRST STUDY

The first study (Postelnicu, 2011) was conducted with 1561 students, Grades 8-10,

enrolled in mathematics courses from Pre-Algebra to Algebra II [1], and their 26 mathematics teachers. All participants completed a Mini-Diagnostic Test (MDT) on aspects of linear functions, and commented on the nature of their difficulties. The MDT tasks, illustrating connections between various representations of linear functions, were those used by Greenes, Chang, and Ben-Chaim (2007) in their study with Algebra I students from United States, Korea and Israel. Across the three countries, the most difficult tasks were those requiring the identification of slope from the graph of a line. Students' difficulties with slope formula and the change in y and the change in x represented as line segments with oriented magnitudes is seen by Schoenfeld et al. (1993) as an example of missing the Cartesian connection. American students also had difficulties determining whether a given point (x_0, y_0) is situated on a line, given the equation of the line, $y = mx + b$, in tasks that illustrate the Cartesian connection from point to line (Postelnicu, 2011).

After completing the MDT, two students from each of the 20 teachers who agreed to be interviewed were selected by the researcher and invited for interviews. In each pair of students, one student had the MDT total score above the group median, and one student had the MDT total score below the group median. Semi-structured interviews (Goldin, 2000) with think-aloud protocol were conducted. Students were asked to present their solutions to the MDT tasks and comment on their mathematical difficulties. Student interviews were coded using open coding at the level of paragraph (Strauss & Corbin, 1998) and analyzed using the Linear Conceptual Field (LCF) framework, a theoretical framework inspired by Vergnaud's theory of conceptual fields (Vergnaud, 1994). The Linear Conceptual Field (LCF) consists of:

- i) Situations that can be modeled mathematically using linearity or linear functions (e.g., the car movement from Task 3, below). These situations reflect the current Intended Curriculum (Robitaille, 1980), namely what Wu (2011) calls the Textbook School Mathematics.
- ii) Schemes of actions, and theorems in action needed to solve problems. Vergnaud's construct of scheme of action and the mechanism of knowledge development are borrowed from Piaget's genetic epistemology (Piaget, 1971). Some schemes of action, used to correctly solve a problem, are in fact algorithms for solving the problem. For example, one successful algorithm for Task 4 (below) has the following steps: 1) substitute the coordinates of the given points (x_1, y_1) and (x_2, y_2) into the equation of the line $y = mx + b$, and 2) solve the system of equations
$$\begin{cases} y_1 = mx_1 + b \\ y_2 = mx_2 + b \end{cases}$$
.
- iii) Concepts of linearity and linear functions (e.g., the concept of slope in geometric-analytical context in Tasks 2 and 3 below), and ways of thinking (e.g., quantitative reasoning).
- iv) Representations of linear functions (e.g., tabular, graphic, symbolic) and mathematical formalizations.

We present here several examples of epistemological obstacles.

Task 1 asked students whether the point with the coordinates $(2, -8)$ is on the graph of the line $y = 3x - 14$. All students described their schemes of action without referring to the Cartesian connection as a formal mathematical theorem. More than 60% of the students ($N=978$) missed the Cartesian connection in Task 1. Students who missed the Cartesian connection from point to line failed to identify the ordered pair $(2, -8)$ as (x_0, y_0) in $y = 3x - 14$ or to check whether the statement $-8 = 3(2) - 14$ is true. They tried (unsuccessfully) schemes of action involving the construction of graphs or symbolic manipulations of the equation of the line. Particularly difficult was the construction of the line $y = 3x - 14$. Some students asked us to provide the graph of the line (e.g., “What graph?”). Even when successful at graphing the line $y = 3x - 14$ and plotting the point $(2, -8)$, there were students who could not decide, based on their graphic representations, whether the point was on the line.

Task 2 asked to identify the slope of a line graphed in a homogeneous system of coordinates (see Figure 1).

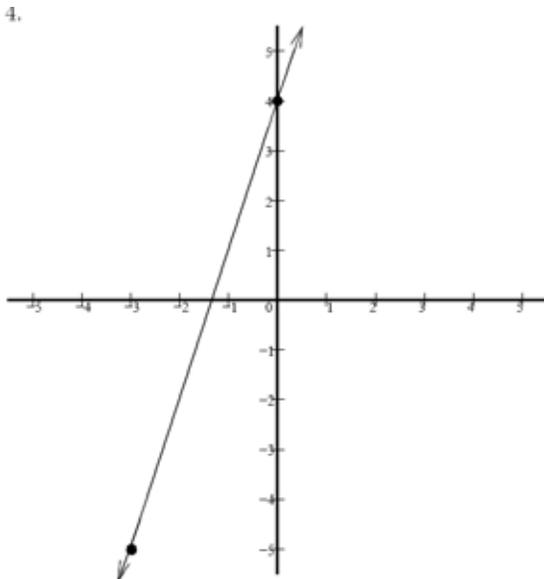

Figure 1: Task 2

To identify the slope in the geometric context from Task 2, one needs to know how to make a quantity. “Making a quantity” is the process of conceiving of a quantity as a quality of an object together with its magnitude. A magnitude is a numerical value assigned to a quantity by direct or indirect measurement. Measuring lengths on oriented axes of coordinates implies conceiving of an origin from where the measurement starts, an appropriate unit of measurement, and a sense of measurement, positive or negative (Freudenthal, 1983). In Task 2 one assigns the magnitude 9 for

rise either by direct measurement (counting tick marks from $(-5, 0)$ to $(4, 0)$ on the Y -axis), or by evaluating the change in y , $y_2 - y_1 = 4 - (-5) = 9$. “Making a ratio” is the process of conceiving of a function of an ordered pair of magnitudes, while calculating a ratio is the numerical operation of calculating the value of the function for a particular pair of magnitudes (Freudenthal, 1983). One makes a ratio for slope by assigning $(9, 3)$ to the ordered pair (rise, run), and calculates the value of slope by dividing 9 by 3. The main epistemological obstacle with the concept of slope in the situation from Task 2 was making a ratio. Some students could conceive of both rise and run, but failed to assign $9/3$ to the ordered pair $(9, 3)$ (e.g., “I can’t remember if I’m supposed to add 9 plus 3 or multiply or divide ...”). Other students conceived only of the rise, ignoring the run (e.g., “I made a line up to -3 and then counted over 3 from 0”).

Another epistemological obstacle occurred in Task 3 (see Figure 2), where students were asked to identify the slope of a line graphed in a non-homogeneous system of coordinates. Task 3 brings in discussion the geometric perspective of slope (slope as a property of the line), and the analytical perspective of slope (slope as a property of the linear function) (Zaslavsky et al., 2002), and the difficulty to reconcile these two perspectives.

Task 3. The graph below represents the distance that a car travelled after different number of hours.

- What is the speed of the car in part R?
- What is the slope of part R of the graph?

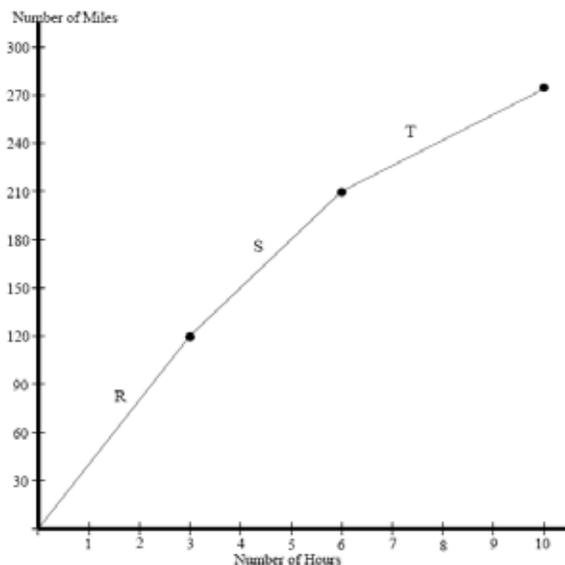

Figure 2: Task 3

Almost half of the students ($N=696$), correctly identified the speed of the car (40 mph). About half of the students who correctly identified the speed of the car failed to identify the slope of the line segment ($N=336$). Moreover, about 82% of those

students who failed to identify the slope of the line graphed in a non-homogeneous system of coordinates correctly identified the slope of the line graphed in a homogeneous systems of coordinates in Task 2 (Postelnicu, 2011). One student expressed his difficulty this way: “In part *b* I didn't know whether to take from the values on the side or the units.” During the interviews, only the students who held a geometric perspective and not an analytical perspective of slope failed to take into consideration the values of the function for rise ($y_2 = 120, y_1 = 0$) when calculating $y_2 - y_1$, and instead counted the “tick marks” on the *Y*-axis. They calculated the slope of part *R* of the graph as “rise over run.” They found that the run, the line segment from the origin of the system of coordinates to (3, 0), had a length of 3 units on the *X*-axis, and the run, the line segment from the origin of the system of coordinates to (0, 120), had a length of 4 units on the *Y*-axis. They concluded that the slope of the line segment was 4/3 (rather than 120/3). When the analytic perspective of slope prevailed, and students used $\frac{y_2 - y_1}{x_2 - x_1}$ to calculate the slope, the interviewed students did not encounter difficulties.

OVERVIEW OF THE SECOND STUDY

The second study included 155 college students from a four-year programme at the university, enrolled in five undergraduate mathematics courses (Intermediate Algebra, College Algebra, Precalculus, Brief Calculus, and Discrete Mathematics [2]). A task sequence on aspects of the Cartesian connection was administered to all participants. After completing the sequence, all participants were asked to compare the tasks (“Are the tasks alike or different? Explain.”) Semi-structured interviews (Goldin, 2000) were conducted with six students, randomly selected by the researcher. Three students had the total score above the group median, and three students had the total score below the group median. The interviewed students were asked to explain to an imaginary student not only how to solve the tasks, but also to justify why their algorithms work.

We discuss here two tasks:

Task 4. Find m and b such that the points (1, 4) and (−2, 10) are situated on the graph of the function $y = mx + b$.

Task 5. Determine b and c such that the points (1, −3) and (2, 0) are situated on the graph of the function $y = x^2 + bx + c$.

Both tasks are applications of the Cartesian connection, but the mathematical object upon which the students had to operate was different, a linear function in Task 4, and a quadratic function in Task 5, respectively. In a Piagetian sense (Piaget, 1971), we wanted to see whether our students’ schemes of action were dependent on the mathematical object upon which they had to apply the Cartesian connection. In other words, our question was whether the students who applied the Cartesian connection

in the case of the linear function from Task 4, could apply the same theorem in the case of the quadratic function from Task 5. The analysis of this epistemological obstacle had to be nuanced, because another question arose: Did the students who correctly solved Task 4 and/or Task 5 apply the Cartesian connection? To frame the discussion theoretically, Piaget (1971) discriminates between three types of knowledge: empirical knowledge abstracted from objects, pseudo-empirical knowledge abstracted from individual actions on objects, and reflective knowledge abstracted from coordinated actions on objects. The latter type of knowledge constitutes the basis for mathematical knowledge. The key difference between empirical and reflective abstractions is that the latter implies a projection from a lower to a higher level of knowledge, together with a reorganization of the entire knowledge in hierarchically superior structures. Given these theoretical considerations, we rephrased our question: What type of abstractions were employed by the students who correctly solved both Task 4 and Task 5? We considered evidence that reflective abstractions were employed if the student could generalize the Cartesian connection (e.g., a point (x_0, y_0) is on the graph of the curve C if and only if its coordinates satisfy the equation of C), apply it regardless of the appearance of the mathematical object C (e.g., symbolic representations like, $y = mx + b$ or $y = x^2 + bx + c$), and state it as the mathematical justification behind Tasks 4 and 5.

Only 31 students correctly solved Task 4. Eleven of the students who correctly solved Task 4, failed to solve Task 5. All the students who correctly solved Task 4, as well as the students who correctly solved both Tasks 4 and 5, compared the tasks by referring to the mathematical objects involved (e.g. linear functions, lines), and the actions performed (e.g., “You must use the slopes”). None of the students referred to the underlying mathematical justifications behind the task sequence, i.e., none of the students could justify their algorithms from a mathematical point of view. The interviews, coded (Strauss & Corbin, 1998) and analyzed using Piaget’s theory of reflective abstractions, confirmed the procedural (instrumental) nature of students’ knowledge (Skemp, 1976) and the lack of justificatory principles. Since none of the students could justify their successful algorithms, we concluded that no reflective abstractions were employed by college students.

DISCUSSION

Analyses revealed that students had difficulty with the Cartesian connection. Notwithstanding that the content of the tasks referring to the Cartesian connection varied across studies, the findings of the present studies and other studies (Lobato and Siebert, 2002; Schoenfeld et al. 1993; Stump, 2001; Zaslavsky et al., 2002) point toward epistemological obstacles.

Identifying the slope of a line graphed in a system of Cartesian coordinates seems to be a more difficult task than, for example, identifying the rate of change of a linear function when two instances of the varying quantities, (x_1, y_1) and (x_2, y_2) are given.

One explanation may be that the graphing context for slope implies knowledge of mathematical conventions (e.g., if the oriented segment representing the rise is toward the positive sense of the Y -axis, its magnitude has a positive sign). Thus, the difficulty in Task 2 in identifying the slope of a graphed line lies with the connection with the graphic representation. Another explanation may be that the complexity of the problem increased for those students with a geometric perspective of slope. Indeed, calculating the slope of a graphed line as “rise over run,” implies knowledge of proportionality in the geometric context of similar triangles, or at minimum, coordination while identifying the rise and the run from a “slope triangle.” By contrast, students with an analytical perspective of slope, who calculated slope as “change in y over change in x ,” or used the formula $m = \frac{y_2 - y_1}{x_2 - x_1}$, had less difficulty since the connection with the graphic representation was reduced to identifying the coordinates of the points, (x_1, y_1) and (x_2, y_2) .

Another possible explanation for student difficulties with slope may lie in the way this topic is presented in the U.S. mathematics curricula. For example, in one Algebra I textbook used by the first study’s participants, the slope is introduced in physical context, followed by the geometric context:

Some roofs are steeper than others. In mathematics, a number called *slope* is a measure of the steepness of a line. The *slope of a line* is the ratio of *rise* to *run* for any two points on the line (Rubenstein et al., 1995, p. 361).

Usually, the geometric perspective of slope as “rise over run” precedes the functional perspective of slope as rate of change, the latter being introduced in advanced mathematics classes, like Precalculus and Calculus. The results of this study showed that from the interviewed students, only those with a geometric perspective of slope had difficulties determining the slope of a graphed line in Task 2.

Insufficient presentation of the mathematical conventions behind the graphic representation of functions may be another explanation for some of the student difficulties in Task 3. For example, in another Algebra I textbook used by the participants in the first study, the graph of a function is not defined explicitly. Students are reminded in Chapter 1 about the procedure to graph a function, and an example is given, with no reference to the units of measurement for the axes (e.g., scale for the Y -axis):

When you are given the rule for a function, you can prepare to graph the function by making a table showing numbers in the domain and their corresponding output values [...] Let the horizontal axis represent the input t (in minutes). Label the axis from 0 to 5. Let the vertical axis represent the output h (in feet). Label the axis from 0 to 400. Plot the data points given in the table. Finally, connect the points [...] (Larson et al., 2004, p. 49).

Difficulty with identifying the scale of the Y -axis in a non-homogeneous system of coordinates was evident in Task 3. Students attempted to calculate the “rise” by

counting the tick marks “by ones” for the Y -axis, instead of recognizing that each interval between two consecutive tick marks was 30 units.

Students had difficulty connecting between the symbolic and graphic representations in Tasks 1, 4 and 5. Knuth (2000) argued that the American curriculum and instructional approach emphasize symbolic representations and manipulations, although symbolic representations encapsulate knowledge that students cannot successfully unpack (Kaput, Blanton, & Moreno, 2008). The graphic approach is often rejected by students and their teachers because graphic representations are not precise, and could introduce estimates and inaccuracies (Arcavi, 2003). The Cartesian connection necessary to solve Tasks 1, 4 and 5 can only add to the difficulty. But even when successful at solving Tasks 1, 4 and 5, students’ knowledge was procedural, and mirrored their textbooks’ knowledge - a collection of algorithmic steps for solving problems, lacking the mathematical foundations that justify the use of algorithms (Harel & Wilson, 2011; Postelnicu, 2011; Wu, 2011).

In short, the association between the epistemological obstacles and the geometric perspective of slope held by some of the students who encountered difficulties suggests that the precedence of the geometric perspective of slope, as well as the reconciliation between the two perspectives of slope, geometric and analytical, together with the mathematical conventions behind the graphic representation of functions, need to be addressed in our curriculum. The college students’ difficulty to advance their knowledge by expanding their successful schemes, suggests that perhaps, even more important to be addressed is the need for active mathematical principles and coherence in our curriculum.

NOTES

1. In United States, linear functions are part of the mathematics curriculum for Grades 8-10. The usual high school course sequence is Algebra I (Grade 9), Geometry (Grade 10), Algebra II (Grade 11), followed by advanced mathematics courses like Precalculus and Calculus. The current trend is to have Grade 8 students enrolled in Algebra I.
2. Upon college admittance, students may be tested and placed in remedial mathematics courses like Intermediate Algebra, College Algebra or Precalculus.

MENTAL MATHEMATICS & ALGEBRA EQUATION SOLVING

Jérôme Proulx

Université du Québec à Montréal

The reported study on mental algebraic equation solving is part of a larger research programme, aimed at better understanding the potential of mental mathematics activities with objects other than numbers. Through outlining the study details, and the activities students engaged with, I report on the variety of interpretations given to what solving an algebraic equation is. Focusing as well on the nature of students' engagement, I discuss some implications/potential for algebra teaching and learning.

CONTEXT OF THE STUDY

To highlight the relevance and importance of teaching mental calculations, Thompson (1999) raises the following points: (1) most calculations in adult life are done mentally; (2) mental work develops insights into number system/number sense; (3) mental work develops problem-solving skills; (4) mental work promotes success in later written calculations. These aspects stress the non-local character of doing mental mathematics with numbers, where the skills being developed extend to wider mathematical abilities and understandings. Indeed diverse studies show the significant impact of mental mathematics practices with numbers: on students' problem solving skills (Butlen & Peizard, 1992; Schoen & Zweng, 1986), on the development of their number sense (Boule, 2008; Murphy, 2004; Heirdsfield & Cooper, 2004), on their paper-and-pencil skills (Butlen & Peizard, *ibid.*) and their estimation strategies (Heirdsfield & Cooper, *ibid.*; Schoen & Zweng, *ibid.*). For Butlen and Peizard (*ibid.*), the practice of mental calculations can enable students to develop new ways of doing mathematics and solving arithmetic problems that the traditional paper-and-pencil context rarely affords because it is often focused on techniques that are in themselves efficient and do not create the need for doing otherwise. There is thus an overall agreement, and across contexts, that the practice of mental mathematics with numbers enriches students' learning and mathematical written work about calculations and numbers: studies e.g. conducted in US (Schoen & Zweng, *ibid.*), France (Butlen & Peizard, *ibid.*; Douady, 1994), Japan (Reys & Nohda, 1994), and UK (Murphy, *ibid.*; Thompson, 1999; Threlfall, 2002).

This being so, as Rezat (2011) explains, most if not all studies on mental mathematics focus on numbers/arithmetic. However, mathematics taught in schools involves more than numbers. This triggers interest in knowing what teaching mental mathematics with mathematical objects other than numbers might contribute to students' mathematical reasoning. In this study, issues of algebra equation solving are probed into. Thus, what learning opportunities solving algebraic equations mentally offer students? What mathematical activity do students engage in? What mathematical strategies emerge? This paper reports on the nature of strategies used by a group of 12 students, and the varied meanings developed about "solving algebraic equations".

THEORETICAL GROUNDING OF THE STUDY: AN ENACTIVIST FRAME

Recent work in mental mathematics points to the need for a better understanding and conceptualizing of how students develop mental strategies. Faced with significant varieties of students' creative solutions and with dissatisfaction about their "classification" in known and precise categories, researchers have begun to criticize the notion that students "choose" from a toolbox of predetermined strategies in order to solve problems in mental mathematics. Threlfall (2002) insists rather on the organic emergence and contingency of strategies in relation to the tasks *and* the solver (e.g. what he understands, prefers, knows, has experienced with those tasks, is confident with; see also Butlen & Peizard, 1992; Rezat, 2011). This view on emergence of strategies is also outlined in Murphy (2004), who discusses Lave's situated cognition perspective on mental strategies as flexible emergent responses, adapted and linked to a specific context and situation.

In mathematics education, the enactivist theory of cognition has been concerned with issues of emergence, adaptation and contingency of learners' mathematical activity (from the work e.g. of Maturana & Varela, 1992; Varela, Thompson & Rosch, 1991). Therefore, aspects of the theory are used to ground this study in its intention to make sense of students' strategy development and mathematical activity. In particular, Varela's (Varela et al., 1991) distinction between *problem posing* and *problem solving* offers a preliminary answer to questions about emergence and the characterization of strategies generated for solving tasks.

For Varela, problem-solving implies that problems are already in the world, lying "out there" waiting to be solved, independent of us as knowers. In contrast, Varela explains that we specify, we pose, the problems that we encounter through the meanings we make of the world in which we live, which leads us to recognize things in specific ways. We do not "choose" or "take" problems as if they were lying "out there," objective and independent of our actions: we bring them forth. The problems that we encounter and the questions we ask are thus as much a part of us as they are a part of our environment: they emerge from our interaction with it, as we interpret events as issues to address, as problems to solve. Thus, we are not acting on preexisting situations: our interaction with the environment creates the possible situations for us to act upon. The problems that we solve, then, are implicitly relevant for us because we allow these to be problems for us.

Hence it is claimed that reactions to a task do not reside inside either the solver or the task: they emerge from the solver's *interaction* with the task, through posing the task. If one adheres to this perspective, one cannot assume, as René de Cotret (1999) explains, that instructional properties are present in the (mental mathematics) tasks offered and that these will determine solvers' reactions. Strategies emerge in the interaction of solver and task, influenced by the task but determined by the solver's experiences and understandings: in his solving habits for similar or different tasks, in his successes in mathematics with specific approaches, in his understanding of the tasks, etc. In this perspective, the solver does not choose from a group of

predetermined strategies to solve the task, but engages with the problem in a specific way and develops a strategy tailored to the task he poses.

Thus, students *transform* the mathematical tasks for themselves, making them their own, which is often different from the designer's intentions (René de Cotret, 1999); Heirdsfield and Cooper (2004) and Rezat (2011) have indeed shown the occasional futility in mental mathematics of varying the type of problem or its didactical variables to encourage students to use specific strategies. When solving tasks, students generate a strategy tailored to the problem (they) posed, as acts of posing and solving are not predetermined but generated in interaction with the task:

As a result of this interaction between noticing and knowledge each solution 'method' is in a sense unique to that case, and is invented in the context of the particular calculation – although clearly influenced by experience. It is not learned as a general approach and then applied to particular cases. [...] The 'strategy' [...] is not decided, it emerges. (Threlfall, 2002, p. 42)

Students are then seen to generate their strategies in order to solve their tasks. These are adapted responses, locally tailored to the tasks, emerging in interaction with them.

THE STUDY – DEFINING MENTAL MATHEMATICS

Because most work on mental mathematics is on numbers (often referred to as *mental arithmetic* or *mental calculations*) and defined accordingly, no formal comprehensive definition of mental mathematics appears in the literature. Based on the work on mental calculations, one tentative definition is: Mental mathematics is the solving of mathematical tasks without paper and pencil or other computational/material aids. This definition helps understanding the “constraints” to which the students are subjected to, the major issue being that students do not have access to any material aid, be it paper-and-pencil or other, to depend on for solving the problems offered to them. This study focuses on (any of) the strategies produced in this context.

METHODOLOGY, DATA COLLECTION AND ANALYSIS

One intention of the overarching research programme is to study the nature of the mathematical activity students engage in through working on mental mathematics. This is probed through (multiple) case studies, taking place in diverse educative contexts designed for the study (classroom settings/activities). The reported study is one of those case studies, conducted in one university mathematics education course, aimed for because these students are not novice solvers in algebra, enabling a focus on their solving of algebra tasks (and less on their difficulties with algebra itself).

Classroom activities were designed to offer algebraic equations for students to solve mentally. A variety of usual algebraic equations of the form $Ax+B=C$, $Ax+B=Cx+D$, $Ax/B=C/D$, $Ax^2+Bx+C=0$ and their variants were presented. The classroom organization took the following structure: (1) an equation is offered orally or in writing on a transparency to the group; (2) students solve the equation mentally

(without paper-and-pencil or material aids to solve or leave traces); (3) at the signal they write their answer on a piece of paper; (4) answers and strategies are orally shared, noted on the transparency. The data collected comes from the strategies orally explained (and noted on transparencies), as well as notes taken after the session.

The data was first looked at, analyzed, in relation to the nature of the strategies generated by students for solving the tasks. Because this analysis is dependent on the type of mathematical objects worked with through the classroom activities, available theoretical concepts found in the literature to guide and enhance the data analysis were used. In algebra, unwinding/undo procedures (Nathan & Koedinger, 2000) or transformation of equations (Arcavi, 1994), to name but two, are examples of relevant dimensions used for the data analysis. This analysis rapidly led to considerations of the meanings given to solving an algebraic equation, the focus of this paper (other analyses regarding the strategy dimensions are to appear in another paper). Following Douady (1994), the goal of this paper is not to report on all learning that took place for students, nor to discuss the long-term outcomes for students in other contexts, but mainly to understand the meaning and functionality of the tools used (i.e. strategies for mentally solving algebraic equations) and explore their potential. The focus in this paper is thus placed on the problem posing aspects, that is, the nature of the mathematical strategies engaged in and its repercussions on the meanings afforded to what solving an algebraic equation is (see Bednarz, 2001).

FINDINGS – MEANINGS FOR ALGEBRAIC EQUATION SOLVING

Through solving the various tasks offered to them, students gave, implicitly, different meanings to what solving an algebraic equation represents. Those meanings are mathematically rich and contribute to deepen understandings of what solving an algebraic equation is. I outline below these various meanings.

Meaning 1: finding the value(s) that satisfy, make true, the equality

Underneath this meaning is the notion of a conditional equality, where it is not only the idea of finding the answers/values that make the equation true, but also the fact that the equality *can* be true or untrue.

When students were given $5x+6+4x+3=-1+9x$ to solve, some rapidly asserted that there was no solution, because one can rapidly see $9x$ on both sides of the equation as well as the fact that the remaining numbers on each sides do not equate. It thus leads to the conclusion that there was no number that could satisfy the given equation, since no x , whatever it could be, could succeed in making different numbers equals. This strategy is related to what is often termed “global reading” of the equation (Bednarz & Janvier, 1992), that requires consideration of the equation as a whole prior to entering in algebraic manipulations, or what Arcavi (1994) calls *a priori* inspection of symbols, which is a sensitivity to analyze algebraic expressions before making a decision about their solution. (Arcavi gives the example of

$(2x+3)/(4x+6)=2$, which has no solution because whatever the value of x , the numerator is worth half the denominator, making futile undergoing additional steps.)

Another strategy students engaged in was one of “solving followed by validation”. When having to solve $x^2-4=5$ one student rapidly transformed it into $x^2=9$, obtaining 3 as an answer. However, because he is in a mental mathematics context and is aware that his answers in this context are often rapidly enunciated and can lack precision, he decides to verify his answer. By mentally verifying if $(3)^2=9$, he realizes that $(-3)^2$ also gives 9 and then readjusts his solution. This manner of solving the equation gets close to the idea not only of finding one value that makes the equation true, but also of finding *all* values that make it true.

Meaning 2: deconstructing the operations applied to an unknown number

This meaning requires reading the equation as a series of operations applied to a number (here x) and attempting to undo these operations to find that number.

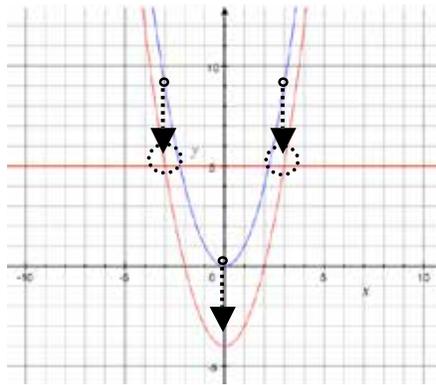

When having to solve equations like $x^2-4=5$, students would say: “My number was squared and then 4 was taken away, thus I need to add 4 and take the square root”. Or, for $4x+2=10$, “What is my number which after having multiplied by 4 and added 2 to it gives me 10?” These are similar to inverse methods of solving found in Filloy and Rojano (1989) and Nathan and Koedinger’s (2000) “unwinding”, where operations are arithmetically “undone” to arrive at a value for x . As Filloy and Rojano explain, when using this method “it is not necessary to operate on or with the unknown” (p. 20), as it becomes a series of arithmetical operations performed on numbers. In this particular case, solving the algebraic equation is focused on finding a way to arrive at isolating x , in an arithmetic context.

Meaning 3: operating identically on both sides to find x

This meaning focuses on the idea that is often called “the balance” principle, where one operates identically on both sides of the equation to maintain the equality and obtain “ x =something”. For example, when solving $2x+3=5$, students would subtract 3 on each side and then divide by 2.

Meaning 4: finding points of intersection of a system of equations

This is about seeing each sides of the equality as representing two functions, and thus attempting to solve them as a system of equations to find intersecting points, if any. For example, when solving $x^2-4=5$, some students attempted to depict the equation as the comparison of two equations in a system of equations ($y=x^2-4$ and $y=5$) and finding the intersecting point of those two equations in the graph. To do so, one student represented the line $y=5$ in the graph and then also positioned $y=x^2-4$. The latter was referred to the quadratic function $y=x^2$, which crosses $y=5$ at $x = \sqrt{5}$. In the case of $y=x^2-4$, the function is translated of 4 downwards in the graph, and then the 5 of the line $y=5$ becomes a 9 in terms of distances. Hence, how does one obtain an image of 9 with the function $y=x^2$? With an $x=\pm 3$, where the function $y=x^2-4$ cuts the line $y=5$. The following graph offers an illustration of what the student did, mentally.

Solving an algebraic equation in this case is not about finding the values that make the equation true, but about finding the x that satisfies both equations for the same y , about finding the x coordinate that, for the same y , is part of each function

Meaning 5: finding the values that nullifies the equation

This meaning focuses on the equal sign as giving an answer (see e.g. Davis, 1975), but where operations are conducted so that all the “information” ends up being on one side of the equation to obtain 0 on the other side. The intention then becomes to find the value of x that nullifies that equation, that is, that makes it equal to 0.

One example of a strategy engaged in was again about seeing the equation in a function view as in meaning 4, but here for finding the values of x that give a null y -value, or what is commonly called finding the zeros of the function where the function intersects the x -axis at $y=0$. For $x^2-4=5$, transformed in $x^2-9=0$, the student aimed mentally at solving $(x+3)(x-3)=0$, leading to ± 3 . The quest was mainly finding the values that nullify the function $y=x^2-9$, which gave point(s) for which the image of the function was zero. Another way of doing it, less in a function-orientation, is to use “binomial expansion” (what is called in French *identités remarquables*) for seeing that for the product to be null it requires that one of the two factors be null. This said, one needs to use neither a function nor binomial expansion to find what nullifies the equation. For example, if $x+4=3$ is transformed in $x+1=0$, one finds that -1 is what makes the left side of the equation equal to 0.

Meaning 6: finding the missing value in a proportion

This meaning was engaged with for equation written in fractional form (e.g. $Ax/B=C$ or $Ax/B=C/D$). In these cases, the equation was conceived as a proportion, where the ratio between numerators and denominators was seen as the same or consistent. In this case, the equality is not seen as conditional but is taken for granted, to be true, leading at conserving the ratio between numerator and denominator in the proportion.

For example, for $\frac{6}{x} = \frac{3}{5}$, reversed to $\frac{x}{6} = \frac{5}{3}$, students solved by saying “If my number is 6 times bigger than $x/6$, then it is 6 times bigger than $5/3$ ”. Another way offered was to analyze the ratio between each numerators and apply it to denominators which had, in order to maintain the equality, to be of the same ratio: “If 6 is the double of 3, then x is the double of 5 which is worth 10”.

Meaning 7: finding equivalent equations

This meaning for solving the equation is oriented toward obtaining other *equivalent* equations to the first one offered, in order to advance toward an equation of the form “ $x=\text{something}$ ”. This is related to Arcavi’s (1994) notion of knowing that through transforming an algebraic expression to an equivalent one, it becomes possible to “read” information that was not visible in the original expression. Through these transformations, the intention is not directly to isolate x , but to find other equations, easier ones to read or make sense of, in order to find the value of x .

An example of such was done when solving $\frac{2}{5}x = \frac{1}{2}$, where some students doubled the equation, obtaining $\frac{4}{5}x = 1$, which was simpler to read and then multiplied by $5/4$ to arrive at $x=5/4$. This is an avenue also reminiscent of arithmetical divisions, where equivalences are established: e.g. $5.08 \div 2.54$ is equivalent to $508 \div 254$, because 254 divides into 508 the same number of times as 2.54 into 5.08.

Similarities and differences in meanings attributed

Albeit treated separately, these varied meanings are not all different and some share attributes. Therefore, in addition to the variety of meanings, significant links can be traced between those, links that can deepen understandings about algebraic equation solving. For example, meanings 2 and 3 share an explicit orientation toward isolating x , where others do not have this salient preoccupation and focus on other aspects (satisfying the equality, finding points of intersection, etc.). Meanings 4 and 5 share a function orientation in their way of treating the equation, emphasizing each part of the equation as representing an image (or simply the value of the function).

Many meanings also focus implicitly on conditional orientations, be it concerning the satisfaction of the equality or simply the possibility of finding a value for x . For example, in meaning 2 and 3, it is possible that no value of x is found and the same can be said for meaning 4, where it is possible that there be no point of intersection of the two equations or for meaning 5, where possibly no value of x could nullify the left side of the equation (e.g. $x^2 + \sqrt{2} = 0$). Without being explicit about it, these orientations represent a quest for finding a possible value, a quest that can be unsuccessful. This contrasts heavily with meaning 6, because treating the equation as a ratio assumes or implies that a value of x exists. Meanings 1 and 6 however do share something in common, which is related to an examination of relations between the algebraic unknown and the numbers in order to deduce the value of the algebraic unknown. Both do not opt for a sequence of steps to undertake, but mainly for working with the equation as a whole (in global reading for meaning 1, in ratios for meaning 6). Meanings 3 and 7 share the fact that operations are conducted on the equation as a whole, be it through affecting both sides in the same way to keep the “balance” intact or to obtain new equivalent equations.

Finally, meanings 1, 2, 5 and 6 share the fact that they explicitly look for a number, where the algebraic unknown is conceived as an unknown number that needs to be

found; a significant issue to understand when solving algebraic equations (Bednarz & Janvier, 1992; Davis, 1975). Hence, be it through looking at which number could satisfy the equation (meaning 1), which number could nullify a part of it (meaning 5), which number satisfies the proportion (meaning 6) or which is the number for which operations were conducted (meaning 2), all of them focus on x as being a number.

DISCUSSION OF FINDINGS

On the emergence of mental mathematics strategies

The variety of meanings brought forth through students' solving illustrates well how the various "posing" of the problems led to various strategies for solving and thus to various meanings attributed to algebraic equation solving. Each equation provoked numerous strategies for solving it, leading to numerous meanings attributed to algebraic equation solving. Thus, the same equation made emerge a variety of posings, of strategies, of meanings. This supports the view that strategies for solving emerge in the interaction of solver and task, where the solver plays an important role as he poses the tasks, and where the nature of the task plays a role as well, with a strategy tailored to it (see e.g. the impact of fractional or second degree forms on the nature of the strategies). Strategies emerge contingently where, as Davis (1995) explains, they are inseparable from the solver and the task, emerging from their interaction. Thus, building on Simmt's (2000) work, one could begin conjecturing that the tasks given were not tasks but mainly prompts for solvers to create tasks with: prompts were offered to students, not tasks. Tasks became tasks when students engaged with them. Students *made* the equations ones about system of equations, about functions, about ratio, etc., allowing a variety of meanings for algebraic equation solving to emerge along the way. This however merits more precise attention and further research investigating the processes of solving in a mental mathematics contexts are definitely needed (see e.g. my arguments about these processes and their emergence in Proulx, in press).

On the potential of mental mathematics for algebra

This variety of meanings, emerging with/in students' posing, shows promise for algebra teaching and learning. These meanings are significant, because they offer different entry paths into the tasks of solving algebraic equations and do not restrict a single view of how this can be done. Numerous authors have outlined difficulties experienced by solvers (from school to university) in solving algebraic equations (see Bednarz, 2001; Filloy & Rojano, 1989; Nathan & Koedinger, 2000). The emergence of this variety of meanings offers significant reinvestment opportunities for pushing further the understanding of algebraic equation solving in mathematics teaching. It opened spaces of exploration that can be taken advantage of in teaching, in order for example to unearth the various meanings given to solving algebraic equations or similarities and differences between those. Issues of conditional equations, of deconstructing an equation regarding operations done on a number, of maintaining the balance, of finding equivalent equations, of seeing an equation as a system of

equations, and so forth, offered varied ways of conceiving an equation and of solving it. It opened various paths of understanding. However, more research is needed to investigate how these reinvestments can be done in classroom contexts (with students or teachers), as well as the sorts of understandings students/teachers gain from this.

For example, and without making paper-and-pencil a straw-men for criticism, the mental mathematics context can be seen to have provoked some strategies and meanings different than ones used in the usual written context for solving equations in algebra. An example is the transforming of equations into equivalent ones (e.g. $\frac{2}{5}x = \frac{1}{2}$ to $\frac{4}{5}x = 1$). This reasoning is at the basis of solving equations in writing. But, it was here quite different than the usual transformations applied to equations, since the equation was not transformed in order to isolate x , but mainly to obtain other equations that were easier to read. In fact, even if many strategies were reminiscent of paper-and-pencil work, the major difference is that there was no paper-and-pencil work, leading to a dialogue taking place between the student and the task, *while* solving. Because students could not leave written traces or transform the equations in writing, and thus could not interact with what was obtained after each written step through manipulating the equation, the monitoring of the solution was done in real-time, through personal dialogue, through a story told in which the solver engaged through telling the story, to keep track of the operations being conducted and their adequacy. In short, students had to invent (to pose) their stories about the problem, to interpret the equation in their own terms, in order to find a way to solve it. These “steps”, oriented by the task at hand, oriented in return the next steps. Solving was done through the action of solving, and not through applying a known procedure, making it quite a different solving experience. Important questions that can be asked at this point is: What can be gained through this experience of solving algebraic equations mentally? What avenues of solving can be developed through these experiences, be them similar or different than the ones in paper-and-pencil contexts? More research is needed along those lines, but already this emerging variety of meanings shows important promise of mental mathematics for enriching algebraic experiences of students and teachers.

THE EFFECTS OF A TEACHING METHOD SUPPORTING METACOGNITION ON 7TH GRADE STUDENTS' CONCEPTUAL AND PROCEDURAL KNOWLEDGE ON ALGEBRAIC EXPRESSIONS AND EQUATIONS

Sevgi Sari* & Elif Yetkin Özdemir*

*MoNE- Taşoluk Elementary School ** Hacettepe University

The purpose of this study was to investigate the effects of a teaching method supporting metacognitive strategy use on improving seventh grade students' conceptual and procedural knowledge on algebraic expressions and equations. The study was conducted in two seventh grade classes from a public school in the 2010–2011 academic year. A quasi-experimental design with pretest - posttest control group was utilized for the study. A Conceptual Knowledge Scale and Procedural Knowledge Scale were conducted with control and experimental groups before and after the implementation of the teaching methods. Data were analyzed using t-tests and a Mann Whitney U test. Results showed that there was a significant difference between experimental and control groups in terms of gain scores on conceptual and procedural knowledge in favor of experimental group.

INTRODUCTION AND RELATED LITERATURE

Algebra is a branch of mathematics, which turns relations examined by using symbols and numbers to generalized equations. Not only does it represent letters and quantities, it also allows calculations using these symbols at the same time (Kieran, 1992). Ideally, algebra lessons lead students to develop a profound understanding of algebraic concepts and the ability to see algebra as a central and connected branch of mathematics and the ability to apply algebra to a wide range of topics. If this happens, then students can be said to have a high algebraic competency (Oldenburg, 2009).

There are two concepts underlying algebraic expressions and equations. These concepts are “variable” and “equality”. A variable concept is usually expressed through literal symbols. According to Philipp (1992), literal symbols have many different uses as label, constants, unknowns, generalized numbers, varying quantities, parameters, and abstract symbols. Equal sign is used for various meanings in algebra. Research demonstrated that children perceive the equal sign as a symbol indicating action instead of a relational symbol (Kiearan, 1992; Yaman et al., 2003). Küchemann (1981) determined that children have 6 different perceptions regarding letters. These are; 1) letters have numerical values, 2) letters can be ignored in a particular task, 3) letters are abbreviations of concrete objects, 4) letters are unknown

numbers and they have only one value, 5) letters are generalized numbers and have only one value, and 6) letters are variables.

Dede et al. (2002) proposed reasons for the difficulties students experience in learning algebra as follows: not knowing about different uses of variables, not knowing about the role of variables in making generalizations, not being able to interpret variables, and failure to perform operations with variables. Baki (1998) listed students' misconceptions as errors in inclusion in parentheses and using operators, carelessness, and turning non-numerical expressions into algebraic expressions. Perso (1992) grouped the misconceptions in algebra under three main headings: the location of the letters, use of variables, and algebraic rules.

In order to address misconceptions in learning algebra, students need to understand concepts like variable, equation, and have preliminary knowledge such as arithmetical operation knowledge. Algebraic comprehension depends not on knowledge by the students of the formulas and understanding the calculations correctly, but instead, understanding of the concepts and operations, and development of mathematical thinking. Therefore, importance should be attached to concepts and relations instead of the procedural means of solution, and learning should be realized through conceptual learning that involves the knowledge of operations and concepts in a balanced manner (Baki & Kartal, 2004).

In sum, research reviewed above shows that students have difficulties in understanding the concepts of variable and equation, forming and solving algebraic equations, using algebraic expressions, and in algebraic problem solving (Baki & Kartal, 2004; Dede & Peker, 2007; Herscovics, 1989; Kieran, 1992; MacGregor & Stacey, 1993).

CONCEPTUAL AND PROCEDURAL KNOWLEDGE

Researchers describe two kinds of knowledge in learning mathematics; conceptual knowledge and procedural knowledge (Van de Walle, 2004). Conceptual knowledge can be defined as any concept, rule, generalization and the relation between them (Hiebert & Lefevre, 1986; Rittle- Johnson & Alibali, 1999). Procedural knowledge consists of two parts. The first comprises the symbols and language of mathematics. The second relates to the rules, algorithms or procedures used to solve mathematical tasks (Hiebert & Lefevre, 1986).

When the algebraic knowledge of students is examined in the context of conceptual and procedural knowledge, it can be seen that it is not based on conceptual learning where conceptual and procedural knowledge are balanced (Baki & Kartal, 2004).

METACOGNITIVE INSTRUCTION

A constructivist learning approach advocates that knowledge is not independent from the learner, and that the individual constructs knowledge him/herself in his/her mind (Olkun & Toluk, 2003). In order to construct mathematical concepts and thoughts in their mind in a meaningful manner, students should have skills such as monitoring

and regulating their own thought processes and mental activities as well as self-control of learning. These abilities are defined as metacognitive skills. Metacognition means one's awareness of one's own thought processes, and one's ability to control those (Beauford, 1996; Brown, 1978; Flavell, 1979).

Instructional practices such as writing, thinking aloud, using behavior cards (Demircioğlu, 2008; Pugalee, 2004; Özsoy, 2007); promoting learning environments that are conducive to the construction and use of metacognition (Schraw, 1998); supporting interactive problem solving (Kramarski, Mevarech, Liebermann, 2001; Schraw, 1997); asking reflective questions (Mayer, 1998; Schoenfeld, 1985); using control lists (Schraw, 1998) are used to improve students' metacognitive skills.

It has been shown that children who are given the opportunity to develop metacognitive skills experience positive and meaningful increases in mathematical success (Naglieri & Johnson, 2000; Özsoy, 2007; Teong, 2002). Even though research has shown a positive impact of metacognitive skills (prediction, planning, monitoring, and evaluation) on mathematical success, little is known about the effect of a metacognitive instruction on students' conceptual and procedural knowledge of algebra, particularly on algebraic expressions and equations.

PURPOSE OF THE STUDY

This research aims to examine the effect of a teaching method supporting the use of metacognitive strategies on conceptual and procedural knowledge of students in the area of algebraic expressions and equations. Moreover, we were interesting in finding out whether a focus on conceptual or procedural knowledge had greater effect.

METHODS

A quasi experimental design with pretest-posttest control groups was used in the study. Participants consist of 80 seventh grade students attending a public school in one of the low socio-economic level districts of the Istanbul province. Among the four seventh grade classes taught by the first researcher, two of them were arbitrarily selected. One of these classes was randomly assigned as the experimental group while the other group was assigned as control group. The experimental and control groups showed a balanced distribution in terms of gender. Both groups also showed no meaningful difference in terms of preliminary test scores assessing their conceptual and procedural knowledge on algebra.

The implementation was held in the fall semester of the 2010-2011 educational year, and lasted for a total of 6 weeks (24 hours) for both groups. The first researcher, who is the teacher of the experimental and control groups, taught the classes of both groups throughout the research. Before starting the process, the experimental group students were informed about metacognition over the course of 2 lesson hours, and were asked to implement metacognitive strategies throughout the process. In order for the students to develop these strategies, pre-implementation lessons were taught

to the experimental group for two weeks using metacognitive strategies and with writing exercises.

Instruction supporting the use of metacognitive strategies was applied to the experimental group. This process included teaching through structured applications based on metacognition together with problem-based learning activities used and suggested in the research (Goldberg & Bush, 2003; Kramarski et al., 2001; Özsoy, 2007; Schraw, 1998; Schoenfeld, 1985; Wilburne, 1997). The lessons involved the exercises of thinking aloud, solving problems with groups of two, class discussions, writing, and keeping learning diaries. Students were expected to use “Problem Solving Metacognitive Behavior List”, adapted from Goos et al. (2000) while solving problems and “List of The Explanation of Thinking Process”, adapted from Beyer (1988) while explaining their thinking processes. The mathematical content of the activities in the experimental group and the control group was the same. No different content was provided to the experimental group than to the control group. The only difference was that students in the experimental group engaged in practices around revealing thought processes and supporting metacognitive skills.

In thinking aloud exercises, students were requested to think (regarding targets, plans, strategies, etc.) and make decisions aloud. In solving problems (with two exercises), one of the students talked about his/her problem solution (what he/she understood from the problem, solution plan, etc.) and his/her friend asked questions that would clarify his/her thinking process. They summarized and reviewed the process from time to time and checked their comprehension. When the thinking processes of the group were shared through class discussion, alternative solution methods were shared and the most suitable solution method for the problem was discussed. Writing studies involved predictions regarding easiness or difficulty of the problem and the time needed to solve it, planning regarding solution of the problem, operations during the solution, views regarding the decisions taken and evaluation of the solution process. The teacher’s task was to make sure that the students used metacognitive steps and explained their thinking processes. The teacher asked several questions in order to improve students’ predictions, planning, monitoring and evaluation skills such as “Can you solve this problem? How long does it take you to solve the problem? How are you going to solve the problem? What are you doing now? Can you summarize what you have done so far? What you should do after this point? How are you doing it? Is this method going to work? Do you think you have done everything correctly? Do you think another method can be tried? What is the best solution method?” An example of a writing study related to acquisition of “Explains linear equations” is shown below:

“Please solve the problem below, writing down your thinking processes. Construction equipment, which has 250 litres of diesel in its tank, consumes 10 litres of diesel per hour;

- a) Please write down the equation of the relation between the amount of diesel and working time.

- b) How many litres of diesel are left in the tank of this construction equipment?
- c) For how many hours has this construction equipment worked when there are 140 litres of diesel in this construction equipment's tank?
- d) How many hours does this construction equipment need to work to finish all the diesel in its fuel tank?
- e) Since this construction equipment can work 5 hours per day at the most, how many days are needed to finish all the diesel in its fuel tank?"

In the control group, student-focused, ordinary instruction was implemented in line with the educational program. All the problems solved throughout the activities in the experimental group were also solved in this group. Active participation of the students was ensured and methods like question-answer, discussion were used. However, metacognitive activities such as writing, thinking aloud, keeping a learning diary and solving problems with groups of two were not used in this group. Teachers and students solved the questions without explicitly expressing their own thinking processes. Since much time was spent in clarification of the decisions made during the solution process and exploring alternative thinking processes in the experimental group, there remained problems that could not be solved during activities and these were given as homework to the students. In the control group, however, there was no such time problem and all of the problems planned for lessons were solved.

Two hour classes in the experimental and control group were observed by the other maths teacher of the school and notes were taken regarding the functioning of the classes. These notes were used for the purpose of collecting information on whether the teaching processes in the experimental and control groups were conducted as planned.

A Conceptual Knowledge Scale (CKS) formed using the body of literature was applied to the study for the purpose of measuring the conceptual knowledge of the students on algebraic expressions and equations (Akkuş, 2004; Hart, et al., 1985). The test involves different uses of the variable. Correct answers count as 1 point and wrong answers count as 0 point for every item. The KR-20 reliability coefficient of the scale consisting of 64 items with sub-problems was found to be 0.86. Some examples of the test items are shown below:

Item 3) Which one of the “ $2n$ ” and “ $n+2$ ” statements is greater in which case? (n is a natural number.)

Item 14) When is the expression $k+m+n=k+n+p$ correct?

- a) Always
- b) Never
- c) Only when $m=n$
- d) Only when $m=p$

A Procedural Knowledge Scale (PKS) formed using the body of literature was applied for the purpose of measuring the procedural knowledge of the students on algebra (Akkuş, 2004). The test consists of 17 free-response questions, which involves routine algebra problems requiring symbolic manipulation and calculations. A five-point rubric (0-4) was used to score the students' responses. Cronbach alpha

coefficient of the scale was found to be 0.94. A t-test was administered and α value was taken as 0.05. Some examples of the test items are shown below;

Item 4) $\frac{3x}{2} + 7 = x + 1$ Please solve the equation of the first degree with one unknown.

Item 10) Please find the value of y for $x=0$ on the line $3x+2=y$.

Both of the scales were arranged to measure conceptual and procedural knowledge on seventh grade algebraic expressions and equations in line with the educational program (addition, subtraction, multiplication; solution of 1st degree equations with one unknown; problem solving with equations, linear equations and charts).

RESULTS

A comparison of the experimental and control groups in terms of their mean scores from CKS shows that their pre test mean scores are low with low variability ($\bar{x}_{\text{Experimental}} = 10.73$, $\bar{x}_{\text{Control}} = 11.13$) but there is an evident difference in favor of the experimental group in their posttest mean scores ($\bar{x}_{\text{Experimental}} = 28.63$, $\bar{x}_{\text{Control}} = 16.93$). However, considering the fact that the highest score achievable from CKS was 64, it was observed that the means of both groups were low.

Using a t-test, a comparison of the means of the gain scores ($\bar{x}_{\text{Experimental}} = 17.90$, $\bar{x}_{\text{control}} = 5.80$) of the two groups revealed a significant statistical difference in favor of the experimental group ($t(78) = 5.701$; $p < 0.05$) (Table 1). Cohen d value 1.28 shows high effect size (Cohen, 1988, as cited in Gravetter & Wallnau, 2004).

Group	n	\bar{x}	s	df	t	p
Experimental Group	40	17.90	7.90	78	5.701	p<0.001
Control Group	40	5.80	10.85			

Table 1: CKS Gain Scores of the Experimental and Control Groups

A comparison of the experimental and control groups in terms of their mean scores from PKS shows, similar to the previous finding, that their pretest mean scores are low with low variability ($\bar{x}_{\text{Experimental}} = 2.80$; $\bar{x}_{\text{Control}} = 3.80$), while there is an evident difference in favor of the experimental group in their post-test mean scores ($\bar{x}_{\text{Experimental}} = 28.05$; $\bar{x}_{\text{Control}} = 14.25$). However, considering the fact that the highest score achievable from PKS was 68, it was observed that the means of the groups are low. Moreover, the standard deviation values are quite high in the distribution of the post test scores ($s_{\text{Experimental}} = 17.51$; $s_{\text{Control}} = 15.32$). This shows that the implementations might have had different effects on the procedural knowledge of the students with different personal characteristics.

A comparison of the means of the gain scores ($\bar{x}_{\text{Experimental}} = 25.25$, $\bar{x}_{\text{Control}} = 10.45$) of the groups revealed a significant statistical difference in favor of the experimental group ($t(78) = 4.633$; $p < 0.05$) (Table 2). Cohen d value 1.04 shows high effect size.

Groups	n	\bar{X}	s	df	t	p
Experimental Group	40	25.25	15.55	78	4.633	P<0.001
Control Group	40	10.45	12.90			

Table 2: PKS Gain Scores of the Test and Control Groups

To examine whether or not the use of metacognitive strategies is more effective on the conceptual knowledge or procedural knowledge gains, the scores from the two scales were transformed to a 100-score scale, and the gain scores of the experimental group were recalculated (Table 3).

Group	Test	n	\bar{X}	s
Experimental Group	CKS	40	27.97	12.34
	PKS	40	37.13	22.87

Table 3: Gain Scores of the Experimental Group on CKS and PKS (Descriptive Statistics)

Because the variances of the distribution of test scores are not homogenous, Mann Whitney-U test was used for unrelated measurements, and no statistically significant difference was found between the conceptual and procedural knowledge scale scores of the experimental group ($U = 610.50$; $p > .05$).

Test	n	Mean Rank	Sum of Ranks	U	p
CKS	40	35.76	1430.50	610.50	.068
PKS	40	45.24	1809.50		

Table 4: Mann Whitney-U Test Results for CKS and PKS Gain Scores of the Experimental Group

CONCLUSION

The first two findings of this research showed that both the conceptual and procedural knowledge gains of the experimental group were significantly higher than the conceptual and procedural knowledge gains of the control group. Considering these findings, it can be said that the educational method supporting metacognition strategies is an effective method for developing the students' understanding of concepts of equation, unknown and equality concepts included in the subject of algebraic expressions and equations, and developing their skills such as forming and solving equations based on such concepts, and for problem solving via equations. These findings are consistent with the prior research findings supporting metacognitive instruction (Mevarech & Fridkin, 2006; Pilten, 2008).

The third finding of the research shows that there was no statistically significant difference between the average of the procedural gain scores and the conceptual gain scores in the method supporting the use of metacognitive strategies. It has been shown in research investigating the algebraic knowledge that students lack conceptual knowledge that their procedural knowledge is not supported by conceptual knowledge (Baki & Kartal, 2004; Bekdemir & Işık, 2007). The finding of the study can be interpreted as meaning that the conceptual algebraic knowledge of the students increases with their procedural algebraic knowledge, and that conceptual knowledge lays foundations for procedural knowledge.

The scores of the experimental and control groups in the conceptual and procedural knowledge scale before the implementation (pretest scores) were quite low, - particularly the pretest scores in the procedural knowledge scale. This might be attributed to the nature of the scales. Each item in the procedural knowledge scale relates directly to the concepts taught in seventh grade algebraic expressions and equations. The conceptual knowledge scale similarly involves questions containing different uses of the variable and measuring conceptual knowledge of fundamental algebra in addition to questions directly related to gains. The students may have had difficulty responding to questions directly related to content that they had not previously been taught.

It was found out that the average of both conceptual and procedural knowledge gain of the experimental group was meaningfully higher than the control group, and the effect of the implementation (Cohen d) was found to be high. Nevertheless, the success of the experimental group was low considering the final test scores. This may relate to low general success and insufficient knowledge and skills of the students respectively in mathematics and in fundamental mathematics. Besides, the study was limited in some aspects. Most importantly, the delayed test practice could not be held to provide greater evidence regarding the effectiveness of the implementation on algebra. Although the effect of the implementation was found to be high, no finding on the permanence of the acquired algebraic knowledge could be obtained.

RELATIONAL UNDERSTANDING WHEN INTRODUCING EARLY ALGEBRA IN PORTUGUESE SCHOOLS

*Leonel Vieira, *Pedro Palhares, **Joaquin Gimenez

*CIEC, Institute of Education, University of Minho, **University of Barcelona

In this paper we describe the findings of a research study about improvements and difficulties found by young Portugal children when using numerical equalities. The study was conducted at the time when a new curriculum was introduced in Portugal. We found that teachers introduced some general perspectives by using examples of algebraic properties, but that teachers generally do not appear to focus in depth on their relational meaning of equalities. The students' results were better than in previous international studies. This may partly be due to the introduction of relational examples in the new curriculum. Nevertheless, the results reveal that Portuguese students still encounter difficulties concerning relational understanding and the meaning of equivalence more generally.

INTRODUCTION

The theme of this work arose from the understanding of the importance of the equality relationship in the development of algebraic thinking, particularly in terms of approaching relational variability (Falkner, Levi and Carpenter (1999)). For many years, it has been known that, when presented with the classic example to insert the missing number in the number sentence $18 + 27 = _ + 29$, many students answer by writing 45 in the space. So, many children see the equal sign as an instruction 'to do', rather than as a symbol representing a relation (Carpenter, Franke and Levi 2003).

Taking into account this situation, and considering that there was a new curriculum in Portugal in which algebraic thinking was explicitly included in Primary schools for the first time, we conducted a pilot research study to analyze the possible positive influences of such a curricular decision, at the end of the first year of implementation. In fact this curriculum stresses relations between numbers and between numbers and operations (DGIDC, 2007). Learning frameworks and programs and aligned professional development initiatives now focus on patterning and structural relationships in mathematics, including equivalence, growing patterns and functional thinking.

Our main research question was *if, with the introduction of the new program, we can find some anticipatory results on questions involving equalities as well as identifying some trends of relational thinking among students*. Fundamentally, Years 2-6 are critically important for developing and consolidating the early understanding of structural relationships developed. Since we could not find any study in Portugal on this issue, prior to the introduction of the aforementioned program, we chose to compare results with studies in other countries.

EQUIVALENCE RELATIONS AND VARIABILITY THINKING

Researchers agree that early algebra involves more than the generalization of arithmetic structures. Some argue that, in addition, understanding of early algebra involves generalized arithmetic, functional thinking and modeling (Blanton & Kaput, 2004), whilst others emphasize three main aspects of algebraic thinking: equality, change and generalizations (Zevenbergen, Doole & Wright, 2004). Warren (2003) extends the understanding of early algebra by identifying four central aspects: (1) Relationships between quantities, (2) Group properties of operations, (3) Relationships between the operations, and, (4) Relationships across the quantities. Research in number properties and operations articulates the important connection between general structural principles underlying numerical relationships and study of invariant properties (Smith, 2011) that assume a special importance on the understanding of some more advanced concepts in Algebra. Schliemann, Carraher and Brizuela (2007) assert that students' difficulties can be derived from the way they were taught during the first years of schooling, because the equal sign is usually introduced as directional operative with the meaning of 'gives' or 'result'. Moreover, since most textbooks limit the tasks presented to students to an operational type (Smith, 2011), it is not surprising that students develop an operational, and not a relational, notion of equality.

We agree with Kieran (2004) that in the transition from arithmetic to algebra, students need to make adjustments in the way they think, including those students who are quite competent in arithmetic. In the initial levels there is a strong emphasis on obtaining the answer rather than on the representation of relations. Confronted by an equal sign, students tend to see it as a frontier between problem and solution with a left-right direction. To counter this tendency, Kieran suggested five ways to develop algebraic thinking and relational understanding: (1) Focus on relations, rather than on calculating an answer, (2) Focus on the inverse operations, not only on the operations themselves, and on the ideas of doing and undoing that are part of the process, (3) Focus as much on the representations as on problem solving, not just on solving. (4) Focus both on the letters and on the numbers, instead of only on the numbers, including working on letters that can be unknowns, variables and parameters, and, (5) Accept open literal expressions as answers and compare expressions for equivalence based on properties; refocus on the meanings of equal.

Following such a perspective, Molina, Castro and Ambrose (2006) conducted research with 3rd grade students aimed at promoting algebraic thinking. Their results indicate that all students showed an operational interpretation of the equal sign. However, when offered tasks of sufficient variety, students progressively evolved to a relational interpretation.

Our current research study was designed to examine whether similar improvements took place in Portugal following the introduction of a national program in which relational perspectives are specifically introduced..

EMPIRICAL STUDY

To observe the possible influences of the new early algebra perspectives to overcome operational perspectives, we have constructed a pilot task involving open numerical equalities. This task was given to a purposively chosen sample of students from the 1st to the 6th graders of a group of schools in July 2011, after the first year of the implementation of the new curriculum. The sample consisted of all students from 6 different schools that were engaged in extra curricular activities during the school holidays. It is usual in Portugal that, for some weeks after the end of the academic year, many schools are open to help some families with financial difficulties. Hence, the sample was selected not for cognitive reasons, but solely for socioeconomic reasons. No students from the third and fifth grades were in the sample because of this situation.

Our study was implemented in a group of schools that had already followed the new program and the follow-on ‘Mathematics action plan’ that was intended to support its implementation. We could not compare the results with previous ones, although we did consult a leader in the region, who informed us about the difficulties the students had encountered previously on equalities. Our final sample consisted of 24, 20, 24 and 27 students, respectively from the 1st, 2nd, 4th and 6th years of schooling.

The task analyzed here, was constituted by eight open numerical equalities with additions in which students had to place a number to make it true. Students were asked to explain how they found the result. Students had no time limitation to complete the task. The equalities were as follows:

$$(a) \quad 8 + 4 = \square + 5$$

$$(b) \quad 8 = 3 + \square$$

$$(c) \quad 17 = \square + 17$$

$$(d) \quad 3 + 5 = 2 + \square$$

$$(e) \quad 6 + \square = 4 + 5$$

$$(f) \quad \square = 4 + 3$$

$$(g) \quad \square + 4 = 5 + 7$$

$$(h) \quad 9 + 7 = \square + 9$$

The items were similar to those used in previous studies, and were particularly designed to encourage students to consider, as solving strategies, relational properties. Item (f) is the regular operation with the unknown at the beginning. Item (c) focuses on the neutral property of zero. Item (h) focuses on the commutative property. Items (e) and (b) are related to the use of lacunar examples of type “ $_ + a = b$ ” that are used regularly in schools. Items (a), (d) and (g) are related to the possible use of the property $a+b = (a+1) + (b-1)$ or $a+b = (b-1) + (a+1)$ used sometimes in mental computation exercises. Only the first item was exactly the same as in the studies of Falkner, Levi and Carpenter (1999) and Freiman and Lee (2004). We note that we did not investigate situations involving subtraction, although these were included in the new curriculum. In fact, all the teachers in the sample informed us that they also considered number sentences such as $39 - 15 = 41 - \square$, or $5 \times 18 = 6 \times \square$. However, only one teacher told us that she also analyzed the effects of changes to the numbers for number sentences involving subtraction or multiplication.

In our sample the results about item (a) were as follows (Table 1):

	Number of students	Answer: $8+4=17+5$	Answer: $8+4=12+5$	Other values	Answer: $8+4=7+5$
1st Year	24	3 (13%)	13 (54%)	4 (17%)	4 (17%)
2nd Year	20	1 (5%)	8 (40%)	1 (5%)	10 (50%)
4th Year	24	1 (4%)	6 (25%)	3 (13%)	14 (58%)
6th Year	27	1 (4%)	5 (18%)	1 (4%)	20 (74%)

Table 1: Students results in the equality $8 + 4 = _ + 5$

From Table 3, we can see that 13% of the first year students added all the numbers to obtain 17. In the other years, it happened too but in only one case per year. We observe that, in comparison to previous studies, a lower proportion of students gave the “operational” response of 12 disregarding the number 5. Similarly, the proportion of correct responses was greater. Given the somewhat opportunistic nature of our sample, these results need to be treated with caution. Moreover, we cannot be certain such answers indicate a fully relational understanding. Nevertheless, we were surprised by these results. In fact, 10% of students established written relational arguments, representing it by quantified arrows. (See Figure 1).

Figure 1: A typical relational argument given by students.

Although this can be considered as a relatively small proportion of students, we consider this a surprising and “unexpected” result.

For items (h), $9 + 7 = _ + 9$, and (c), $17 = _ + 17$, the presentation of the problem appears at first similar to the first, item (a). The empty space immediately follows the equal sign. Yet the items are quite different. For item (h), the commutative property can be used, whereas for item (c), the neutral property of zero is used. The results for item (h), 17% of the 1st year correct, 55% in the 2nd, 75% in the 4th and 82% in the 6th year of schooling, are slightly better than for item (a), with much better results in the 4th year. Similarly, the results for item (c) are quite different with much better performance in all years of schooling. Whilst we really cannot be absolutely sure that this is because of the use of neutral property, we consider that this is highly likely since the neutral property is introduced from the first year of school. When asked,

some teachers supported this hypothesis, commenting “it’s sure, we did in the school the idea of $0+a= a$ ”.

	1st Year	2nd Year	4th Year	6th Year
$8 + 4 = _ + 5$	17%	50%	58%	75%
$9 + 7 = _ + 9$	17%	55%	75%	82%
$17 = _ + 17$	63%	95%	88%	96%

Table 2: A comparisons of correct results for items (a), (c) and (h)

Although we there is not space to analyse the remaining equalities in detail, we note that in general the results were better than expected. However, only in two questions did all the students of a given year answer correctly: item (b), $8=3+\square$, in the 6th Year and item (f), $\square=4+3$, for the 2nd year students.

The best performance of the 1st year students was in item (f), $\square=4+3$, with 80%, whilst their worst performance was for item (a), $8+4=\square+5$, and item (h), $9+7=\square+9$ with 17%. The worst performance of the 2nd year students was for item (a), $8+4=\square+5$, with 50%. The best performance of the 4th year students was for item(b), $8=3+\square$, with 96% and the worst was for item (a), $8+4=\square+5$, with 58%. The worst performance of the 6th year students was for item (a), $8+4=\square+5$, with 74%.

In order to identify the possible curricular influences, after the summer, we asked the students; teachers about the students’ previous work. All of them told us that they introduced some examples of arithmetical relations, because, as one teacher put it, “*it’s prescribed in the new curriculum*” [1]. Three out of six teachers commented in similar terms the following teacher: “*it’s not enough to use the equal sign as a result of an operation, as it’s shown in the new curriculum*”. According to these teachers’ self reports, they used *some* examples of equalities in which the equal sign is *not* related to a result of an operation. None spontaneously volunteered the use of problems in an equation form. But when they were asked to show examples of missing value arithmetic problems, they did show us examples such as $_ + 9 = 11$. In addition, a few examples like $4 + _ = 10 + 1$ were given in which the missing value appears on on the left side, and both sides consist of sums.

When we asked the teachers about the use of arithmetical properties, they referred to commutativity, zero as the neutral element, and the distributive law. However, none mentioned other relational properties of equalities as “ $a+b = (a+1) + (b-1)$ ” or “ $a+b= 2a + (b-a)$ ”. We observe that the teachers did not perceive a need to make explicit the variability relations underlying mental computation exercises. For example, teachers commented that “*My dear, since the new curriculum, we use computation strategies as doubling one element and halving the other gives the same result*” and “*it’s difficult for the students to see that many properties appears for every pair of numbers*”. One teacher explained “*We did exercises with equalities, but we never insist on the fact of generalizing the property, as I know it is, for every number, if we*

add two to a one member of an addition, and decrease two, the result is the same". Some teachers also explained that *"I always write the correct answer in the blackboard to correct their mistakes"*. One of them asserts that *"I know it's better to discuss about the properties, but I tell them look if it's true or not"*.

We also asked the teachers about the use of technological tools for studying arithmetic relations. All of them answered that *"we use variables in geometrical or functional tasks, but I never used technological tools for observing arithmetical properties... because I don't know how to do"*.

CONCLUSION

First and foremost, we note that this was a pilot study and the results should be treated with some caution. Nevertheless, our study offers Portuguese data relating to an important aspect of the learning of algebra: the extent to which students understand equality operationally or relationally (Smith, 2011). From our study, we observe that, whilst some Portuguese teachers interpret the increased use of relational properties by the students as a very good result, they are not aware of the importance of the students verbalizing the relational meaning, even with the new curricular influences. Indeed, one of the teachers bemoaned *"the lack of a protagonist role of the students in the moment of exploration"*.

It appears that, even though the results are better than for previous studies, it is of the utmost importance to promote further changes to teaching practices in Portugal. In our study, it appeared that *"although the new program explicitly includes algebraic thinking, students are still below what should be for the subsequent formal teaching of Algebra"*. Many students possess an interpretation of the equal sign included in an operational view instead of relational. We concur with previous research that the students' difficulties are related to the way they were taught and not an expression of any inability to understand relations between quantities (Molina, Castro and Ambrose, 2006; Schliemann, Carraher and Brizuela, 2007; Haylock, 2006). So, for example, we infer from the results for items (a), (d) and (g) that many students are not aware of the general property $a+b = (a+1) + (b-1)$. Nevertheless less percentage of errors are due to the operational perspective.

In conclusion, although these results suggest there may have been some improvement, there is still a long way to go before we achieve acceptable student performances (Knuth et al., 2011). For that, more care is necessary in the teacher's practices to emphasize the use of numeric relations (and manipulative or technological representations. Such work should be linked to a certain development of algebraic thinking, because as Kieran (1992) points out, the distinction between arithmetic and algebraic thinking is the change from a procedural vision of operations towards a structural one.

CONCEPTUAL CHALLENGES FOR UNDERSTANDING THE EQUIVALENCE OF EXPRESSIONS – A CASE STUDY

Larissa Zwetzschler & Susanne Prediger

TU Dortmund University, Germany

Whereas students' conceptual understanding of variables and equations has often been investigated, little is known about students' pathways to understanding the equivalence of expressions in generational instead of transformational activities. The case study reconstructs two conceptual challenges that must be overcome on these pathways to conceptual understanding of equivalence: (1) limited degrees of generality for variables and figures, and (2) operational versus relational perspectives on expressions.

THEORETICAL AND EMPIRICAL BACKGROUND

Understanding of equivalence as one meaning of the equal sign

Students' limited understanding of algebraic equality has often been problematized in empirical studies (e.g., Kieran, 1981; McNeil & Alibali, 2005). Many students only interpret the equal sign as a prompt to calculate the value, but algebraic thinking also necessitates the *relational* meaning as signifying symmetric structural relations between the left and right side of the equal sign. Whereas most research has focused on equations like $7x + 28 = x + 4$, the relational interpretation of the equal sign is not only addressed (A) in algebraic equations, but also in three other important aspects; (B) arithmetical identities like $7 \cdot (10+4) = 7 \cdot 10 + 7 \cdot 4$, (C) equivalence of expressions like $7 \cdot (x+4) = 7x + 7 \cdot 4$, being generalized from (C), and (D) contextually bound identities like "Right triangles with hypotenuse c and legs a , b satisfy $a^2+b^2=c^2$ " (see Prediger, 2010 for these aspects). Aspect (B) refers to arithmetic; (A), (C) and (D) to algebra, but with different meanings of the variable. Whereas variables in equations (A) serve as unknown to be solved, variables in aspects, (C) and (D) serve as generalized numbers (Usiskin, 1988, p. 17). Hence, generalization is crucial for understanding algebra. Building an understanding of (A) and (B) has often been investigated, whereas (C) is considered more rarely (see next section). We defined the aspect of a relational understanding of equivalence (C) as the core subject of our design research project (see Prediger & Zwetzschler, 2013, for an overview).

In this paper, we present a small descriptive study within a larger design research project that focuses on the empirical specification of conceptual challenges that students encounter while developing conceptual understanding for the equivalence of expressions. We investigate these individual conceptions in a learning arrangement that promotes generational activities before transformational activities (Mason et al., 1985), as will be further explained in the next sections.

Three meanings for the equivalence of expressions

In our approach, we *generalize the operational-relational dichotomy from the equal sign to the equivalence of expressions*: How should students understand equivalences

like $a \cdot b + 2 \cdot b \cdot h/2 = b \cdot (a+h)$? In line with the wrong priority attributed to operational meanings of the equal sign (Kieran, 1981; McNeil & Alibali, 2005) is the fact that many students (and some curricula) think about equivalence of expressions only in terms of *transformational activities*. But how to ground these transformation rules in conceptual understanding? Mathematically, they can be derived from the basic arithmetical laws (like commutativity and distributivity). But as Demby (1997) has pointed out, the general deduction from arithmetic to algebra is too complex and abstract for many learners (e.g., Lee & Wheeler, 1989). That is why a learning arrangement that fosters the development of conceptual understanding of equivalence of expressions should first involve its inclusion in *generational activities*, in which algebraic expressions are not only understood as a system of meaningless signs (being transformed according to arbitrary rules), but as pattern generalizers of arithmetical or geometrical pattern (Mason et al., 1985, p. 46 ff.). Within these activities, a *relational* understanding of the equivalence is achieved by comparing expressions with respect to equivalence (Kieran & Sfard, 1999) To sum up, three meanings of the equivalence of expressions are to be acquired, first, (a) and (b), then (c):

- (a) *description equivalence*: ..., if they describe the same phenomenon (same geometric pattern, same situation, same function, ...);
- (b) *insertion equivalence*: ..., if they have the same value for all inserted numbers;
- (c) *transformation equivalence*: ..., if they can be transformed into each other according to the transformation rules. (Malle, 1993; Prediger, 2009)

For (a), description equivalence, a relational perspective on expressions, Kieran & Sfard (1999) compare functions where the table representation immediately leads to (b), the insertion equivalence. As an alternative approach to that Pilet (2013) focuses on an operational perspective (b) to build a conceptual understanding (see also, Solares & Kieran, 2012; Rittle-Johnson et al., 2011). Our tasks in Figure 1 (Prediger et al., 2011) follow Mason et al. (2005) and Malle (1993) by establishing description equivalence for areas of varying geometric shapes, complemented by establishing insertion equivalence.

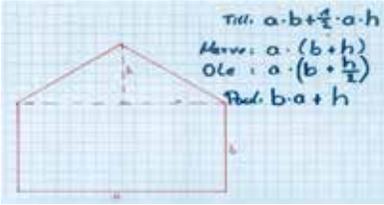

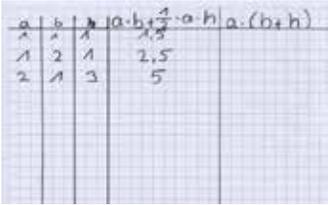

<p>(I) Which students calculate the same area? And which of the <i>expressions</i> calculate the area of the given geometric shape correctly?</p> 	<p>(II) Insert different numbers for the variables. Check which of the expressions are equivalent.</p> 
---	---

Fig. 1. Tasks (I) for experiencing description equivalence and (II) for insertion equivalence

In this paper, we reconstruct critical moments in the learning pathways towards description and insertion equivalence; the latter completion by transformation equivalence is not treated here. Generalizing the *operational-relational dichotomy from the equal sign to expressions*, we developed Task I to prioritize a relational perspectives on algebraic

expressions against purely operational perspectives. That means, we do not emphasize the activity of *calculating* values of expressions, but that of *formulating, interpreting and structuring* expressions while relating them to geometric shapes. However, our empirical analysis will show (in Section 3) that students still adopt other variants of operational perspective which produces conceptual challenges for their pathway to description equivalence.

Additionally, we will show that the *degree of generality* is a relevant source of difficulties. The insertion equivalence is quite natural for students for one *specific* insertion, namely the specific side lengths in the given geometric shapes; this interpretation of variables is known as “letter as object” (Küchemann, 1981). However, two expressions are only equivalent if they have the same value for *all* inserted numbers. We will show how a limited degree of generality (being transferred from geometry to algebra) forms a second conceptual challenge for understanding general insertion equivalence.

METHODOLOGY

This study is embedded in a larger design research project (Prediger & Zwetzschler, 2013) that follows the methodology of Cobb & Gravemeijer (2006) with its dual aim of deepening the understanding of learning processes and designing learning arrangements. Therefore, it applies iterative cycles of (re)design and empirical investigation. Here, we concentrate on one step of empirical investigation with the following research questions: (1) Which conceptions do students activate or develop in a learning arrangement designed to foster the conceptual understanding of description and insertion equivalence? (2) How do the individual conceptions of variables, expressions and geometric shapes influence the learning pathways? Where do conceptual challenges appear?

Data gathering in design experiments

The tasks presented in Table 1 were part of the teaching-learning arrangement used for twelve design experiments in laboratory settings (Komorek & Duit, 2004). A teacher worked with 12 pairs of students in grade 7 to 9 in German comprehensive secondary schools), for three to five sessions of 45 to 60 minutes, the presented task lasted 20 to 50 minutes. All experiments were videotaped and partly transcribed.

Data analysis: Vergnaud’s analytical model of concepts- and theorems-in-action

For the interpretative analysis of individual conceptions (research question Q1), we operationalized “conceptions” by adapting the theoretical constructs concepts- and theorems-in-action from Vergnaud’s theory of conceptual fields, as this theory offers “a fruitful and comprehensive framework for studying complex cognitive competences and activities and their development” (Vergnaud 1996, p. 219).

The *first step* of our analytic procedure allows to reconstruct, for each of students’ visible activity or utterance, the underlying operational invariants: *Theorems-in-action* are defined as “proposition that is held to be true by the individual subject for a certain range of situation” (Vergnaud, 1996, p. 225). In order to adapt Vergnaud’s construct to our specific needs, we symbolize theorems-in-action by $\langle \dots \rangle$ and always formulate the

purpose and the means, e.g., <For calculating the value of an algebraic expression, I can replace the variable by the specific measures in the drawing>. These theorems-in-action are shaped by *concepts-in-action*, being defined as “categories (...) that enable the subject to cut the world into distinct (...) aspects and pick up the most adequate selection of information” (ibid.), e.g., ||Variable as unique hidden number||. In the *second step* of analysis, we categorize the reconstructed concepts-in-action according to their subject (variable, expression, connection between expression and geometric shape, ...), their degree of generality and the underlying operational or relational perspective on the subjects. This allows us to identify connections that could be interpreted as sources for typical conceptual challenges (research question Q2).

RESULTS: RECONSTRUCTING CONCEPTUAL CHALLENGES

Without being able to provide wide empirical evidence from the case studies, we present short extracts of our analysis, show typical moments in the processes and discuss the connection between the reconstructed theorems- and concepts-in actions.

Episode 1 of Paula & Daniel: Degree of generality for variables and figures

Paula and Daniel (grade 9) collaborate on Task I (Fig. 1). Before Turn 62 they evaluate two given algebraic expressions as correct by relating sub-expressions to sub-areas of the figure, guided by the concept-in-action ||Relation between expression and shapes as corresponding by substructures||. For Till’s expression $a \cdot b + \frac{1}{2} \cdot a \cdot h$, they don’t find structural correspondences and calculate instead:

- | | | | |
|----|---------|--|--|
| 62 | Paula: | So $0.5 \cdot a \cdot h$, you need values to calculate it. [...] | |
| 66 | Daniel: | Therefore, we would need this height here. | |
| 67 | Paula: | Ah, just count it, don’t know. That’s 1 2 3 4. [...] | |
| 71 | Paula: | So a was 8, right? | |
| 72 | Daniel: | Yes. | |
| 73 | Paula: | 8 (writes down $a=5$), so the half would be, that would be 4 hm (counts the units, then counts side lengths and calculates the area). | |

Paula’s activities in Turns 62-73 are guided by her individual theorem-in-action: <For finding out which expression is correct, I can calculate the value of the expressions>. Beyond it, we reconstruct her concept-in-action ||Relation between expression and shape as decidable by quantities||. Both students search for specific measures for calculating (Paula in Turn 62, Daniel in Turn 66). They solve their need by the theorem-in-action <For calculating the value of an algebraic expression, I can replace the variable by the side lengths in the drawing> (Turn 71ff), beyond which we reconstruct the concept-in-action ||Variable as hidden specific number||. Like many other students in our study, Paula und Daniel are guided by their individual focus on specific lengths. A short while later, they compare algebraic expressions by their values for a specific insertion:

- | | | |
|----|---------|--|
| 93 | Daniel: | that was Till (writes $Till = 48$ $Ole =$) |
| 94 | Paula: | mhm – Maybe we calculate about Ole, which result is the right one. |

The theorem-in-action <For comparing two expressions, I can compare the results of the expressions> assists Paula to correctly evaluate Till’s and Ole’s expression as equiva-

lent. However, the underlying concept-in-action ||Equivalence as equality of results|| is only partially correct, since it limits the insertion equivalence to specific numbers. Their limited degree of generality for the variables is connected to a well-known misconception about geometric shapes: Paula and Daniel do not apply the geometric concept ||Geometric shape as general figure|| in which changeable side lengths (and as a consequence the form of the shape) are considered, but instead they apply the individual concept-in-action ||Geometric shapes as specific drawings|| (see Parzys, 1988) in which side lengths are fixed to the specific drawn measures.

Paula's and Daniel's restriction to ||Equivalence as specific insertion equivalence|| and ||Variable as hidden specific number|| becomes an evident obstacle for developing the concept of general insertion equivalence when working with Task II where the fictitious student Till inserts several numbers for comparing the expressions in the next scene.

- 27 Paula: We filled in the right numbers and he took anyones?
 ...
 30 Daniel: Huh? That's not possible.
 31 Teacher: Why is that impossible?
 32 Daniel: You just can't insert different numbers.

a	b	h	$a \cdot b / 2$	$a \cdot h$	$a \cdot (b+h)$
1	2	1	1	2	3
2	1	3	1.5	6	7.5

Due to their concept-in-action ||Variable as hidden specific number||, their theorem-in-action <For comparing two expressions, I can compare the results of the expressions> is limited to one insertion (the specific drawn lengths), so that they cannot get access to the general insertion equivalence. From this snapshot and comparable episodes from other case studies, we conclude that at this point in the learning process, the individual concepts-in-action on variables and geometric shapes, like those of Paula and Daniel,

Table 1. Degree of generality as a challenge on the pathway to insertion equivalence

	Specific	→	General
Conceptions for variables	hidden specific number		changing / generalized numbers
Conceptions for geometric shapes	specific drawing with fixed side length		general figure with varying side lengths
Conceptions for Equivalence of expressions	specific insertion equivalence / specific description equivalence		general insertion equivalence / general description equivalence

provide a challenge for the development of conceptual algebraic understanding (see Table 1). Although in the later part of the design experiment, many students succeed in overcoming this challenge of limited degree of generality, we emphasize that in the first encounter, the geometric interpretation of expressions can become a source of a conceptual challenge if limited geometric understanding is activated.

Episode 2 of Jan & Niclas: Intermediate generality in operational perspectives

Jan and Niclas (grade 7) also work on Task I and start by finding an own way of calculating the area. Niclas struggles with Ole's expression $a \cdot (b + h/2)$. The understanding of generality in the tasks is a similar challenge for them.

- 56 Niclas: Me, for example, I would know how to calculate the area, but the whole expression.
- ... Niclas: (*explains correctly how he would calculate the area of the drawing*).
- 61 Teacher: Mhm, just write it down anyway.
(*Jan wants to know, if he got right in understanding Niclas.*)
- 63 Niclas: ... can I just do it with units, that I count this (*he first touches the lower side and afterwards the height of the triangle*) so or just six units?
- ...
- 66 Jan: ... there is nothing specified.
- 67 Niclas: Yes
- 68 Jan: There are none, so now that is, I mean, how many, let me say, that are 3 meters (*hints to side b*) that are 4 meters (*hints to side a*). It is only now that it is specified how long the sides are.
- 69 Teacher: How long could they be, the sides?
- 70 Jan: Different, as you can actually choose, x-variable.
- 71 Teacher: mhm
- 72 Niclas: Or maybe one unit as one meter, that are 16 meters (*hints to side a*) that are 9 meters (*hints to side b, gives a shrug*), aren't they?
- 73 Jan: Also possible.

Both boys operate with the individual theorem-in-action <For calculating the area of the given shape, I can insert values for the variables>, but, while negotiating which value to insert, divergent concepts-in-action appear. Whereas Jan emphasizes that different values can be inserted (Turn 68, 70) and thus activates a high degree of generality, Niclas first starts with the concept-in-action ||Variable as place holder for specific numbers|| in Turn 63. Reacting to Jan's objection in Turn 72, he broadens his theorem-in-action to <For calculating the area of a given shape, I can insert the side length with variable scales>. Thus, he changes his concept-in-action to ||Variable as a place holder for specific numbers but variable scales||. This concept-in-action is in line with the geometrical concept-in-action, ||Geometric shape as drawings with specific side length but variable scales||. Since this concept-in-action is still restricted to geometrically *similar* drawings, we classify Niclas' concepts-in-action as having an intermediate degree of generality (locating between the columns of Table 1). With these higher degrees of generality, their further pathway to *insertion equivalence* is smoother than that of Daniel and Paula.

However, their pathway to *description equivalence* is challenged by serious difficulties in connecting the shape and the expression. The problem first appears in Turn 56, when Niclas claims not to be able to formulate his own expression. His use of variables seems to be restricted to inserting and calculating, so we reconstruct the operational concepts-in-action ||Expression as prompt to calculate|| and beyond that ||Variable as place holders||, but not ||Expression as description for structures|| (see Table 2). In contrast to Daniel and Paula who can (sometimes) activate ||Relation between expression and shapes as corresponding by substructures||, Niclas and Jan only draw connections between expressions and shapes when the expressions are written with numbers instead of variables. Later, the teacher prompts them to find sub-expressions with variables in the figure:

- 406 Teacher: Mhm and why did Till actually first multiply a times b and than a times h – and afterwards divide that by two? – Do you have an idea how he could have

- found that out?
- 407 Niclas: Uff – well, maybe to make it easier or something like that.
- 408 Jan: Well, actually he did a times h...
- 409 Niclas: ...Because he has – he has these lengths [*hints to a and b*] or this information [*hints to the expressions*] this is what he already has, that's why you can do this ... [*interrupts himself, break 8 sec.*]
- 410 Jan: Do you know how Ole works?
- 411 Niclas: Hm – no idea [*laughs*] – how you can find it out

In Turn 409, Niclas explicitly refers to the algebraic expressions and the figure, but interrupts himself when trying to relate them to each other. The formerly used individual theorem-in-action <For connecting the shape and the expression, I can insert the side lengths> is explicitly excluded by the teacher's prompt to consider the sub-expressions with variables, but he does not find any other way to relate the shape and the expression. The challenge, therefore, is that they have a completely operational perspective of the expression, namely the concept-in-action ||Expressions as prompt to calculate|| which is directly connected to ||Variable as place holders|| (see Table 2).

Table 2. Operational – relational dichotomy as a challenge on the pathway to description equivalence

	Operational perspectives on variables and expressions	→	Relational perspectives on variables and expressions
Main activities	calculate		formulate, interpret, structure
Conception for algebraic expression	prompt to calculate, numbers must be inserted before dealing with expressions		description for structures (e.g., pattern) for unknown / general numbers
Conceptions for variables	place holder for numbers		specific numbers or changing / generalized numbers
Correspondence between algebraic expression and geometric shape	Relate only quantities (numbers, values <-> side length, areas)		Relate also structures (operations or subexpressions <-> substructures and parts of shape)
Conceptions for equivalence of expressions	only insertion equivalence		insertion and description equivalence

Turns 406-411 show how these concepts-in-action hinder the boys' capacity to relate the shape and the expression. Table 2 is the condensed outcome of a comparison of several cases and systematizes the observed problems and logical connections. It generalizes the well-known relational-operational dichotomy from the equal sign to variables, expressions and the understanding of equivalence. The restriction to the main activity in the operational perspective (calculating expressions) has consequences for the variable as well as for the correspondence between algebraic expression and geometric shape. For the pathway to description equivalence, operational perspectives on expressions must be complemented by relational ones that focus on own formulations of expressions, structures and interpretations. Unless the variable is considered only as place holder and the expression only as prompt to calculate, the correspondence between expressions and shapes can not be drawn by relating substructures. In this way, the con-

cepts-in-action in the different lines of Table 2 are deeply connected and the transition from operational to relational perspectives is crucial.

CONCLUSION AND OUTLOOK

The empirical analysis of typical challenges showed two important dimensions in which students have to develop their initial conceptions on their pathways to a conceptual understanding of the equivalence of expressions. To understand a general insertion and description equivalence: (1) the degree of generality attributed to variables and geometric shapes (Table 1; vertical axis in Fig. 2), and (2) the operational versus relational perspectives on variables, expressions and - as a consequence - the relation between expressions and geometric shapes (Table 2; horizontal axis in Fig. 2) are the main challenges that have to be overcome. Although the four students finally succeeded in overcoming these challenges, our extracts of their processes show typical moments and intermediate states of the development in these two dimensions of challenges. The first episode with Paula and Daniel shows how a specific understanding of variables and geometric shapes limits students' conceptions for the equivalence of expressions.

In the second episode, Jan provides a higher degree of generality, and Niclas adopts an intermediate conception on variables as specified numbers with variable scales. Jan and Niclas additionally struggle with their purely operational interpretation of expressions, variables and the connection between geometric shapes and algebraic expressions. This interpretation hinders their pathway towards description equivalence.

General  Specific	general insertion equivalence <i>(Episode 2b: Jan)</i>	 general insertion and description equivalence <i>(Intended Understanding)</i>
	intermediate state <i>(Episode 2a: Niclas)</i>	intermediate state
	only specific insertion equivalence	only specific insertion and description equivalence <i>(Episode 1: Paula and Daniel)</i>
	Operational perspectives	Relational perspectives

Fig. 2. Overcoming conceptual challenges in two dimensions: Overview on the cases

In the larger design research project, these findings initiated the design of additional tasks that help to overcome these challenges (see Prediger & Zwetschler, 2013). In those tasks, our purpose was to broaden students' perspectives from being purely operational to also becoming relational. Therefore, we integrated tasks that focus on structural connections between geometric shapes and (first arithmetic and later algebraic) expressions by making explicit the strategies for finding substructures in expression and shapes. One example is given in Task (III) in Fig. 3 (Prediger et al., 2011). As the figure shows, the students need to adopt a relational perspective in order to find out which elements belong together. The focus on substructures is strengthened by the verbalization of strategies as a third element that serves as conceptual bridge to overcome the gap between the drawing and the expressions.

(III) What belongs together?
Add the missing expressions.

I have added something; that's what I must subtract later.

I have split the figure and moved one part.

I have split the figure twice and moved one part.

I doubled something, I have to regulate that.

$(3 + 8) \cdot (4 / 2)$

$[(8+3) \cdot 4] : 2$

Fig. 3. Design of a task that focuses on drawing connections of substructures

The following design experiments showed that this task encourages students to draw connections and thus to gain access to the learning pathway towards understanding description equivalence. Further analysis of the generated learning processes are conducted in Zwetschler (2013).

HOW EXPERTS GRAPH FORMULAS

Peter Kop¹, Fred Janssen¹, Paul Drijvers²

¹*Iclon, Leiden University, The Netherlands*

²*Freudenthal Institute, Utrecht University, The Netherlands*

Keywords: graphing formulas, heuristics, recognition.

Introduction

In secondary school, students learn to manipulate algebraic expressions, to solve equations and to graph formulas. In order to graph formulas easily, one has to read the formula. ‘Grasping the structure of expressions’ (Sfard & Linchevski, 1994) is an aspect of symbol sense (Arcavi, 1994), rarely addressed in textbooks. As a consequence, teachers have to develop their own teaching methods in this area, which requires pedagogical content knowledge including subject matter knowledge and teaching strategies (Hill, Ball & Schilling, 2008).

In our research we investigate Dutch teachers' pedagogical content knowledge in this context. As the first stage of the project we address the following questions: Which formulas can experts instantly visualize as a rough graph? And if instant visualization (recognition) is lacking, which strategies do they use to graph a formula? We analyse experts' performances in identifying knowledge involved and heuristics needed to complete these tasks. The experts' results will allow for a comparison of experienced and novice teachers and students on the same tasks. With these results we will get a clear view on the differences between experts and teachers and will be able to develop a professional development trajectory.

Theory

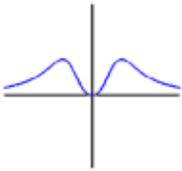

Chi, Feltovich & Glaser, (1979) and De Groot (1965) both claim that experts, compared to others, recognize more and deeper patterns and are more sensitive to critical features. They use larger hierarchically organized units of knowledge (chunks). In problem solving they perform qualitative analyses, consider potential actions and categorize problems. During the execution of such tasks they apply self-monitoring, evaluate result and processes, and look for alternative solutions. More specifically for mathematics, Polya (1945) formulates heuristics as strategies for problem solving in general. In line with this, Van Streun (1989) uses heuristics based on Polya's, but he explicitly identifies recognition as the starting point of the problem solving process. On the basis of these general perspectives we designed a framework for specific strategies for graphing formulas (figure 1), in which we distinguish two steps, first recognition and then heuristic search.

Method

The experts involved in the pilot interviews each have more than 10 years' experience in their work, which often requires graphing formulas. We selected teachers at universities, a teacher educator, a textbook-author and a teacher who develops national mathematics exams. For this stage of the project we have developed a matching formula-graph task and a card sorting task in order to establish the experts' thinking units. A thinking unit is a formula which the expert can instantly visualize as a rough graph. In the third task we want

experts to move beyond their recognition-zone and force them to use a heuristic search. We ask them to graph a more complex formula and work in the opposite direction: to find a formula that fits a given graph. During this task we ask experts to think aloud.

Task 3: Draw a rough graph for $y = 2x\sqrt{8-x} - 2x$ and write down a formula that fits the graph:

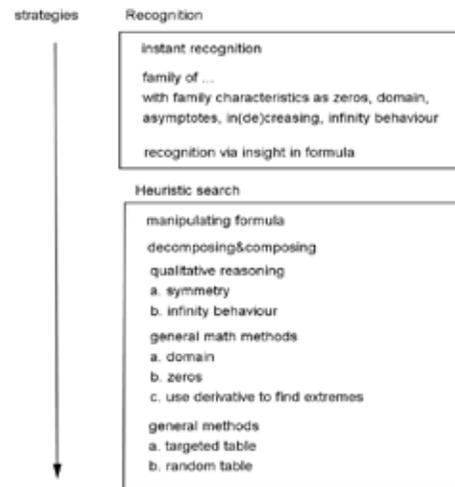

Results and Conclusions

Experts differ in the number of formulas they can instantly visualize as rough graphs. All experts show characteristics as formulated by Chi et al., especially regarding monitoring and evaluation. In general experts prefer qualitative reasoning and hesitate to start calculations. There seem to be two kinds of experts: those who try to decompose the formula into known components (thinking units) and those who start a standard program of strategies, formulated in our framework as general (math) methods. We hypothesized that experts first use recognition and then a heuristic search. The data suggest, however, that recognition guides the heuristic search. Gobet and Charness (2006) found for chess players a trade-off between knowledge and a heuristic search. We intend to adapt our framework (figure 1) according to these findings.

GENERALIZING AND JUSTIFYING PROPERTIES OF REAL NUMBERS: A STUDY AT GRADE 9

Joana Mata-Pereira* & João Pedro da Ponte**

*UIDEF, **Instituto de Educação, Universidade de Lisboa, Portugal

KEYWORDS: Reasoning, Generalization, Justification, Real Numbers

ALGEBRAIC REASONING PROCESSES

Developing mathematical reasoning is an essential condition for understanding mathematics and also for using mathematics in a proficient way. Also, as reasoning is recognized as inseparable from the representations and language through which it is expressed (Arzarello, Bazzini, & Chiappini, 2001), algebra, which forms the basis of the symbolic language of mathematics, is eminently suited to its development. To give some structure to the complexity of ideas, notations and activities involved in Algebra and algebraic reasoning, Kaput (2008) advocates a perspective of symbolism that emphasizes two central aspects of algebra: (i) algebra as symbolizing systematically generalizations of regularities and constraints, and (ii) algebra as syntactically guided reasoning and actions as generalizations expressed in conventional symbolic systems. One of the areas these aspects are embedded in is algebra which is the study of structures and systems of abstract relationships and procedures, including those from arithmetic (algebra as generalized arithmetic) (Kaput, 2008).

Reasoning ability is crucial to students. Developing students' algebraic reasoning involves far more than just memorizing concepts and routine procedures. Instead, a focus on memorization leads the students to develop a vision of mathematics as a disconnected set of rules rather than a logical and coherent science (ME, 2007). However, to develop reasoning is challenging for teachers, particularly in everyday classrooms, in all mathematical topics. In order to understand how to promote the development of students' algebraic reasoning, a fruitful step is to take a close look at two key mathematical reasoning processes – generalizing and justifying. Generalizing plays an essential role in the understanding of mathematics as this process of reasoning is one of the foundations of mathematics as a science. Also, justification is an essential process as it allows students to clarify their reasoning, contributing to the development of a deeper understanding of algebra.

AIMS AND METHODOLOGY

This study aims to analyse grade 9 students' algebraic reasoning processes while working on tasks involving real numbers and to know how those tasks contribute to develop students' mathematical reasoning in an algebraic context. Based on a collaboration with a grade 9 mathematics teacher, the study developed within a teaching unit supported by exploratory tasks involving real numbers. Following an interpretative and qualitative methodology, data collection includes videorecording of

the lessons and students' written tasks. Data analysis is undertaken according to two main categories related to reasoning processes – generalization and justification. Two other transversal dimensions that go along with reasoning processes – representations and sense making – are also considered in the analysis. This poster focuses on two students working on a particularly significant task on the properties of operations with real numbers, involving a mixture of closed and open questions.

CONCLUSIONS

The results suggest that exploratory tasks with real numbers promote the development of students' conjecturing processes, particularly generalizations, but are not enough to make them to use justifying processes. While making generalizations, most students follow an inductive approach, generalizing the relations observed in particular cases to a larger class of objects. Sometimes these generalizations have a deductive nature. In contrast, justifying is not done spontaneously, but, in response to the teacher's questioning, students show that they are able to make justifications based on previous knowledge of properties or mathematical concepts and based on counterexamples that refute a statement. Therefore, we conclude that, alongside exploratory tasks, teaching practices such as questioning play a key role in promoting the use of reasoning processes. In these tasks, as students have ease on using more than one representation, the use of various representations seems not to limit the development of their mathematical reasoning. Sense making is intrinsically linked to the generalizations or justifications presented. Thus, when students' depict difficulties in making connections between concepts and properties required to solve the task, they also seem to have difficulties in generalizing or justifying. Exploratory tasks allied with teacher questioning practices, emerged as key elements to develop students' use of reasoning processes as well as to promote their deeper understanding of the properties of real numbers. Also, the use of a framework involving reasoning, representations and sense making showed to be useful to study the relationships between these three aspects.

IMPROVING THE COVARIATIONAL THINKING ABILITY OF SECONDARY SCHOOL STUDENTS

Tobias Rolfes, Jürgen Roth, & Wolfgang Schnotz

University of Koblenz-Landau, Campus Landau, Germany

Keywords: Functions, Covariation, Forms of Representation

THEORETICAL BACKGROUND

Vollrath (1989) considers three aspects of the concept of function to be essential. First, in the point-wise view, every value of the domain corresponds to exactly one value of the range. Second, in the dynamic view, the aspect of covariation requires taking into account the neighborhood of the point: How does the function value vary if the input value is varied? Third, the global view contemplates the function as a whole. This is necessary if statements are made about symmetry, for example.

Researchers point out that the aspect of covariation is not sufficiently implemented in mathematics curricula (Malle, 2000; Thompson, 1994). Instead, school teaching mainly focuses on the point-wise aspect of functions even though it is hardly possible to construct adequate mental models of the concept of function without considering the covariational aspect. Despite researchers' consensus on the importance of this aspect, there is a lack of research on how to develop it in secondary education.

AIMS AND RESEARCH QUESTIONS

By developing empirically based training sessions in covariational thinking, we hope to better prepare students for the infinitesimal calculus and also to show a way of improving a neglected aspect of mathematical literacy in secondary grades. A research hypothesis is that covariational thinking is not restricted to upper secondary grades and that students from grade 5 onwards are able to make substantial improvements with regard to this aspect of functional thinking. On the one hand, we want to identify students' misconceptions when dealing with covariational tasks. On the other hand, we aim at identifying students' cognitive resources in the area of covariational thinking. As we conjecture that the forms of representation play a decisive role, we want to find out which form of representation is more intuitive when dealing with covariational tasks.

METHOD

A training session in seventh grade ($n = 27$) started with a material-based analysis of the covariation of different functional dependencies (linear vs. quadratic) with a discrete domain. Initially, the students explored the covariation in a qualitative and quantitative manner based on self-generated representations, namely tables of values and graphs, in a discovery learning environment for 20 minutes. Afterwards, the solutions were discussed in a teacher-class dialog for another 20 minutes. At the end

of the lesson, the students were given a paper-and-pencil test consisting of six tasks, which were analyzed with mixed methods.

RESULTS AND PRACTICAL IMPLICATIONS

In the analysis of misconceptions we discovered that students confused the first and second difference. Many students incorrectly identified a function with constant second differences as a linear function instead of a quadratic function. This conflation forms an essential obstacle when dealing with covariation. Research on the development of teaching concepts to deal with this problem is still needed.

Furthermore, some students extrapolated linear growth as if it were proportional growth. These findings are consistent with the documented preference for proportional reasoning (De Bock, Van Dooren, Janssens, & Verschaffel, 2002). As a consequence, teaching in early secondary grades has to put more emphasis on non-proportional growth (e.g., exponential, quadratic, or logistic growth) to prevent an overgeneralization of proportional reasoning.

In a quantitative analysis, the role of the form of representation was investigated in a within-subjects design. The students performed significantly better at value table production than graph construction (sign test: $g = .35$, $p < .001$). This raises the question of whether the table of values activates students' cognitive resources in covariational thinking more than graphs. Accordingly, further research on this topic is necessary.

Moreover, students had more difficulty extrapolating quadratic functions than linear functions (sign test: $g = .24$, $p < .01$). This result underlines that school teaching should deal with different types of growth as early as possible.

INTRODUCTION TO EQUATIONS: THREE CASES AS PART OF A VIDEO STUDY

Ann-Sofi Røj-Lindberg, Anna-Maija Partanen and Ole Björkqvist

Åbo Akademi University, Vasa, Finland

Keywords: comparative video study, introduction to equations, classroom interactions

In an international comparative video study called VIDEOMAT (Kilhamn & Røj-Lindberg, 2013) the aim has been to document mathematics lessons in Finland, Norway, Sweden and the USA on the introduction to algebra. A more specific teaching content, introduction of letters as variables, was determined through textbook analyses in each country. A series of consecutive lessons were video recorded in two to five schools in each country with the primary aim to make comparative analyses concerning algebra teaching and learning. As part of data collected within VIDEOMAT, the first recorded lesson in three primary schools in the Swedish speaking part of Finland has been analyzed. The analysis shows similarities on a structural level as well as remarkable differences in the classroom-specific approaches to the introduction of equations.

THEORETICAL BACKGROUND

The introduction of algebra is problematic for large groups of students, particularly when the numerical system is expanded to the use of letters to represent variables or unknowns. Concerning the introduction of equations, a distinction can be made between arithmetic and algebraic types. In arithmetic equations, letters appear as variables or unknowns on just one side of the equal sign, and hence the learner might approach the equal sign in a dynamic way. The adjustments from arithmetic to algebraic thinking include a focus on the equal sign as structural (Kieran, 2004), and on the possibilities for participating in public sense-making processes in the mathematics classroom (Schoenfeld, 2008). Furthermore, the nature of those processes needs attention. The problems connected with the introduction of equations in the mathematics classroom may be related to limitations in teaching approaches. Thus, an exploration of how the content of equations is introduced in classrooms becomes an interesting focus for research.

RESEARCH QUESTION AND METHODOLOGICAL FRAME

The research aims to address the question: What kinds of approaches to the introduction of equations are used in the three grade 6 classrooms, and how is each approach socially constituted? A sequence of four lessons on introductory algebra was videotaped in three grade 6 classrooms. The three schools followed the same national curriculum and the same textbook. Data were collected with three stationary video cameras, which recorded the class from up front, the interactions of a small group of students and the actions and voice of the teacher. In addition, information

was obtained through teacher interviews, written work of the students and various lesson files. The content taught in the first recorded lesson in each class was similar: arithmetic equations (addition, subtraction) with one unknown term. A micro case study of these three lessons was performed, including a fine-grained analysis of the sections coded as ‘teacher-led’ (TL) or ‘teacher-led with students’ (TLS) (see Kilhamn & Røj-Lindberg, 2013). Similarities and differences between the three lessons were identified, with a particular focus on the roles students constructed through interaction, on the positioning of the students as evidenced in the use of pronouns in the TL and TLS sections (Rowland, 1999), and on the external representations used by the teacher.

RESULTS

The study shows similarities in the approaches to the introduction of equations at the level of lesson structure, as well as in the expectations on students to listen and answer questions, to learn procedures and to grasp the structural meaning of the equal sign. In each class, equality was represented as a structural relation between quantities. The clearest difference among the classes was found in the spaces for students to participate in the types of dialogue that may support shifts in the transition from arithmetic to algebra (e.g. reasoning and argumentation). In classes A and B, limited space was afforded for student initiatives: only 3-4% of the pronouns used during the teacher-led sections of the lessons appeared within student-talk. In class A, the teacher focused on recall and reproduction of steps in solving equations. In class B, the students were expected to solve problems, explain solutions and construct the corresponding equations. In class C, 28% of the pronouns appeared within student-talk as the students expressed their thinking, asked questions and examined statements of others. The study suggests that teachers should critically examine the interactions during their own lessons and in those of other teachers.

INTRODUCTORY LESSONS ON ALGEBRA: A VIDEO STUDY (VIDEOMAT)

Unni Wathne, Jorunn Reinhardtsen and Maria Luiza Cestari

University of Agder, Kristiansand, Norway

Keywords: comparative video study, the introduction of algebra

VIDEOMAT is an ongoing collaborative research project that focuses on the contribution of video studies to the comparative analysis of mathematics lessons from Finland, Norway, Sweden, and the USA (California). The primary aim is to do comparative analyses concerning introductory algebra teaching and learning. The introduction of algebra has been defined in the scope of this project as the introduction of letters as variables. A second aim is to use the collected data for dialogue and professional development among teachers through analysis of their own practices and those of fellow teachers.

BACKGROUND

The VIDEOMAT project belongs within the framework of sociocultural studies (Säljö, 2006). In this approach, many concepts are used as analytical tools to make explicit the learning process in the classrooms, such as mediation (Carlsen, 2008) and dialogue (Bjuland, Cestari, & Borgersen, 2008). The analytical interests of the VIDEOMAT project are towards seeking similarities and differences in how algebra is introduced in the mathematical classroom, and discussed as well as analysed among teachers.

RESEARCH QUESTIONS

The following general questions will be addressed in this project:

1. Which teaching approaches to algebra are used and how are the lessons organized in the four countries?
2. How are the main components of an algebra lesson structured, implemented and discussed by the teachers?
3. How are the main components of algebra lessons discussed by teachers?

RESEARCH METHODS

Participants in the project were teachers and students. There were four or five teachers in each country from two to five schools. The specific grade level when the formal introduction of algebra takes place was not well defined in the curriculum from any of the countries. The research group decided to define this introduction through textbook analysis. In Norway data was collected in grade 7 and 8, where the students are 12 and 13 years of age, in Sweden and Finland in grade 6 and 7 where the students are the same age. In the USA the data was collected from grade 6 and 7 and here the students are one year younger, respectively 11 and 12 years.

Five consecutive lessons from each participating teacher were video-recorded. The timing was limited to the introduction of algebra. During the first four recorded lessons, the class followed the standard curriculum. During the fifth lesson all classes focused on three problems adapted from the TIMSS 2007 so as to obtain comparable material. Interviews were conducted after the fifth lesson with the teachers and comments were given by them at the end of each recorded lesson. Students' written work and teachers' lesson files (lesson plans, tasks, textbook, etc.) were collected as well. Lessons were videotaped by three stationary cameras. One camera was focusing on the students, one on the teacher and the third on a group of students.

Following the agreement between the participating countries to obtain comparable materials, the first lesson from each teacher and the interview have been transcribed. To make comparative analysis possible we have structured and organized a databank. The large sets of video data (60-70 hours from each country) were codified. The coding procedure was influenced by the manual for the 1999 TIMSS Video Study (Jacobs et al., 2003). The structuring of data has three different features: coverage codes, lesson graphs and key words (Kilhamn & Røj-Lindberg, 2013). Coverage codes serve the purpose of describing types of activity and interaction, lesson graphs give an overview of each lesson as a whole, and keywords highlight where and when specific aspects of algebraic content is treated (e.g., order of operations, variable, unknown, expression).

THE SECOND PHASE

In a second phase a virtual platform will be created to stimulate dialogues and professional development among the participating teachers through collaborative analysis of their own practices. The intention is to investigate how video recorded lessons could be used to mediate professional development. Teachers will select, share and discuss episodes from the recorded lessons.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG4: GEOMETRICAL THINKING

Michela Maschietto, Joris Mithalal, Philippe R. Richard and Ewa Swoboda

Università degli Studi di Modena e Reggio Emilia (Italy), Université Paris Diderot (France), Université de Montréal (Canada) and Uniwersytet Rzeszowski (Poland)

As with earlier CERME conferences, the working group on geometrical thinking was interested in reports of empirical or developmental research studies, and in theoretical essays, on the teaching and learning of geometry. One report has proved to be quite useful for recent meetings of the working group, especially since CERME5, and it served as inspiration to organize the functioning of the group at CERME8. It relates to the concept of geometrical work spaces developed by Kuzniak and his collaborators that received very detailed attention during the plenary lecture by the author (see references to the plenary talk entitled *Teaching and Learning Geometry and Beyond...*). By extending the idea of mathematical work, without standing in strict continuity with the approach of Kuzniak, the working group at CERME8 used the idea of four geometrical competencies (see Figure 1) as unifying elements to group the working group papers. Starting from the contributions of the participants, we identified as far as possible the dominant competency that emerged from each text in order to focus, in sub-groups, more specifically on certain challenges or consequences in the development of these competencies.

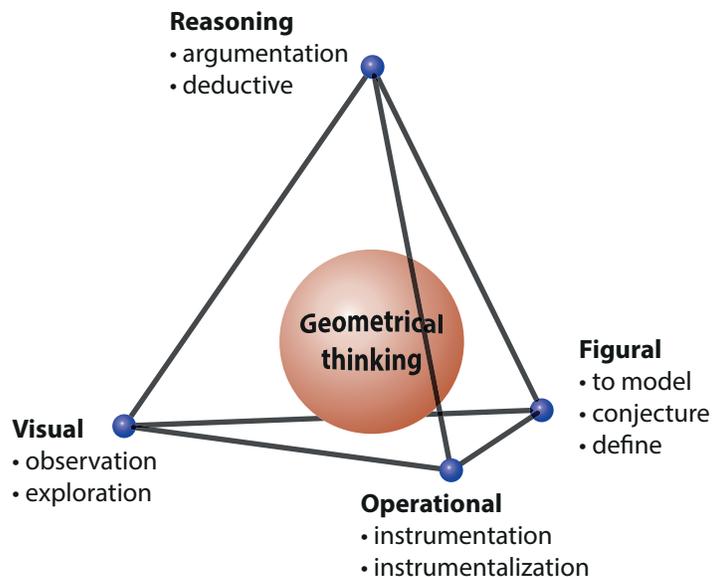

Figure 1: The geometrical competencies

Each geometrical competency acts as a pole of interest around geometrical thinking, so that if one focuses on the issues, or the effects, of a given competency (eg, argumentation and deduction in the reasoning competency), links are generated with the plane of the other three competencies (eg, visual-figural-operational) that also contribute to a better understanding of the competency in question. Because the geometrical competencies arise in relation to the mathematical work being

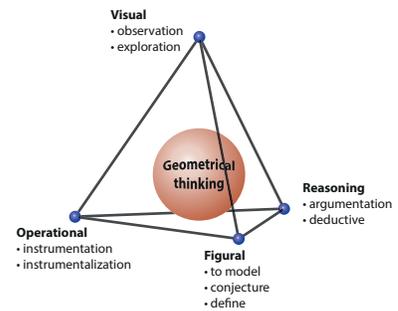

undertaken, they address situations of training, education and learning. Although this is a practical notion that facilitates simultaneously the examining of geometrical thinking and the team working, the group has set up the following criteria for transversal comparison, in anticipation of the synthesis of the works:

1. Descriptions of the competencies we worked about;
2. Type of research questions;
3. What and how theoretical approaches are used to answer those problems;
4. On-going questions;
5. How the other competencies are involved / link between the questions.

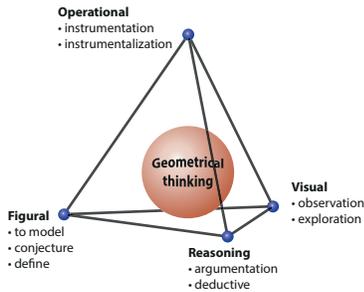

On the thread of these criteria, we summarize hereafter the results of the team and we conclude by projecting the results of the WG4 on the formation of geometrical thinking.

VISUAL POLE

In the visual competency sub-group, the role of visualization was considered in two distinctive ways; first, it compared with the entities of geometry that are not accessible materially and secondly, as the form or recoding and reporting information such a type of language. If we differentiate the habits of seeing from the field of experience, we underline that observation with making-sense entails some action – children start with this «observation», even if the geometrical thinking is more exigent and the observation process involves more than one competency. In the group, dynamic visualization appeared crucial to generate strong visualizing skills. Research has questioned how student capacity can be developed in order from them to become inventive visualizers, what are the relations maintained between visualization and the other ostensive modes of expression, what are the relations between the perception and the definition of geometrical concepts, and how students solve problems that require a topological introduction in the understanding of space, for example, by the movement or gesture.

To answer these questions, the works needed theoretical frameworks that required the use of constructs or competencies (like the visual and the reasoning) to better understand the behavioural diversity among the different habits/skills of the students and, when we need to observe more than one at the same time, to interrogate also the categories/competencies/constructs of reasoning, etc. We note that there is a tension between top-down theories that impose structure and constructs on that which they study, and those studies that look for emergent constructs in the activity of the geometrical thinking. The discussions led to a more thorough examination of the issues, especially to what extent do children take up the pictorial as a resemblance or as a symbolic rendering, how the visual competency is consistent with the other competencies in the development of the geometrical thinking, and what are the theories of perception that underlie our choices of research?

OPERATIONAL POLE

The wide variety of technological tools, jointly with the constant evolution of IT tools, provide a privileged role in the development of geometrical thinking. The competency on which we worked was oriented toward the re-organization of what is already present cognitively in the tools or with the use of the tools; more specifically:

- to create a new reality through images of changes;
- to implement, operate with, and transform, strategies in order to create a new technical or cognitive scheme (not necessarily to achieve a goal);
- to internalize a tool to develop/to foster the conceptual aspects;
- to use a tool to answer new questions/to face new tasks;
- to use a tool to facilitate to reason at a higher level of abstraction;
- to facilitate to link geometrical thinking with other kinds of thinking.

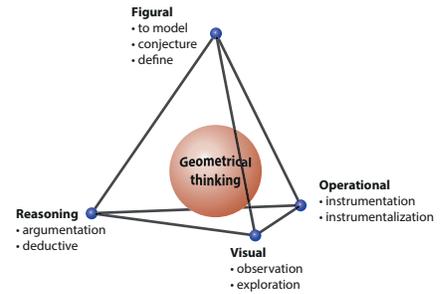

From the transfer of learning, the use of tools and particularly, the gestures and visualization, the research presented asked in what ways do gestural-haptic modalities factor into students' spatial reasoning as they engage in problems through topological rather than Euclidean concepts, what is the role of gestures and manipulation in solving geometrical problems and what is the understanding of how the use of technology may help to face some of the problems that are related to seeing and the study of spatial geometry.

In addition to Fischbein's theory of figural concepts, Rabardel's instrumentation theory within cognitive ergonomics, and the van Hiele theory and its structuring stages of development, the problems raised the importance of gesture in geometry problem solving, the interactions between everyday thinking, idealized mathematical thinking and the «geometrician-physicist» approach – for example, when the use of a tool allows the exploration of a figure directly from the figural expression. The distinction between seeing and knowing was a constant element of discussion, as was the issue of the transfer of learning. Although several open problems were highlighted in the working group, the on-going questions on the uses of tools and on the relationship with proof that principally featured were the following:

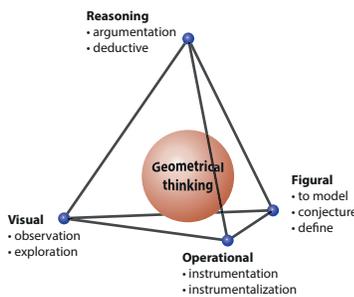

- Does the set square inhibit or delay the development of the interaction between students' figural and conceptual aspects of axial reflection by providing too much assistance? Is the set square a stumbling block for the internalisation of axial reflection?
- Which kinds of perception do teachers in initial training have with respect to the use of tools for geometrical construction?
- Why proving something that can be verified simply by measuring?

FIGURAL POLE

Traditionally, the figural and the visual are used in combination in the same process of representation. In our group, the meaning of the competency has converged on the interpretation of the drawing; that is to say a representation, with conceptions about the object recognizing its generic character, the status of the geometrical object, linking it to a theory, to properties, definitions, theorems, etc. First, there is a significant link between experimentation on drawings (with or without tools) and proof, especially related to the exploration on figures, the determination of what can be said about it and the motivation to proof, and secondly, the link between the construction and the definition of the geometrical objects, commensurate in the relationships with «the real world», the geometry as a model, and the figures as ideal objects. Two different perspectives were considered to tackle this competency: the students and the teacher, as well in the relations of teaching as of training.

In the contributions of the group, research approached the role of the figural aspects in a given task, at a given level, to determine its type and the kind of geometrical work involved. If the general research questions pose some links between the other competencies, the studies enhanced the way that technological tools influences the figural pole, particularly in regard to measurement, approximation, discretization and continuity, whether in terms of status of objects as their role in the geometrical work. Indeed in geometrical thinking, we recognize two-folded relations between the reasoning pole and the opposite face «operational-figural-visual». When the place allotted to the figural grows while working on this face, one might wonder how the reasoning pole is affected. But deductive activity may have consequences on the way students conceive the generic role of figures, and on the design of operations on drawings and the anticipated capacities of children.

REASONING POLE

Because the other competencies are clearly involved in all of the studies, we can say that the reasoning competency is a window in/on the geometrical thinking. The classical semiotic and cognitive theories participated at the definition of this window (e.g. Duval, Godino). A standpoint developed in the group is «reasoning in action», following an approach that complements the notion of discursive-graphic reasoning (Richard). Even if the operational competency is not so evident with traditional activities, the idea of reasoning in action was manifest in research comparing discovery and proof processes with origami, and solving unfolding problems with physical and mental images. If the knowledge model of Balacheff and Margolinas was helpful in comparing textbooks, the links between knowledge and behaviour shown in the model can be found useful in explaining reasoning in action.

In addition, to find the space in which conceptions are made possible to develop geometrical thinking from textbooks, the sub-group of reasoning competency focused its activity on the impact of manipulations on the generating of logically-correct deductive arguments, including comparisons in teaching with and without origami, and how the analytical and the visual thinking are cooperating (possible different objectives) and / or collaborating (same objective) in solving problem with unfolding. To answer the research questions in studies, theoretical approaches that we mentioned above were carried out by using a knowledge model to compare conceptions with textbooks, contrasting two teaching styles and implementing a pre-test/post-test tool to see the evolution, and applying a semiotic theory to analyse the synergy between two kinds of language. Although some research must continue – in some cases to complete the *a priori* studies from real experiments with pupils, student and/or teacher – we should consider to transfer the acquired competencies with/in other environments (paper-pencil, technological, informatics, ...) and to orchestrate different forms to teach in the development of the geometrical thinking.

During the discussions, or in the studies, all participants have pointed out the particular role of the reasoning pole. By way of summary, the reasoning competency helps to animate, structure and control the visual, figural and operational competencies. This is especially helpful in discovery, mathematization and validation steps. Moreover, from the geometrical work/working space point of view, this competency intervenes both in the video-figural genesis (visualisation-figuration), the instrumental genesis (instrumentation-instrumentalization) and the discursive-graphic genesis (devolution-institutionalisation). These geneses (Coutat & Richard) show how geometrical competencies are closely involved in the geometrical work and linked between the issues raised by the group.

CONCLUSION

At a time when visual information and the availability of technological tools have never been so present in our societies, the cultural role of geometry and its privileged place for the development of scientific attitudes should guarantee itself the future of the discipline in the curricula. However, during the exchanges between the members of the working group, we have raised many times a concern about the tendency, in several countries, to marginalize the geometry curriculum in favour of the study of probability and statistics. It seems that the common denominator is a logic that consists at substituting the considerate attention for the formation of the mind in favour of a utilitarian and technical preparation to market values. Research and the discussions of the working group have followed an opposite direction. Instead, they noted firstly the importance of «take for oneself» the universe of space and shapes, recalling that our societies are modelled by shapes and they belong to the world of space, to the point of shaping forms every day or naturally transform space by the action, often even unknowingly. Secondly, how the motivation for learning geometry begins with the understanding of the meaning of its objects, its formal structure and the challenges of the mathematical work and the geometrical competencies.

USING ORIGAMI TO ENHANCE GEOMETRIC REASONING AND ACHIEVEMENT

Sevil ARICI Fatma ASLAN-TUTAK

Boğaziçi University, Turkey

This paper was part of a broader study that examined the effect of the instruction on spatial visualization, geometric reasoning and geometry achievement. This paper focused on the geometric reasoning and geometry achievement. Participants were 167 high school students in Turkey. In a pre-test/post-test design, the experimental group was instructed with the origami-based instruction and the control group was instructed with the traditional instruction for four weeks. Geometric Reasoning Test and Geometry Achievement Test were prepared to measure geometric reasoning and geometry achievement, respectively. The results of the repeated measures Analysis of Variance on test scores showed that the origami-based instruction had a statistically significant effect on geometric reasoning and geometry achievement.

Key-words: origami, geometric reasoning, geometry achievement, high school geometry

INTRODUCTION

Reasoning, proving, creativity and problem solving are involved in Turkish high school geometry curriculum. These skills are expected to be developed through effective geometry instruction. For an effective geometry instruction, a closer look into the geometry learning may be necessary. Three theoretical frameworks may give insights in understanding geometry learning of students. Duval (1998) argues that geometric thinking combines three cognitive processes which are *visualization*, *construction*, and *reasoning*. Visualization is keystone for geometry instruction since students should be able to identify geometric figures in different dimensions in order to reach conclusions about geometric entities. Duval's (1998) cognitive processes formed the mainstay of the test design of our study. Besides, Smith (2010) asserts that geometric thinking is based on *proving*, *justifying*, and *argumentation*. Smith's (2010) categorization of geometric thinking was used in preparing the scoring rubric of the Geometric Reasoning Test (GRT). Furthermore, as a developmental model on geometric thinking, the van Hiele (1959/1985) theory states that geometric thinking progresses in hierarchical stages. Van Hiele stages were considered in the design of the instruction of the existing study. These three theoretical frameworks all agree on the use of manipulative materials in teaching geometry for effective learning of abstract concepts and relationships. The use of manipulatives in teaching geometry and mathematics is also suggested in the literature (e.g. Dorier, Gutiérrez, & Strässer, 2003; Sriraman & English, 2005). Manipulatives can be useful in facilitating students' progression to higher levels of geometric thinking. Thus, origami, the art of paper folding can be used in teaching geometry considering its manipulative nature.

Origami was remarked as a beneficial tool in geometry education in a wide age range of learners by many authors (e.g. Boakes, 2009; Çakmak, 2009; Golan, 2011; Hull, 2006; Pope & Lam, 2011; Sağsöz, 2008; Winckler, Wolf, & Bock, 2011). Origami is connected with many mathematical and geometric concepts and principles such as angle bisectors, fractions, division, ratio, triangles, polygons, congruence, and symmetry. Origami is also referred as a trigger for proof and strong mathematical arguments (Pope & Lam, 2011; Winckler et al., 2011) so that origami may be used to develop students' geometric reasoning and geometry knowledge.

Although origami is recommended by many authors as a useful instructional tool, research on the use of origami in schools is limited (Boakes, 2009; Çakmak, 2009; Sağsöz, 2008). Besides, the research involving origami is concentrated on primary and middle school students (e.g. Boakes, 2009; Çakmak, 2009). Therefore, there exists a need for investigating the effect of origami on high school geometry education. Thus, the focus of this paper was to investigate the effect of origami-based instruction on tenth-grade students' geometric reasoning and geometry achievement in a Turkish high school.

METHOD

Settings

The Turkish education system has kindergarten, primary, middle, secondary and higher education levels. The secondary school level consists of 4-year education (9th to 12th grade). There are seven types of high schools: Science High School, Anatolian Teacher High School, Anatolian High School, Social Sciences High School, Fine Arts and Sports High School, General High School, and Vocational High School. After middle school, there is an entrance exam to high schools except general and vocational high schools. Students who can enter to Science High Schools have the highest scores in the entrance exam. However, students in the General High Schools and Vocational High Schools have the lowest scores in the high school entrance exam. Thus, the academic achievement of Vocational High School and General High School students was generally low compared to other types of high schools.

A common curriculum, which is determined by the Turkish Ministry of Education (MEB), is implemented in all high school types. Students select their courses according to their interests and orientations. Science-Mathematics Orientation (SM), Turkish-Mathematics Orientation (TM), Turkish-Social Orientation (TS), and Foreign Language Orientation (FL) are the types of orientations that students select at the 10th grade. Students with SM orientation have courses like Mathematics, Geometry, Physics, Chemistry and Biology. Students with TM orientation also have Mathematics and Geometry lessons but do not have Science courses. Students with TS orientation do not have Science courses, either.

The study was conducted among 167 10th graders of a General High School in Turkey. The students were chosen from all three different academic orientations: SM, TM, and TS. There are 10 classrooms of 10th graders in the school. One TS classroom

was excluded because the instructor was different than the instructor of other nine classrooms. Two classes of each orientation were randomly selected. Then, one of the two chosen classrooms with each orientation was randomly assigned to be in the experimental group and the remaining class was taken to be in the control group. So, the experimental group and the control group each have three classes with three different academic orientations. Students in the control and experimental groups had equivalent conditions. The same teacher instructed both groups. Besides, the same geometry topics were taught in both groups. Students' geometric achievement was similar at the beginning of the study when their previous exam grades were checked.

Treatment

Students were instructed on a geometry unit (triangles) for four weeks based on the curriculum objectives of the Ministry of National Education (MEB). The control group received traditional instruction, which followed the 10th grade MEB textbook. The traditional instruction is the instruction that teaches triangles without any origami activities. The traditional instruction is a non-origamic instruction. On the other side, the experimental group received origami-based instruction, which contained origami activities in addition to following the same textbook with the control group. The traditional instruction and origami-based instruction differed only in containing origami activities. Besides, the same teacher (the first author) instructed both the experimental and control groups. Each week, the control group had two lesson hours for the geometry instruction whereas the experimental group had three lesson hours since one extra lesson hour was used for instructions on folding. The topics for the instruction were the basics of triangles, angle and side relationship in triangle, angle bisectors, medians, perpendicular bisectors, and altitudes in triangles. The model of knowledge by Balacheff and Gaudin (2002) may help to enlighten the origami-based instruction. The folding is the operator in the origami-based instruction in order to reach logically deductive arguments in the concerned geometry topic. Besides, the representation system is the fold that represent line segment in geometry. The structure of the control is the deductive reasoning.

Week	Topic	Origami activity
1	Basics of triangles, classifying triangles	Dart; equilateral triangle
2	Angle and side relationship in a triangle	Swan
3	Angle bisectors in a triangle	Whale
4	Altitude, median, and angle bisector relationships, perpendicular bisectors	Folding a square paper

Table 1: Origami-based instruction

Table 1 shows the origami activities used in the origami-based instruction. The origami activities were developed considering the related literature (e.g. Hull, 2006). Lesson plans were prepared for both groups (Arıcı, 2012). In the origami-based

instruction, students initially folded the origami models and then they were guided by the instructor to make the necessary geometric relationships and proofs. In the traditional instruction, students were also guided to make proofs about triangles but no origami activities were used in guiding students in the process of proving. In the traditional instruction, students used only geometrical statements in order to prove related conjectures. However, in the origami-based instruction, students were mediated through origami folds to deal with the aimed deductive arguments.

Figure 1 presents an example of origami activities in the origami-based instruction. Folding an equilateral triangle is based on Hull (2006). To fold an equilateral triangle, students were initially told to fold and unfold a square paper in half. Then, the teacher wanted students to fold a bottom corner (the D point) up to the fold line and mark the point on the line (the point C). After this, students were guided to fold the equilateral triangle (ACD). Folding the equilateral triangle lasted approximately 15 minutes. After folding, students were questioned about geometric relationships. They were asked why the folded triangle was an equilateral triangle (ACD). As a hint, students were asked to find the angle measures and side lengths of the triangles that were formed after folding. Students had to recognize the congruence of the triangles (ADG and ACG) in order to prove the triangle ACD to be an equilateral triangle (see Figure 2).

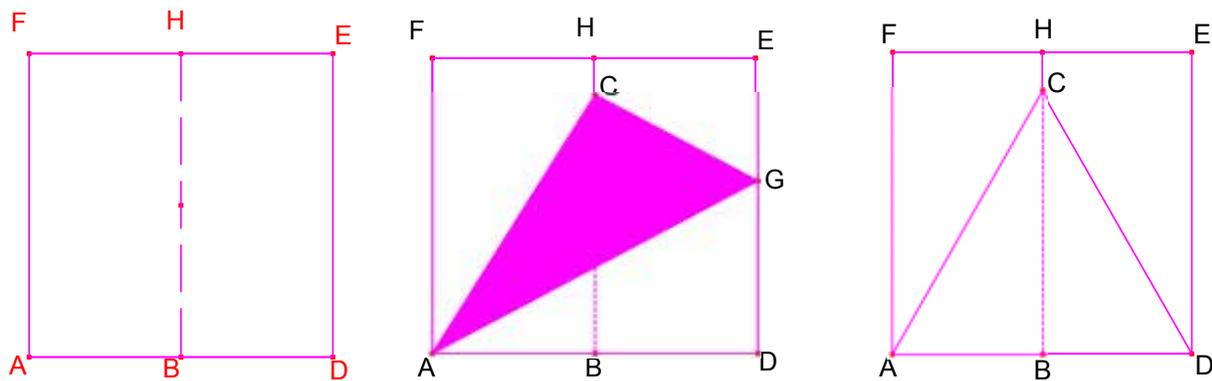

Figure 1: Folding an equilateral triangle

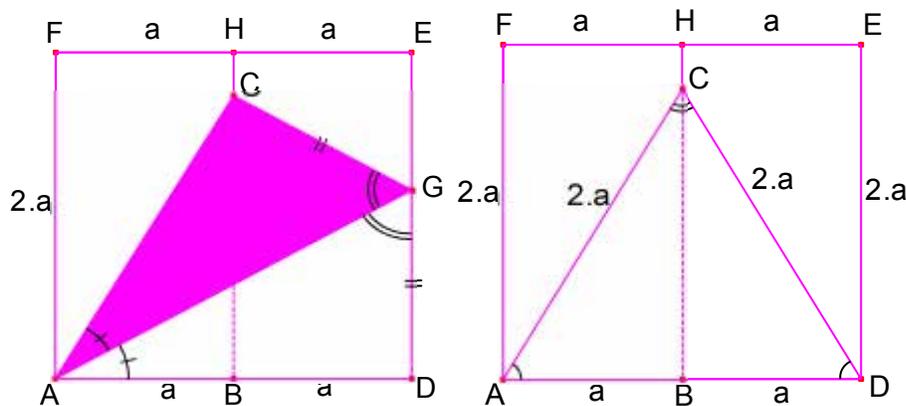

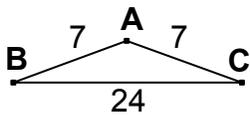

Figure 2: Steps to prove that the folded triangle was an equilateral triangle

Instruments

The pre-tests were administered to all students a week before the geometry instruction. After the instruction, post-tests were administered. The Geometric Reasoning Test (GRT) was prepared to assess students' geometric reasoning abilities related with triangles. Besides, the Geometry Achievement Test (GAT) was formed to assess students' geometry achievement concerning triangles that were instructed during the study. GRT and GAT were piloted before the administration of the tests. After the instruction, the GAT was administered and the GRT was administered one week later from the GAT.

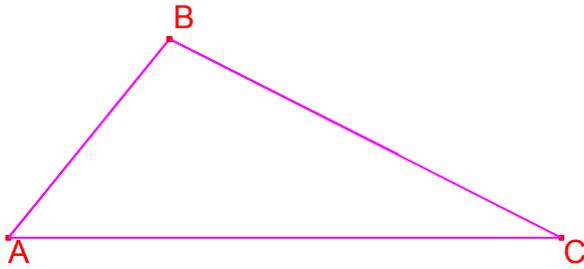

The GAT was developed based on the objectives of the curriculum concerning triangles. There were 11 open-ended items in the GAT. Parallel forms of the GAT were prepared as pre-test and post-test (Figure 3, a sample item from the post-test). The GAT was administered in 45 minutes (one lesson hour). A scoring rubric for the GAT was generated considering the solution steps of the questions. Items in the GAT contain at most four steps so that the maximum score for an item is given as 4. The Cronbach alpha for the GAT was 0.86.

Is it possible that the triangle ABC in the figure with length sides of 7, 7, and 24 units exist? Explain.

Figure 3: An item of the Geometry Achievement Post-test (translated from Turkish)

The GRT was prepared based on the literature about proof and construction questions including triangles (e.g. Jacobs, 2003). Duval's (1998) framework was used as a basis to form the items in the GRT. Duval's (1998) cognitive process of construction includes using tools and GRT has items based on construction. Items were about isosceles triangle, congruence of triangles, angle bisectors, inscribed and circumscribed circles of triangles, angle and side relationships. There were 13 open-ended items in the GRT (Figure 4, a sample item). The maximum score for an item in the GRT is 2 points because an item has at most two steps of the solution. Moreover, the Cronbach alpha for the GRT was 0.70. Scoring of the items in the GRT was based on the Smith's (2010) framework of reasoning. Responses which were aligned with the *argumentation* were given the lowest score in the GRT. Besides, responses which were aligned with the *proving* were given the highest score in the GRT. Proving contains a comprehensive explanation of geometrical expression. Justifying gives some reasons but these reasons are not sufficient to explain the geometric expression. Argumentation also involves explanation but this explanation is not necessarily accurate or geometrical.

How can you draw the incircle of a triangle ABC using lines? Draw the incircle and explain your answer.

Figure 4: An item of the GRT (translated from Turkish)

RESULTS

A repeated measures of Analysis of Variance (ANOVA) was done on each test. Data were analyzed to investigate whether there was any statistically significant difference between mean pre-test scores, between mean post-test scores, between mean pre-test and post-test scores of the experimental group and the control group. The significance level was kept on 0.05 during the analyses. The between-subjects factor was group (control or experimental) and the within-subjects factor was time (pre-test or post-test).

Descriptive statistics for the Geometry Achievement Test (GAT) and Geometric Reasoning Test (GRT) are shown in the Table 2. At the beginning, there were 90 students in the experimental group and 94 students in the experimental group. However, there were missing students during the test time so the missing ones were excluded from the analyses. GRT was administered after GAT so that the number of students who took the tests differed.

Test	Group	\bar{X} (pre-test)	SD	\bar{X} (post-test)	SD
GAT	Control (N=88)	1.52	2.54	5.95	6.79
	Experimental (N=79)	2.13	3.56	12.80	11.05
GRT	Control (N=90)	3.79	1.97	4.79	2.16
	Experimental (N=77)	3.14	2.38	6.42	3.78

Table 2: Means and standard deviations for the tests

According to the repeated measures ANOVA on the Geometry Achievement Test (GAT) scores, the interaction effect between time and group ($F(1,165)=25.02$, $p<0.001$, $\eta_p^2=0.13$), the main effect of group on GAT ($F(1,165)=19.53$, $p<0.001$, $\eta_p^2=0.11$), and the main effect of time on GAT were statistically significant ($F(1,165)=146.60$, $p<0.001$, $\eta_p^2=0.47$). Moreover, the pairwise comparisons for GAT by group and time indicated that there was not a statistically significant mean difference between pre-test scores for the experimental group and the control group ($F(1,165)=1.61$, $p=0.206$, $\eta_p^2=1.61$) but there was a statistically significant mean difference between post-test scores for the experimental group and the control group ($F(1,165)=23.75$, $p<0.001$, $\eta_p^2=23.75$). The results also revealed that the mean

difference between post-test and pre-test was statistically significant for the experimental group ($F(1,165)=0.01$, $p<0.001$, $\eta_p^2=0.46$) and for the control group ($F(1,165)=26.68$, $p<0.001$, $\eta_p^2=0.14$). Besides, the mean difference between post-test and pre-test was higher in the experimental group than that in the control group.

According to the repeated measures ANOVA on the Geometric Reasoning Test (GRT) scores, the main effect of time on GRT ($F(1,165)=102.86$, $p<0.001$, $\eta_p^2=0.38$) and the interaction effect between time and group ($F(1,165)=29.10$, $p<0.001$, $\eta_p^2=0.15$) were statistically significant. However, the main effect of group on GRT was not statistically significant ($F(1,165)=1.97$, $p=0.162$, $\eta_p^2=0.01$). Furthermore, the pairwise comparisons for GRT by group and time indicated that there was not a statistically significant mean difference between pre-test scores for the experimental group and the control group ($F(1,165)=3.68$, $p=0.057$, $\eta_p^2=0.02$) but there was a statistically significant mean difference between post-test scores for the experimental group and the control group ($F(1,165)=12.06$, $p<0.005$, $\eta_p^2=0.07$). The results also showed that the mean difference between post-test and pre-test was statistically significant for the experimental group ($F(1,165)=0.01$, $p<0.001$, $\eta_p^2=0.40$) and for the control group ($F(1,165)=12.22$, $p<0.005$, $\eta_p^2=0.07$). Moreover, the mean difference between post-test and pre-test was higher in the experimental group than that in the control group.

CONCLUSION AND DISCUSSION

The results suggested that the origami-based instruction could have an effect on students' geometry achievement and geometric reasoning concerning triangles.

The results about geometry achievement revealed that there was a statistically significant change in geometry achievement scores of students, who received origami-based instruction, from pre-test to post-test time. The geometry achievement scores of students who received traditional instruction also showed a statistically significant change from pre-test time to post-test time. However, the average difference in geometry achievement scores from pre-test time to post-test time for students who received the origami-based instruction was more than that for those who received the traditional instruction.

Although there were some studies that found no significant effect of origami on students' geometry knowledge (e.g. Boakes, 2009), most teachers and authors recommended using origami in geometry teaching to enhance students' geometry knowledge (Golan, 2011; Pope & Lam, 2011). The difference of the test types might have affected the results concerning geometry achievement. For example, Boakes (2009) used a multiple-choice test to measure geometry achievement. But, our study used a geometry achievement test with open-ended items that were prepared in parallel with the curriculum objectives. Besides, the grade level might have affected the results concerning geometry achievement. Boakes' (2009) study involved middle-school students as the sample but our study used high-school students. The design of the instruction also had an effect on students' geometry achievement. The origami-

based instruction combined Duval's (1998) cognitive processes of visualization, construction, and reasoning. Such an instruction might have facilitated students' knowledge about the related topic. Golan (2011) reported that using origami in geometry lessons aligned with van Hiele theory helped students to develop their geometry knowledge for higher levels of abstraction. The existing study also took into consideration the van Hiele theory in designing the geometry lessons using origami activities. Besides, Pope and Lam (2011) noted that origami was a good way to enrich school curriculum by providing opportunities for problem solving and creativity. Aligned with the literature, the results suggested that origami could be an additional source of instruction to enhance geometry knowledge of high school students.

The results about geometric reasoning were similar to those about geometry achievement. The results concerning geometric reasoning presented a statistically significant change in geometric reasoning scores of participants, who received origami-based instruction, from pre-test time to post-test time. The geometric reasoning scores of students who received traditional instruction also showed a statistically significant change from pre-test time to post-test time. However, the average difference in geometric reasoning scores from pre-test time to post-test time for students who received the origami-based instruction was more than that for those who received the traditional instruction.

Geometric reasoning involves proving (generating logically correct deductive arguments as Smith (2010) suggested) so that it requires a higher level of geometric thinking. Origami as a tool might have facilitated students to reason at a higher level of abstraction in geometry. The connection of origami with geometric reasoning was also stressed in many resources (e.g. Pope & Lam, 2011; Winckler et al., 2011). For instance, Pope and Lam (2011) presented proof examples that used origami to show that origami could be an important context to develop reasoning. Furthermore, Winckler and his colleagues (2011) stated that origami was an enjoyable way to teach geometric principles to high school students as a bridge between theory and practice. In parallel with previous publications related to origami and reasoning, the results of our study pointed out that origami-based instruction could promote high school students' geometric reasoning related with triangles.

There are certain limitations in our study. For example, classrooms of students were randomly chosen as to be in the experimental or the control group. However, students themselves were not randomly chosen because the school policy did not allow changing students' classrooms.

The effect of origami-based instruction on participants' geometry achievement and geometric reasoning mentioned in this paper implied that origami could be incorporated in geometry lessons. Teachers and curriculum planners should also take into consideration the benefits of integrating origami in high school geometry instruction. Origami is not just for fun but also may be a meaningful context for high-level thinking in geometry.

LEARNING AND TEACHING GEOMETRY AT THE TRANSITION FROM PRIMARY TO SECONDARY SCHOOL IN FRANCE:

THE CASES OF AXIAL SYMMETRY AND ANGLE

Aurélie Chesnais and Valérie Munier

LIRDEF (EA 3749), Université Montpellier 2 - Université Montpellier 3, France

We are currently running a three year research project focusing on the teaching and learning of geometry at the transition from primary to secondary school in France. In a global approach, we take into account teaching contents, pupils and teaching practices at the same time. This research aims at identifying continuities and gaps in curriculum, textbooks but also in teachers' practices, in order to get a better understanding of the difficulties related to this transition. In this communication, we present the first results of the part of this project dedicated to axial symmetry and angle. Our analysis shows a large variety of choices concerning crucial aspects of the concepts, likely to facilitate the transition or make it more difficult.

INTRODUCTION

This paper presents an overview and the first results of a three year research project that started in January 2012. This study focuses on the teaching and learning of geometry at the transition from primary to secondary school in France. This transition is decisive for pupils future education but difficult for some of them, and may even lead to academic failure, in France as in most of the industrialized countries. Previous studies on mathematics teaching dealing with the questions of transition generally approach these questions from the angle of pupils' difficulties, or they compare the intended curricula showing for example the conceptual changes (see for example Salin, 2003). Colomb *et al.* (1987) take into account teachers too, but they are mostly focused on the teachers' representations of mathematics and mathematics teaching; however, later research (Robert, 2007) showed that representations are not the only factors which influence teachers' practices: Robert distinguishes institutional, social and individual determinants. More recently, Bednarz *et al.* (2009), aiming at developing connections between both orders of education (elementary school and middle school), also point out the necessity of considering teachers' point of view. Given that the involved processes are very complex, we choose to tackle the question with a global approach. We take into account several aspects of the problem (institutional, teachers' and pupils' points of view) and their connections. We thus study the following research questions: what is the nature of pupils' difficulties? In what extent are they connected to the notions? Can we identify, in curricula, textbooks and teaching practices of both levels, elements which can explain these difficulties or, on the contrary, facilitate the transition? Another specificity of this project is to focus on some particular concepts. Eventually, our aim is also to develop resources for teachers and devices for teachers' training in order to facilitate the

transition. Datas include videos of class sessions, textbooks and the results of some tests pupils were submitted to.

In this communication we only expose the first results of the project part related to axial symmetry and angle. Those two mathematical subjects are chosen because of their ability to reveal various phenomena concerning the transition, as we will develop in the first part through a curriculum study. Using literature and our previous research, we then point out some crucial aspects of these two concepts as subjects of teaching and learning. In the third part, we study textbooks from both levels of education: we consider them both as resources for teachers to help them interpret the official instructions (OI) and as examples of classical tasks pupils are exposed to in classrooms. Finally, in the fourth part, we show some examples of ways teachers deal with these crucial points. Let us add that in the two last parts, we complete the analyses with the results of the tests.

CURRICULUM STUDY

In France OI for 5th grade (last grade in primary school, 9-10 y. o.) and 6th grade (1st grade in secondary school, 10-11 y. o.) show few differences on the subject of geometry. However, a change of status of the objects, from drawings to figural concepts (Fishbein, 1993) has to be initiated in 6th grade in order to prepare a transition from the paradigm of geometry 1 (G1) to geometry 2 (G2) (Houdement & Kuzniak, 1999). This change of status is explicated in the introduction of the OI (MEN, 2008b) but the way it has to be adapted for each subject is not detailed. This transition is supposed to be complete in 8th grade (Houdement, 2007).

Axial symmetry is one of the subjects usually chosen by textbooks and teachers to initiate this change (Chesnais, 2012). In primary school, pupils learn how to draw mirror images on graph paper, how to draw them on plain paper using tracing-paper and folding and how to identify axes of symmetry on a figure. The work is validated by perception or using tools such as tracing-paper. In 6th grade, pupils are supposed to extend their knowledge to the case where the axis crosses the figure and to learn how to construct mirror images on plain paper using geometrical tools (ruler, set square – triangle – and compass). The validity of the constructions is related to mathematical definitions and properties of the objects.

Concerning the angle concept, elementary school instructions (MEN, 2008a) introduce the right angle in grades 1-2 when pupils learn to distinguish between different geometric shapes (triangle, square ...), but the general angle concept is introduced in grades 3-5. In both primary and secondary school, this concept is present in two parts of the instructions: “geometry”, where pupils study plane figures, and “attribute and measurement”. In grades 3-5, pupils learn how to compare angles and how to reproduce a given angle. They discover the different angles, and they must use a set square to validate their estimation of the acute, right or obtuse character of an angle, tasks that relate to paradigm G1. In 6th grade (MEN, 2008b) in the “attribute and measurement” part of the instructions, pupils are firstly supposed to

compare angles without measuring them (using templates or tracing-paper); the main teaching objective is then learning how to measure angles with a protractor (using degrees), and how to construct an angle with a given measure, which are tasks related to G1. However the teaching of angle concept in 6th grade can also contribute to the transition from G1 to G2: some tasks may involve deductive reasoning based on the properties of the figures and not only measuring.

Some researchers suggest ways to deal with this transition problem. For example, Perrin-Glorian (2003) suggests a way to get primary school pupils used to considering figures according to their properties; she notably created a new kind of construction tasks called “figure restoration”: pupils are given a figure and the beginning of a reproduction of it; they have to complete it using geometrical tools. In another perspective, Houdement and Kuzniak (2003) question the relevance of teaching G2 within compulsory education. Without entering this debate, we consider that, if G2 is part of the curricula, besides special tasks, a specific work has to be done expliciting the “rules of the mathematical (geometrical) game”.

What we will seek for in textbooks and teacher’s practices are evidence of how they deal with this change of status of objects. In 5th grade, how do they prepare pupils to this change? In 6th grade, how do they deal for example with the apparent contradiction which is inherent to requiring measurement of angles in some tasks and considering it as non relevant when the measure of an angle has to be determined knowing the measure of its mirror image and the property claiming that symmetry preserves angle measures? We expect, for these two subjects (axial symmetry and angle), to observe phenomena of different nature, since they play different roles with regard to the transition from G1 to G2.

CRUCIAL ASPECTS OF AXIAL SYMMETRY AND ANGLE CONCEPTS

Mitchelmore and White (1998) underline that angle is a highly complex and multifaceted concept, which is constructed slowly and progressively. The construction process runs into numerous obstacles (see for example Lehrer *et al.*, 1998). The major one is that many pupils think that an angle's size depends on the length of its sides (Berthelot & Salin, 1994-95; Mitchelmore & White, 1998). Another element likely to hinder the conceptualization of angles and reported in several experimental studies (Baldy *et al.*, 2005, Lehrer *et al.*, 1998) is the prototypical conception of right angle (a right angle that opens on the right with arms parallel to the edges of the paper). The connection between those two obstacles was even recently pointed by Devichi & Munier (2013). Van Hiele (1986) considers that pupils must actively manipulate and experiment with geometric objects. In the same way, Mitchelmore and White (1998) point out the necessity of drawing upon children's informal knowledge to teach them geometric concepts like “angle” (White & Mitchelmore, 2010). In France, Berthelot and Salin (1998) stress a similar idea in saying that pupils should be taught geometric concepts using concrete activities, and they propose an adidactic introduction of angle, entitled Geometriscrabble (Berthelot

& Salin, 1994-95). These authors recommend also that pupils experiment in meso-space. Taking this approach, we proved the interest of using physical situations involving angles that pupils had to model (Munier & Merle, 2009). Mitchelmore and White (1998) suggest another way of invalidating side length: using situations involving both static and dynamic angles, which can be done using technology (Clements & Sarama, 1995). Other studies suggest using body movements to apprehend the angle (Wilson & Adams, 1992; Fyhn, 2008).

Using Vygotski's terms (Vygotski, 1962), we claim that axial symmetry is not only a mathematical concept but also an everyday concept (Chesnais, 2012). Moreover, we distinguish symmetry as an innate property of a figure (static aspect) and as a geometric transformation (dynamic aspect) (Chesnais, 2012). Mathematically speaking, the transformation precedes the property, since the last one results from the invariance of the figure under the transformation. In the everyday concept, the transformation is almost absent, except in the folding movement, but in this case a symmetrical figure is a figure such that half of it is the image of the other half: the symmetrical character of the figure is not associated to global invariance. We claim that linking both aspects is necessary to achieve the conceptualization of symmetry. This led us to point out one of the main misconceptions of symmetry, which is partly related to folding: symmetry as a transformation moving from one half-plane onto the other one. Overcoming this conception is necessary to conceptualize the fact of being symmetrical as global invariance. This misconception and the fact of not being able to link the static and dynamic aspects of symmetry don't prevent pupils to successfully perform classical tasks like constructing the mirror image of a figure located on one side of the axis or identifying axes of symmetry on a single figure. Some tasks may allow children's conceptions to change. For example, constructing the image of a figure crossed by the axis requires considering the symmetry not only as a one-way transformation. Also, having to complete a figure for it to become symmetric (task explicitly recommended in the 4th grade OI) requires to link the static and dynamic aspects of symmetry (Chesnais, 2012).

Curricula remain vague about what should be aimed at in terms of level of conceptualization concerning symmetry. In a G1 perspective, the static aspect of axial symmetry could be taught in a perceptive way or related to folding but it could not then be related to global invariance. However, global invariance can be considered in a G1 perspective, when associated to flipping tracing-paper over instead of folding it. In the perspective of the transition to G2, one must find a way to validate constructions or the existence of axes of symmetry without using instruments. It requires considering axial symmetry as a plane transformation acting on points. Let us add that previous instructions (until 2005) explicitly required teachers to distinguish between the transformation and the innate property and to define the last one as global invariance.

The above analysis shows the complexity of the concepts of angle and symmetry. Given that curricula don't contain details about how to handle these difficulties for

each teaching level and how to handle the transition (particularly the change of status of geometrical objects), we can expect difficulties for both pupils and teachers. For instance, 6th grade teachers might overestimate pupils' knowledge about the status of the geometrical objects and figures or the meaning of measurement. They might also underestimate pupils' difficulties. In the following parts we analyze textbooks and teaching practices to identify how they deal with these questions.

TEXTBOOKS STUDY

In this part, we study lessons and exercises proposed by textbooks in order to analyze the way they deal with angle and symmetry; in particular, we will look for tasks designed to help pupils to overcome the above-mentioned misconceptions.

For axial symmetry, we studied eight elementary school's textbooks: *Cap maths* (Hatier), *Outils pour les maths* (Magnard), *Petit Phare* (Hachette), *La clé des maths* (Belin), *Au rythme des maths* (Bordas), *Euromaths* (Hatier), *J'apprends les maths* (Retz), *La tribu des maths* (Magnard). We also studied eight textbooks of 6th grade: *Multimath* (Hatier), *Dimathème* (Didier), *Bréal*, *Transmath* (Nathan), *Magnard*, *Diabolo* (Hachette éducation), *Triangle* (Hatier) and *Phare* (Hachette éducation). Concerning the angle concept, only a few of them were chosen as being representative of the variability of approaches: *Euromaths*, *La tribu des maths* and *J'apprends les maths* for elementary school and *Triangle*, *Phare* and *Sésamaths* (Generation 5) for 6th grade.

At both 5th and 6th grades levels, we could find some textbooks proposing exercises designed to make pupils overcome the sides' length misconception but also some which don't include any exercise of this type, the teacher's handbook sometimes not even mentioning this difficulty. One of the 5th grade textbooks (*Euromaths*) introduces angles using the Geometriscrabble situation designed by Berthelot and Salin.

At elementary school level, concerning the introduction of angle measurement, we could find one textbook which introduces angle measurement using 1° templates, anticipating the 6th grade OI: it even includes tasks in which pupils have to construct figures knowing the measure (in degrees) of some angles. Making other choices, *Euromaths* proposes tasks using fractions of a right angle (in compliance with the 5th grade instructions) which can help pupils to construct the meaning of angle measurement unit.

In 6th grade, the way the different textbooks introduce angle measurement is variable, from textbooks taking explicitly into account the introduction of measurement (using arbitrary units before degrees), to textbooks introducing it very quickly, directly using degrees (supposing obvious for pupils that the measure of the angle formed by two adjacent angles is the sum of their two measures).

Tasks related to G2 are present in all the textbooks: for example, exercises where pupils have to calculate measures of angles, reasoning on freehand drawings. One

textbook clarifies explicitly the status of observation, measurement and demonstration but it remains implicit in all the other ones.

Concerning axial symmetry and elementary school, about the link between the static and dynamic aspects, only five out of eight textbooks contain at least one task consisting in completing a figure for it to become symmetric, although it is recommended in the OI; five of them contain a task consisting in identifying axes of symmetry on figures constituted of two different parts. Only two of them (*Petit Phare* and *Euromaths*) do both. These two textbooks are also the only ones trying to make pupils overcome the misconception of transformation from one half-plane onto another: the first one by adding elements on both sides of the axis when completing a figure for it to become symmetric; the second one proposes an exercise where the number of axes of symmetry of a figure is related to the number of ways it can be positioned to match its outline after flipping it over. The *Euromaths* teacher's handbook mentions the objective of enriching pupils' mental pictures. It also suggests teachers to experimentally bring up some properties of symmetric figures like the invariance of the axis' points or the fact that a segment joining a point and its image is perpendicular to the axis. In another perspective, *La Tribu des maths* mixes perceptive tasks and constructions of mirror images on plain paper using instruments, which should be dealt with only in 6th grade.

Half of the 6th grade textbooks separate what corresponds to the static and dynamic aspects of symmetry in two different chapters. Three of them show double figures in the chapter devoted to the axes of symmetry: this facilitates links between the two aspects. About the static aspect, three of them restrict the work to perceptive tasks; half of them mention global invariance but sometimes in an illogical way: *Transmath* introduces global invariance in the lesson right after exercises on folding and before bringing up the transformation; *Phare*, *Multimath* and *Bréal* link folding and global invariance but only *Multimath* mentions it in the lesson. All the textbooks contain constructions of figures crossed by the axis of symmetry.

Finally, we can say that the textbooks' approaches are very different. What we note is that textbooks handle the transition problem in various ways. Namely, some of 5th grade textbooks choose to introduce notions or tasks which correspond to 6th grade's curricula expectations whereas other ones make different choices: for example, *Euromaths* tries to prepare pupils to 6th grade precisely by working on the difficulties, the misconceptions and specifically on the meaning of the concepts (dynamic and static aspects of symmetry, meaning of measurement unit for angle etc.). Depending on the textbooks, it then appears that misconceptions are not necessarily handled in 5th grade. On the other hand, most of 6th grade textbooks consider that some aspects of the two concepts have already been grasped by pupils. Hence, the responsibility of dealing with certain aspects of the concepts and enabling pupils to overcome their misconceptions is devoted to teachers.

TEACHING PRACTICES

The methodology we use to study teaching practices focuses on the mathematical activity the teacher organizes for students during classroom sessions and the way he manages the relationship between students and mathematical tasks in two approaches: a didactical one and a psychological one (Robert & Rogalski, 2005). However we'll only mention here the didactical analysis. We worked on videos made during 'ordinary' lessons on axial symmetry and angle in six 6th grade classrooms. In each class, pupils were submitted to tests designed by the research team. For each teacher, we collected all the videos of the sessions concerning these notions, even if we will only mention in this paper some short extracts from four classrooms (the four teachers are named T1, T2, T3 and T4). Our examples aim at showing how some 6th grade teachers deal with the characteristics of the concepts we mentioned in the second part of this paper.

Example 1: Misconceptions about angles (T1, T2, T3)

Concerning the sides' length misconception we have seen that instructions recommend starting with comparison activities independently of measurement, and that some textbooks propose such exercises which may facilitate the overcoming of this misconception. Yet the analyses of teaching practices show that some teachers use these exercises (for example T2 and T3), without seeming fully aware of what is at stake. Some of them seem to consider that it is not necessary to work further on this misconception. However, the misconception of the sides' length still appears frequently in both grades when pupils are asked to compare pairs of angles (for one of these pairs, the rate of success in the tests varies between 14 and 67 % in 5th grade and between 43 and 86 % for 6th grade).

As a second example, the following extract of the transcript shows that T1 underestimates this misconception and the salience of the prototypical right angle:

- T1: What is an angle for you? [...] Océane?
 Océane: An angle it is like a right angle
 T1: a right angle, OK, a right angle is an angle.

T1 then asks Océane to draw it and she draws a right angle. Then he asks her to draw another angle which should not be a right one. She draws again a right angle, modifying only orientation and sides' length [making it less recognizable]. T1 agrees and says that this angle is too small to be seen from the back of the classroom, then he removes all the drawings and draws two obtuse angles, totally different, with arbitrary orientation of the sides and he goes on with the lesson.

The results of the tests we ran show the salience of the prototypical right angle in both levels: for example when pupils are asked to draw an angle, then a different, a smaller and a larger one, numerous pupils are unable to produce a different angle or to change its size (see example below).

The rate of this answer varies between 0 to 57 % in 5th grade, and between 0 and 28 % in 6th grade).

Example 2: Misconceptions about symmetry (T2, T4)

Both teachers propose to their pupils a task where they have to overcome the misconception of symmetry as a transformation from one half-plane onto another: T4's pupils have to construct the mirror image of a polygon crossed by the axis on graph paper; T2's pupils have to identify if two triangles crossed by a straight line are symmetrical of each other with regards to this line or not. In both classes numerous pupils seem unhinged by the task and ask questions to the teachers; for example, in T2's class: "Can we still talk about symmetry when the two figures cross each other?" T4's reaction reveals that he underestimates the difficulty, ("nothing makes it impossible", "*don't forget* to construct point C's image"). He mentions the rigor when using the techniques, instead of using a conceptual argument. T2 uses the folding of a piece of tracing-paper to make pupils check that the two parts of the figures coincide one-by-one and conclude that the two triangles coincide: she uses the fact that the transformation is working in the two directions.

Note that the results of T2's class are much better than T4's one for the task of the test where pupils have to construct the mirror image of a figure crossed by the axis.

Example 3: Transition from G1 to G2

Some items of the tests were designed to determine whether 6th grade pupils are able to mobilize the paradigm G2 or not. We ask them to draw an angle measuring 89° , then to say if this angle is a right one or not and to justify their answer. In the 6th grade classes a large part of the pupils (between 11 and 57 %) base their estimation on the validation with the instruments, protractor or set square. We identified moments of classroom sessions when problems related to this question arise.

CONCLUSION

Our analyses point that some of the choices done by textbooks' authors and teachers in 6th grade may cause difficulties for pupils during the transition from primary to secondary school. We have namely highlighted a lack of coherence between primary and secondary school textbooks. Indeed the results of the tests at both levels show that pupils haven't overcome the main misconceptions.

This research project has just started but the first results we expose here seem to confirm the validity of a global approach in order to understand pupils' difficulties in the transition from primary to secondary school. However, more data has to be collected and the analyses have to be completed in order to confirm our hypotheses and especially to study to what extent the observed teaching practices are representative of ordinary practices. Another objective is also to try to evaluate their effects on pupils' learning.

WHICH GEOMETRICAL WORKING SPACES FOR THE PRIMARY SCHOOL PRESERVICE TEACHERS?

Annette Braconne-Michoux

Université de Montréal, CANADA

Abstract: This paper is to describe the various GWS pre-service teachers could be working in, in connection with the different mathematics curricula implemented in primary and secondary schools in the province of Québec (Canada). It results from this study that the GWS¹ of reference in primary and secondary schools seem to be based on a parcelled out geometry GII (GII/GI) but pupils at both levels can succeed while working in a personal GWS being based on an assumed Geometry GI (GI/gII). It derives from this report that the primary school pre-service teachers work in a personal GWS near or identical to the GWS being used by the primary school pupil. Is this an ideal situation for pre-service teachers?

INTRODUCTION

In the Elementary and Secondary School Levels curricula in the province of Québec, Mathematics is presented as one of the best subject for training in reasoning and argumentation, the example given being a geometry task. And doing so, the curriculum refers to a description of different sorts of reasoning in mathematics such as “*deductive, inductive or creative*” reasoning (p. 140).

In the introduction to the Secondary School Level curriculum, one can read that, thanks to mathematics, “*students continue developing the rigour, reasoning ability, intuition, creativity and critical thinking skills they began acquiring in elementary school*” (p. 183). More precisely, Geometry is a mathematical subject particularly relevant for hypothetical-deductive reasoning as:

in Geometry, students use reasoning when they learn to recognize the characteristics of common figures apply their properties and perform operations on plane figures by means of geometric transformations. [...]. They learn the definitions and properties of the figures they use to solve problems involving simple deductions.

[...]

- Observations or measurements based on a drawing do not prove that a conjecture is true, but must be used to formulate a conjecture.(p. 201)

Since no example of geometrical work is given at both schools levels, it is difficult to foresee what kind of geometry pupils are expected to work in and what knowledge of geometry should derive from that. As a consequence one may wonder what kind of geometry will pre-service teachers master when entering their geometry course at

¹ The expressions ETG of reference, suitable ETG and personal ETG, are to be taken within the meaning of Kuzniak (2009)

university. To address these issues I will refer to the three geometrical paradigms as defined by Houdement-Kuzniak (2003) and the Geometrical Working Spaces as described by Kuzniak (2009).

To start with, I will give a very quick summary of the theoretical framework. Then I will analyze some tasks from Primary and Secondary textbooks along with the teacher's handbooks. This will lead to the issue I want to address: in which WGS are Primary School Pre-service teachers able to work?

THEORETICAL FRAMEWORK

Geometrical paradigms

According to Houdement-Kuzniak (2003), in the context of Euclidean Geometry as taught in Primary and Secondary Schools, one can distinguish three paradigms. These paradigms (see Table 1) can be characterized by their components: intuition, experience and deduction, the kind of space the pupil is working in, the status of the drawing and the privileged aspect of the drawing (or the object) for validation.

	Geometry I (Natural Geometry)	Geometry II (Natural Axiomatic Geometry)	Geometry III (Formalist Axiomatic Geometry)
Intuition	Sensible, linked to the perception, enriched by the experiment	Linked to the figures	Internal to mathematics
Experience	Linked to the measurable space	Linked to schemas of the reality	Logical
Deduction	Near to the Real, and linked to experiment	Demonstration based upon axioms	Demonstration based on a complete system of axioms
Kind of spaces	Intuitive and physical space	Physical and geometrical space	Abstract Euclidean Space
Status of the drawing	Object of the study and of validation	Support of reasoning and "figural concept"	Schema of a theoretical object, heuristic tool
Privileged aspect	Self-Evidence and construction	Properties and demonstration	Demonstration and links between the objects. Structure.

Table 1: Geometrical paradigms (Houdement-Kuzniak, 2003)

From different studies (Kuzniak, 2003; Kuzniak –Vivier, 2009; Kuzniak, 2010), it appears that in Primary School most curricula, textbooks and tasks in the classroom refer to GI. GII may appear from time to time in very specific situations. In Secondary School, it seems that either GI or GII can be referred to, the transition

from one to the other being an important matter to address (Braconne-Michoux, 2008).

When considering a pupil or a mathematician working in Geometry, these paradigms were to lead Kuzniak to the idea of Geometrical Working Spaces. Moreover observations proved that the different paradigms are interlinked and the boundaries from one another are not clear cut.

Geometrical Working Space

In this paper the words Geometrical Working Space (GWS) will be understood in Kuzniak's meaning (2009):

The Geometrical Working Space is the place organized to ensure the geometrical work. It makes networking the three following components: the real and local space as material support, the artefacts as drawing tools and computers (...) and a theoretical system of references possibly organized in a theoretical model depending on the geometrical paradigm.

Kuzniak (2009) refined the connections between the different paradigms according to their contributions to each other.

Assumed GI Geometry (GI/gII). In this geometry, the pupil is working on configurations from the real world, the validation relying on perception or measurements. But it may happen that theorems proved only in GII may be of use as "*technical tools avoiding measure or making calculations easier*".

Kuzniak presents an assumed GII Geometry referring clearly to Euclidean Geometry and its logical organisation. But in this geometry, theoretical properties emerge from intuition of space.

Parcelled out GII geometry (GII/GI). In this geometry, properties derive from GI experience. But here some hypothetical-deductive pockets can be developed using the properties already established.

Surreptitious GII Geometry (GI/GII). Adapting Kuzniak's definition of Surreptitious GIII Geometry, we may say that here, geometry teaching is drawn by more theoretical reasons aiming to GII, the pupil being left aside in the shift from one paradigm to the other. Examples of such geometry may be found only in textbooks.

In the province of Quebec only approved textbooks are to be published and are available in the classrooms. So we can assume that the interpretation of the curriculum and its expression in the textbooks are close. In other words, the referential WGS and the appropriate one are close to one another.

GWSS LIVING IN ELEMENTARY SCHOOL

If we are to quote the introduction to the curriculum, we may understand that during Primary School, a pupil works in GI then moves to GII:

Mathematics involves abstraction. Although it is always to the teacher's advantage to refer to real-world objects and situations, he/she must nevertheless set out to examine, in the abstract, relationships between the objects or between the elements of a given situation. For example, a triangular object becomes a geometric figure, and therefore a subject of interest to mathematicians, as soon as we begin to study the relationships between its sides, its vertices and its angles, for example. (p. 124)

If the teacher is to guide the pupils to abstraction, the meaning of “a geometric figure” has to be questioned. Is it as Laborde and Capponi (1994) meant it: a geometrical figure establishing the relationships between a theoretical object of geometry and the attached drawing? Or is it in a more general meaning where a precise drawing is made with geometrical instruments? This double-entendre is met further in the curriculum since the outcomes of year-2 are: “*the students [...] construct plane figures...*” (p. 147). And at the end of year-6, one can read: “[...] *the students [...] can describe and classify plane figures, [...] estimate, and measure or calculate lengths, surface areas ...*” (p. 147). If we are to stick to the word “figure”, we can suppose that there is a switch in the curriculum from the general meaning to Laborde and Capponi's meaning thus introducing a shift from GI to GII. But at the same time, the pupils can validate their answers mainly by measurement, and keep working in GI.

Furthermore according to tradition in teaching geometry in Quebec, students are working on instrumented drawings and the properties of the figures derive from their global aspect or measurements. So students mainly work in GI and gain some general knowledge from experience and “empirical generalizations”. Such information is named “properties”. What is the status of these properties? Theoretical or empirical? There is no clear answer to such a question. So if the WGS of reference at the end of Elementary School is probably a parcelled out GII Geometry (GII/GI) even a surreptitious GII one (GI/GII) insofar as proto-axiomatic considerations are to be taught whereas the supports on which the pupils work are drawings, are the pupils working in these very paradigms, the status of which being not clear and most of the validations being visual or instrumented as in GI?

To illustrate this interpretation of the WGS living in the classroom we will analyze some geometry tasks excerpt from two textbooks (year 4 and year 5) by the same authors.

In figure 1 we give an example of a year-4 textbook (Clicmaths, 4^e année). In task n°3, the questions can be answered in different geometries.

E Reproduis 3 fois le segment de droite ci-contre sur la feuille qu'on te remettra. Utilise une règle. Chaque segment sera l'un des côtés d'un quadrilatère.

A À partir du premier segment, trace un losange.

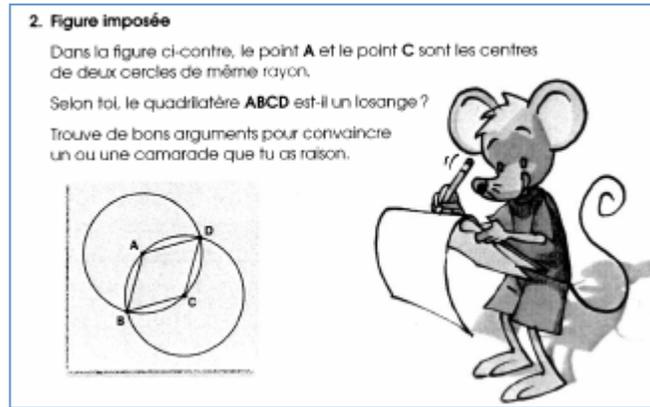

B À partir du deuxième segment, trace un parallélogramme.

C À partir du troisième segment, trace un trapèze.

Figure² 1: Clicmath 4^e année (p. 65)

Here the pupil works on a squared paper with instruments. He/she can validate his/her drawings perceptively thus working in GI. If he/she uses general properties when counting the number of squares in the grid or relying on axes of symmetry, he/she works in an assumed GI (GI/gII).

The example in Figure 2 is to be found in the year-5 textbook by the same authors.

Figure³ 2: Clicmath 5^e année (p. 53)

To answer this question, the pupil can say right away: “It’s a rhombus. I can see it”. But, because of the last sentence, he/she knows that such an answer is not allowed. So he/she can measure the lengths of the different sides and be convinced that it is rhombus. In both cases we can say that the pupil is working in GI. But as the last sentence suggests it, the pupil can guess that he/she must go deeper in his/her reasoning, reaching some part of GII, thus working in a parcelled out GI (GI/gII). The question which may arise then is: how the different reasons should be organized? Is there a first one and a second one or could they be worded in any order? According to the teacher’s handbook, the expected answer is a formal proof which is then clearly in an assumed GII (GII/gI): “Points B and D are radiuses of the circle of centre A so $AB = AD$”.

We can see there a shift from GI to some parcelled out GII Geometry and even an assumed GII but we cannot be sure that the pupils will be aware of this new paradigm. How pupils can make the distinction between the drawings they observe or they produce and the theoretical objects represented? We cannot be sure of that. This exemplifies how difficult it is to manage the shift from GI to GII (Braconne-Michoux, 2008). One could say that the different WGS living in an elementary

² Free translation: “N°3: Copy this line 3 times on the (squared) sheet of paper you’ll be given. Each line will be the side of a quadrilateral.

- A. Starting from the first line, trace a rhombus.
- B. Starting from the second line, draw a parallelogram.
- C. Starting from the third line, trace a trapezoid.

³ Free translation: “In the figure opposite, point A and point C are the centers of the two circles having the same radius. In your opinion, is the quadrilateral ABCD a rhombus? Find good reasons to convince a friend that you are right.”

classroom are: a WGS of reference aiming to a parcelled out GII geometry or a surreptitious one, a suitable WGS taking into account the WGS of reference but tending to GI and a personal WGS clearly in GI. But the shift from GI to GII is not clear: the drawing often has the status of a figure, without the pupil's knowledge, though it seems that this shift might be the pupil's responsibility.

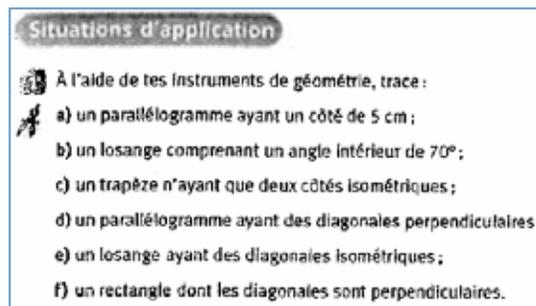

WGSS LIVING IN SECONDARY SCHOOL

The Secondary School Level curricula are in continuation of the previous ones.

In geometry, the students make the transition from the observation to the reasoning. They state and use properties, definitions and relations to analyze and solve a situational problem. They construct figures if necessary, using a geometry set or dynamic geometry software. (p. 198)

In this curriculum, in a footnote related the contents of learning, one can read: *“In a geometric space of a given dimension (0, 1, 2 or 3), a geometric figure is a set of points being representing a geometric object such as a point, line, curve, polygon or polyhedron.”* (p. 216). Is a geometric figure to be understood as a theoretical object? Perhaps ... The geometric properties the students must know at the end of each cycle are presented as “Principles of Euclidean Geometry” and are worded as geometrical facts: *“All the perpendicular bisectors of the cords of a circle meet in the centre of the circle”* (Cycle One, p. 219) or *“The midpoint of the hypotenuse of a right triangle is equidistant from the three vertices.”* (Cycle Two, p. 127). So it seems that the WGS of reference is based on GII. But what sort of GII: an assumed one or a parcelled out one? As we did before we will work on examples, excerpt from a textbook “Perspective Secondaire 1”, by the same authors as “Clicmaths”.

In activity n°1 (see figure 4), the student is asked to draw specific quadrilaterals.

Figure⁴ 4: activité 1 p 89 (Perspective Secondaire 1 vol. A1)

From questions d) to f) the quadrilaterals have different names (i.e.: in f) a square is drawn). But these particular quadrilaterals are not questioned. Moreover, according to the teacher's handbook, the objective of this activity is to get more dexterity with the

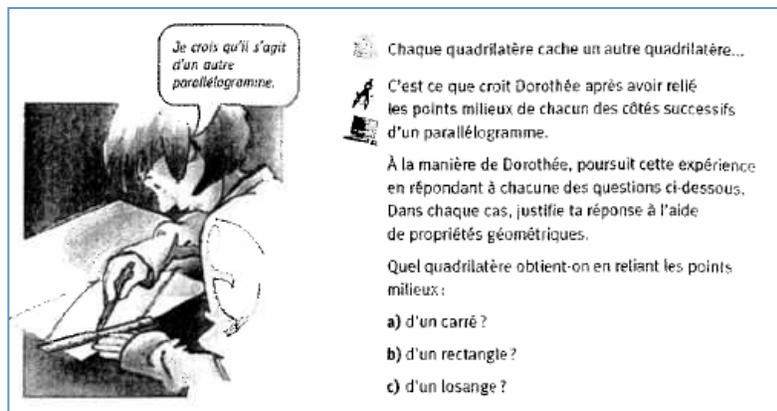

⁴ Free translation : “Using your instruments of geometry, trace:

a) A parallelogram with a side 5 cm long; b) A rhombus with an interior angle of 70° ; c) A trapezoid having only two equal sides; d) A parallelogram having perpendicular diagonals; e) A rhombus having isometric diagonals; f) A rectangle whose diagonals are perpendicular.”

handling of the instruments. So this task has to be worked in GI. In our opinion, an opportunity to move from GI to GII is missed.

Further in the textbook, the student is asked to build different quadrilaterals using two toothpicks as diagonals, draw the figure he/she gets and justify the nature of the quadrilateral. In doing so the student goes back to real objects and his/her validations are mainly perceptive. But as a justification is required, students know they must quote the properties of the diagonals of the quadrilaterals. Here we can consider that the students work in GI using tools of GII, and in doing so, being in some parcelled out GII geometry. Are they reasoning or just giving the expected theoretical answer?

Exercise n°9 (see figure 6), is very interesting since the property of the midpoints in a triangle is unknown at this school level, the pupil cannot give a formal proof as a justification. So one can wonder in which paradigm the pupils may work.

Figure⁵ 6: exercice n°9 p. 92 (Perspective Secondaire 1 vol. A1)

They can make a conjecture out of their detailed drawings. The best justification they can give is to report on the position of the diagonals of the new quadrilateral and derive its nature from that. So even if the question seems to be worded in GII, the answer the students can give is in GI: the validation is instrumented or perceptive. The justification given in the teacher's handbook refers to the lengths or the positions of the diagonals ("vertical" or "horizontal" as in their prototypic positions). So it is clearly worded as an assumed GI (GI/gII) task would be. We have here another example of the difficult transition from GI to GII.

In other textbooks in order to justify their conjectures students have to refer to a list of theoretical properties (referring to GII). But they are not asked to organize their reasoning nor have to search for theoretical reasons in order to build a convincing argumentation, along with a deductive reasoning. We can conclude that, though they have been approved by the government, the textbooks offer very rare opportunities to

⁵ Free translation: "Every quadrilateral hides another quadrilateral..."

That's what Dorothée believes after having connected the midpoints of every consecutive sides of a parallelogram.

As Dorothée did it, carry on with this experiment answering every question below. In each case, justify your answer using geometric properties. What quadrilateral do we get when connecting the midpoints

a) of a square? b) of a rectangle? c) of a rhombus?"

work in GII and the suitable WGS rests at most on a parcelled out geometry GII, while pupils keep on working in a personal WGS resting on GI. Since, as far as geometry is concerned, the following years of Secondary School are dedicated to geometrical calculations, many students may leave Secondary School with no experiment of an assumed GII (no formal proof or hypothetico-deductive reasoning).

WGSs FOR PRESERVICE TEACHERS

Most pre-service teachers, now University students, have been trained according to these curricula. So we can assume that their personal WGS rests on an assumed GI geometry or at best a parcelled out GII one, very few of them being able to work in an assumed geometry GII. In other words, many students have a personal WGS which is not different from that of an elementary school pupil. We can fear that this WGS is likely not to be adapted to the teaching of geometry at Elementary School Level, pre-service teachers sharing their pupils' difficulties and their misconceptions.

In order to illustrate our words, we report two class experiments. In the first one, we asked students to do the activity illustrated in Figure 7, excerpt from a year-5 textbook.

Minh s'amuse à former des polygones à l'aide de cure-dents.
Comment doit-il disposer 4 cure-dents pour former un quadrilatère qui n'est pas un carré?

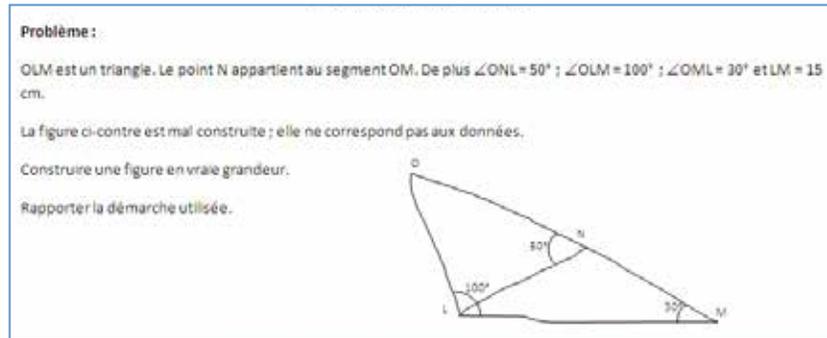

Figure⁶ 7: Presto 5^e année

To start with, as no toothpick was available, several students found it difficult to switch from toothpicks to pens. They kept on forming squares with the 4 pens in a prototypic position on the table. We had to help them to get to rhombuses. None of them tried to draw a schema of the situation. After discussion it appeared that this activity had highlighted the fact that several students were facing great difficulties in moving from real objects to represented ones and theoretical ones. These students' conceptions were still GI connected.

In the second one, we asked them to draw the triangle as asked in figure 8, excerpt from Repères-IREM (1993).

⁶ Free translation :

Minh is enjoying forming polygons with toothpicks. How should he arrange 4 toothpicks to form a quadrilateral which is not a square?

Figure⁷ 8: construction of triangles

For many students, the process consisted in being very careful while using their instruments (protractor and ruler), keeping in mind that $\angle ONL$ should measure 50° . Though all the students knew that the sum of the angles of a triangle is 180° , very few of them were able to use it in order to set up a reliable drawing process. Very few students noticed that the triangle OLN is isosceles in L and none put forward the idea that point N could be drawn using compasses. Most students had been working in an assumed GI (GI/gII), not an assumed GII (GII/gI), just as elementary pupils might do. Then one can wonder how as teachers they will look at their pupils' work and how they will be able to help them.

The origin of the situation is probably to be searched in the different WGSs living at Secondary School level. As we saw in the previous section they are not different enough from the WGSs living in Elementary School: tasks to be answered in an assumed GII (GII/gI) are very rare or non existent in some Secondary School textbooks.

CONCLUSION

In conclusion, we can say that in either Elementary or Secondary Schools, the WGSs in use are based on an assumed GI geometry (GI/gII) tending to a parcelled out GII (GII/GI). The shift from GI to GII being difficult to deal with, more than often, the tasks can be answered successfully by students working in GI. If a stress were to be on a real move to an assumed GII at Secondary School Level, we could hope that this would help our future pre-service teachers in geometry. How can we make students who work only in GI move to GII and make familiar with a new WGS close to the WGS of reference? The concern is that the contents of the handbooks are not always a relevant support and the duration of training is probably too short to let the students adapt to this new situation. We have to set up geometrical questions which cannot be solved in GI and where the students' misconceptions will be revealed. This is a great challenge.

⁷ Free translation :

OLM is a triangle. Point N is on the line OM. Moreover $\angle ONL = 50^\circ$, $\angle OLM = 100^\circ$, $\angle OML = 30^\circ$ and $LM = 15$ cm. The figure opposite is badly drawn; it does not fit with the given. Draw a figure at real size. Tell the process you followed.

(DIS)ORIENTATION AND SPATIAL SENSE: TOPOLOGICAL THINKING IN THE MIDDLE GRADES

Elizabeth de Freitas & MaryJean McCarthy

Adelphi University

In this paper, we focus on topological approaches to space, and we argue that experiences with topology allow middle school students to develop a more robust understanding of orientation and dimension. We frame our argument in terms of the phenomenological literature on perception and corporeal space. We discuss findings from a quasi-experimental study engaging 9 grades 5-8 students in a 6-week series of school-based workshops focused on knot theory. We discuss video data that shows how students engage with the intrinsic disorientation of mathematical knots through the use of gesture and movement.

Spatial sense, topology, corporeal space, embodiment, knots

INTRODUCTION

Fielker (2011) suggests that we need to broaden our conception of geometry and recognize that “geometries” are diverse kinds of approaches to space, some more suitable than others to the study of movement, transformation, connectedness, dimensionality and orientation. Taking this more expansive approach by inviting students to experiment with spatial reasoning creates an opportunity for students to attend to the corporeal and material aspects of mathematics. We focus on topological approaches to space, and we frame our analysis in terms of the literature on perception and corporeal space. We discuss data that suggests students’ gestures often function as devices for orienting a knot in relation to a moving frame of reference. Our analysis suggests that the students are operationalizing gesture and vision and voice to literally dislocate themselves in relation to the knot so as to better explore it, and that the experience provides an opportunity for them to develop the topological concept of dimensionality, which we define as degrees of freedom of movement.

METHODS & DATA

Nine students (grades 5-8), three female and six male, were recruited from a New York State elementary school to participate in six two hour afterschool topology workshops over a three month period. These workshops led by the two principal investigators were offered as non-credit extra-curricular opportunities. The

participants had not studied topology previously and their school math curriculum had not provided many opportunities for exploring spatial reasoning. The following questions guided our research: How do students solve problems that entail topological approaches to space? In what ways do gestural-haptic modalities factor into students' spatial reasoning as they engage in problems through topological rather than Euclidean concepts? How does the concept of dimension factor into students' spatial reasoning, and in what ways can problem solving with knots and knot diagrams develop a robust topological concept of dimension? We focused on knot theoretic activities that involved identifying, creating, modifying, comparing, sorting, decomposing and diagramming knots. Various media were used, such as strings, ropes, pipe cleaners, sculpie clay, ipads, and paper and pencils. The software Knot Plots generated dynamic images of knots which could be spun around and modified by the students. The focus of the activities was on how students moved back and forth between image, object and diagram, and how this entailed particular working concepts of dimensionality, directionality and orientation. Although the concepts of invariance and non-rigid transformations were introduced and explored at the first workshop, the PIs gave no other direct instruction, allowing students to develop collaboratively various knot theoretic tools as they problem solved, such as the (un)crossing number, the Reidemeister moves and the colorability constraints. Activities that shed significant light on the questions guiding the research were tasks that were: (1) open-ended and invited inventive diagramming practices for representing 3-D objects, (2) involved working with orientable and non-orientable surfaces, (3) entailed identifying discrete Reidemeister moves in continuously unravelling mathematical knots displayed in video. Project data consists of video and audio recordings of (a) workshops and (b) performance-based interview tasks completed 6 weeks and 6 months after completion of the workshops, as well as (c) drawn artifacts produced by students during both workshops and interviews. In order to focus carefully on the students' entire corporeal space as they worked, we coded the video data by tracking (a) student use of spatial language to describe their activity, and (b) hand gesture as a form of embodied orientation (in relation to a set of coordinate axes).

THE VESTIBULAR LINE & THE VISUAL LINE

Recent research on the kinesthetic perception of physical space and students' deployment of gestural/haptic modalities in problem solving and other mathematical activity has begun to shed light on the complex facets of spatial sense (Nemirovsky & Ferrera, 2009; Núñez, Edwards, Matos, 1999). Hostetter and Alibali (2008), for instance, draw on Gibson (1979) and others to argue that perception and action are mutually determining, and that knowledge emerges through these co-adaptive processes. This "tight coupling of motor and perceptual

processes” underscores the ways in which we activate sensorimotor processes when working with concepts (Hostetter and Alibali, 2008, p. 497).

The mathematician Bernard Teissier describes “mathematical intuition” as being a fusion of two modes of perception, the *visual continuum* and the *continuum of motion*. Drawing on recent work in neurophysiology (i.e Berthoz, 2005), Teissier (2011) puts forth what he calls the “Poincaré-Berthoz isomorphism” that links these two modes, suggesting that their fusion is at the source of mathematical invention “For instance, when we perceive a mathematical line or curve, we actually perceive two fundamentally different things: One, a “vestibular line” that is dynamic, seemingly flowing, “parametrized by time and Rhythmed by the steps” (p.237) and two, a “visual line” associated more with boundaries and ambient spatial coordinates. In the case of the *straight* line, we either perceive it in terms of its intrinsic mobility (constant velocity) or as a “curve having everywhere the same orientation” in relation to a frame of reference (p. 238). The cognitive research of Berthoz (2005) suggests that the human mind makes strong links between the vestibular line and visual line, which accords with Poincaré’s insights, noted by Teissier, that “the position of an object in space is related to the set of muscular tensions corresponding to the movement we must make to capture it by the equivalent of a coordinate change” (p. 238). The fusion of these two perceptions generates a “protomathematical object” which then lends itself to all sorts of mathematizing.

In order to study the fusion of these two modes of perception, we focus here on topology defined as the study of those properties of geometric objects that remain unchanged under bi-uniform and bi-continuous transformations (Debnath, 2010). Informally referred to as “rubber sheet geometry”, topology is concerned with bending, stretching, twisting, or compressing elastic objects (O’Shea, 2007; Richeson, 2008; Stahl, 2005). Despite thousands of years of studying the metric relationships of polyhedra, no one prior to Euler had studied the non-metric relationships of connectedness.¹ Through the work of Gauss, Klein, Riemann and Poincaré, topology became the qualitative study of surfaces, manifolds, boundary relationships and curvature. Topology shifts our attention away from concepts of measure and rigid transformation, and focuses on the stretching and distortion of continuously connected lines and regions. In *Geometry and the Imagination* (1932/1952), David Hilbert claimed that “in topology we are concerned with geometrical facts that do not even involve concepts of straight line or plane but

¹ We know that Leibniz was already familiar with the formula, and historians speculate that Descartes was aware of a similar one (Richeson, 2008). Although Euler’s solution to the bridges of Königsberg problem (1736) comes prior to his letter to Goldbach about polyhedra, the significance of the latter is noted here due to the way it breaks with prior mathematical treatments of polyhedra.

only the continuous connectiveness between points of a figure”. In this paper, we are concerned with how particular aspects of topological thinking allow for a better fusion of the two kinds of perception mentioned above. For instance, topology deploys a more robust concept of dimension than what we normally find in the geometry curriculum –rather than the ‘size’ of a space, topologists refer to dimension in terms of degrees of freedom of movement. Also, the concept of orientation in topology is defined in terms of the capacity to move around space and return to a particular point “oriented” in the same direction as when the motion began, rather than in terms of a fixed Euclidean frame of reference. Finally, the topological focus on distortion and stretching more generally fuses the two kinds of perception, since it transforms the static line into a mobile continuously varying object.

According to Smith (2006), “Euclidean geometry defines the essence of the line in purely static terms that eliminate any reference to the curvilinear (‘a line which lies evenly with the points on itself).” He contrasts this rectilinear concept with the “operative geometry” of Archimedes, in which the straight line was characterized dynamically as ‘the shortest distance between two points.’” (p. 148). Smith suggests this definition marks the line as a continuous operation and a “process of alignment” pursuing its own inherent variability.² A more elastic definition of the line attributed to Heron is “A straight line is a line stretched to the utmost” (Metrica, 4. Gray, 1979, p.128).

Student experiences with knots afford opportunities for developing an understanding of orientation and dimension as operative concepts rather than attributes. Instead of defining the line solely in terms of Euclidean measure and planar existence, knots embody a twisting stretching multi-dimensional line of flight that breaks through the plane. Knot theory emerged in the eighteenth and nineteenth century and developed within the field of topology. Mathematical knots are closed multi-dimensional (knotted) curves that are deemed equivalent if one can be deformed into another (note that this deformation is not a Euclidean rigid transformation). Mathematical knots take up the line as a non-linear and non-planar process of becoming (without end or origin), a process of actualization whereby new dimensions and new entanglements unfold. The curve or line in n-space is a multi-dimensional entity, suddenly possessing perspective and depth. One can relax the knot and loosen its crossings, and then imagine crawling along the rope, following its path into the depth of the page. The knot has no interior or exterior; it is all line, or all outside. Recent interest in including knot theory in the middle school curriculum points to how it helps students develop spatial reasoning

² According to Netz & Noel (2007), Archimedes treated diagrams as physical models while attending more to the “broader, topological features of a geometrical object” (Netz & Noel, 2007, p. 105).

through visual and tactile exploration of both quantitative and qualitative invariants (Adams, 2004; Handa & Mattman, 2008). Knot theory offers students a creative and generative approach to ‘spatial reasoning’. It captures the dynamic multiplicity of space as a process of dimensional unfolding. One is always in the middle of a knot, pursuing its lines of flight.

KNOTS AND KNOT DIAGRAMS

From 1988-1991, Carol Strohecker ran a “knot lab” in an urban elementary school where 20 fifth graders explored topological thinking through the study of knots. Students used string and other media to compose knots, developing and discussing strategies for doing so. Using the snake method, which involved placing the string on the table, identifying a starting point and fixing one end of the string while moving the other end, students were able to perceive the relationships between strands differently, conceptually integrating the more entangled parts with the various loops that fed into them. The use of this method also seemed to occasion students’ efforts at re-orienting their knots (rotating them on the desk), which further developed their “body syntonicity” (Papert, 1980) in that they began to decenter themselves as a perceiver located at a fixed position, and instead identified with the mobility and disorientation embodied in the knot. Strohecker suggests that the medium itself (the pliable string) afforded students an opportunity to develop their spatial reasoning in this way, describing how “many of the children involved their bodies in expressing their conceptions of knots and knot-tying, often relying on their arms or legs to represent ends of string moving into the form of a knot.” (p.6). She also indicates that student language use while describing their knots, for instance expressions such as “up/down, top/bottom, above/below, over/under, in/out”, revealed how they worked the string as though it were a boundary, dividing space into neighbourhoods that were either in or outside of the knot. Her research clearly shows that students dealt explicitly with topological concepts.

As Kuechler (2001) suggests, the capacity of the knot “to fashion decentred spatial cognition” (p.82) explains in part our fascination with knots in textiles and symbolic forms. She offers an “ethnography of knots” pointing to the prevalence and power of knotted effigies and knotted patterns across various cultures and times. Knots seem to refuse to be seen from one particular point of view or perspective. Knots are all movement along a curvilinear line, evoking fluid spatial relationships. “Each knot is, in a sense, its own universe, which invites contemplation of its topology both as it is being formed and as a completed object” (Strohecker, 1991, p. 215).

For middle school students, one of the biggest challenges – as well as being one of the richest areas for developing spatial reasoning – involves tasks of creating and decoding *diagrams* of knots. Knot diagrams introduce depth into the plane, conjuring a virtual dimension within the two-dimensional surface. The crossings in knot diagrams create a multi-dimensional effect, suggesting a layering precisely where Cartesian geometry would have imposed an intersection. Making sense of knot diagrams demands that one construe an “over/under” relationship in two dimensions and that one follow the continuity of a line as it seems to leap off the surface of the page. Moreover, knots are defiantly without orientation, and yet diagrams are attempts to capture and orient knots on the plane. Students have to decide what is in the foreground/background (and in some cases how that relationship might be evoked) and decide on a perspective and an orientation. Because of the absence of axes and other straight lines to structure one’s vision, and because students are learning to pay attention to topological relationships rather than Euclidean ones, drawing knot diagrams often entails positioning oneself (as the observer) in multiple and diverse locations. Châtelet (2006) argues that knots and knot diagrams disrupt fundamental Euclidean spatial practices. They introduce a new manner of intervention and a new way of making mathematical images. They express both entanglement and rupture in the way they disobey the plane. Thus the knot and its diagram contest the usual epistemological barrier between geometric space and corporeal space. Thus any attempt to locate the knot within a mathematical frame of reference is complicated by its 'tied' nature, its folds and twists, connectedness and relationality.

ORIENTATION, MOVEMENT AND CORPOREAL SPACE

We see from the literature that (dis)orientation and dimensionality figures prominently in our engagements with knots. Ahmed (2010) argues that orientation is an essential aspect of spatial sense making. Put simply, “orientations are about the direction we take that puts some things and not others in our reach.” (Ahmed, 2010, p. 245). Body orientations thus shape and map space by generating operative axes around which we define our movements. Thus orientation marks a “here” and a “now” from which we proceed. One might even suggest that orientation and motion are mutually implicated. With reference to the phenomenology of Husserl, Ahmed (2010) suggests that orientation marks a “zero-point” or starting point “from which the world unfolds” (p. 236). This implicit structuring of a zero-point for the body entails a sense of movement or potential movement, and this in turn conditions our perception of what is foreground and what is background. Indeed, the perception of depth (and dimensionality) is not as simple as one might first imagine, as it depends on a tactile-kinesthetic fusion of sensory impressions. The body is thus “something that I move with, not something I move, i.e., it has the

characteristic of direct motility – I do not have to place my body in order to move it.” (Rush, 2008, p. 18).

CASE STUDY

In this section, we discuss data collected during the post-intervention interviews with the student participants of our study. We focus on one task where the students were shown a 2-D depiction of a knot (figure #1), asked to explain if and how they might simplify the knot, and then asked to identify key moves in a video of the same knot unravelling into the unknot. We discuss below how Maya moves back and forth between the vestibular line and the visual line as she engages with this picture of a knot. The image demands a great deal of depth perception since there are loops under loops under loops. This layering of the rope makes for a complex perceptual task. Each time one focuses on one crossing and ‘sees’ a particular relationship of over/under on a plane of reference, one is then forced to dislocate that plane of reference when either the same two strands reverse the relationship of over/under at the adjacent crossing or a third strand appears beneath the other two and the student has to penetrate the imagined plane to incorporate this third strand in making spatial sense of the relationships. Despite the seeming complexity of the knot, it is reducible to the unknot after a series of moves.

Figure #1

Figure #2

Maya is first asked to count the crossings. She tilts her head and body as her fingers trace the path of the knot (figure #2). She names the crossings as either over or under *because* her finger follows the vestibular line and thus there is a *relative* experience of over or under. Then she stops and looks up and says, “but if you look at it from the other perspective wouldn’t it be over or under?” (0:15) When asked to say more, she removes her hands, and explains, “You can see this one going under, this one going under, but you have to like focus on one and the one that you focus would go over or under. (0:52)

In so doing, Maya is shifting from perceiving the vestibular line to perceiving the visual line. With the visual line, the concepts of over and under cannot be assigned to a crossing unambiguously. In other words, at each crossing there are two strands, so there is no sense that a *crossing* has a definitive over or under designation. Such a designation only makes sense if one imagines oneself actually moving along one of the strands on the vestibular line.

Asked where she would start in order to simplify the knot, she picks a strand (lower right for her, labelled A on figure #3 below) and gestures as though she had used her pointer finger to stretch and pin the strand (Figure #4). She affixes this finger to the page, as though she were holding down the rope, while her other hand takes on the gesture of a pincher or grabber, hovering and rocking slightly back and forth in the air above the knot.

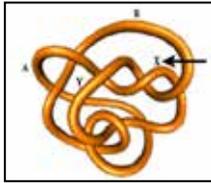

Figure #3

Figure #4

Figure #5

She then places both hands on the table and she taps her fingers rhythmically and in unison while she thinks. She switches her first answer and picks a second strand (labelled X on figure #3), and then she gestures to pull and stretch the strand out from under strand B. She flips her hand palm up (figure #5) to show that it would “go like that”. This is not a pointing gesture, even though it looks like one. It is a flipping gesture that is meant to embody the inversion required as the loop moves from background to foreground. The hand is working as a proxy here as she embodies the new sense of orientation. She could have kept her hand oriented as in figure #3 and simply indicated the grabbing or pinching of the strand and its being stretched to a new location, but in order to capture the new relative relationships between over and under, she inverts her hand so that it’s palm up. This is significant. It shows how she is following the vestibular line using the orientation of her hands (palms up or down or other). What was under is now over, what was up is now down – she is back to following the vestibular line and enacting – through her hands – the changing relationships. In this sense, the hands are proxies for the disorientation embodied in the knot. In relation to the space of the room, Maya is upside down and looking up at the backside of the knot, as though she were on the other side of the paper. Maya is shifting her projected perspective on the knot as she engages with the task. In other words, she is moving around the knot – within, behind, beside, on top – in ways that speak to her embodied engagement. It is usually her left hand that performs the flipping while the right hand performs the stretching. She then pauses saying “Oh, this one’s complicated” and spins the sheet of paper around, until it is oriented as in Figure #6.

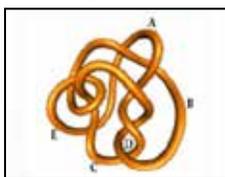

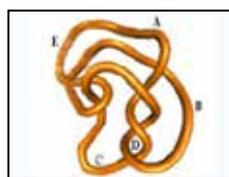

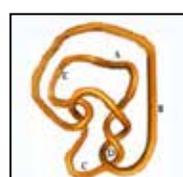

Figure #6

Figure#7 First Move

Figure#8 Next Move

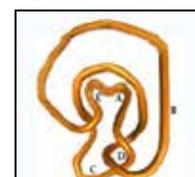

Figure #9 Next Move

Rotating the paper shows that she is engaged with the disorientation of the knot and that she is aware that the image isn't locked into a particular perceptual grid of 'proper' up/down orientation. She then confidently suggests a series of moves: pulling strand C out, flipping strand C over D and towards B, pulling strand A out, and then flipping strand E over the body of the knot. Although the first two moves don't seem to simplify the knot, the combination of these last two moves is indeed a move that will begin the unravelling (notice that strand E is linked to strand A in such a way that the two are part of a loop that is buried beneath the knot, and three of the adjacent crossings are under the rest of the knot). One can grab and stretch the loop towards the left, eliminating these three crossings (Figures #7).

One of the challenges in this task is 'seeing' into and behind the knot, shifting one's imagined perspective, and noticing these kinds of patterns related to depth and adjacency. This entails shrinking and stretching lines, which we found to be associated with student gesturing of both hands simultaneously. One hand was consistently used to gesture the pulling and stretching of a particular strand, but both hands were used – as though at either end of an elastic – when the students wanted to eliminate a crossing using Redeimester moves #2 and #3.

CONCLUSION

Studying students' experiences with topology revealed how orientation is a complex component of spatial sense. Analysis of video data showed how students' corporeal space entailed a moving rather than fixed perspective, and that gestures embodied this implicit mobility. Rather than seeing the gestures as iconic or indexical, we analyze them as embodiments of perspective. Students' gestures reveal how they follow both the vestibular line and the visual line as they make sense of knots. We see here how the two modes of perception – the visual continuum and motion continuum – were taken up in her gestures as she pursued the shifting orientation entailed in the diagram.

AN APPROACH TO SPATIAL GEOMETRY

Francesca Ferrara^{*}, Maria Flavia Mammana[°]

^{*} Dipartimento di Matematica “Giuseppe Peano”, Università di Torino

[°] Dipartimento di Matematica e Informatica, Università di Catania

In this paper we present an experiment that we conducted last spring (May 2012) in a high school in Sicily. The activities concerned some properties of quadrilateral and tetrahedron and aimed to introduce spatial geometry through a correspondence that can be established between the two figures, by using suitable definitions. The study is part of a wide research centred on the investigation of visual challenges involved in doing spatial geometry and the role of technology to address these challenges.

Keywords: visualization, spatial geometry, dynamic geometry software

INTRODUCTION

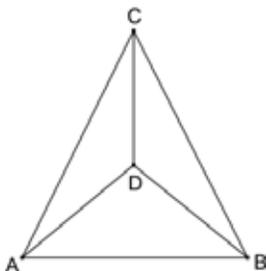

1. “Good night mum. Please, leave the light on!”, used to say little James every single night before falling asleep.

“Good night mum” said little James few nights ago... He was scared of dark. But all of a sudden, he realized that in the dark –well not dark dark!– *he could see*. In the dark, everything was clear. He did not need the night light on anymore.

2. It was June 2012 when Giorgia Florenza, a seventeen-year-old student, taking pictures during an excursion with her classmates near Siracuse, noted that there was *a face* in the rock she was taking a picture of: “With a simple click can come out prodigious things that sometime may escape to naked eye (from: La «scoperta» durante una gita del Liceo Galilei alla riserva del Plemmirio, *La Sicilia*, 11 Giugno 2012, p. 47, our translation).

3.

Teacher: And *what do you see* in the figure?

Student: A quadrilateral and/or a tetrahedron.

This is what a student said last May during a classroom activity in a scientifically oriented high school, in Giarre (Catania).

What one –being little James, Giorgia, or the student– sees or is able to see is *not* established *a priori* or universal, but it *may* depend on many heterogeneous factors in many heterogeneous contexts and experiences. It is situated and relative.

This paper presents a teaching experiment on Euclidean Geometry that we carried out in May 2012 in a high school in Sicily. The experiment dealt with some properties of quadrilateral and tetrahedron, and aimed to introduce the study of 3D geometry through a correspondence established between the two figures, by using suitable definitions. This study is part of a wide research whose focus is on aspects related to visualization and visibility, which are crucial for students when dealing with the shape of space and three-dimensional objects.

THEORETICAL CONSIDERATIONS

The fifteen-year-old students most repulsive subjects in mathematics were spatial geometry and statistics. Only ten percent of teachers taught spatial geometry. They said that they did not have enough time to teach it, but the real reason is that the students ‘cannot see in 3D’. (Bakó, 2003, p. 1)

This quotation regards a study that was conducted in France, but it marks a delicate situation that is still recognized as widespread at school, no matter what country is taken. In fact, the teaching of spatial geometry is often neglected and pushed in the background and not given great priority (Mariotti, 2005; Villani, 2006; Oldknown & Tetlow, 2008), partly due to the poor knowledge and confidence of teachers about the topic, and partly to the general reputation that spatial geometry is difficult because it is difficult *to “see”* (among teachers as well as among students).

Nevertheless, 3D geometry plays an essential role in all scientific disciplines, from physics to astronomy and chemistry, from engineering to figurative arts, as well as in everyday life. So, it seems very important to regard the study of spatial geometry at school and the development of spatial sense as crucial for shaping the mathematical literacy required to future citizens aware and able to make decisions. After all, the National syllabus endeavours to promote it as an integral part of the mathematics teaching and learning since early grades. We agree with Villani (2006) that “the cultural and operational-technical worthiness of spatial geometry must prevail over the difficulties of its teaching in all school grades” (p. 66, our translation).

The question of *seeing* is certainly primary. 3D geometry involves visual challenges, mainly depending on the fact that we have to do with representations of geometrical entities, these being bi-dimensional representations of three-dimensional objects. In so doing, the perception of third dimension is not easy, and strongly implies issues of visibility and visualization (see e.g. Hershkowitz, Parzys & Van Dormolen, 1996). Based on the double aspect of geometrical figures, that is, the distinction between their figural and conceptual properties (Fischbein & Nachlieli, 1998), the transition from the perceptual to the conceptual (from the drawing to the geometric figure) is even more difficult. As Rojano (2002) pointed out, in fact, a

problem source for geometry students in their transition to the conceptual is the lack of previous visual education that can aid the systematization of their visual experiences, for instance, in the search for patterns or in the distinction between the role of drawings as geometric objects or as diagrammatic models of these objects. (Rojano, 2002, p. 153)

In a study of the late eighties, Parzysz (1988) already highlighted the presence of a “knowing vs seeing” conflict in the teaching of space geometry, which entails that

The problems of coding a 3D geometrical figure into a single drawing have their origin in the impossibility of giving a close representation of it, and in the subsequent obligation of ‘falling back’ on a distant representation [...] an insoluble dilemma, due to the fact that what one *knows* of a 3D object comes into conflict with what one *sees* of it. (pp. 83-84)

The relationship between vision and perception of space had also been discussed by Jules-Henri Poincaré (1905), who, in his famous book *Science and Hypothesis*, was taking care of the problem of conceptualizing space. He was arguing that space is not a pre-existing concept, our knowledge of it being instead determined by our way of being and staying in the world, that is, by our ordinary experience with space and three-dimensional objects. Our eyes form bi-dimensional images of the 3D world but

sight enables us to appreciate distance, and therefore to perceive a third dimension. But everyone knows that this perception of the third dimension reduces to a sense of the effort of accommodation which must be made, and to a sense of the convergence of the two eyes, that must take place in order to perceive an object distinctly. (p. 53)

The effort of accommodation of the eye is very important in the play of working with a drawing of a three-dimensional figure and recognizing in it the figure, as well as regarding the capacity to shift from the figural to the conceptual and back. The use of technologies may be relevant with this respect, since

Computer software for the teaching of 3D geometry should allow students to see a solid represented in several possible ways on the screen and to transform it, helping them to acquire and develop abilities of visualization in the context of 3D geometry. (Christou *et al.*, 2007, pp. 3-4)

Our research interest in this paper is mainly the question of seeing: what one does see when looking at a three-dimensional figure; whether one is able to see a drawing as a three-dimensional figure, and its properties. At the same time, we want to understand how the use of technology may help to face some of the problems that are related to seeing and the study of spatial geometry. Visibility concerns the first face of the coin, meant as making things visible through images, or “thinking in terms of images” as outlined by Calvino (1988). Visualization instead regards the second face of the coin, in which means intervene in supporting making of images. The two faces are both part of thinking processes, neither a final result nor a static part.

In the literature, very few studies have regarded 3D geometry teaching and learning with technology. Some focused on students’ exploration of the relationships between geometric figures in solid geometry (Accascina and Rogora, 2006; Baki, Kösa, and

Karakuş 2008; Oldknow and Tetlow 2008), on students' perceptions (Bakó 2003), on the use of virtual reality microworlds (Yeh and Nason 2004; Dalgarno and Lee 2010).

With the activity we consider here, we intend to open a debate about how the study of spatial geometry can be approached at high school, starting from known figures of the plane (quadrilaterals) and simple Euclidean properties of those figures that can be transferred in space through suitable definitions (holding for tetrahedra).

TEACHING EXPERIMENT AND ACTIVITY

The teaching experiment is part of a wider research, in which we became interested last year, with the main purpose to investigate *visual challenges* involved in doing spatial geometry and the role of technology to address these challenges. To this aim, we started from the consideration of previous research that, given suitable definitions, a correspondence can be established between simple figures like quadrilaterals and tetrahedra (Mammana, Micale & Pennisi, 2009). The correspondence entails a move from plane to space that we think of as a possible basis to introduce the study of 3D geometry at high school and that can be realised through the use of Dynamic Geometry Software. The potentiality of the DGS is to allow for visibility and visualization of properties of the figures, bridging the gap between what can be seen and what can be learnt. The cognitive potential of the correspondence as a powerful didactical means is thus of interest for our research.

In particular, this paper regards a classroom activity that we carried out last May in a grade 11 class of a scientifically oriented high school in Giarre (Sicily). The students did not have any formal instruction about spatial geometry. Primary aim of the activity was to introduce them to the discovery that some properties that hold for quadrilaterals in the plane are preserved for tetrahedra in space, when the former are suitably defined. In this way, students are shown two different kinds of figures that share definitions and properties, and are stimulated not only processes of exploration in space but also the need for arguing the validity of certain properties. Here, attention will be drawn only to high school work.

Definitions and properties. To establish the correspondence, we gave the following definitions, using four non-collinear points and the six segments they identify:

1. A *convex Quadrilateral* F is determined by four coplanar points, A , B , C and D , any three of which are non-collinear, called *vertices*, and by the six segments determined by these vertices, AB , BC , CD , DA , AC and BD , called *edges*. The triangles identified by any three vertices are called *faces* of the quadrilateral.
2. A *Tetrahedron* F is determined by four non-coplanar points, A , B , C and D , called *vertices*, and by the six segments determined by these vertices, AB , BC , CD , DA , AC and BD , called *edges*. The triangles identified by any three vertices are called *faces* of the tetrahedron.

Both figures have four vertices, six edges and four faces (letter F is expressly used in both cases, as well as same name for corresponding objects). No matter what F is, the

couples of opposite edges and opposite face and vertex are equally defined. In addition, the segment joining the midpoints of two opposite edges is a *bimedian* of F , the segment joining one vertex with the centroid of the opposite face is a *median* of F . Given these definitions, the properties below are satisfied for F , again irrespective of its being a quadrilateral or a tetrahedron:

- Property A. i) The three bimedians of F all pass through one point (*centroid*).
 ii) The centroid of F bisects each bimedian.

- Property B. i) The four medians of F meet in its centroid.
 ii) The centroid of F divides each median in the ratio 1:3, the longer segment being on the side of the vertex of F .

The activities in which our students participated essentially focused on the discovery of properties A and B, and on their preservation in the passage from the quadrilateral to the tetrahedron. From the exploration of the quadrilateral in the plane, one can think of *moving* one vertex off the plane to transform the initial figure and to obtain a polyhedron, that is, a tetrahedron. So, the passage from plane to space can occur by means of the movement of a point, even encouraging to see changes and invariants.

Tasks and methodology. The whole experiment was based on the use of a DGS, Cabri Géomètre. We chose to use Cabri II Plus for the tasks about quadrilaterals and Cabri 3D for those regarding tetrahedra. Even if the students never met it before, Cabri 3D is the only DGS for 3D geometry released up to date. Providing learners with opportunities to redefine points, it furnishes a means to realize the move from quadrilateral to tetrahedron: the *Redefinition* tool. One way this tool works is to change a point into a free point in space, requiring an action that involves the uppercase key of the keyboard (entailing a certain awareness of the action).

The activities were carried out in a computer laboratory, in which the students were divided into groups (of three/four people). Each group had two computer at disposal, to use Cabri II Plus on the one side and, on the other, Cabri 3D. The group work was alternated with class discussions guided by one of the authors, while the other author filmed one group and the collective moments. The teacher of the class was present as an observer of the activity of the students.

The tasks given to the students are shown in what follows, every voice corresponding to an assigned worksheet:

- $Q1.$ Definition and identification of the quadrilateral Q and of its main elements: vertices, edges, opposite edges, opposite face and vertex.
 $Q2.$ Definition and identification of the bimedians of Q ; their properties.
 $Q3.$ Definition and identification of the medians of Q ; their properties.
 $T1.$ Construction of the tetrahedron T ; definition and identification of its main elements: vertices, edges, opposite edges, opposite face and vertex.

- T2.* Definition and identification of the bimedians of T ; their properties.
- T3.* Definition and identification of the medians of T ; their properties.

The worksheets on quadrilaterals had parallel worksheets on tetrahedra. In general, the tasks Qx presented three sections: Definition, Construction and Exploration, while those of the kind Tx contained sections about Definition and Exploration, except for the first task that asked first to construct the tetrahedron using the Redefinition tool.

The activities centred on conjecturing and discovering, being that of Exploration their main section. Formal proofs were not involved, even if reflections on ways to test conjectures with the DGS were made by the students for the properties on bimedians and medians.

ANALYSIS AND DISCUSSION

In this section, we present short episodes from the activity in Giarre that show the interplay between seeing and the use of the DGS. Attention is drawn to the way seeing in space is encouraged by the use of the software. In particular, we discuss how the discovery of properties in space is prompted and determined by processes of both seeing in space and knowing what happens in the plane. The role of the DGS is crucial in this phase, which leaves room for proof of the validity of properties.

The episodes involve three girls, Chiara, Cristina and Gabriella, that work together in front of two computers, one with Cabri II Plus and the other with Cabri 3D. We are at the second meeting with the class. In the previous meeting, the students have used Cabri II Plus to define the main elements of a convex quadrilateral F in the plane and to construct them, completing the requests of the first two worksheets, essentially bound to identifying the defined elements ($Q1$) and to exploring what happens with the bimedians when dragging the quadrilateral from its vertices ($Q2$). They have also learnt the concept of medians of a quadrilateral and how to construct them. During the second meeting, the students first summarised their discoveries in a class discussion (“*the bimedians all pass through one point*”, “*we conjectured that the intersection point of the bimedians is the middle point of each bimedian*”, from written texts). Then, they started the group work again, looking for properties of the medians of the quadrilateral ($Q3$), finding that they all pass through the centroid. After that, the class comes to deal for the first time with Cabri 3D and the passage from plane to space through the use of the tool *Redefinition* ($T1$). The groups are first asked to construct a quadrilateral F in the visible (grey) part of the base plane, given by default by the DGS (Figure 1a). Then they have to move one vertex of F off the plane by redefining it as a point in space and to reflect on the new figure T (Figure 1b shows the arrows active during redefinition of vertex D).

First episode (May 21, $T1$). Chiara, Cristina and Gabriella are rotating the figure they obtained with the redefinition and they are watching how it changes. The task asks them to identify its elements, given their definitions:

- Chiara: There are four vertices A, B, C, D and four edges, that is, DC, BC (looking at the computer screen)...
- Gabriella: One, two, three, four, five, six (counting the edges and pointing to them on the screen), yeah
- Chiara: The four faces, one, two, three, four (pointing to the faces on the screen)... are (reading the worksheet) the vertices, the edges and the faces of T
- Gabriella: Here it is, the face opposite to this vertex (pointing to one vertex) is this one (tracing the corresponding triangular face on the screen; Figure 1c)
- Chiara: (suddenly, covering Gabriella's voice while she is still acting on the screen) Yeah! The faces, the faces of a pyramid! Ahhh, they became the faces of a pyramid! (aloud and astonished) Wow, wonderful! (satisfied; Figure 1c). Before they were the faces of a quadrilateral, then with this [meaning the Redefinition] they became those of the pyramid. Good! (convinced)

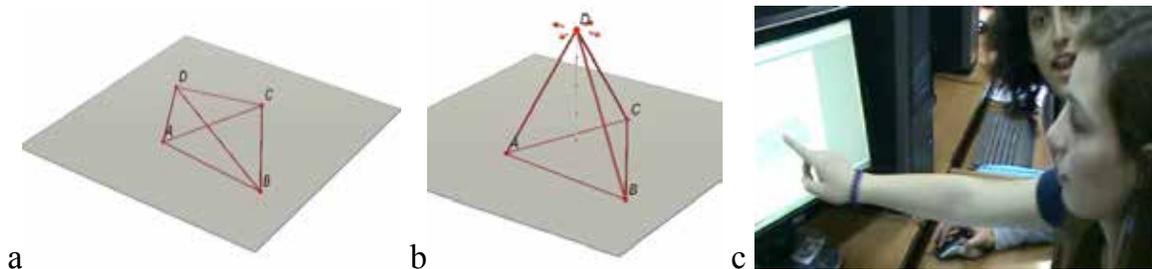

Figure 1. a) and b) Quadrilateral and redefinition of vertex D; c) Chiara astonished, and Gabriella acting on the screen

This brief episode shows the surprise of the students when they recognize and are able to see the faces of the pyramid/tetrahedron as previous faces of the quadrilateral (see Chiara's words "Wow, Wonderful!" and her facial expression in Figure 1c). The recognition occurs through the rotational movement enabled by the DGS that sustains the process of counting and identifying edges and faces of the tetrahedron. By means of this process the students start to discover the correspondence between the two figures ("Before they were the faces of a quadrilateral, then with this they became those of the pyramid"). The use of the verb "to become" is significant: it gives the idea that the passage from plane to space is occurred, as even the final use of the word "Good" accompanied by a convinced face points out. This action of becoming hides the change entailed by the redefinition of point D from a point of the base plane to a point off the plane.

Second episode (May 21, T2). The groups are requested to explore and conjecture what happens for the bimedians of a tetrahedron, again using the Redefinition (T2). To do so, they are given a Cabri 3D file that already contains a quadrilateral on the base plane together with its bimedians. Chiara, Cristina and Gabriella are looking at the quadrilateral on the screen, when Cristina begins to trace the three bimedians with her fingers.

Chiara: (taking the mouse) Do we have to rise point D? (trying to redefine it)

(The observer suggests rotating the figure to see if the point lies on or off the plane)

Chiara: (realizing that the point is on the plane) Ops, it's on the plane! So, we didn't redefine it (Figure 2a)

Observer: You have to get the arrows to be able to redefine it

(Gabriella takes the mouse and redefines the point correctly)

Chiara: Here it is, now it's ok

Gabriella: Ok (going on to rotate the figure)

Chiara: Arrange it (to see it better). Further up, turn, there... What does it happen to bimedians? (taking the mouse and starting again to rotate the figure very quickly) Hmmm, that they meet in a point in space (Figure 2b)

Gabriella: The same happening for a simple quadrilateral!

Chiara: That the middle point... Wait

Gabriella: That the middle point of the...

Chiara: These are opposite edges (pointing to them on the screen; Figure 2c), so it's the middle point of the opposite edges

Gabriella: No, the point of intersection is the middle point of each bimedian, because the bimedian is the segment that passes through the two middle points of two opposite edges

Figure 2. a) Point D on the base plane; b) and c) seeing the meeting point of bimedians

As soon as Redefinition is applied in the right manner and vertex D is raised off the base plane, the three girls do not have troubles to realise that the bimedians “meet in a point in space” (Figure 2). The rotational movement given by the DGS again supports seeing, revealing this property. Through it, the students are constantly changing their visual perspective just as if they were looking at the figure from many different points of view, physically moving around it. Gabriella, in a clever way, underlines the preservation of the property in space, evidencing the correspondence between the quadrilateral and the tetrahedron (“the same happening for a simple quadrilateral!”). This also entails the final conjecture that “the point of intersection is the middle point of each bimedian”. The initial explanation given by Gabriella, concerned with the definition of bimedian (“the segment that passes through the two middle points of

two opposite edges”), is not sufficient. The conjecture is instead verified using the distance tools of the DGS to measure suitable segments and to compare their lengths.

Once more, the students are able to reason in space transferring what they already know from the previous situation in the plane. Looking at the written texts produced by the groups, we can say that this is not an isolate case. For example, searching for properties satisfied by the medians of a tetrahedron, some of the students write: “Like for the medians of the quadrilateral, the point where they meet divides the medians so that their ratio is 3” (an expression not exactly correct, but that gives the idea).

The role of the DGS is fundamental here. The visualization capacities guaranteed by the actions of rotating and redefinition allow discovering invariances and changes in the move from plane to space, from the quadrilateral to the tetrahedron (and back). At the end of the activities, we had the feeling that the students were keen on shifting in a natural manner from plane to space. This is not only due to an increased familiarity with the DGS. The rotation and the redefinition effected a different kind of vision, one that strongly encompassed embodied engagement. The way to see in space was effectively changed and refined, much that the students became able to treat the object of the introduction both as quadrilateral and tetrahedron, that is, to “see” in a single drawing two geometrical figures (what we may interpret like *to close their eyes and see*). We might say to imagine one or the other, according to what they want to see for the purpose of the task. In this sense, our students learned things that are crucial in thinking about spatial geometry. Especially, they learned to accommodate the eye to make it work as a more expert eye that is able to discern relevant elements of an object, to change perspective, to take on multiple perspectives, and to make visible features that are not present at a first glance. All these factors entail positions from which to view the object, being physical or imagined, and shifts of attention, being overt or covert. This kind of engagement marks that the students enhanced their visual skills in relation to problem solving.

ARE MATHEMATICS STUDENTS THINKING AS KEPLER? CONICS AND MATHEMATICAL MACHINES

Francesca Ferrara*, Michela Maschietto[°]

* Dipartimento di Matematica “Giuseppe Peano”, Torino, Italy

[°] Dipartimento di Educazione e Scienze Umane, Modena e Reggio Emilia, Italy

Our interest is the analysis of the thinking processes of some university students who worked on the design of a machine that uses a tightened thread to draw a hyperbola. Previously, the students worked with other machines for conics. We focus on the way past experience becomes part of a new experience, in which making of the machine is the end point of the task. This implies the presence of technological and scientific aspects, whose interplay is fundamental to shape thinking.

Keywords: instrumental genesis, mathematical machine, transfer.

INTRODUCTION

This paper centres on an activity that asked some university students to think of the way to design a machine using a tightened thread to draw hyperbolas. The activity is part of a course on Elementary Mathematics from an Advanced Standpoint (in the tradition of Klein; Bartolini Bussi *et al.*, 2010) that the students attend at the second year of their Master’s Degree in Mathematics. The topic of the course considers conic sections and their properties, starting from Greek Mathematics. During the course, the students worked through laboratory activities with some mathematical machines for drawing conics. A mathematical machine is defined as a tool that forces a point to follow a trajectory or to be transformed according to a given law (Maschietto, 2005; Maschietto & Bartolini Bussi, 2011). The students dealt with the use of machines in two manners: first, they explored some curve drawers for ellipse and parabola, and then they were given the task to construct a machine to trace hyperbolas.

Our interest in this paper is focused on how aspects and elements coming from the previous activities with mathematical machines are transferred in the new situation, and on how they imply and originate new ways of writing, new ways of drawing, new ways of thinking.

To this aim, we will cite Kepler’s thought about the construction of a new machine. We will also refer to theoretical elements relative to transfer of learning and the utilization schemes that are concerned with the use of an artefact. In the analysis, attention will be drawn to how acquired schemes shape new schemes for the new machine. Additionally, we will address other matters that intervene in the task.

KEPLER, ANALOGY, AND TRANSFER

In his *Ad Vitellionem paralipomena*, Kepler (1604) considers the way to draw conics:

Analogy also helped me a lot to draw conic sections. From reading Propositions 51 and 52 [concerning the metric properties involving the foci] from Apollonius’s Third Book,

one can easily see how to trace ellipses and hyperbolas: these tracings can be made with a thread (Figures 1A and 1B). [...] I regretted that for long I wasn't able to describe the parabola in the same way. At the end, the analogy revealed to me that to trace this curve is not much more difficult (and the geometric theory does confirm it) (Figure 1C). (Kepler, 1604, Italian version, pp. 4-5; our translation)

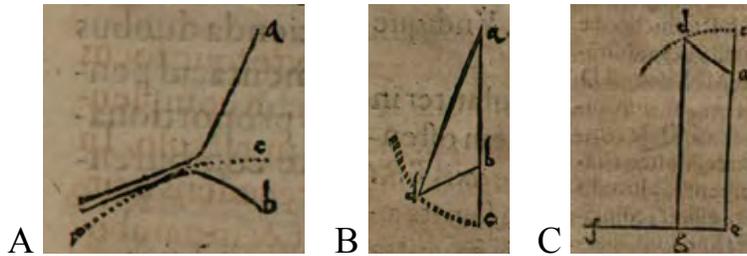

Figure 1. Kepler's drawings: A) Hyperbola; B) Ellipse; C) Parabola.

Kepler's text (1604) is an example of the use of *analogy* in mathematics. We were already in the final part of our university course when we reencountered Kepler's text. We were surprised of the relevance given to analogy in geometrical reasoning:

I love analogies a lot, considering them as my very reliable masters, experts of all the mysteries of nature; in geometry, one has to pay attention to them, especially when they enclose –even if with expressions that seem absurd– infinite cases intermediate between their extremes (and a centre), and thus put before our eyes, in full light, the true essence of an object. (Kepler, 1604, Italian version, pp. 3-4; our translation)

Mathematics Education research had studied analogy and analogical reasoning a lot (English, 1997), so Kepler's use was strikingly meaningful. But our aim is not to adopt a specific sense for analogy over the many that have been pointed out in the literature. Instead, here we want to refer to analogy in a naïve manner, following Kepler. He explains how, starting from reading Apollonius, he could trace hyperbolas and ellipses using a tightened thread, but not describe a parabola as easily. Analogy (the main form of reasoning in mathematics at that time) helped him in the case of the parabola. We can think of analogy as “continuity” and extension of thinking, say, transfer of knowledge, since knowledge acquired about the other conics is used in order to describe the parabola. Kepler's analogy as if he were thinking of a machine with tightened thread to obtain the tracing is significant to us.

The type of reasoning adopted by Kepler is interesting with respect to the kind of task given to our students (a kind of task that was chosen with the aim to study the effect of previous tasks). In a manner similar to Kepler, our students can recall aspects and elements of their past experiences with the other machines in order to face the task at hand about the new machine. In these terms, we can think of reasoning by analogy as a sort of ‘transfer’ of knowledge, of learning. Nemirovsky (2011) speaks of *transfer of learning* “in the context of common and experiential phenomena of learning”:

I see transfer as part of the study of how one experience becomes part of another. People can all sense that experiences do become part of other experiences. It is also clear, I

think, that such participation can be lived in numerous ways, some of which I suggest calling “transfer”. (p. 309)

Nemirovsky suggests the importance of developing case studies describing learning experiences as “instances in which an experience clearly comes to be part of another in the view of the subject and/or the authors of the case study.” (p. 310).

We present a case study investigating the question: How does previous experience with a parabola drawer and an ellipsograph with tightened thread become part of a new experience when students are asked to think of a machine to draw hyperbolas?

In past tasks, the students were required to study the functioning of a machine. In the new task they are challenged to make a machine to draw hyperbolas. An artefact is being built, so the ways to use it, the subject’s utilization schemes, are also decided. Following Koyré (1967), the construction of the new machine implies a “creation of scientific thought or, better yet, the conscious realization of a theory” (p. 106).

UTILIZATION SCHEMES AND MATHEMATICS LABORATORY

Knowledge of a machine involves knowledge of the *utilization schemes* that can be activated with it, for reaching the task’s goals. A machine is an artefact, according to the instrumental approach (Rabardel, 1995; Rabardel & Samurçay, 2001). An artefact is a material or abstract object produced by human activity and aimed to sustain new human activity for facing tasks. It is designed and constructed with a purpose and given to a subject. In the hands of the subject, as part of an educational task, the artefact becomes an instrument, a mixed entity composed of both the artefact (object) and the utilization schemes developed by the subject to reach the specific goal of the task. So, the instrument has a subjective and cognitive character. The development of the instrument, that is, the *instrumental genesis*, is composed of complex processes, instrumentalization and instrumentation, linked to the artefact’s potentialities and constraints, and to the contextual activity, background and knowledge of the subject. In addition, Guin *et al.* (2005) asserted that instrumental geneses are conceptual geneses, and stressed then their importance for learning, in particular in mathematics. Furthermore, the recognition of the importance of the teacher’s action in encouraging and guiding instrumental geneses, gave rise to various directions of study within the instrumental approach (e.g. Trouche, 2004; Trouche & Drijvers, 2010).

From the methodological point of view, activities with artefacts are typical of the *mathematics laboratory* deeply rooted in the Italian teaching tradition, in research studies about innovation in mathematics education, and in the mathematical tradition concerning the use of tools (Maschietto & Trouche, 2010). The laboratory is not meant as a physical space with equipment, but as a structured set of activities aimed to the construction of meanings for mathematical objects (Anichini *et al.*, 2004). In laboratory activities are essential the task(s) to be addressed, the presence of tools that one can use and manipulate, the work methodology that affects relationships and interactions (students and teacher), and the presence and role of the teacher.

In this paper, the perspectives of the instrumental genesis and mathematics laboratory are relevant at least at two levels. First, regarding utilization schemes that a student activates to perform a given task with a given mathematical machine. Second, in terms of knowledge that a student uses when a mathematical machine is involved in the task. In the first case, the specific purpose of the activity guides the choice of certain schemes so action is aimed to reach a purpose. In the second case, previous knowledge is used to create new knowledge and meanings so that utilization schemes acquired in the past may be purposefully adapted to the new situation.

The mathematical machines studied by the students make use of a tightened thread and a pencil attached to draw curves for particular conic sections on a flat surface: ellipse, hyperbola, and parabola. These machines work in accordance to determined rules that are connected to the definitions of the curves under consideration.

The laboratory use of a mathematical machine, to study the way utilization schemes previously met are transposed (transferred) in the new situation and how this originates new ways of drawing and thinking, is interesting. To this aim, we need first to look at the kind of tasks given to the university students.

MATHEMATICAL MACHINES AND TASKS

In the course on Elementary Mathematics from an Advanced Standpoint, the students worked with curve drawers for conics [1] in the context of mathematics laboratory, after studying Apollonius's theory of conics (Heath, 1931). In five laboratory sessions we proposed five machines (we just describe in details drawers with tightened thread).

D1: Cavalieri's drawer for parabola [2]. It concerns Menaechmus's definition in which the parabola is identified by a proportion among segments.

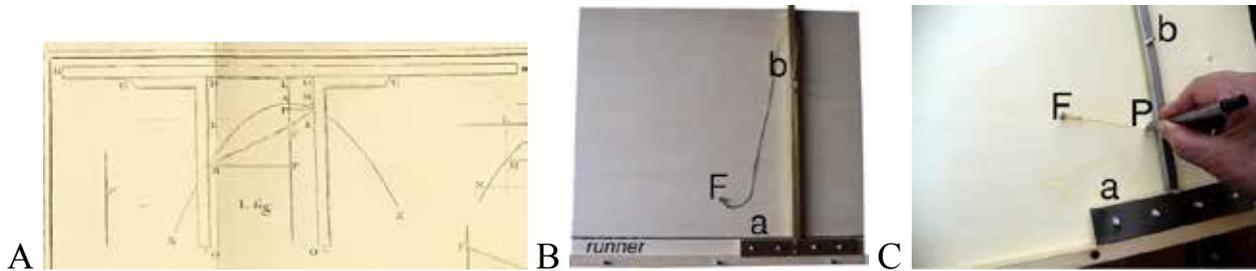

Figure 2. Parabola drawer with tightened thread

D2: Parabola drawer with tightened thread [2] (Figures 2B and 2C). It is composed of two perpendicular rods shaping a T. With respect to Figure 2B, the shortest rod (a) slides on a runner fixed to a wooden flat surface, a thread is linked to the free end of the longest rod (b) and to a pin (F) on the surface. In order to trace a parabola, a pen always has to stretch the thread near the rod (b) as the rod (a) is pushed and moves (Figure 2C). F is the focus of the parabola. When the thread's length is the same as the rod's (b), the runner is the directrix. In his *Traité analytique des sections coniques*, de l'Hôpital (1720) defined conic sections as curves drawn in the plane by particular tools with tightened thread (Figure 2A).

D3: Ellipsograph with tightened thread (gardener's method to draw elliptical flower beds) [2]. Two pins (foci of the ellipse) are fixed to a wooden flat surface. A pen stretches a thread linked to the pins and traces a curve when moving around them.

D4: Hyperbola drawer with tightened thread [2]. From an historical point of view, two kinds of machines were created. One of them (Figure 3B) mainly corresponds to Kepler's description. In both models, two pins (foci of the curve) are fixed to a wooden flat surface. The model in Figure 3A shows two foci, two rods constrained each to turn around one focus, and a thread fixed to the other focus and to the free end of the rod. For every rod, a pen stretches the thread near it and traces a branch of the curve when moving around a pin.

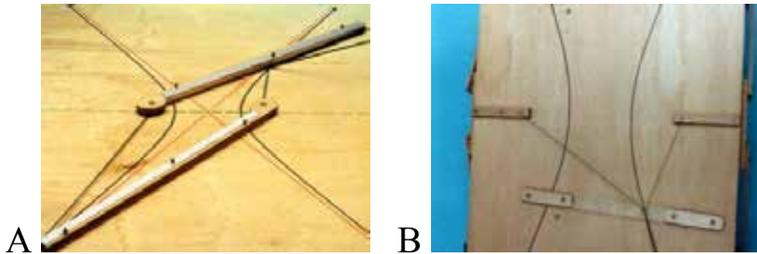

Figure 3. Hyperbola drawers

D5: Ellipse drawer with articulated crossed parallelogram [2]. It is composed of a crossed parallelogram with two couples of unequal rods.

In each session, the students worked following the methodology of the mathematics laboratory: group work, collective discussion and individual work. The teacher proposed the exploration of the drawers D1, D2, D3 and D5 through three general questions (in line with other teaching experiments that used mathematical machines). The first question “how it is made” aims to describe the physical structure of the machine and to detect parts and spatial relations. This task supports processes of instrumentalization. The second question “what it traces” focuses on the product of the machine. After putting a lead into a hole or keeping the thread well tightened by the means of a pen (see Figure 2C), the students can trace a curve (they can act on the machine) and analyze it. The third question “why” encourages the students to produce conjectures, to argue them, and to construct proofs.

The task was changed in the case of the drawer D4. The students were asked to imagine a mathematical machine with tightened thread to draw hyperbolas. Different from the previous tasks, the students were faced with a problem solving situation, in which they knew the final curve to obtain, but they did not have any machine to trace it. This specific activity constitutes the core of the paper.

At the end of the group exploration, the students were asked to write an individual report. A collective discussion followed, in which the teacher could share elements of the students' exploration processes and ask about the relationships between the explored machine and the drawn curve.

From the methodological point of view, the eight students attending the course were divided into two groups (A and B). One student per group had the role of observer. Our analysis is based on the students' reports and the notes by the observer.

TRANSFER OF LEARNING AND UTILIZATION SCHEMES

In this section, we present sketches of the work of group B, through different phases. The situation can be considered as a learning situation: the students were dealing with a new experience in which they were implicitly required by the nature of the task to use their previous experience with drawers. In fact, the task specifically demanded for thinking of the construction of a new machine. The novelty of the machine lies in the request to draw a new curve: a hyperbola, not in the kind of machine, which still has to use a tightened thread.

We focus on the strategy that group B adopts to face the task, using written texts and drawings produced, as well as the notes taken by a student-observer that followed the entire work of the group. The students are referred to as B1, B2 (observer), B3 and B4. Four phases can be distinguished in their work, the first three depending on the tools with which the students work (paper and pencil; a wooden plan with two pins and a thread; a rod).

1) The students began by stating the metric definition of the hyperbola, writing down the relationship between foci and the generic point, or the equation. From the observer, we know that they made some considerations, like: "Surely, the machine draws only one branch", "The distance between the foci is constant, so the pins will be fixed". Since the beginning, the group thinks of the functioning of a machine that keeps the difference constant, what is present in the metric definition of hyperbola, and considers some components of the machine, like the pins.

This is where the previous experience with other machines comes into play. First, the students look for "a machine initially similar to the ellipsograph, but that keeps the difference constant" (B3). In so doing, they first join the point with the foci and draw a certain configuration depending on the definition of hyperbola (Figure 4A). Then, they explore the situation recalling the tightened thread of the ellipsograph (Figure 4B). The final tracing of the hyperbola by means of the potential machine (Figure 4C) does not suggest any way to keep the difference constant, so the configuration is abandoned (the rectangles mark the flat surface of the machine, as in Figure 4B).

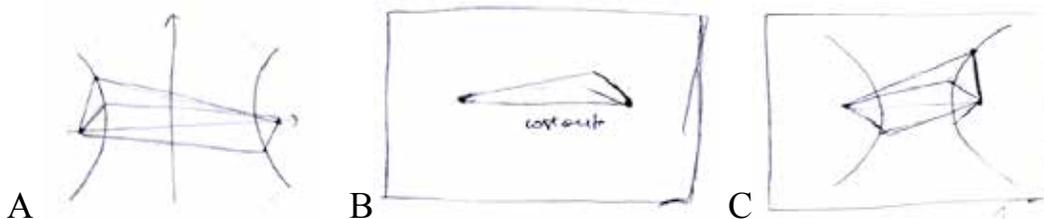

Figure 4. B4's sketches

The students go back to previous experience again, recalling the parabola drawer and the rod. Many sketches are produced in which the position of the rod is varied or two

rods are considered, one for each focus, in the search for the suitable model for the machine (see Figure 5A).

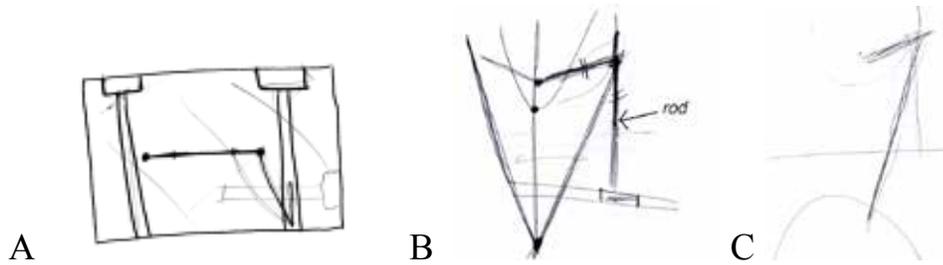

Figure 5. A) B3's sketch; B and C) B1's sketches

This is a phase of instrumental genesis for the rod (a new utilization scheme, a rod added with respect to the parabola drawer) and for the runner (for instance, different positions with respect to the case of the parabola drawer), aimed to the solution of the task, that is, to drawing the hyperbola. The students transfer a component of the artefact (the rod) from experience with the parabola drawer, and activate utilization schemes consistent with the functioning of that machine. For example, the tightened thread with respect to a point of the curve. Figure 5A instead marks the side of the machine as the runner with a rod for each focus. In Figure 5B, the rod is sketched together with the runner it is supposed to move. This constraint changes when the second focus is considered (Figure 5C). Unfortunately, this phase is not successful.

2) The teacher asked the students if they needed some material components, recognizing their presence in the students' discussion and drawings (for instance, pins and thread are also there; see Figure 5A). A wooden plan with two pins and a thread were given to each group. Once the length of the thread is chosen, student B2 tries to put it around the pins, falling in the configuration of the ellipsograph. The trial is soon abandoned since "the shape of the thread does not trace the hyperbola. It is like in the parabola drawer". This reflection is crucial: even if the drawing of the metric definition of the hyperbola is the same as that of the ellipse, the students confirms in a material way that the use of the thread and its related movement has to change. So, the students first try to tie the tread to the pins with the help of a pencil as a rod, then they experiment new movements. Seeking to create a machine that can draw a hyperbola, after a while, they transform the parabola drawer into a new artefact: "Observed that the two foci ordered the distance to keep constant, we removed the runner and put a second point below" (Figure 6).

Figure 6. B1's report

The arrow between the two graphical representations in Figure 6 emphasizes the passage, while the removal of the runner is marked by the dotted line.

In the group discussion, the students highlight that it is not relevant to have rods in a chosen configuration, but the rods must be able to turn. Thus, using pencils as rods, the students can explore new movements.

3) Students' drawings and speech referred to other components of the machine (like the rods in Figure 5A, 5B and Figure 6). Aware of this, the teacher asked student if they need some other materials. As soon as a rod is furnished, two issues became relevant: 1) the way the thread has to be tied, and 2) the position of the pencil. For the latter, the teacher recalls the relationship between the positions of the pen to tighten the thread and the points of the curve. Then, the students are able to overcome troubles and to find a way to proceed when the rod is based on one of the two pins with the ends of the thread "anchored to the two pins, which we have interpreted as foci of the hyperbola, and keeping the thread tightened along the rod, we have tried to represent a figure that looks like a hyperbola" (from B3's written report).

In this way, at the end, the students are able to trace a branch's arc of hyperbola.

4) The curve traced, the students want to justify that it is effectively a hyperbola.

Figure 7. B4's sketch

After some doubts, they first try to use algebraic calculation and then they recover on the machine all the useful parameters, from the length of the rod and of the thread and the constant difference (see Figure 7). However, the students do not make any reference to the fundamental elements of the curve drawer, especially to the position of the pencil.

CONCLUDING REMARKS

Our interests in this paper are on the way previous experience with a parabola drawer and an ellipsograph with tightened thread becomes part of a new experience. This experience in particular asks for the creation of a hyperbola drawer. The task differs from the previous ones, in which a machine was the starting point not the final one. In particular, we have observed the work of one group, B, and we could see that the process of constructing the new drawer implies both technological and scientific aspects (following Weisser, 2005). Technological aspects concern having a machine and the ways it can be used (like in "so the pins will be fixed" or "it has to be able to

turn”, and in drawings the sketch of a rectangle, rods, etc.). Scientific aspects mainly regard the mathematical constraints that have to be satisfied for drawing a precise curve (like in “the distance between the foci is constant” or “it keeps the difference constant”, and in drawings reference to constant difference). The teacher is aware of these two dimensions and of their connections. Sometimes, in fact, she furnishes material objects to the students, so that they can test possibilities of functioning for the machine that before they only could imagine and reproduce by diagrams.

At least for group B, the interplay of technological and scientific aspects is affected by past experience with the other drawers. A lived experience that enters in the new situation bringing components of those machines that the students already used. The interesting thing is that these tools are part of the process in two manners. First, the new machine is being based on variations of the previous machines, recalled at different times (that is, instrumentalizations of those machines). Second, the “ways of use” have to furnish different configurations. In fact, it is when the students discard a configuration that the utilization schemes of the previous drawers clearly appear.

We may possibly speak of *gestures of usage* (or *gestures of ways of use*) that entail movements of the components, these movements recalling or not past experiences (and, in the second case, being similar to thought experiments). The image of gesture implies action. In effect, the instrumented activity is fundamental here; it is the basis for movement and dynamicity, not only of the machine, but also of the students’ thinking processes. It is in this sense that we see both continuity and extension of analogous thinking in a way similar to Kepler’s. So, when the students say, for example, “like in the parabola drawer”, we can interpret that they are thinking as Kepler. In the same sense, we look at the entire situation as an example of transfer of learning. First, it is a learning situation. Second, learning is not acquired by the automatic activation of previous schemes. Instead, it is shaped by the continuous back and forth between technological and scientific aspects entailed by the task that constrains the actors (learners) to constantly review and vary their ideas.

NOTES

1. In Italian secondary school, the conics sections are mainly studied in analytical geometry, starting from their definitions as loci of points.

SYNERGY BETWEEN VISUAL AND ANALYTICAL LANGUAGES IN MATHEMATICAL THINKING

Juan D. Godino¹, Teresa Fernández², Margherita Gonzato¹ and Miguel R. Wilhelmi³

¹ Universidad de Granada, ² Universidad de Santiago de Compostela, ³ Universidad Pública de Navarra

Visualization is a research field of growing importance in mathematics education. However, the study of its nature and relationship with other forms of recording and reporting information continues to be subject of reflection. In this paper we propose a way of understanding the language and the visual thinking, and their relationship with the language and analytical thinking, using the theoretical tools of the "onto-semiotic approach" of mathematical knowledge. By analyzing the mathematical activity deployed in solving a task, we show cooperative relations between the visual and analytic languages.

INTRODUCTION

Visualization has received much attention as a research topic in mathematics education, especially in the area of geometry (Bishop, 1989, Clement and Battista, 1992, Hershkowitz, and Van Dormolen Parzys, 1996, Gutiérrez, 1996). Presmeg's work (2006) provides a comprehensive perspective of research on the role of visualization in teaching and learning mathematics in the International Group of PME. This survey concludes by stating 13 big research questions on this research field, and on which we focus on the following, in this paper: "What is the structure and what are the components of an overarching theory of visualization for mathematics education" (Presmeg, 2006, p. 227).

In this paper we are interested in advancing an answer to the problem of devising a theory to clarify the nature and components of visualization and its relationship to other processes involved in mathematical activity, their teaching and learning. A key aspect of developing a theory of visualization in mathematics education should include studying the relations of this form of perception with other ostensive modes of expression (in particular, sequential analytical languages), and especially its relation to non-ostensive mathematical objects (usually considered as mental, formal, or ideal objects).

As background on the problem of theoretical clarification of visualization in mathematics education we found Presmeg (2008), who expands the initial taxonomy suggested by Marcou and Gagatsis (2003) in terms of Peirce's triadic semiotics. Rivera (2011) analyzes the visual root of mathematical symbols and mathematical reasoning, and the implications of visualization to mathematics instruction.

THEORETICAL FRAMEWORK

As it can be read in Phillips, Norris & Macnab (2010) there is no clear consensus on how to define visualization, both in its role of process as object, and in its internal (mental) and external (perceptive) version. In our case we assume Arcavi's (2003, p. 217) proposal, which describes visualization in very general terms: "Visualization is the ability, the process and the product of creation, interpretation, use of and reflection upon pictures, images, diagrams, in our minds, on paper or with technological tools, with the purpose of depicting and communicating information, thinking about and developing previously unknown ideas and advancing understandings". However, we consider necessary to deepen the distinction between visual and non-visual objects and processes, in order to study the necessary coordination between both types of objects in the construction and communication of mathematics.

We will analyze the notion of visualization by applying some tools of the "onto-semiotic approach" of mathematical knowledge (OSA) (Godino, Batanero, and Font, 2007). In this framework it is considered that the analysis of mathematical activity, the objects and processes involved in it, first should focus the attention on the practices carried out by people involved in solving certain mathematical problem situations. Applying this approach to visualization leads us to distinguish between "visual practices" and "non-visual practices" (symbolic/analytical practices), and to study the relationships between them. To this end we fix our attention on the kinds of languages and artifacts involved in a practice, which will be considered as visual if they put into play iconic, indexical or diagrammatic signs (Peirce, CP, 2.299).

Although symbolic representations (natural language or formal languages) consist of *visible inscriptions*, those inscriptions will not be considered as strictly visual, but as analytical or sentential. Sequential languages (e.g., symbolic logic, natural language) use only the relation of concatenation to represent relationships between objects. On the contrary, the diagrams use spatial relationships to represent the objects and relationships. "The idea is that sentential languages are based on acoustic signals which are sequential in nature, and so must have a compensating complex syntax in order to express certain relationships - whereas diagrams, being two-dimensional, are able to display some relationships without the intervention of a complex syntax" (Shin and Lemon, 2008, p.10).

Visual objects and visualization processes from which they come, form configurations or semiotic systems constituted by "the intervening and emerging objects in a system of practices, along with the interpretation processes that are established between the same (that is to say, including the network of semiotic functions that relate the constituent objects of the configuration)" (Godino et al, 2011, 255).

In the OSA it is highlighted the essential role of the ostensive dimension in mathematical practice when postulating that every mathematical object (abstract

ideal, generally immaterial, not ostensive) has an ostensive facet, that is, publicly, visually, perceptually or otherwise demonstrable. This ostensive facet may consist of symbolic inscriptions, needed to represent the objects, understood as a unitary whole, and to be able to "operate" with them in progressive levels of generality, or using iconic or diagrammatic means that show the structure of the object, understood in a systemic way.

In the next section we show, by analyzing the solving of a task usually considered "of visualization" and using some onto-semiotic tools, that in mathematical activity participate, next to visual ostensive objects, other ostensive objects non visual (textual or analytic) to refer the non-ostensive objects involved (concepts, propositions, procedures, arguments). Both types of ostensive objects (visual and non-visual) play a role in the performance of mathematical activity, so that mathematics teaching should pay attention to the relationship between the two forms of semiotic representation of mathematical objects. Mathematical activity is analyzed theoretically and by using an example as being based on a variety of representational and linguistic or more general semiotic means. The goal is to highlight the intricate interplay of those means.

A MATHEMATICAL TASK AS A CONTEXT OF REFLECTION

In this section we discuss a mathematical task that uses visualization processes. The analysis of the proposed solution shows the network of visual and non-visual objects used, and the relationships established between them, namely, the semiotic system that forms. Briefly, the goal is to reveal the knowledge involved in the resolution and the synergy that exists between visual and analytical objects.

Statement: Write which of these figures represent the unfolding of a cube.

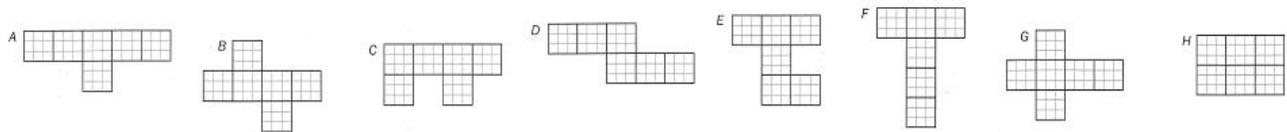

Figure 1: Potential unfolding of a cube

Solution:

The hexamine B, D, F and G correspond to a cube; in fact if we match (paste) the sides marked in figure 2 with the same symbols we get a cube.

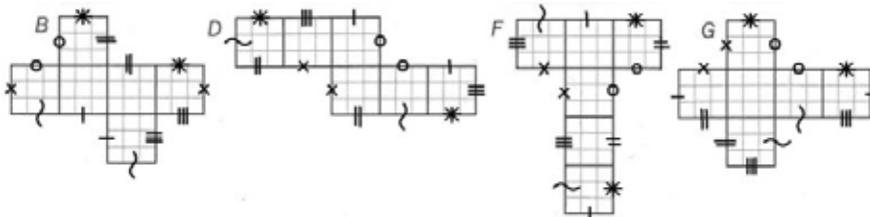

Figure 2: Unfolding of a cube

The remaining hexamine do not represent the unfolding of a cube. Indeed, the hexamine A, C and E do not correspond to a cube because of the overlap of two cube faces to fold the unfolding: in figure 3 we marked with the letters *a* and *b* the faces that overlap.

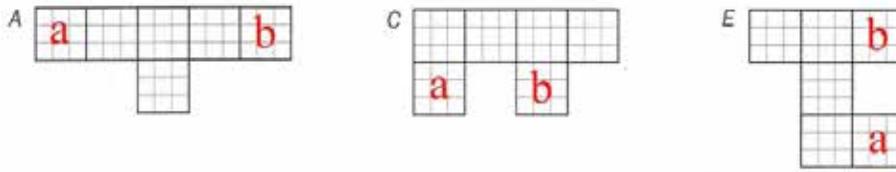

Figure 3: Faces that overlap

It can be visually tested (either empirically or mentally) the impossibility of closing the unfolding.

Onto-semiotic analysis of the solution

This is a visual mathematics task according to the characterization previously presented, but in justifying the answer, different analytical elements that are needed to prove its validity, emerge. To "see" the solution in figures 2 and 3 it is necessary to perform various visual operations and semiotic interpretations that may not be immediately perceived by the students. Such visual operations are supported by analytical elements that define the objects involved. For example, to justify that the sides marked with the same symbol overlap after the folding operation it must be made explicit the knowledge that the adjacent faces of a cube, by definition of this mathematical object, form a dihedral angle of 90° . Therefore, to construct the cube, the contiguous faces of the unfolding must rotate in the space 90° around the segments (which coincide with imaginary axes *x* and *y*). The direction of rotations varies as the considered unfolding.

The wording of the task is made up of linguistic elements (words) and visual elements that interact between them. The term "figure" refers to the drawings in figure 1: visual ostensive objects that have to be put in relation to the non-ostensive object "cube" regulated by a definition. To solve the task, the student must know the intuitive meaning of unfolding a polyhedron and recognize that the surface of the cube is developable. Intuitively, a surface is developable if it can be made from a Euclidean plane by "folding", which is "visually" manifested when it is possible to make appropriate models from a sheet of paper or flat cardboard. The development of the surface would be the plane figure obtained by the whole unfolding in the plane. This intuitive definition has to be applied to the particular case of the surface of a cube. The process of "unfolding" the surface of the cube in the plane can be represented visually (figure 4) and/or interpreted analytically.

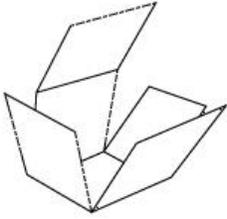

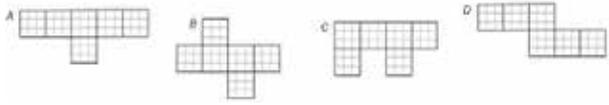

Figure 4: Possible way of unfolding a cube

Since the cube is a polyhedron with six square congruent faces, its unfolding is a set of six squares connected by one and only one side, so that: a) Each face of the cube corresponds to a single square of the development; b) It is possible to match all the sides of the squares that belong to the edge of the unfolding so that each pair corresponds to one and only one edge of the cube. Based on this last (analytical) condition it is argued (a visual way, figure 2) that the B, D, F and G hexamine represent unfolding of a cube, marking with the same symbol equivalent sides, that is, the pairs of external sides of the squares of the unfolding that are joined to form an edge in the cube.

In figure 3 it is visually argued that the hexamine A, C and E do not correspond to a cube due to superposition of a face when folding the unfolding. In fact the superposition of a face contradicts the (analytical) condition that each face of the cube corresponds to a single square of the unfolding. As regards the H hexamine it is showed that it does not represent an unfolding of a cube. This quite intuitive (and visual) statement can be justified asserting the impossibility of constructing a trihedral angle from four faces which sharing one vertex (fairly easy to visualize), or seeing that the representation contradicts the cube unfolding definition.

This example shows the synergistic relationships between visual and non-visual objects in mathematical activity carried out to solve a problem of visual type. In particular, we can observe that the visual explanation of the task solution is supported by analytical elements related to the conceptual properties of the cube development. Some key semiotic functions involved in the visual justification of the task are summarized in Table 1.

Visual expression	Analytical content
"Cube", as mental image (non-ostensive visual object) that the person internally represents.	Concept of "cube" (Definition 1): polyhedron of six square congruent faces.
Figure 1: 	Concept of "unfolding of a cube" (Definition 2): Set of six squares connected by one and only one side, such that: a) Each face of the cube corresponds to a unique square of the unfolding

 <p>They are visual ostensive objects referring to potential unfolding of a cube.</p> <p>The recognition of the unfolding of a cube can be accomplished through the visual operation "<i>fold / unfold</i>". The procedure may consist of the mental simulation of the physical action (non-ostensive visual process), be physically carried out (cut and paste) (ostensive visual procedure), or illustrated through visual language, as shown in Figure 4.</p>	<p>(property1).</p> <p>b) It is possible to match all the square sides belonging to the unfolding edge, so that each pair corresponds to one and only one edge of the cube (property 2).</p>
<p>If we fold the hexamine B, D, F and G along the sides and join together (physically or mentally) the sides marked with the same symbols, we obtain a cube (Figure 2):</p>  <p>There are not overlap of faces and the unfolding closes. (Visual checking, ostensive or mental)</p>	<p>The hexamine B, D, F and G represent the unfolding of the cube, since it fulfills definition 2.</p> <p>In particular, Figure 2 illustrates the analytical property 2.</p>
<p>In Figure 3 the faces marked with letters <i>a</i> and <i>b</i> overlap each other to perform the folding and one face would remain uncovered:</p>  <p>(Visual checking, ostensive or mental)</p>	<p>The hexamine A, C and E do not represent the unfolding of the cube because they do not respect the property 1.</p>
<p>It is visually verified (either ostensive or mentally) the failure of closing the unfolding.</p>	<p>The hexamine H is not an unfolding of a cube because the impossibility of making a trihedral angle starting from four faces sharing a vertex.</p>

Table1: Semiotic functions implicated in visual justification

It is not always necessary to deploy the explicit analytical long speech that explains all the rules (concepts and propositions) which effectively support the justifications of the solutions. In this case, visual representations are revealed as a resource of effective expression to convince the reader that, indeed the hexamine B, D, F, and G

correspond to the cube development, while this is not the case with hexamine A, C, E and H. But in any case, the rules defining the concepts and properties are still latent.

Fischbein (1993) notes that the mental transformations of three-dimensional objects are not only visual in nature (figural in the author's terminology): it is because we work with faces of a cube which has edges of equal size, faces which are square, angles which are right, and so on. "This is *tacit* knowledge that is involved in mental operations. Without this tacit conceptual control, the whole operation would have no meaning "(p. 159).

The delicate network of visual and non-visual ostensive objects, to refer to non-ostensive objects, always present in mathematical activity (cube concept, face, edge, vertex, and the related properties), and also for the effective realization of procedures and justifications, is put into effect not only with geometric tasks, but also with other mathematical contents. Godino, Gonzato, Cajaraville and Fernández (2012) analyze an algebraic task (proving that the sum of the first n odd numbers is n^2) with the support of visual representation, thus showing the same cooperative relations between the visual and analytical languages.

FINAL REMARKS AND IMPLICATIONS FOR MATHEMATICS EDUCATION

As conclusions of the analysis performed in this paper on visualization, we can say that the configuration of objects and processes used when carrying out a mathematical practice are the following:

- (1) It always involves analytical languages in greater or lesser extent, although the task refers to situations on the perceptible world. This is essentially due to the regulatory-sentential nature of concepts, propositions and mathematical procedures.
- (2) A non-visual task can be addressed, at least partially, through visual languages which enable to effectively express the organization or structure of the configuration of objects and processes used, especially with diagrams or with metaphorical use of icons and indexes.

Consequently, the configuration of objects and processes associated with mathematical practice will usually consist of two components, one visual and another analytic, which synergistically cooperate on the solution of the corresponding task (figure 5). The visual component can play a key role in understanding the nature of the task and at the time of making conjectures, while the analytical component will be in the moment of generalization and justification of solutions. The degree of visualization used in solving a task depends on the visual or non-visual character of the task and also on the subject's particular cognitive styles that resolved the task, as has been emphasized by several studies (Krutetskii, 1976; Presmeg, 1986; Pitta-Pantazi and Christou, 2009).

The analysis of visualization we have carried out, using some of the OSA tools, provides a complementary view regarding to other perspectives more focused on the

description of visual/analytical cognitive styles and its influence on problem solving. Our goal has been to deepen into the nature of visualization and its relation to analytic-sequential forms of mathematical thinking. We sought to characterize mathematical practice in tasks involving visualization, whether performed by an individual (subjective knowledge), or shared in an institutional framework (objective knowledge), identifying the types of objects and processes involved in the performance of the practice.

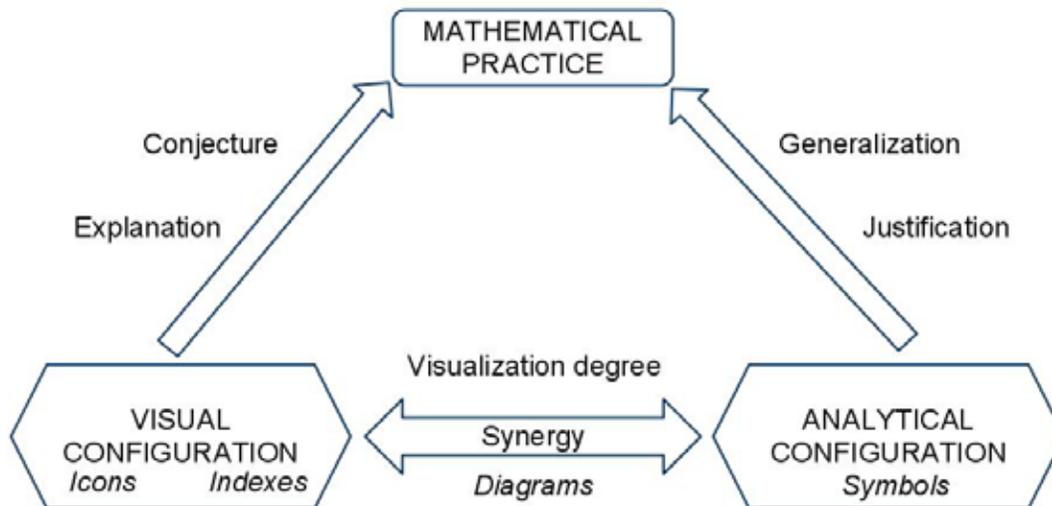

Figure 5: Synergy between visual and analytical configurations

A visual task can be tackled with analytical tools and vice versa, a non-visual task can be approached analytically with visual tools. Moreover, in conducting a visual practice non-visual objects are actually involved, and in the implementation of an analytical practice, visual objects, particularly diagrams, may be involved. This is a result of the implementation of the ostensive non-ostensive duality (Godino et al, 2011) to different types of mathematical objects, which carries out the dialectic between the visual and analytical. For any mathematical object the presence or intervention in its emergence and operation of an ostensive aspect (public, visible, symbolic or visual) and other non-ostensive aspect (rule, logic, ideal, mental) which interact in a synergistic way is postulated, as was shown in the analysis of the example in section 3.

An educational implication of our analysis is that subjects whose cognitive style is basically analytic (respectively, visual) should be instructed to develop visual skills (respectively, analytical), because both skills are useful for mathematical practice at different stages of their execution. Hence, it would be necessary to favor the development of the harmonic cognitive style described by Krutetskii (1976), which combines visual and analytical features.

It seems clear that visualization penetrates in all branches of mathematics, not only in geometry, in coordination with other forms of expression, especially analytical/sequential languages. It is also present in the various levels of mathematical study, as

well as in elementary as in higher education, or even professional. However, the analysis of the relative effectiveness of visual modes of reasoning regarding analytical modes, depending on the types of tasks and phases of study, is a subject that requires investigation. The interest of using iconic and diagrammatic representations has been generated by the assumption that somehow they are considered more effective than traditional logical representations for certain tasks. However, although there are some psychological advantages in using diagrams, they are often ineffective as representations of objects and abstract relations (Lemon and Shin, 2008).

The role of visualization in school or professional mathematical work is complex because it is often interwoven with the use of symbolic inscriptions, which although "are visible", their meaning is purely conventional. The problem is relevant even when the visualization referred to the use of visual objects, which interact not only with symbolic inscriptions, but also and mainly with the network of conceptual, procedural, and propositional objects that necessarily intervene in mathematical practice.

Teachers, curriculum developers and teacher educators should be aware of the role of visualization in building and communicating mathematics. On the other hand, one should not confuse the mathematical object with its ostensive representations, whether visual or otherwise. It is necessary to take into account the non-ostensive immaterial nature of mathematical objects and the complex dialectical relationships that are established between these objects and their material representations.

CHARACTERISING TRIANGLE CONGRUENCY IN LOWER SECONDARY SCHOOL: THE CASE OF JAPAN

Keith Jones* & Taro Fujita**

*University of Southampton, UK; ** University of Exeter, UK

Congruence, and triangle congruence in particular, is generally taken to be a key topic in school geometry. This is because the three conditions of congruent triangles can be used when proving geometrical theorems and also because triangle congruency relates to the idea of mathematical similarity via similar triangles. Despite the role of congruency, and of congruent triangles in particular, there appears to be limited research on the topic. In this paper we report on the approach to triangle congruency in textbooks used in lower secondary school in Japan, specifically in Grade 8 (students aged 13-14). We found that the modicum of practical tasks entailed various conceptions (measuring, transformations, etc.) whereas the proof problems which predominated expected students to utilise corresponding parts and known facts.

Keywords: geometry, congruency, textbooks, Japan, secondary school

INTRODUCTION

The thirteen books of Euclid, compiled over 2000 years ago, are universally acknowledged as a ground-breaking example of the use of the deductive method in proving a collection of mathematical theorems. Covering mostly plane and solid geometry, but also some aspects of elementary number theory and algebraic methods, the set of books subsequently became what Boyer (1991, p. 119) has called “the most influential textbook of all times”. Many of the geometrical theorems that are proved in the books of Euclid use the three conditions for triangle congruency: the side-angle-side (SAS) condition (proved as Proposition 4), the side-side-side (SSS) condition (proved as Proposition 8), and the side and two angles (SAA) condition (proved as Proposition 26). These three conditions for congruency (SAS, SSS, SAA) are subsequently used in the books of Euclid to prove many subsequent propositions.

The power of the three conditions for triangle congruency for proofs in geometry, exemplified by the books of Euclid, together with the link from triangle congruency to the even more powerful mathematical idea of similarity (via the topic of similar triangles), means that triangle congruency generally constitutes a key topic in school geometry (exceptions occur when a transformations approach is used in which isometries are transformations that are equivalent to congruence). As an example of the position of congruence, the curriculum framework for TIMSS (Trends in International Mathematics and Science Study) specifies geometry within two components; “position, visualization, and shape” and “symmetry, congruence and similarity” (Robitaille et al., 1993, appendix C).

Despite the importance attributed to congruence, there is, as far as we have been able to ascertain, limited research on the teaching of congruency (at least, limited research published in English). Exceptions include González and Herbst (2009) and some papers in Japanese; the latter including Moriya, Kondo and Kunimune (2005), which provides ideas for daily lessons, and Shimizu (1979), where the mathematical and pedagogical values of the congruency conditions are discussed.

The approach of González and Herbst (2009) was to utilise the notion of ‘conception’ from Balacheff (see Balacheff & Gaudin, 2003, 2004; plus see Mesa, 2004), a notion derived from the epistemological position that “A knowing is characterised as the state of dynamical equilibrium of an action/feedback loop between a subject and a milieu” (p. 8). Referring to this framework, González and Herbst define four “conceptions of congruency” (ibid p. 155) and show how when using dynamic geometry software “There was evidence for students’ learning in their shift from a visual perception conception of congruency to a measure-preserving conception of congruency” (ibid p. 179).

This raises the issue of how triangle congruency is characterised in other situations. As part of a larger-scale project examining how geometry is presented in school mathematics textbooks (see, for example, Fujita & Jones, submitted; Jones & Fujita, in press), here we report on a component of the project that addressed the following research questions: what characterises the approach to triangle congruency in textbooks used in lower secondary school in Japan? In what follows, we first expand on our focus on the geometry curriculum and school mathematics textbooks. Next, we outline the theoretical framework of four “conceptions of congruency” as introduced by González and Herbst (2009, p. 155). Following an explanation of the context for our study, and an outline of our methodology, we then provide our analysis of sample chapters from a Grade 8 textbook commonly used in Japan for students aged 13-14.

THE GEOMETRY CURRICULUM AND SCHOOL TEXTBOOKS

While geometry is an indisputably-important component of the school mathematics curriculum, arguments about the structure of the geometry curriculum have been going on for at least one hundred years (see, for example, Sinclair 2008; Usiskin 1987). As one well-known curriculum team from the early 1970s commented “Of all the decisions one must make in a curriculum development project with respect to choice of content, usually the most controversial and the least defensible is the decision about geometry” (The Chicago School Mathematics Project staff, 1971, p. 281). Such controversy means that the geometry provides an intriguing focus for studying how the mathematics curriculum is enacted through the medium of school mathematics textbooks.

In terms of textbooks, evidence from TIMSS (such as that documented in Valverde et al. 2002) has revealed the extent to which such textbooks provide the link between the *intended curriculum* that is contained within National Curriculum documentation

and the *attained curriculum* that is learnt by students. This is done through the *implemented curriculum* that is taught by teachers. Textbooks lay out what Foxman (1999) has called the ‘potentially-implemented’ mathematics curriculum; that is, the curriculum that the teacher might implement in actual classroom practice. According to Thompson, Senk and Johnson (2012, p. 254) textbooks are a “particularly critical link between the intended and attained curriculum in school mathematics” because “they help teachers identify content to be taught, instructional strategies appropriate for a particular age level, and possible assignments to be made for reinforcing classroom activities”. It is how triangle congruency is enacted in school geometry textbooks in Japan that is the focus of what we present in this paper. It is to that context that we turn next.

TRIANGLE CONGRUENCY IN SCHOOL MATHEMATICS IN JAPAN

The specification of the mathematics curriculum for Japan is given in the ‘Course of Study’ (MEXT, 2008). Mathematical content is divided into ‘Numbers and Algebraic Expressions’, ‘Functions’, ‘Geometrical Figures’ and ‘Making Use of Data’. Our focus is ‘Geometrical Figures’ in Grade 8; Table 1 gives the detail of this topic.

- (1) Through activities like observation, manipulation and experimentation, to be able to find out the properties of basic plane figures and verify them based on the properties of parallel lines.
 - (a) To understand the properties of parallel lines and angles and basing on it, to verify and explain the properties of geometrical figures.
 - (b) To know how to find out the properties of angles of polygons based on the properties of parallel lines and angles of triangle.
- (2) To understand the congruence of geometrical figures and deepen the way of viewing geometrical figures, to verify the properties of geometrical figures based on the facts like the conditions for congruence of triangles, and to foster the ability to think and represent logically.
 - (a) To understand the meaning of congruence of plane figures and the conditions for congruence of triangles.
 - (b) To understand the necessity, meaning and methods of proof.
 - (c) To verify logically the basic properties of triangles and parallelograms based on the facts like the conditions for congruence of triangles, and to find out new properties by reading proofs of the properties of geometrical figures.

Table 1 ‘Geometrical figures’ in course of study for Grade 8 in Japan

From Table 1 it can be seen that the understanding of congruent figures is one of the main objectives. Also it can be seen that the conditions of congruent triangles are expected to be used in verifying various properties of geometrical figures. Our interest is what characterizes the approach to congruency presented in textbooks as this mediates between the intended curriculum (in Table 1) and classroom practice.

ANALYTIC FRAMEWORK AND METHOD

As we note above, in this paper we are following Balacheff and Gaudin, (2003) and González and Herbst (2009, p. 154) in taking a ‘conception’ as being “the interaction

between the cognizant subject and the milieu – those features of the environment that relate to the knowledge at stake”. By this framework, a conception comprises the following quadruplet (P, R, L, Σ) (Balacheff & Gaudin, 2003; González & Herbst, 2009):

- P: a set of problems or tasks in which the conception is operational,
- R: a set of operations that the agent could use to solve problems in that set,
- L: a representation system within which those problems are posed and their solution expressed, and
- Σ : a control structure (for example, a set of statements accepted as true)

In their paper, González and Herbst (2009, pp. 155-156) propose the following four conceptions of congruency.

- The *perceptual conception of congruency* (PERC) “relies on visual perception to control the correctness of a solution to the problem of determining if two objects (or more) are congruent”.
- The *measure-preserving conception of congruency* (MeaP) “describes the sphere of practice in which a student establishes that two objects (e.g. segments or angles) are congruent by way of checking that they have the same measure (as attested by a measurement instrument)”.
- The *correspondence conception of congruency* (CORR) is such that “two objects (segments or angles) are congruent if they are corresponding parts in two triangles that are known to be congruent”.
- The *transformation conception of congruency* (TRANS) “establishes that two objects are congruent if there is a geometric transformation, mapping one to the other, which preserves metric invariants”.

For our analysis we selected *Mathematics 2* because it is widely used in Japanese lower secondary schools (Grades 7-9). Our first step was to identify the geometry lessons in the Grade 8 textbook. We found that there were 34 geometry lessons, with the idea of congruent triangles introduced in lesson 8. Following this lesson that introduced the idea of congruent triangles, a further 22 lessons referred to congruent triangles. In terms of proof, of the 23 lessons that referred to congruent triangles, 19 included some proving opportunities (for additional analysis, see Fujita & Jones, in preparation; Jones & Fujita, in press).

Our next step was to look closely at the first eight lessons on congruent figures (presented in Chapter 4 Section 2 of the textbook). The lesson details are given in Table 2. From these lessons, we analysed tasks from lessons 8, 9, 10, 11 and 13 (we excluded Lesson 12 from our analysis because this lesson aimed at consolidating students’ knowledge and understanding of elements of proofs such as suppositions, conclusions, and so on).

Lesson No.	Description
8	Introduction to congruent figures with 1 activity & 2 problems
9	Introduction of conditions of congruent triangles 1 activity & 1
10	problems
11	How to use the conditions of congruent triangles with 3 problems
12	Proofs using the conditions of congruent triangles with 1 activity
13	How to write proofs with 1 activity and 2 problems
	Two proof problems with section summary

Table 2: Lesson details in chapter 4 section 2 congruent figures

Our next steps were to undertake an *a priori* analysis of the tasks in the textbooks:

- identify the quadruplet (Problems; Operations; Representation system; Control structure) in the selected lessons in the Grade 8 textbook;
- use the information from our analysis to characterise the approach to triangle congruency utilised in the textbook

• P: Problem	9Pa: The use of given data.
R: Operation	9Ra: To measure given data by using measurement tools. 9Rb: To draw triangles by using given data. 9Rc: To observe the figure resulting from movement. This involves either physical or mental manipulations. 9Rd: To measure sides and angles of triangles. 9Re: To overlap two constructed triangles. 9Rf: To observe appearance of triangles.
L: Representation system	9La: The constructed diagram is the medium for the solution of the problem. 9Lb: Measurement tools are the medium for lengths of sides and sizes of angles. 9Lc: Numerical values of angles and sides.
Σ : Control structure	9 Σ a: If two constructed triangles look the same/different 9 Σ b: If all sides and angles measured are the same then two triangles are congruent. 9 Σ c: If two triangles are just overlapped then these two triangles are congruent.

Table 3 Conception of congruency in lesson 9

As an example of how we analysed the textbook lessons, we take ‘Problem 1’ in Lesson 9 (noting that, at this stage, the conditions of congruent triangles, SSS, SAS, ASA, have yet to be formally introduced); “Will each of the following conditions result in only one possible triangle? Investigate by actually drawing triangles. (1) A triangle with three sides: 4cm, 5cm, 6cm. (2) A triangle with a side of 6cm and two angles measuring 30° and 45°”. We coded the above problem in terms of the quadruplet (P, R, L, Σ) as set out in Table 3.

For ‘P’, this problem focuses on the number of triangles (whether only one or more than one) by using the given data. Students are expected to *operate* various actions to tackle this problem, e.g. drawing various triangles by using given data, observing whether two triangles are identical, and so on. Also, students might measure angles, they might overlap triangles to verify whether two triangles made by given data are identical (congruent) or not. *Representations* mediate operations and control systems, and in this problem they are mainly graphical, e.g. the constructed diagrams as the medium of solutions, measurement tools as the medium for lengths of sides and sizes of angles, numerical values of angles and sides as the medium of solutions and so on. The operations are validated by *control structure*, i.e. overlapping two figures are validated if they exactly overlap, two triangles can be the same if all sides and angles measured are equal, and so on.

FINDINGS

In what follows, in addition to the analysis of Lesson 9 Problem 1, we focus on analysing Lesson 8 and Lesson 13. Lesson 8 is the first lesson in which students in Grade 8 study congruent figures. The result of our coding is given in Table 4. The first task in the lesson (as shown in Table 4) is a practical task that can be completed in several ways, either physically (e.g. moving triangles, measuring sides and angle, and so on) and/or mentally. Some students might rely on visual appearance to judge whether two particular triangles overlap completely or not.

Following this lesson, the conditions of congruent triangles are formally introduced in Lesson 9 (as analysed in Table 3). The subsequent lesson, Lesson 10, starts from the following narrative “It can be determined if two triangles are congruent by checking to see if they satisfy any of the congruence conditions without having to check to see if they can completely overlap”. In this way, after Lesson 10 the conceptions of congruency intended in the activities and problems relate to the correspondence conception of congruency (CORR). After Lesson 10, students are expected to use the congruency conditions to prove various statements. For example, in Lesson 13, students are required to undertake reasoning problems involving two steps, as illustrated in Table 5.

Using González and Herbst’s four conceptions of congruency, the conceptions identified in the activities and problems in Lessons 8 and 9 are characterized as ‘PERC’, ‘MeaP’, and ‘TRANS’. For example, in Lesson 8,

- PERC (P, R, L, Σ) as (‘8Pa: To use given triangles’, ‘8Rd: To observe appearance of triangles’, ‘8La: Actual paper shapes are the medium for the presentation of the problem’, ‘8 Σ c: If two constructed triangles look the same/different)
- MeaP (P, R, L, Σ) as (‘8Pa: To use given triangles’, ‘8Rc: To measure lengths of sides and sizes of angles of each triangle’, ‘8Lc: Measurement tools are the

medium for lengths of sides and sizes of angles’, ‘ $8\Sigma b$: If all sides and angles measured are the same then two triangles are congruent’)

- TRANS (P, R, L, Σ) as (‘ $8Pa$: To use given triangles’, ‘ $8Ra$: To move triangles and overlap them’, $8La$: Actual paper shapes are the medium for the presentation of the problem, ‘ $8\Sigma a$: If two triangles are completely overlapped then these two triangles are congruent’)

In Lesson 10 and subsequently, the activities and problems are mainly proofs and are characterized as ‘CORR’ because the tasks rely on identifying corresponding parts that are the same. Table 6 summarises the characterization of the lessons on congruency in the Japanese Grade 8 textbook.

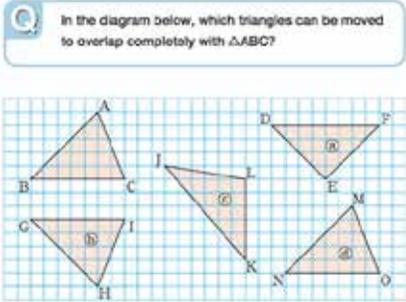

P: Problem	 <p>$8Pa$: To use given triangles.</p>
R: Operation	<p>$8Ra$: To move (rotating and translating) triangles and overlap them.</p> <p>$8Rb$: To observe the figure resulting from movement. This involves either physical or mental manipulations.</p> <p>$8Rc$: To measure lengths of sides and sizes of angles of each triangle. This involves either physical or mental counting for length as squared paper is used.</p> <p>$8Rd$: To observe appearance of triangles.</p>
L: Representation system	<p>$8La$: Actual paper shapes are the medium for the presentation of the problem, but some simple cases can be done mentally by diagrams on paper.</p> <p>$8Lb$: Squared papers are the medium for measuring lengths of sides.</p> <p>$8Lc$: Measurement tools are the medium for lengths of sides and sizes of angles.</p> <p>$8Ld$: Numerical values of angles and sides.</p>
Σ : Control structure	<p>$8\Sigma a$: If two triangles are completely overlapped then these two triangles are congruent (no specific functions or vectors are mentioned)</p> <p>$8\Sigma b$: If all sides and angles measured are the same then two triangles are congruent</p> <p>$8\Sigma c$: If two constructed triangles look the same/different</p>

Table 4 Conception of congruency in lesson 8

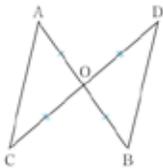

P: Problem	<div style="display: flex; align-items: center;"> <div style="margin-right: 10px;"> <input type="checkbox"/> Check 2 </div> <div> <p>In the diagram shown on the right, if O is the midpoint of line segments AB and CD, then $\angle OAC = \angle OBD$.</p> </div> <div style="margin-left: 20px;">  </div> </div> <p>13Pa: To use the conditions of congruent triangles.</p>
R: Operation	<p>13Ra: To identify what assumptions and conclusions are.</p> <p>13Rb: To identify congruent triangles.</p> <p>13Rc: To apply known facts to identify equal angles and sides.</p> <p>13Rd: To apply the conditions of congruent triangles.</p> <p>13Re: To deduce and identify equal angles.</p>
L: Representation system	<p>13La: The diagram is the medium for the presentation of the 13Lb: problem.</p> <p>13Lc: The symbols are the registers of equal sides and angles.</p> <p>13Ld: Already known fact such as the conditions and properties of congruent triangles mediate for the solution and reasoning.</p>
Σ : Control structure	<p>13Σa: If we can find three equal components of triangles (SSS, ASA, SAS).</p> <p>13Σb: If one of the conditions of congruent triangles is applied to two triangles.</p> <p>13Σc: If two triangles are congruent, then the corresponding sides and angles are equal.</p>

Table 6 Conceptions of congruency in grade 8 textbooks in Japan

DISCUSSION AND CONCLUSION

Our aim of this paper is to characterise the approach to triangle congruency in textbooks in Japan. By using congruency conceptions as our analytical framework, we identify various intended conceptions in lessons related to congruency in textbooks. What we also found was that practical tasks contain various conceptions whereas proof problems expect students to have CORR as the main conception to solve problems. It seems that the Japanese textbook we analysed assumes, by designing the lesson progression, there will be conception changes from MeaP or

PERC to CORR. An issue with this is that it is still uncertain that students who have just finished Lesson 10 have fully developed CORR after several practical activities over two lessons and a statement that “It can be determined if two triangles are congruent by checking to see if they satisfy any of the congruence conditions without having to check to see if they can completely overlap.”

In fact, Japanese Grade 8 still struggle to solve geometrical problems involving congruency. For example, a recent national survey in Japan reported that the proportion of Grade 9 students who could identify the pair of equal angles known to be equal by the SAS condition in a given proof was 48.8% (National Institute for Educational Policy Research, 2010). This indicates that many students in Japan have not fully developed their CORR conception of congruency despite studying congruent triangles and related proofs during Grade 8.

When we consider the “interaction between the cognizant subject and the milieu” (González & Herbst, 2009, p. 154), we should not simply conclude that these students are not capable to do proofs, but they might still be utilizing their MeaP or PERC when they face these proof problems instead of utilising control structure in CORR ‘ Σ : If two triangles are congruent, then the corresponding sides and angles are equal’.

The conceptions we focused in this paper are those in textbooks, i.e. the intended conceptions. Our next task is to characterise actual students’ conceptions when they interact with various congruency problems. Also it is necessary to design learning progressions and activities which enable students to develop rich conceptions of congruency as well as how to control their conceptions when they face various problem situations. One way to do the latter might be to use technology, such as that reported by Miyazaki et al. (2011).

AN INVESTIGATION ON STUDENTS' DEGREE OF ACQUISITION RELATED TO VAN HIELE LEVEL OF GEOMETRIC REASONING: A CASE OF 6-8TH GRADERS IN TURKEY

Yusuf Koç¹, Mine Işıksal², Şerife Seviş², Aslıhan Osmanoğlu³, Bülent Çetinkaya²,
Cengiz S. Aşkun², Safure Bulut²

¹ *Gaziantep University*

² *Middle East Technical University*

³ *Trakya University*

The aim of this study was to examine 6-8th grade students' performances when they were asked to identify, name, and draw geometrical objects. In order to investigate students' geometrical structures, van Hiele theory was employed with the help of a model developed by Gutierrez et al. (1991, 1998). The data was collected from 809 6th to 8th grade middle school students. The analysis of the data revealed that most of the students had difficulty to think 3 dimensionally, and so to reach 1st van Hiele level with complete acquisition. The findings are discussed and implications for educational field are presented.

Key Words: Geometric reasoning, van Hiele theory, degree of acquisition

It is a well-known fact that understanding students' thinking improves the quality of instruction (Anderson, 2000; Carpenter, Franke & Levi, 1998). Studies investigating students' geometrical understanding (Battista & Clements, 1996; Ben-Chaim, Lappan, & Houang, 1985) emphasize that to design and implement effective instruction for meaningful learning, students' thinking structures should be understood. Since developing three-dimensional understanding is important, many researches have focused on the ways of improving students' abilities on visualizing, drawing, naming, and constructing geometric solids (Ben-Chaim, Lappan, & Houang, 1988; Meng & Idris, 2012; Pittalis & Christou, 2010). While most of those researchers investigated the effect of using manipulatives (Meng & Idris, 2012), 3-D simulations, games, and virtual environments (Dalgarno & Lee, 2010); some others focused on drawing solids (Ben-Chaim, Lappan, & Houang, 1985, 1988). Ben-Chaim and colleagues (1985) found that 5-8th grade students had difficulties in relating isometric type drawings to the rectangular solids which those drawings represent. Another study explored students' thinking in 3D geometry, and argued that there is a close relation between the representation reasoning and the mathematical properties reasoning, and so between the figural and the conceptual aspects in 3D

geometry (Pittalis & Christou, 2010). The authors also suggested to curriculum developers to enrich the activities by addressing different types of reasoning. Moreover, Duval (1999) distinguished four types of apprehensions for a “geometrical figure”; namely, perceptual, sequential, discursive and operative. Deliyianni and colleagues (2009) used Duval’s framework to understand primary and secondary students’ geometrical understanding and found that perceptual and recognition abilities appeared as first order effect on developing better geometric understanding. The authors suggested giving sufficient emphasis on geometrical figure apprehension in both primary and secondary school levels (Deliyianni, Elia, Gagatsis, Monoyiou, & Panaoura, 2009).

All those studies in the literature highlighted the importance of investigating how students construct geometrical understanding and how understanding students’ geometric thinking informs teachers to improve their instruction (Panaoura, & Gagatsis, 2009). The present study contributes to the literature by investigating Turkish 6-8th grade students’ level of naming, identifying and drawing 3D geometric solids. Specifically, this study intended to understand at which van Hiele level Turkish 6-8th grade students identify a geometric solid and to what degree they acquired this level of reasoning.

Van Hiele Theory

The van Hiele theory was developed by Dina van Hiele Geldof and Pierre van Hiele in 50s in order to examine children’s geometrical thinking structures (Pegg et al., 1998). In this theory, children’s geometrical thinking structures are classified into 5 different levels (visual-level 0, descriptive-level 1, theoretical-level 2, formal logic-level 3, rigor-level 4 (van Hiele, 1984, 1986). While this theory is a strong model to analyze students’ geometrical thinking structures, it has also some limitations. For example, multiple choice tests may not accurately assess students van Hiele levels because such tests do not provide any space for students to explain their answers or reflect their ideas. Thus, another test developed by Gutierrez, Jaime, and Fortuny (1991) was adapted in this study.

Gutierrez, Jaime, and Fortuny (1991) suggested a way to assess the level of reasoning of students via creating an instrument with open-ended questions and providing explanation on evaluation of student responses through utilizing van Hiele model of reasoning. In the present study, one of the tasks adapted from Gutierrez et al. (1991) was employed to determine both van Hiele level and reasoning/acquisition level of the students.

The purpose of this study was to investigate students’ geometrical structures, and so to examine 6-8th grade students’ performances when they were asked to identify, name, and draw geometrical objects on a dot paper. The research questions were: 1) At which van Hiele levels 6-8th grade students responded to the questions in Gutierrez Test? and 2) What was the students’ degree of acquisition related to van Hiele levels in Gutierrez Test?

METHOD

Participants

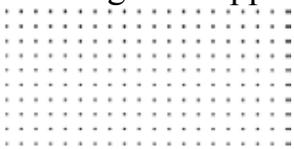

In this study, 809 6-8th grade students (283 6th, 259 7th, 267 8th grade students) during two class hours in 2009-2010 academic year. Considering the grade level differences, students are varied in terms of the previous knowledge about 3-dimensional geometry. Moreover, no training was provided to students before administration of the test because this study intended to understand students' performances in detail and how those performances vary in terms of grade level.

Data Collection Tool and Procedure

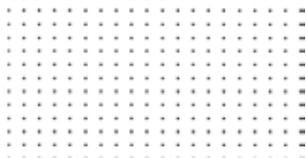

To collect data, an adapted version of an item from Gutierrez et al. (1991) was given to 6th-8th grade Turkish students. The item was piloted with 75 sixth to eight grade students. The final form of the item is provided below.

Please draw the objects on the dot paper provided below according to the given properties, and write the names of the objects into the boxes.

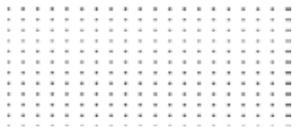

- 1) A vertical geometric object with rectangular lateral faces, and parallel and congruent opposing faces

- 2) A vertical geometric object with parallel triangle bases, and rectangular lateral faces

- 3) An object with a polygonal base and lateral faces which meet in one point

The item was composed of three sub-items. Since each sub-item has the potential to display whether students considered only one or more than one property to draw and/or to name the geometric object, it serves well to understand students' performances on identifying, naming, and drawing geometrical objects on a dot

paper. Moreover, the item measures students' performance in two ways: (1) determining van Hiele level of students, and (2) determining reasoning processes that students went through (Gutierrez & Jaime, 1998). The reasoning processes and brief descriptions are presented below (Table 1).

Table 1: Reasoning processes and descriptions

Reasoning Process	Descriptions
Recognition	Identification of types, attributes and properties of geometric shapes
Definition	Defining geometric concepts. This level of reasoning includes two different aspect: (1) Formulation of definitions of the concepts learned, and (2) Utilizations of definitions which are either read in the book or learned from teacher and peers
Classification	Classifying geometric shapes and concepts into different groups
Proof	Proofing properties and statements

Gutierrez and Jaime (1998) also determined which van Hiele levels were associated with the item and which reasoning process were included. The item might be in different levels since students may produce answers in different levels with different reasoning processes. Students may produce answers to this item at level 0 and level 1 of van Hiele theory by using *Definition* as a reasoning process. (Gutierrez & Jaime, 1998).

Data Analysis

Researchers conducted a series of meetings to form a coding process following the van Hiele Model and test the reliability of scoring. The quality of students' responses indicated which of the van Hiele levels were attained. Then, students' responses to each sub-item were carefully read and classified according to van Hiele levels. Additionally, students' degree of acquisition of the levels 0 to 3 was analyzed by using the "percentage intervals" developed by Gutierrez and Jaime (1998) (Table 2).

Table 2: Acquisition levels and their intervals

Percentage Value of The Interval	Acquisition Level
0%-15%	No Acquisition
15%-40%	Low Acquisition
40%-60%	Intermediate Acquisition
60%-85%	High Acquisition
85%-100%	Complete Acquisition

Each sub-item was analyzed separately since van Hiele level of students' responses varied in each sub-item. Students who could not answer the item or produced unrelated answers were removed from the data set.

FINDINGS

Below, selected findings are presented for the first sub-item. Due to space limitations, the results of second and third sub-items are only summarized briefly.

It should be noted that in the case that students did not answer the item or answered it incorrectly, their van Hiele level could not be determined. If students drew or named the geometric object by considering only one property, then these students were assigned to the level 0. Students who correctly drew and named the geometric object by considering all of the properties given were grouped into the van Hiele level 1.

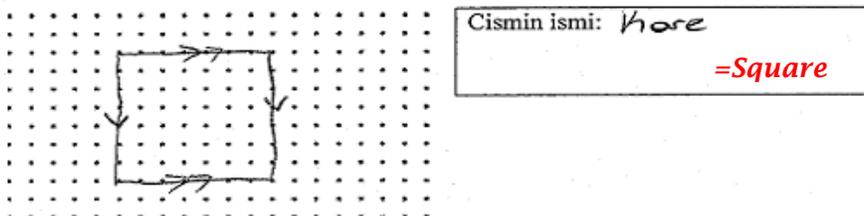

Sub-item-1

The first sub-item described a geometric object which is vertical and has rectangular lateral faces, and parallel and equal opposing faces; and asked students to write the name of the geometric object and draw it to the given dot paper.

Sub-item-1: Van Hiele level not determined

Considering the evaluation described above, van Hiele level of 171 (20.5%) students could not be determined. A student response resulted with no interpretation is illustrated below.

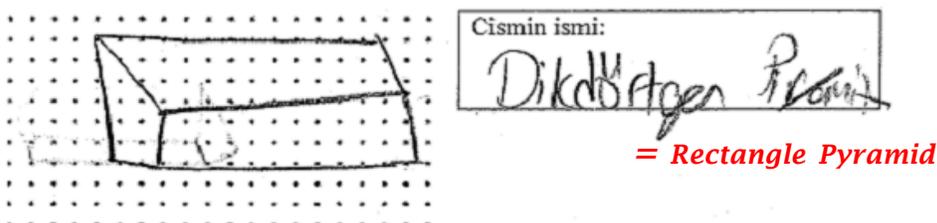

Sample student response #1:

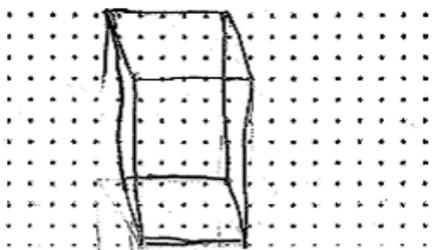

Sub-item-1: van Hiele Level 0

316 (38.1%) students answered this sub-item in the level 0 of van Hiele theory (112 sixth, 115 seventh, 89 eight graders).

Sample student response #1:

Sample student response #2:

Cismin ismi:

As seen in student responses above, students either correctly wrote the name of the geometric object but could not draw it properly, or drew the object correctly but could not name it or named it wrongly.

When the results were analyzed according to degree of acquisition (Table 3), it was found that majority of 8th graders (88.8%) had *no acquisition* of the level. Half of the 6th and 7th graders had *no acquisition* of the level while the other half of them possessed the level with *low acquisition*. In this sub-item, there were no 6th graders, but a few 7th and 8th graders in *intermediate level of acquisition*. Again none of the 6th and 8th graders acquired the level completely. Only one 7th grade student reached *complete acquisition* of the level.

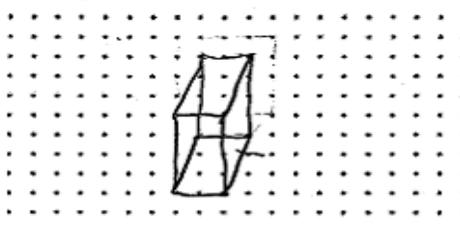

Table 3: Distribution of students' responses on sub-item-1 at van Hiele Level 0 across grade levels

Level of Acquisition	6 th grade		7 th grade		8 th grade	
	N	%	N	%	N	%
No Acquisition	56	50,0	59	51,3	79	88,8
Low Acquisition	56	50,0	53	46,1	9	10,1
Intermediate Acquisition	0	0,0	2	1,7	1	1,1
Complete Acquisition	0	0,0	1	0,9	0	0
TOTAL	112	100	115	100	89	100

Sub-item-1: van Hiele level 1

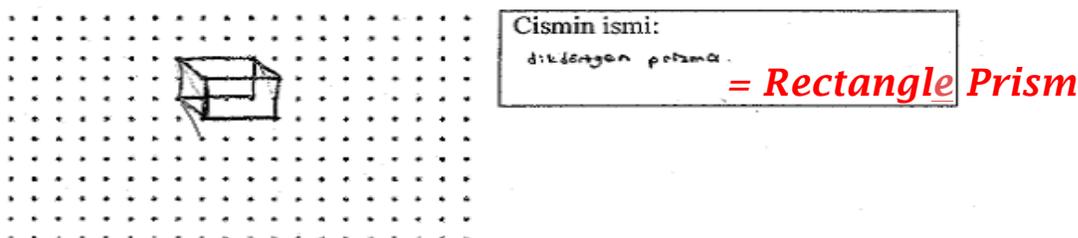

346 (41.4%) students produced responses in the first van Hiele level (111 sixth, 115 seventh, 120 eight graders).

Sample student response #1:

Cismin ismi: Dikdörtgen
PRİZMG

= Rectangle Prism

Sample student response #2:

The sample student answers reveal that some of the students were able to identify the object, draw it, and name it correctly.

With respect to the students' degree of acquisition (Table 4), majority of the students in all three grade levels had *complete acquisition* of the level. In other words, 68.4% of 6th graders, 73.9 % of 7th graders and 67.5% of 8th graders attained the second van Hiele level completely. As seen in Table 4, approximately a quarter of students in each grade level had *intermediate acquisition* of the level for sub-item-1. Even though there were few students having the level with *low acquisition* and *no acquisition*, the students' responses reflected 1st van Hiele level with a high degree.

Table 4: Distribution of students' responses on sub-item-1 at van Hiele level 1 across grade levels

Level of Acquisition	6 th grade		7 th grade		8 th grade	
	N	%	N	%	N	%
No Acquisition	3	2,7	1	0,9	4	3,3
Low Acquisition	1	0,9	3	2,6	5	4,2
Intermediate Acquisition	31	28,0	26	22,6	30	25,0
Complete Acquisition	76	68,4	85	73,9	81	67,5
TOTAL	111	100	115	100	120	100

Sub-item-2: Van Hiele level not determined, and van Hiele levels 0 and 1

In this sub-item, students were given properties such that “*A perpendicular object with parallel triangle bases, and rectangular lateral faces*”, and asked to name and draw this geometric object. Similar to Sub-item-1, students produced answers in van Hiele levels 0 and 1. While 296 (35.7%; 116 sixth, 95 seventh, 85 eight graders) students answered the sub-item in the level 0 mostly with *low* and *no acquisition level*, 283 students (33.9%; 81 sixth, 108 seventh, 97 eight graders) were in van Hiele

level 1 with *complete* and *intermediate level of acquisition*. Also, there were 254 (30.4%) students the answers of whom could not be determined.

Sub-item-3: Van Hiele level not determined, and van Hiele levels 0 and 1

This sub-item asked students to name and draw a 3D geometric object which had a polygonal base and lateral faces meeting in one point. The results were similar to that of sub-item 1 and 2. In other words, there were 288 (34.5%) students of whom van Hiele level could not be identified; there were 291 (35.1%; 100 sixth, 91 seventh, 100 eight grade) students in van Hiele level 0; 254 (30.4%; 85 sixth, 96 seventh, 73 eight grade) students in van Hiele level 1 with *complete* and *intermediate level of acquisition*.

DISCUSSION AND CONCLUSION

The findings revealed that 36% of the students in average drew 3D object properly and named it correctly, and reached to van Hiele level 1. Most of the students attained the 1st van Hiele level 1 with *complete acquisition*. The number of 6-8th grade students slightly differed from each other. This finding contradicts to Wu and Ma (2006)'s study with 5581 randomly selected 1-6th graders in Taiwan that their conclusion was that the higher the grades the higher the van Hiele levels. At this point, the fact that the methodologies, cultural aspects, and students' experiences with the topic were different in these two studies should be taken into account.

In short, more than 25% of the 6-8th graders' van Hiele level could not be determined; 36% of them had van Hiele level 0 mostly with *no and low acquisition*; and other 36% was in van Hiele level 1 mostly with *complete and intermediate level of acquisition*. This finding reveals that 64% of the students could not reach the 1st van Hiele level supporting that students' geometrical understanding and reasoning is low (Duval, 1998; Gutierrez et al., 1991). This might be attributed to the fact that the teaching strategies might be based on memorization (Battista, 2001).

Van Hiele (1986) stated that if students can not reach even to the descriptive level of geometry, it might be because they had no chance to experience geometric problems before. Instruction is believed to be the way for development through the van Hiele levels (Koehler & Grouws, 1992), and quality instruction is one of the most effective ways to improve students' understanding of geometry (Usiskin, 1982). We suggest curriculum developers and teachers to provide more opportunities for students to deal with three dimensional geometry. Moreover, even though 36% of students were found in the level 0 of van Hiele theory, they had either low acquisition or no acquisition at all. This might be another evidence of their need of geometrically rich experiences like the item utilized in this study or the original item developed by Gutierrez et al. (1991) in order to develop three dimensional thinking in geometry. Further studies are suggested to be conducted to understand how the classrooms could be transformed to support students' 3D reasoning. It is also recommended to analyze reasons of low or no acquisition in a particular van Hiele level so as to inform teachers and curriculum developers about the needs of students.

CONSTRUCTIONS WITH VARIOUS TOOLS IN TWO GEOMETRY DIDACTICS COURSES IN THE UNITED STATES AND GERMANY

Ana Kuzle

University of Paderborn, Germany

In this article, I report on a study on experiences and perceptions from two culturally different cohorts of preservice teachers about teaching geometric constructions using different construction tools (compass and ruler, set square, patty paper, Mira, dynamic geometry software). The analysis of written reports indicated that the teaching experiment challenged participants' existing perceptions about teaching constructions and enabled them to reexamine their future practices. Both groups reflected on the experience both through the lenses of themselves as learners and as future practitioners arguing for and against benefits of using different tools when teaching constructions, and its effect on the development of geometric thinking.

Keywords: geometric constructions, geometric reasoning, construction tools, preservice teachers, reflection

INTRODUCTION

The topic of geometric constructions played an important role in the antiquity; likewise, nowadays, it has an important role in the mathematics curriculum. Euclid's "*Elements*" has been the most enduring and widely used mathematical work in the history of mathematics. In addition, it contains many geometric construction problems that had to be carried out using very specific tools: a collapsible compass and a straightedge, which are nowadays somewhat synonymous for constructions in school. Even though many attribute the teaching of geometric constructions to its long tradition, this topic is tightly connected to the central goals of teaching geometry, such as discovery learning, proving, concept learning and problem solving (Weigand & Ludwig, 2009) and, for these reasons, is of immense importance.

Though compass and straightedge have a long history as construction tools in geometry and in teaching geometry, many other tools are suitable for a constructive access to geometry. These include, but are not limited to, dynamic geometry software, Mira [1], patty paper [2], a protractor, a set square, TESE (a two-edged straightedge) and inch cards (Pandiscio, 2002; Serra, 2003; Weigand & Ludwig, 2009). According to NCTM (2000), construction tasks can encourage students to "draw and construct representations of two- and three-dimensional geometric objects using a variety of tools" (p. 308) and to recognize and connect mathematical ideas as a way to "develop robust understandings of problems" (p. 354). Use of these construction alternatives provide both a fresh view on the classical geometry topic and, together with classical tools, fosters different mathematical ideas promoting in-depth understanding of geometric concepts and highlights the connections among different ideas (Pandiscio, 2002; Serra, 2003). However, the pitfall of teaching this

topic is that teachers often deliver mere construction steps to their students and emphasize the importance of precision (Schoenfeld, 1988). He asserted that such instruction, however, inhibits the students' possibility to develop problem-solving competencies, understanding of geometry, and development of mathematical power.

THEORETICAL CONSIDERATIONS AND AIMS OF THE STUDY

Perception is a central issue in epistemology. They are views or opinions held by an individual resulting from experience and external factors acting on the individual. Individual's perception is a broader look at the construct of beliefs encompassing beliefs, meaning, preferences, concepts, and mental images (Philipp, 2007). Our perceptions are influenced by our past experiences, beliefs and expectations. Researchers often apply conceptual lenses of teachers to interpret teachers' knowledge, beliefs and practices. Beliefs are often robust, permeable mental structures that evolve with experience (Thompson, 1992) and they influence the ways in which teachers perceive and deploy tasks. Perceptions and beliefs are formed very early in life whereas our thoughts and behavior patterns are governed by these. Teachers' individual perceptions, beliefs about the sense and nature of mathematics education and preparation are becoming increasingly recognized as fundamental contributors influencing the way they teach and in which innovative teaching concepts are implemented into day-to-day mathematical lessons (Philipp, 2007; Thompson, 1992). Consequently one's perception of reality is different and beliefs need to be challenged in order for a change to occur (Wilson & Cooney, 2002). Researchers (Thompson, 1992; Wilson & Cooney, 2002) place reflection as the agent of change where as a consequence teachers can consolidate their knowledge, shape the forms of knowledge produced, question their existing perceptions and values about teaching, influence their future classroom practices and so on.

The integration of tools and technologies is an important and actual theme today in teaching mathematics. New and emerging tools and technologies are introduced into the mathematics classroom that continually transform the mathematics classroom and redefine ways mathematics can be taught (Barzel, Drijvers, Maschietto, & Trouche, 2005). Several different perspectives have been developed, in particular instrumental approaches, which help explain the use of tool from a cognitive point of view (Rabardel, 2001). The main tenet in the instrumental approach is the difference drawn between an artifact and an instrument; the artifact is the object that is used as a tool, whereas tool is a material artifact that has a purpose to perform a task. However, the instrument involves techniques and schemes developed by the user during its use (instrumentalisation) that then guide the way the tool is being used and the user's thinking (instrumentation). When integrating different tools in the mathematics classroom different dimensions have to be taken into account: the relation between the use of tool and learning, the role of the teacher in technology-rich mathematics education, and the characteristics of technological tools (Barzel et al., 2005).

In light of these considerations, this was designed to seek an understanding about how learners from two different classrooms and learning cultures appreciate and

make sense out of construction endeavors using different construction tools. The question arises: Do such opportunities allow development of a deeper understanding why and how can geometry meaningfully be taught? Hence, I explore how different conscious perceptions about different construction tools may influence the intention to implement innovations into their future classroom as suggested by a course initiative. The following research questions guided the study: Which elements of reflection can be identified in preservice teacher communication of experiences on using different construction tools when solving standard construction tasks? How do preservice teachers perceive the importance of using different construction tools with respect to teaching the topic of constructions?

METHODOLOGY

This was an exploratory study with participants from two cohorts of preservice middle and junior high school teachers from the United States and Germany. The research design differed for both countries because of the different classroom and learning culture. However, the similarity of items within the two designs allowed for a comparison study. The following is a discussion of two research designs.

Teaching experiment in the United States

This research was conducted during a mathematics education course “Teaching Geometry and Measurement in the Middle School” in Spring 2011, which is a part of the middle school teacher education program (grades 5-8) at a large southern university. The course focused on teaching methods, curriculum materials, and topics and psychological factors for developing geometric and measurement structures in grades 5-8. The class met twice per week for 75 minutes, where the professor and the teaching assistant (author of the paper) led the discussion and organized the lesson plans, and supported by two additional teaching assistants. In this study, a cohort of 36 prospective mathematics middle school teachers students participated. Data collection took place in the 3rd week of the course when topic of construction began. The class was divided into three groups in which a different manipulative was used: a compass and a ruler, the Mira, and patty paper. The students were instructed to solve standard Euclidean construction problems (duplicating a segment, duplicating an angle, constructing a perpendicular bisector, construction of an angle bisector, constructing a line parallel to a given line and a point not lying on the given line) with the guidance of the instructor. After 20 minutes they rotated to a different room where they engaged in the same activities but using a different manipulative. During the next class meeting time was spent on learning how to work in a dynamic geometry environment, namely in the Geometer’s Sketchpad (GSP), performing afterwards the same construction tasks as in the previous class meeting.

Data collection methods for this part of the study consisted of the following: mathematical autobiography, written reports, and field notes. The purpose of the mathematical autobiography was for the students to reflect on their experiences as a mathematics learner in geometry thus far. Written reports were 2 to 3 page reflection

papers that students submitted every 2 to 3 weeks designed for students to relate what they were learning in class to their own practice or experience. They needed to choose one aspect of class that was of interest to them, and discuss it in depth both through the lenses of a student and future practitioner. I analyzed 20 of those papers that reflected on the events in the above described class-meeting. All participants reflected on the four construction tools. Additional data were my own field notes I took while observing students performing the above described tasks.

Teaching experiment in Germany

This research was conducted during a mathematics education course “Didactics of geometry for grades 7-10” in the spring 2012 semester which is a part of the teacher education program for grades 5-10 at a large university in Germany. The course focused on developing and consolidating content and didactical competencies relevant to grades 7-10. The class met twice per week for 90 minutes in a form of a lecture and discussion, respectively. In this study, a group of 20 prospective teachers participated who attended one of the discussion sessions. Data collection took place in the 4th week of the course where the students learned about different tools that can be used when teaching constructions (a compass and ruler, a set square, GeoGebra) as suggested in the literature (Weigand & Ludwig, 2009). In the discussion the students had the opportunity to have a practical experience with constructions using compass and ruler and patty paper. Similar to the previously discussed case, the students were given a sheet of paper with list of standard constructions they were to perform using first the patty paper and afterwards using a compass and a ruler. The students had 20 minutes to engage in these activities with a particular manipulative. As a part of their homework they performed the same activities using GeoGebra and set square.

Data collection methods for this part of the study consisted of the following: questionnaire with open-ended questions, written reports, and field notes. The questionnaire was divided into two sections. The purpose of the first sections was to learn more about the general background of the participants and their school experiences with respect to the topic of constructions. The second section asked the participants to circle if a given tool (compass and ruler, set square, patty paper, technology) should be used in teaching constructions where Likert scale (1–5) was used followed by an open question to elaborate on their decision. The study included a survey yielding quantitative data, however, those data were not intended for statistical analysis but as a way to help the participants reveal their thinking about aspects of their experiences, teaching, and perceptions. In addition, two open questions were posed so that the students could reflect on the benefits of these events on their current professional learning and future teaching, which allowed study comparison. Additional data were my own field notes.

Data analysis

Once data collection was completed, the textual analysis (Bernard & Ryan, 2010) of all written data reports, where conceptions and reflections about different

construction tools were articulated, was used. For the purpose of this study, two stages of analysis, the within-case analysis and the cross-case analysis (Bernard & Ryan, 2010) were carried out. Within-case analysis focused on an analysis of different written reports. During this phase of the analysis, I read all documents and analyzed participant responses according to topics such as background and perceptions that allowed me to situate the participants according to their experiences as well as to ascertain the soundness of the development of the geometric thinking when using different construction manipulative. Once I identified these themes from the reports, I reexamined the data, taking note of any new evidence that came to light in support of these major ideas. The cross-case analysis was used to create a theory offering general explanations of perspectives on the experience of using manipulative for both groups.

RESULTS

Elements of reflection on the experiences of using different construction tools when solving standard construction tasks

The mathematical autobiography written by the American students revealed previous experience with the topic and the different tools; almost half of the students perceived having experienced a teacher-centered middle- and high-school geometry classroom rather than a student-centered one. Other students reported having ample opportunities to engage in discovery learning and individual or group problem solving using different manipulative. With respect to different construction tools, all participants had instrumented a compass and a ruler when solving construction tasks “I have used a compass and straight edge in the past”, but three people reported their teachers also used different technology software “but she [teacher] used it only to demonstrate the construction steps. We didn’t get the chance to use it”. They perceived geometry as “an exciting and interesting part of mathematics”. On the other hand, a questionnaire was administered to German students for the same reasons. The analysis of the questionnaire revealed that, though the participants had a positive experience with geometry in their previous educational experiences, the participants’ beliefs about teaching constructions varied. While 11 participants were comfortable with the topic, 8 were rather anxious about the topic. The construction problems they had experienced were easy for most of the participants, while only 3 participants experienced difficulties. All of the participants instrumented the compass and ruler together with a set square in school, while one participant reported having instrumented the former two and technology. The topic was mainly taught in a teacher-centered classroom where the teacher explained specific construction steps and then they would practice the steps, which is similar to previous results (Schoenfeld, 1988). For the rest of this section, I discuss students’ reflections on the experiences using different construction tools.

Mira – The Mira was only used with the American students, as this tool was not available for use in the didactics course in Germany. For most students this was their first encounter with the Mira, that is, the tool has not been instrumented thus far by

them. Though a teaching assistant shortly introduced them to the tool, the participants struggled with its use, for instance, when duplicating a segment:

But I have never used the Mira...I had the most difficulty in trying to replicate the dots on the other side of the Mira so that I could connect them with a straight edge. It was after exploring the tool I figured out I need to place Mira adjacent to the segment, look through the Mira to identify the endpoints on the other side of it. The Mira was the hardest tool for me to understand and use correctly.

Hence, after they instrumented the Mira taking into account affordances of the tool, they were able to use it as a construction tool. This experience prompted them to stress the importance of letting the students have an opportunity to “play with the tool before using it”. Moreover, all of the participants instrumentalized Mira as a reflection tool in addition that can then be used when introducing the concepts of reflection, congruence and symmetry “As I played with the Mira, I noticed more about symmetry and reflections by moving the Mira...I would definitely use the Mira to teach sections regarding reflection.” However, three students did not believe that the Mira should be used as a construction tool because “it may not be very useful in applying and relating constructions and properties to students’ day-to-day experiences as easily as other tool.”

Patty paper – For both group of students, this was their first encounter with the patty paper and similarly to the experience with the Mira the tool needed to have been instrumented by the participants. This process by German students was very interesting. First they tried to adapt their previous compass and ruler strategies. They used the compass and ruler on the patty paper similar as when constructing on a DIN-A4 paper before getting instructed by the teaching assistant (the author of the paper) that they are only allowed to use the patty paper and a ruler. Only after having considered the affordances of the tool their thinking guided how the tool got used. The use of the patty paper as a construction tool was very well received from the American students. The participants perceived that the tool is “very easy to manipulate”, “its translucent appearance helps with copying lines on multiple patty paper sheets as well as visualizing angles and intersecting lines”, “inexpensive, and it has so many possibilities” and promotes geometric reasoning

By using the patty paper I got clarity to many geometric relationships. As a teacher, I will use patty paper because there are many ways that I can use the paper to help my students learn mathematics...not only to visualize, but also to experiment and discover the geometric principles for themselves.

Five students after having instrumented all of the tools in addition offered a trajectory with regards to using different construction tools in the classroom

I really feel these three activities go hand-in-hand, and feel it might be very beneficial to go through them in the order discussed [patty paper, Mira, compass and ruler]. I would use the patty paper as a opening activity with younger students who might not be necessarily able to correctly use Mira or compass and ruler. After discovering concepts and basic relationship the progression to Mira and then to compass and ruler would come naturally.

The other participant added that technology would be used at the end to “solidify their earlier findings or help with questions that may arise from the other teaching methods”. Hence, such experience allowed the participants to reflect on their current student role and experiences allowing to reexamine their beliefs about the teaching of the construction and shift in their future teaching practices. Perception of German students with respect to patty paper was divided; 7 participants were against its use, 9 were neutral and 4 were for its use when teaching constructions. The participants who were against its use included the following reasons: “it is imprecise”, “does not support understanding of the topic and geometric relationships”, “praxis-irrelevant” and “not usable in later education”. Some participants were extremely vocal and believed that “That is not mathematics!” Opposite to those statements, the rest indicated that it supports “a student-centered classroom where student can learn new concepts and discover new relationships” while also helping students “illustrate and visualize figures”.

Compass and ruler – All of the participants had previously instrumented compass and ruler. Only one student from the United States shared his belief that this tool should be used because it is “a classic approach to constructing and examining shapes, angles, and segments” and part of “old school”, while others mentioned reasons, such as focus on mathematical reasoning, making connections between the geometric relationships, and its ease of use.

I was forced to recall properties of whatever I was attempting to construct or translate in order to make it work. The mathematical reasoning behind this activity is very deliberate in forcing students to make connections. Further, the tools used are ones that they can more easily use in their daily lives and relate to.

Hence, having reflected as learners and future practitioners on their own activity and reasoning they developed their perception towards the tool and consequently recognized how the tool might promote their students’ reasoning, respectively. On the other hand, 19 German participants (strongly) believed that compass and ruler should be used in teaching construction for the following reasons: “compass and ruler are the foundation of constructions”, usability in praxis, ease of use, effective and precise construction tool, promotes discovering geometric relationships, and teaches precision and finger-abilities. Students in both cohorts recognized the historical value of the use of compass by “viewing” the tool as a part of “mathematics culture”. Hence, beliefs towards the use of the tool in the future was influenced by the cultural, historical value assigned to the tool. The question that remains open is if the shift in belief did not occur because it was not challenged sufficiently or because the value is extremely instilled and therefore was not able to have been changed.

Set square – Set square was only used with the German students, as this tool is not a part of the American mathematical culture. The participants have had instrumented this tool throughout their education yielding homogeneous beliefs about its use when teaching construction; seventeen of them argued for its use because it was instrumentalized both as a construction and a measurement tool. They also believed

that it is “more precise than compass and ruler”, “integral part of geometry”, “time efficient”, “self-explanatory” and “supports development of finger ability”.

Technology – Participants’ opinions to using technology as a construction tool was similar for both groups. For the first group, some argued against its use because it does not require much thought to make connections and experiment compares to other tools “I really loved the hands-on engagement that this activity requires of the student, rather than simple dumb luck.” The majority of the students were thrilled by the vast opportunities GSP offers such as visualization, illustration, drawing locus, and as an aid tool for lower achieving students

I also think we would be doing students a disservice if we did not allow them to explore programs like GSP because it makes the relationship much easier to see, understand and to solidify their earlier findings. Technology makes all of this easier.

On the other hand, with respect to using technology when teaching construction, the answers from German students were not as homogenous: in total 14 students were for its use, 3 were neutral and 3 were against its use. Some reasons against its use, but not limited to, were: “not easy to use”, “by a click of the mouse a figure can be constructed failing to promote understanding of the geometric relationships”, “not usable in every day situations”, “lack of availability to students”, and “hinders the need for a proof”. Hence, the participants had a limited view of the affordances of technology a perceived technology as a “product tool”. Reinforcement of proof and visualization of geometric relationships between figures that technological tools allow was not recognized because they did not reflect as future practitioners. The rest argued for its use because of the affordances technology brings in general: visualization, speed, and accuracy.

Preservice teachers’ perception on the importance of using different construction tools with respect to teaching the topic of constructions.

At the end of their report, the participants reflected about the influence of the experience of using different construction tools on their future teaching. All American students and eight German students experienced a shift in their beliefs towards the topic of construction “using different tools gives the students a tangible experience where use of the tool promotes problem solving and proving through the use of reasoning”. However, some did not fully grasp the value of the experience writing that they learnt that “figures can be constructed with different tools”, “construction with software is precise”, and “different tools make teaching fun without connecting it to students’ learning”. In addition, fourteen German students said they will use the tools they used when they were in school. This apprenticeship of observation (Lortie, 1975) provides preservice teachers a limited understanding of teaching, which should not be underestimated. Such preconceptions that preservice teachers hold about teaching should be challenged to allow for a new geometry classroom. The rest remarked they would like to use them in their future career to differentiate instruction and support students’ independent learning. On the other

hand all of the American participants expressed that they plan on implementing these activities in their classroom, as these tools will deepen students' understanding of geometry explaining, "those [hands-on activities] are what students get the most out of in class." One of the participants summed up her thoughts by using her high-school teacher's saying: "Tell me and I will forget, show me and I may not remember, involve me and I will understand." Hence, by focusing on hands-on work students can expand their outlook on different tools helping them to broaden and deepen their understanding of mathematics (Pandiscio, 2002).

In summary, both groups of students reflected through the lenses of current learners and future practitioners. The American students reported on elements portraying broadening of their mathematical perspective, such as consolidating their knowledge about constructions and geometry and the mathematics behind each tool. The latter was communicated likewise by the German students. The participants' perceptions to the importance of different tools were centered around these qualities: development and promoting of geometric thinking, problem solving activities and processes, hands-on experience, and visualization. The analysis yielded rather remarkable results with respect to their future profession and with no doubt broadened their didactical perspective. Both group of students recognized that by using different construction tools, they could arrange a student-centered classroom focusing on the students' independent learning and strengthening their conceptual understanding of different topics. On the other hand, stressing the historical and cultural value of a tool, namely the compass and the ruler, was given by the German students.

FINAL THOUGHTS

Construction tasks are of immense didactical meaning in teaching geometry for many reasons, such as development of deductive reasoning, problem solving, argumentation and proving abilities, connections within geometric topics, and creativity (Weigand & Ludwig, 2009) but this topic does not get the necessary attention in mathematics (Pandiscio, 2002; Weigand & Ludwig, 2009). The results of this study show that a short lesson with carefully designed activities with well-chosen tools may enable prospective teachers' to learn about new instructional strategies, shift in their future teaching practices towards more student-centered pedagogies and broaden their content and pedagogical perspective targeted towards promoting geometrical reasoning. Hence, it is clear that beliefs and practices are linked; teachers' perceptions are critical factors in better understanding the development of quality mathematics teaching that we as educators need to confront during their education (Wilson & Cooney, 2002). Preservice teachers should have experience in solving construction tasks using different tools as well as opportunities to discuss curricular, pedagogical, and learning issues in variety of contexts before becoming in-service teachers and taking those responsibilities on themselves. Such experience with new tools has a profound effect on preservice teachers' knowledge of geometry and without a doubt is a powerful medium for the transformation of teaching and learning geometry.

NOTES

1. The Mira is a device constructed of red or green semitransparent plastic with a beveled lower edge that generates reflected images of geometric objects.
2. Patty papers are the waxed square papers often used for baking. They are translucent but also show creases when folded.

INVESTIGATING MANIPULATIONS IN THE COURSE OF CREATING SYMMETRICAL PATTERN BY 4-6 YEAR OLD CHILDREN

Ewa Swoboda, University of Rzeszów, Poland

Summary. In this paper the role of gestures and manipulation in solving geometrical problems is investigated. Children aged 4–6 were subject to a series of observations during an experiment, aimed at finding a special placement for the figures in the symmetrical pattern. Results show, that rotation was taken as the first, most intuitive movement for them. Manipulation with rotation was taken independently on visual recognition of the relation of axis symmetry. It suggests that such approach can have a great impact on „tacit knowledge” used in further learning about geometrical transformations, and as consequence the dynamic imagination of rotation could be closer to acquaintance than other rigid movements on the plane.

Key words: geometrical intuition, tacit knowledge, rotation

IMPORTANCE OF GESTURES AND MANIPULATION IN EDUCATIONAL RESEARCH

In recent years, there have been a number of works dealing with the role of gestures and manipulation in the process of solving mathematical problems (Edwards, 2005; Radford, 2005; Freitas and Sinclair, 2012). The basis for such study is a convince that the construction of mathematical knowledge, at all school levels, should develop through activities that favor perceptuo-motor learning and involve interactions with body experiences (Arzarello *at al.*, 2009). Generally, the relationship between the language, gestures and mathematical reasoning is considered. Sometimes, the distinction between different kind of gestures is made, for example between pointing and movements along the axis of the coordinate system (Bjuland *at al.*, 2005) or gestures indicating the relations between some parameters (Steinbring, 2005) According to some opinion, the gestures related to linguistic expressions stimulate dynamic thinking in real time among his subjects (Nunes 2004).

It seems that gestures, movements and any other manipulations can play a crucial role in geometrical thinking. They can replace a verbal utterance (using language at the lower level of geometrical reasoning is quite difficult). But first of all they can represent various geometrical relations and transformations. For this reason, investigating gestures in the course of solving geometric problems can have a high educational value. This is confirmed by research carried out in different age groups (Bazzini, *at al.*, 2010, Freitas and McCarthy 2013, Ferrara and Maschietto, 2013).

THE ROLE OF MANIPULATIONS IN THE DEVELOPMENT OF GEOMETRICAL THINKING

Theories that describe the development of geometrical concepts indicate how the process of geometrical reasoning functions. There is not much said about the very

beginnings of the geometrical cognition. A Czech mathematician and educator M. Hejny and philosopher of mathematics – P. Vopenka are the few ones who examine the very beginnings of the development of geometrical concepts and include it into the whole theory. According to their views, geometrical concepts "emerge" from the surrounding world through a specific "geometrical sensitivity", a kind of a sixth sense. "To notice something" is the first condition for the consciousness to focus on the geometrical phenomena. This first cognition is passive and static. Such an attitude is a mathematical specification of this, which developmental psychology defines as a place of visual thinking in the development of intelligence: The use of the images is considered to be one of the basic characteristics of the thinking of preschool children (Jagodzińska, 1991). Epistemology of geometrical reasoning requires the transition to further levels, in which an imagining of dynamic changes is desirable. Geometrical reasoning is consistent with operational thinking: while solving problems, we create a new reality; passage to the new reality requires the use of dynamic images of changes. Thus, finding and describing the mechanism of creation of operational geometrical concepts, based on dynamic transformation of imaginations, becomes an important research issue.

My previous investigations lead to the conclusion that 4- 6 year old children are able to act in the geometrical pattern environment (Swoboda, 2006). Children spontaneously arrange the plane, creating such relations between figures which may be described with the language of geometric isometric transformations. However, it is an activity which takes place on the visual level, and child is interested only in the final arrangement of objects and the results of the action is verified visually.

It is worth to investigate very young (up to 7-year-old) children's dynamic actions in such geometrical environment. At this level we couldn't expect the children's reflection on movement used, but intuitive movements and gesture can create a solid base for the further, more conscious activities. So it's worth to discern when and what actions children undertake when they try to solve problems associated with the arrangement of one object in relation to the other.

RESEARCH – AIMS, RESEARCH TOOL

The experiment took place in March and April 2008. Children from a typical Polish kindergarten, aged 4 – 6, were subject to a series of observations (altogether – 60 children). This experiment was part of a broader study (Swoboda, *at al.*, 2008; Swoboda and Tatsis, 2010), but for the purpose of this paper I will focus only on the aims described below. Children were tested individually and all sessions were videotaped and transcribed afterwards. As a research tool two types of tiles were used (fig. 1). The tiles were arranged separately on the table.

Fig. 1 – research tool

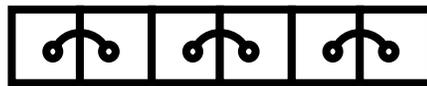

Fig.2 – a segment of the pattern prepared by a teacher

At the beginning a child was asked to continue the pattern prepared by the teacher (fig.2). When a child was not able to create the regularity, the teacher helps him in this.

Later on the teacher replaced one tile from a pattern by a different one in such a way that the regularity was distorted. The child was asked to show where a change was done and “to repair” the regularity [1].

The basic research aim was to investigate movements used by children. The research questions were as following:

1. How did the children recognize the symmetry in the tiles (visually, or by using any action)?
2. What kind of placement of the two congruent figures provoked the children to make any movements?
3. What kind of movement played the most important role in children’s actions?

For creating a pattern, it was necessary to use two kinds of tiles - the motifs on the tiles were either “left” or “right”. The left motif presented was a mirror reflection of the other one, thus, none of the types could have been obtained by rotating the other tile. Additionally, there was no motif on the back of the tiles, which made it impossible to correct the distorted pattern by making movement out of plane.

Building and correcting pattern required manipulations. Some of them were not interesting for me (browsing the tiles on the table, pointing the “wrong” place in the distorted pattern). I was interested in movements related to the verification of tiles placements. Such movements were observed in both parts of the experiment: during creating the pattern and during correcting it.

MOVEMENTS DURING CONSTRUCTING PATTERN

Two different strategies were observed in all children groups: 1. after visual recognition of difference between the tiles (placed on two separated piles) a child created pattern taking consciously two tile types, 2. a child starts by “blind searching”, to connect tiles in order to obtain symmetrical configuration.

Example 1. Kacper (4-year-old boy).

Teacher: *Kacper, look at this pattern and try to continue it.*

Kacper: Takes one tile (the correct one) from the left pile, attaches it to the pattern but after a moment he starts to rotate it and later puts it back. Now takes a tile from the right pile, looks at this, says – no – and puts it back to the left pile. Takes another “right” one, visually compares it with the tiles at the table, put it over piles, but afterwards slides it under the right pile. After a moment he decides to take the right tile again and now he puts it in the pattern line, however without connecting it (keeping an empty place for one tile). In the second hand he takes another right tile and rotates it, trying to adjust to the gap between the pattern and non-connected tile. Next, he exchanges the right tile with the left one and constructs the whole symmetrical motif. He connects it with the pattern.

This boy started from “blind searching”. The first movement, important for him, was the rotation. Although the first position he chose (and the tile) was correct, he felt the need to investigate its different placements. It is clear that he didn’t know how to use the visual information in a constructive way, he was only able to state, that some of his choices were not proper. In spite of this, he was very persevering in the work. Thanks to manipulation he gains some experiences, useful for solving his task.

Older children worked on the visual level. They successfully utilized the information, that two piles contains different types of tile. But also in such a situation some of them felt the need to investigate whether it was possible to obtain a symmetrical position, by using two tiles of the same type. It is clearly visible in the work described below:

Example 2 . Martynka (6-year-old girl).

At the beginning she takes one tile from the right pile, later on a second tile from the left pile. She joins them and puts together as the pattern’ continuation. After that, she takes simultaneously two tiles from two different piles and using them creates another motif. From that moment she works very fast, sometimes taking simultaneously tiles, sometimes – taking one tile at time, but even in that situation she is aware where the tile should be put (fig.3) She uses almost all the tiles form the table. Two last tile were of the same type. She takes them into two hands and starts to manipulate – for a long time (23 sec.). She rotated them, trying to connect (fig.4). After that she looks at the teacher, by this informing that it is impossible to use these tiles for the pattern.

Fig. 3

Fig.4

Martynka’s work, described above, was not typical for older children. It seems that for the 6-years-old children the visual identification of one type of tile stopped any actions on them. It is visible in the Example 3.

Example 3. Karolek (6-year-old boy).

K: At the beginning of his work he makes some trials and afterwards he works very fast, taking successively the correct tiles form the table without any doubt. In this way he builds a very long pattern, extending it on the right and left side. At the end, there are three identical tiles on the table left (fig.5).

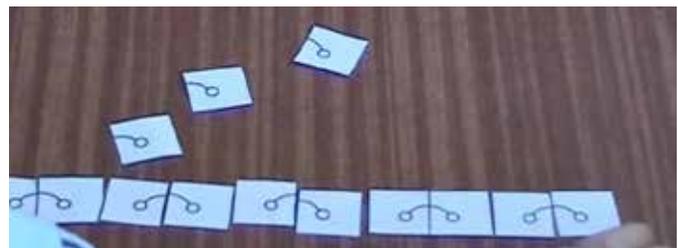

Fig 5

The boy sits (18 sec.), looks at the tiles.

T: *Do you still want to work?*

K: *no.*

This boy preferred to make a visual analysis than a manipulation – supposedly, the visual information was more important to him. In addition – he knew how to use these information. Perception was the foundation for each of his decisions, manipulations only supported and verified the undertaken actions. At the end of his work no action was needed – it was clear for him, that tiles are ‘the same’. Those tiles were placed ‘almost’ parallel, the child didn’t feel obligate to make movements to check anything.

MOVEMENTS DURING CORRECTING PATTERN

Again, two different strategies emerged here. The first one – ‘replaced strategy’, when the child exchanged the tiles, taking the proper one from the table. The other one – ‘manipulative strategy’, when child tried to obtain a correction by manipulation of tiles lying in the pattern.

Almost all 4-year-old children started their work from manipulation, making rotations. This way could be independent from the previous stage (creating pattern), where they differentiated ‘right’ and ‘left’ tiles.

Example 4. Zuzia (4-year-old girl)

Teacher: *You built a very long pattern, it is enough for us. Now, please close your eyes, I will change something* (she distorted the regularity). *Open the eyes and say if there is something wrong.*

Zuzia: (7s.) *here* (she shows by her hand, pointing a place in the pattern)

T: *why?*

Z: *Because here is in this direction and here in this one* (showing).

T: *so, please, correct it.*

Z: immediately starts to rotate - firstly by one tile, than by both tiles. Later she moves two tiles close to her, still making rotations. Movements starts to be slower and slower.

Finally she takes one tile from the table and finalizes her work.

T: *Perfect! But – did you notice, that the tiles were different in two piles?*

Z: *Yes.*

At the first part of the experiment (creating the pattern) Zuzia muddled up all the tiles on the table. Teacher, wanted to help her, decided to tidy up and put tiles into the proper piles. After that the girl benefits from this. We may make a conclusion, that this ‘teaching episode’ was too weak for Zuzia to take an advantage of in the next stage of the experiment. Therefore it seems that maybe we should focus on children who in own way distinguished two types of tiles. Ola (4-year-old), described below, is one of these children. But, while correcting the pattern, she started from rotations, too.

Example 5. Ola (4-year-old).

O: (2s.) she takes one ‘left’ tile from the pile, puts it in some distance from the patter (to keep a place for the ‘right’ tile). She moves her hand to the same pile, but immediately

recognizes, that this is not what she needed, than takes the ‘right’ tile and makes the whole motif. Next motives she builds very fast, creating long patterns (through the whole table).

T: *Fantastic! And now I will give you a riddle (she changes the tile). Tell me where something is wrong?*

O: (immediately) *here* (she removes one of the double tiles, takes it in the hand – fig. 6).

T: *any why?*

O: *because it should be differently*

She moves one of the ‘left’ tiles to the right place in the pattern, the second one rotates by 180° . Comes back to the first tile and rotates it many times (fig. 7). After some time she changes the action – she starts to manipulate with the second tile (fig.8), and in a moment she turns it on the blank side (fig. 9). She makes some other rotations, one by one with different files. Sometimes she changes an order of tiles (making shifts). Finally she stops to manipulate, keeping the tiles in her hands.

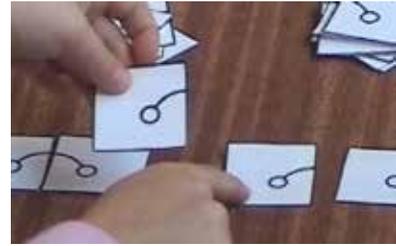

Fig 6

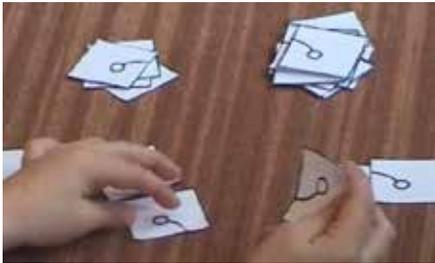

Fig 7

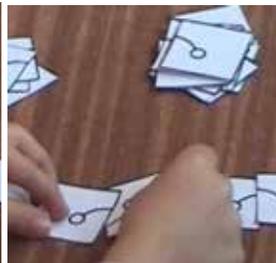

Fig 8

Fig 9

T: *is it possible to correct the pattern using those tiles?*

O: *no (with determination).*

T: *Do you know what I did? I replaced one tile by the other, from the table.*

O: she immediately takes the correct tile from the table and finalizes the work.

Ola showed a great awareness of how to build pattern. In spite of this, she starts its correctness from manipulations. She makes lot of movements, which have different meaning. First movement – parallel shift – is used for the convenience only. Movements used for searching for solution are rotations. She started from rotations, after that an idea of the mirror reflection emerged (when she turned a tile to the back side). If the tile would have been printed on both sides, she would have been successful. In the present situation Ola came back to the rotation, trying to compose the rotation with translation. After an investigation she states that it is impossible to solve this task.

Approach to the ways of repairing patterns vary in subsequent research groups – older children used replaced strategy more often. It is visible in the Table 1

Age	Numer of children	Manipulative strategy	Replaced strategy	Helpless
4	18	13 (72%)	4	1
5	25	9 (36%)	14	2
6	17	6 (35%)	10	1

Table 1: Approach to the ways of repairing patterns

DOES A LACK OF SUCCESS IN REPAIRING PATTERN BY USING ROTATION FORCES A REFLECTION ON PERFORMING MOVEMENT?

It seems that the answer for this question should be positive. It is supported by children's reactions, described in examples presented in this paper: after some trials with manipulations, children draw conclusion, that such actions are pointless. Although their attention was focused on the visual recognition of the motif, performing many repetitive rotations without obtaining expected result caused some awareness about its features. Children were conscious that it is impossible to achieve some placements of the figure by using it.

In order to illustrate the opinion that children can differentiate various types of movements, I use an example taken from the following stages of this experiment. The session took place some days later. In this session, the child who participated in the first session took a role of a teacher and tried to lead an experiment with his/her colleague from kindergarten [2].

Example 6. Michał (6-year-old boy).

Michał's task is to repair the pattern distorted by his colleague, Ola. (fig. 10)

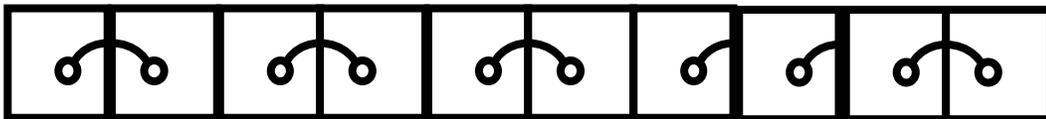

Fig 10

He gazes at the pattern motionlessly (4 seconds), locates the error – two tiles of the same type lying next to each other. Ejects one tile (lying on the right side), moves it over the first one (fig. 11). By 6 seconds he compares the two tiles, making almost unnoticeable rotations with the upper tile. For the moment he stops making any movements, then slightly rotates the bottom tile. Then, he shoves it below the pattern line and inserts the upper tile at this place (fig. 12). He puts his right hand down and for 7 seconds he assesses the relationship between the tiles, than again he makes the minimum turns of the bottom tile (fig. 13) Suddenly he puts the tile back on the pile on the table, and with his right hand he reaches for the proper tile (fig, 14), fits it into the pattern and sits straight on a chair informing by this that his work has been done.

Fig 11

Fig 12

Fig 13

Fig 14

It seems that all the work on a solution of the problem was done in the mind. Diverse manipulations were aimed at obtaining different aims. The first movement - a parallel offset of one tile over another - was an auxiliary movement only, to help to assess the difference between tiles. The boy saw that both tiles are of the same type, but still wondered whether this fact excludes the possibility of axially-symmetrical arrangement. Minimum swivel movements firstly by one tile, and then the by other one testify that the student made the thought rotations.

SUMMARY

Observing children's work it was clear that the possibility of manipulation played a great role for them. Rotation was used as the main movement for investigating of changes in figure's placement. The reader can rightly state that children's behavior was provoked by the research tools. It doesn't change the fact that the children presented many behaviors (mainly during repairing pattern) that require deeper interpretation. Manipulation indicate for a need and a manner of such discovering, going beyond on visual recognition of geometrical phenomena.

Referring the results of observations to basic research questions, I conclude that:

1. Deciphering visual information concerning mutual position of two congruent figures clearly falls into two levels. The first one can be defined as 'I know that' and the second as 'I know how' On the first level, each possible arrangement is perceived on the level of impression and some arrangements are aesthetically preferred. Axis symmetry and parallel shift belonged to these preferred ones. But it does not give a sufficient basis to understand what actions can lead to an expected position of one figure in relation to another. Such understanding, knowledge 'know how' develops with age, what should be associated with gaining more and more experiences (both visual and manipulative). Younger children started from 'blind' discoveries, using manipulations and checking their effects visually. For older children, visual information was frequently sufficient enough.
2. Former information (visual and manipulative), that for axis-symmetrical position two different tiles are needed, does not have to prevent further study of this position through movement. It could be observed in children's behaviour while arranging the pattern and it was even more explicitly marked while improving the band. The fact that children from their own wouldn't

decide to exchange (replace) the tile can be interpreted twofold. One of the possible explanation is “didactical contract”, evoking the tacit conviction that if the teacher asks to repair the pattern that it is possible to do with the use of such tiles which are already used only. Even if so, children showed what are the sources of their actions which appear to be effective for such tasks. Other explanation – (quite obvious) is the lack of knowledge of the properties of isometric transformations. They could have known, that the tiles are right and left, but not, that by using “right” tile they are not able to receive the “left” one by making the physical manipulation on a plane. In mathematical terminology children could assume that the composition of rotation and translation would lead to a mirror symmetry.

3. When a child *searches for* an appropriate arrangement of two congruent figures relative to each other it starts from rotation. Rotations as treated as the basic way of object transforming. They are like an elementary tool used in solving problems with placement of figures on plane.

Children's behaviours related to the use of rotations are easy to explain: In the rotation and mirror reflection pieces looks differently than the model, unlike in the parallel transformation where pieces looks the same as model. In translation an identification of figure and its image is immediate and doesn't require any conscious action. In rotation and mirror reflection the identification is easier after manipulation. Therefore such placements forces making manipulations. The manipulation of flat figures by rotations is more natural (and therefore more spontaneous) than mirror reflection.

However, that is not the explanation that I consider as the most important effect of the carried out research. Much more crucial to me is the statement that children *need* manipulations even in a situation where the former visual cognition suggests senselessness of such actions. This indicates child's need to examine various solutions through movement, the visual information proves to be insufficient.

In psychology, an archetype is defined as reflection or instinctive reaction to the particular situation. Intuition can be treated as thinking on visual level. The results, presented here, clearly show that when child look how to compare one figure with another one placed differently, he/she starts from rotation. The child's attention in such action is still directed by the arrangement of two pieces in relation to each other and not to the movement as such, but these results can suggests that rotation can be used as the first tool for turning children's attention on movements on the plane.

NOTES

1. Here, only one part of the research' scenario is presented. More detailed description can be found in Swoboda, E; *Natural differentiation in a pattern environment (4 year old children make patterns)*, Proceedings of CERME6,
2. In Poland this research method is quite popular. It is taken for observing the resistance of children's behaviors.

AN ACTIVITY ENTAILING EXACTNESS AND APPROXIMATION OF ANGLE MEASUREMENT IN A DGS

Denis Tanguay, Loïc Geeraerts, Mireille Saboya, Fabienne Venant

Université du Québec à Montréal (UQAM), CANADA

Lourdes Guerrero, Christian Morales

Universidad Michoacana de San Nicolás de Hidalgo (UMSNH), MEXICO

We describe here an activity seeking a coordination between geometry and arithmetic. It starts from a geometric manipulation with GeoGebra – the iterate rotation of an isosceles triangle forming a regular polygon – and gradually leads students to consider the divisors of 360 and to reflect upon approximations and exact representations of rational numbers related to angle measurements. Through the issue of measurement in geometry, the activity takes place in the ‘geometer-physicist’ paradigm proposed by Tanguay & Geeraerts (2012) and instilled by Jahnke (2007). We propose an a priori analysis of the activity, set within the theoretical frame of Kuzniak (2010, 2013) on Espace de Travail Mathématique (ETM).

Keywords : linking arithmetic and geometry, exactness, approximation, measurement, dynamic geometry software, geometer-physicist’s paradigm

In his most recent contribution to the symposium *Espace de Travail Mathématique* (ETM 3, Université de Montréal, October 2012), A. Kuzniak (2013) reflects, from a teaching and learning standpoint, on the role expected from bridging different mathematical fields when students are involved in a problem-solving process requiring a back and forth between two fields [1]. As a typical example, we may think of these problems in which one must optimize the area of a polygon subject to inscriptibility constraints, and where geometry is bridged to the algebraic/functional field. In the present article, we propose the *a priori* analysis (Artigue, 1988) of an activity mingling geometrical work and arithmetical work with GeoGebra. We will set it in a theoretical framing based on the work of Kuzniak (2010, 2013) on ETMs. By doing so, some aspects of the frame will be examined.

PHYSICS, BETWEEN EVERYDAY THINKING AND MATH THINKING

In a 2007 article, H. N. Jahnke compares generally valid statements depending on whether they come from mathematics, from physics or from everyday life. General statements from everyday life and physics share their empirical basis and the fact that the set of all conditions limiting their scope of validity is virtually unattainable. In everyday life, searching for completeness as regards these conditions is more often irrelevant. For instance in a given specific context, one may examine some precise conditions invalidating the statement “every evening, Johnny comes back from work around 18:00”, but trying to figure out all possible misfortune in the world would be foolish. By contrast in physics, we try to relate each general statement to the most accurate domain of validity, even if we know that the theory will always remain

subject to falsification by new observed phenomena (e.g. Popper, 1991). In established mathematics, determining the domain of validity of a general statement is not only possible but essential: it is indeed what accounts for the way mathematics operate, according to which the set of conditions is fixed and closed by the building of a (preferably axiomatized) theory.

In this respect, physics could be situated at the passage between the two others: as in mathematics, general statements in physics are connected by hypothetico-deductive developments that integrate them into a network and build them up as a theory. Yet the empirical bases of physics are not disqualified but rather enriched: any experimental verification about a statement not only corroborates it, but also increases the conviction that all other statements connected to it in the network are true. These considerations bring Jahnke (2007) to advance that in the classroom, dealing with mathematics as in physics would provide a more harmonious transition between everyday life thinking and mathematical thinking, and would also lay out a stronger epistemological foundation for teaching proof, with respect to its aim and to the type of certainty it brings.

A TRANSITION PARADIGM RECONCILING MEASURES AND PROOF

Following Jahnke, we propose in Tanguay & Geeraerts (2012, 2013), for the first years of secondary school, an approach of synthetic geometry [2] modelled after experimental physics. We speak of it in terms of *paradigm*, namely the *geometer-physicist paradigm*. We use the term ‘paradigm’ first to put forward its role as an articulation between two paradigms, the GI paradigm referring to the geometry of perception and intuition (Houdement & Kuzniak, 2006) and the GII paradigm referring to classical euclidean geometry. But also to stress the importance, regarding this approach, of considering the class (the school group) as a scientific community (Wenger, 1998) where are decided and assumed the motivations, the premises, the (didactical) contracts and prescriptions at the basis of such an experimental practice: it appears to us an essential condition for engaging students into progressively moving this practice towards the building up of a theory. Finally, because according to the historical/epistemological analysis of Jahnke (2010), such an approach would have been the one followed by the Pre-Socratic geometers, thus being at the very source of the developments that led to Euclid’s *Elements* as a culmination.

With this paradigm, experimentation and empirical validations are brought back into the fold. In geometry, experimentation is mainly conveyed through construction and measurement: with a ruler, a protractor, a compass, or with specific functionalities of dynamic geometry software packages (DGSs) such as *Cabri-Géomètre* or *GeoGebra*. Researchers and teachers have often blamed measurement for engendering a hindrance to proof and proving: why prove something that can be verified simply by measuring? The measurement tools of DGSs magnify this effect (e.g. Boclé, 2008) because of their precision, but also because the dragging functionality allows an efficient investigation of examples. In the approach that we propose, each tackled

statement is written and diagrammatically illustrated on a card (24 cm × 16 cm). Statements verified experimentally and statements proved deductively are systematically distinguished, and the two different statuses are made apparent on the cards. These are classified in a ring binder that each student has always at hand in his working space. The binder concretely accounts for the theoretical frame of reference. For more details, see Tanguay & Geeraerts (2012, §3). Empirical verification does not come into conflict with proving to the extent that every experimentally validated result keeps an hypothetical status which is explicitly stated and exhibited, and that the certainty of any deductively proved result remain dependent on results the proof uses as ‘rules of inferences’ (Duval, 1991 or Tanguay, 2007), in particular on the hypothetical results among them :

The epistemological motivation of proof is not to be founded on the idea that proofs in contrast to measurement provide absolute certainty, but on the idea that proofs open new and more complex possibilities of empirical corroboration. In short, in an empirical environment *proofs do not replace measurements but make them more intelligent*. (Jahnke, 2007, p. 83, italics from the original text)

MEASUREMENTS, APPROXIMATIONS AND NUMBERS

To consider experimentation with measurement as would do a physicist in his lab, one must assume that measuring, even with DGSs, provides nothing more than approximations (see Tanguay & Geeraerts, 2013). In our opinion, neither textbooks nor ministerial programs deal adequately with this issue, leaving in limbo the epistemological status of measurement in geometry : « It is for us symptomatic that institutional teaching resources rebuke equalities such as $\frac{4}{3} = 1,33$ or $\sqrt{2} = 1,414$, but in the same time agree without a murmur with equalities such as $mes[AB] = 5$ cm, in contexts where inferred measures and measures obtained with the geometry tools are blithely combined » (Tanguay & Geeraerts, 2012, p. 21; our translation).

Besides, discussing about measurements as approximations allows discussions about the ideal character of the measured objects : points without dimension, line segments and lines without thickness, angles sprawling at infinity, with edges of zero measurement... These discussions then lead to institutionalizations whose content is no more the sole responsibility of the teacher. For instance, we may well imagine a class-discussion about the following GeoGebra display :

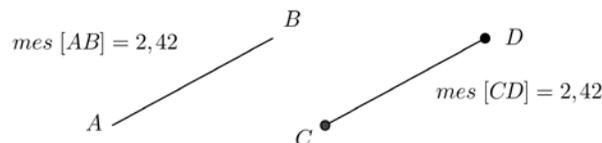

Fig 1 : what is the ‘thickness’ of point A ? of point C ?

If we now analyse how measurement can be situated into the *mathematical working space* (Kuzniak, 2010, 2013), using Kuzniak’s two planes model, we observe that

measurement contributes to, and is part of, both *figural genesis* and *instrumental genesis*. The latter is of course related to the measuring tools. As for figural genesis, the outcome follows from the fact that while putting a ruler down on a line segment with the aim of measuring it, the student tracks it down and isolates it as the side of a given figure, whose *dimensional deconstruction* (Duval, 2005) is thus sparked off: the sides must be located as the boundaries of the shape, the « corners » as endpoints of the sides, the endpoints being matched with the graduations of the ruler. This dimensional deconstruction is certainly resulting from a form of visualization but also refers to a set-theoretical modelling of the plane, with points as (atomic) elements and the sides as subsets of the figure. In this sense, through the cognitive activity of measuring, there is indeed a projection into the theoretical frame of reference, here the one pertaining to GII. Recall that the theoretical frame of reference is in Kuzniak or in Coutat & Richard (2011) one of the two poles of *discursive genesis*.

Besides, the effort of visualization on the measured figure – the figure as a ‘*representamen*’ or ‘signifier’ in the *epistemological plane* of Kuzniak (2013) – is built on an effort of coordination with other signifiers, namely the numbers resulting from measurement: these numbers constitute a ‘property’ of the measured objects but *are not* these objects themselves. So, it is not a coordination between registers of representation in Duval’s sense (1993) because the *signified* are not the same. Moreover, they belong to two different fields, the field of (synthetic) geometry and the field of arithmetic. In the perspective of Kuzniak’s theoretical framing, it is as if the epistemological plane had been split in two, with a plane in each field and round trips between the two via the cognitive plane. Through these considerations, one can evaluate the complexity of what is involved in a measuring activity, be it conducted for construction, validation or experimentation purposes.

Regarding complexity, the subject is indeed not exhausted. In a geometric problem-solving context, it happens frequently that the task also deals with *computed* measures, for example when some measures are inferred from Pythagoras’ or Thales’ theorems, thus giving rise to irrational numbers or rational numbers with infinite decimal expansion. The representations of all the related numbers may then come from several registers [3]: the register of finite decimal or repeating decimal (with the period overlined), the register of quotients written in the form p/q , the register of representations using the root symbol, etc. There is then a need for a *coordination between registers*, as the one brought up by Duval. But in order for this coordination to be ‘scientifically coherent’, the non exactness of the decimal numbers resulting from measurement must be fully taken into account. For an example of a problem lacking in such a coherence, see the problem *Marie et Charlotte* in Kuzniak & Rauscher (2011) or in Kuzniak (2013).

In sum, if measuring in geometry belongs mainly to mathematical activities relevant to figures, it also resorts to numbers, so to a field that is not synthetic geometry and has its own representations and theoretical references. We insist that in that instance, the duality exactness-approximation should be a teaching goal and issue. Then almost

inevitably, the issue will echo with the representations of rational and irrational numbers and their approximation by decimal numbers, and in parallel with the problem of (visually) representing ideal geometrical objects. In the proposed activity, the measurements are not carried out with the usual geometrical tools but rather, are obtained from the ad hoc functionalities of GeoGebra. Then, students' relationship to the displayed numbers gets more intricate (Tanguay & Geeraerts, 2013). The issue of exactness, for both the measurements and the associated numerical representations, is directly linked to the possibility of 'closing' (or not) the regular polygon to be produced. We put forward the hypothesis that regarding these issues, the discussions and reflections thus prompted will be rich and significant.

A SITUATION PLACING AT ITS CENTRE EXACTNESS OF MEASUREMENT AND OF NUMERICAL REPRESENTATIONS

Description

The following teaching situation has been designed by a group of researchers from Quebec and Mexico, working in collaboration. We started from a situation designed by L. Guerrero, in which working on regular polygons with GeoGebra was planned. The situation was intended for students from the beginning of secondary school (12-14 years old). Revising it brought us to extend the task towards arithmetic, via the measures of the angles involved. The arithmetic topics singled out – mainly divisors and divisibility – and the study of regular polygons are prescribed subjects from the secondary curricula of Quebec and Mexico.

The activity provokes a back and forth between geometry and arithmetic by considering the GeoGebra displays of the measures related to a well chosen angle. It can easily fill up two lessons. The first lesson involves the decomposition of the n -sided regular polygon in n isosceles triangles grouped around the centre, the decomposition being linked to the divisibility of 360 by the degree measurement of the central angle. The students are thus brought to examine, within a geometrical context, the list of divisors of 360. They work in teams of two, one team per each computer terminal. The instructions are open :

The triangle $\triangle ABC$ visible at the screen is isosceles, with $[AC] \cong [BC]$. Form all the regular polygons you can by rotating $\triangle ABC$ around point C. You may vary $\angle ACB$ either with the slider α or by typing directly α , the measure of $\angle ACB$, in the given box. The slider n allows you to change the number of triangles obtained as images of $\triangle ABC$ by repeated rotations around centre C and of angle α . Do you know the name of each polygon you formed? As you go, fill in the following table. You can add as many lines as you want.

Measure α of angle ACB	Number of triangles, images obtained by rotating $\triangle ABC$	Name of the regular polygon you formed
	$n =$	
	$n =$	
	$n =$	
	$n =$	

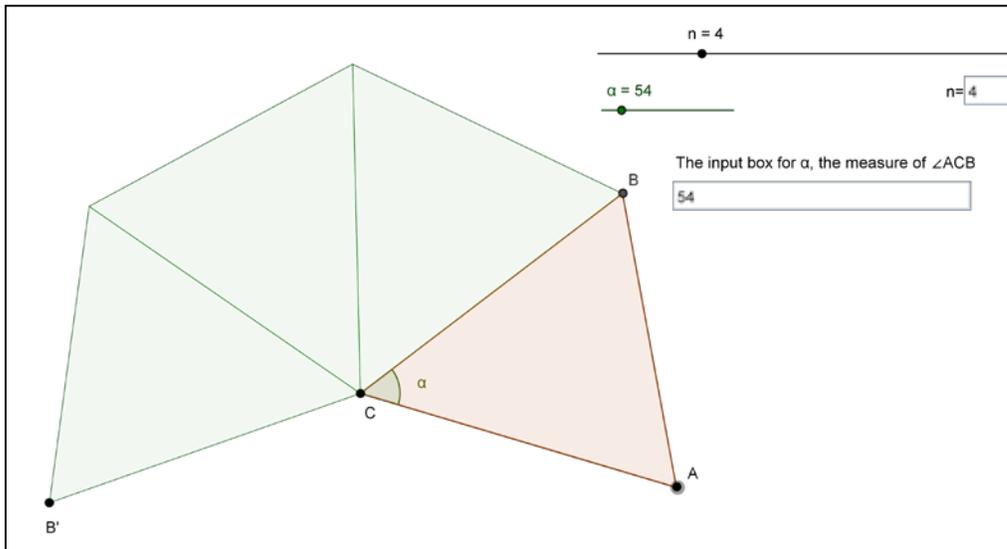

Fig 2 : The GeoGebra screen given from the start

To do the task, students lean on the fact that any regular polygon can be decomposed in as many isosceles triangles as there are sides. These triangles share a common vertex, the centre of the circumscribed circle. Some knowledge elements are thus activated here, that the students could have previously met or as well, that they may be discovering through the activity.

A priori analysis : the divisors of 360

The students can either fix a value for α and modify n afterwards, trying then to ‘close’ the figure; or keep n fixed and modify the angle, by exploring with the slider or by entering directly a value for α . We assume that exploration by trial and error with the two sliders will spontaneously be initiated, but will remain relatively ineffective: because of the imprecise control of the angle with the slider, students will probably obtain nothing more than the usual polygons met in elementary school, with standard values for α : the square, the hexagon, the octagon, possibly also the equilateral triangle. It should be noticed that the colour of $\triangle ABC$ differs from the colour of its images, enabling an easy perception of overlaps. In this respect, it is important to provide the students with a slider for n [4] and not only a box where the number is entered. Indeed, seeing the triangles unfurl like a fan when dragging the

slider allows to realize that the value for n is not the right one when $\triangle ABC$ and its images coincide perfectly, e.g. when $n = 5$ and $\alpha = 90^\circ$.

We assume that through this trial and error process, the link between the correct value of n for a given α , and the fact that $n\alpha$ must be equal to 360° , will emerge. By seeking for a better control of their trials, students will explore this link in a more systematic way, by considering the divisors of 360 and by using the input box for α .

We put forth the hypothesis that while engaging a whole-group discussion at about two-thirds of the first lesson, some teams will invoke the divisors of 360 (of course in their own words). In his/her institutionalization, the teacher clarifies the underlying reasoning and establishes, with the whole class, the list of all divisors of 360. Complying with the strategies he/she observed from his/her students, he/she can construct this list by considering the possible values for n (along an increasing list starting at 3) or by considering the values for α along a decreasing list, beginning with $\alpha = 120$. For each divisor, he/she asks the class what is the associated value, of α or n , respectively. He/she shows onto the screen the corresponding polygon and gives its name. He/she supplies the list of divisors with 1, 2, 180 and 360. He/she asks the class if an associated regular polygon could be considered for each of these four values. It appears to us important that the teacher carries the discussion to its ending, namely that depending on the adopted strategy, we won't keep the same divisors to construct the regular polygons : either we keep 1 and 2 as the degree measure of the central angle and we set aside 180° and 360° , or we set aside 1 and 2 as the number of sides and we construct polygons with 180 and 360 sides. At this point, the teacher may suggest that fractional angle measures are possible, for example by considering the regular polygon with 48 sides, and central angle measuring $15^\circ \div 2 = 7,5^\circ$. The status of these 'special cases' must then be explicitly clarified with respect to the notion of *divisor*.

A priori analysis : the heptagon

The goal of the following lesson is to tackle the notion of approximation, both from a numerical standpoint (the written representation, exact or not, of a rational number) and a geometrical standpoint (the status of the figure).

The starting point is brought up by the teacher, who comes back to the cases where the division of 360 by n does not result in an exact decimal value. He/she asks students to investigate these cases further. In principle, the case of the heptagon ($n = 7$) should be the first to turn up. Research (e.g. Krikorian, 1996) shows that spontaneously, secondary students don't make use of fractional notation. We anticipate that students will enter in the α box the approximation of $360/7$ they'll get from their pocket calculator. GeoGebra then displays 51.43, its standard round up. The teacher must watch for teams who got to that point, first to ask them for a verification that the polygon is well closed, using the zoom [5]; and once they acknowledge that the polygon *is not* well closed, to show them how to get the maximum of 15 decimals into the menu bar (\rightarrow Option \rightarrow Rounding). Then the

teacher gives the following instruction : “add one by one the decimals of $360/7$ in the input box for α , and at each step, zoom in to check if the figure is well closed”. The students must then find a way to obtain the decimals beyond the scope of their pocket calculator.

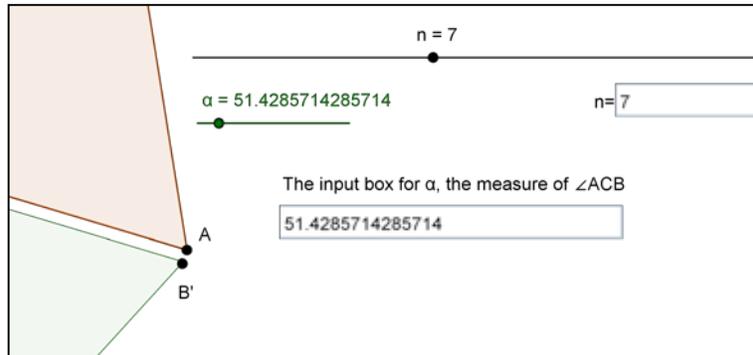

Fig 3 : a close zoom, for an approximation of $360/7$ with 13 decimals

Even with 13 decimals, a sufficiently close zoom shows a figure which is not well closed. Entering 15 decimals or more, GeoGebra (version 4.0.41.0) rounds up at 14 decimals and displays 51,42857142857143. Then as close as we get with the zoom, we see a polygon *seemingly* closed. When the teams have reached that point, a whole-class discussion is called upon. The issue of the exact value of $360/7$ is raised : “what is it? Is it 51,42857142857143? If I multiply this number by 7, do I get 360 back? Compute the product by hand.” In the same time, the teacher enter the multiplication into the input bar (at the bottom of the screen), and 360 is displayed in the *Algebra View*. “Are these computations by GeoGebra exact? The polygon appears to be closed but can we rely on GeoGebra here? It seems that we have reached the limit of the software! So, this polygon with seven sides, we can close it or not?”

In accordance with our theoretical framing, the idea is here to bring students to reflect on the ideal character of the heptagon regardless of what is produced and seen on the screen, and then to extend this ideal character to the already produced polygons and ultimately, to any geometrical object. Going back to arithmetic, students reflect upon what exact angle should be produced (and hence measured) to be able to construct this ideal heptagon. This brings them to consider in parallel the notion of exact representation of a rational number.

It may be an opportunity for asking students to do the long division of 360 by 7 by hand. The teacher may then explain the period and insists that the exact value of $360/7$ needs, to be written exactly into a decimal form, an infinity of digits or else, the representation with a bar over the period to account for this infinity. “Under what form can we propose this exact value to the software? Is it but possible? And what about entering $360/7$ into the box, as a value for α ?” Even with “ $360/7$ ” entered in the input box, GeoGebra displays 51,42857142857143. The teacher may then

confirm that the numbers handled by the software are approximations. He/she moves on to say that the regular polygon with 7 sides does exist (in theory), and that the exact measure (in degrees) of its central angle does not admit a finite decimal expansion, but can nevertheless be exactly represented by the notations $\frac{360}{7}$ or $51,428571$. He/she concludes by stating that there exists a regular polygon with n sides for each integer n greater than 2 and that for each one, the central angle measures $\frac{360}{n}$ degrees.

CONCLUSION

So in a meaningful context, the students become aware of the dualities *ideal object – visual representation*, *exact measurements – approximations* in geometry, and link these to the representations of rational numbers. They know that some fractions don't have a finite decimal expansion and they now understand that one must not make use of the equality sign between such a fraction written in the form $\frac{p}{q}$ and any notation referring to a finite decimal expansion.

The activity has been the object of a pre-experimentation outside school with five children (aged 11 to 13), and our hypotheses have then been largely confirmed. More systematic classroom experimentations, in Quebec and Mexico, are to come. The activity is part of a larger research programme about the geometer-physicist paradigm (Tanguay et Geeraerts, 2012, 2013), in which more issues pertaining to measure and measurements will be explored. This programme is also in its early stages.

NOTES

1. The French word for *field* used by Kuzniak is *domaine*. It is closely related to the word and concept *cadre* considered by Douady (1986). Here, *field* should be understood according to a meaning referring to school mathematics, rather than to advanced mathematics.
2. By *synthetic geometry*, we mean geometry without coordinates, as opposed to *analytic geometry*.
3. They are indeed distinct registers in Duval's sense (1993), since for example one cannot add or multiply 5,6 with $4\sqrt{2}$ or with $360/7$ without changing the representation of one of the two numbers.
4. Hence from the teacher and a teaching perspective, providing a slider for n is a form of *instrumentalization* of GeoGebra, in Rabardel's sense (e.g. Vérillon & Rabardel, 1995).
5. The zoom is easy to use with GeoGebra : use the mouse wheel ! To avoid the figure being pushed off the zone we want to zoom in – in this instance the neighbourhood of point A – one must just insert the mouse cursor in this neighbourhood.

MATHEMATICS TEACHERS' PERCEPTIONS OF QUADRILATERALS AND UNDERSTANDING THE INCLUSION RELATIONS

Elif TÜRNÜKLÜ, Elif Nur AKKAŞ, Funda GÜNDOĞDU ALAYLI

DEU, Buca Faculty of Education, Department of Elementary Mathematics Education

Abstract: *The aim of this research is to investigate how mathematics teachers comprehend the properties of specific quadrilaterals, how they construct the relations and classify quadrilaterals. This research was conducted on 9 mathematics teachers. 7 problems were designed. Semi structured interview and content analysis was used. The results indicated that properties of quadrilaterals which are best known by participating teachers were square and rectangles. The another results of the study was that teachers correctly defined properties related angles and sides quadrilaterals but have problems with properties related diagonals. In addition to this results some teachers were not classify quadrilaterals, and the teachers who use hierarchical classification were not fully established family relations.*

Key Words: Perceptions of Quadrilaterals, Classification of Quadrilaterals

THEORETICAL FRAMEWORK

Concepts are quite important in mathematics. In order to express the entire cognitive structure about concept, Tall and Vinner (1981) have used the term “concept image” and stated that concept image includes mental image about the concept, properties and processes about the concept. When considered in the sense of geometry, there are 3 different situations about geometrical concepts. These are definition, image and properties of the shape of geometrical concept. Definitions are structured in a way that would features minimum information of the properties of concept. It was aimed for definitions as the basic principle that they would be economically short and understandable (De Villiers, 1998; Fujita, 2012). Apart from the definitions of concepts, every geometrical concept has a visual image. Visual image might be one step further than the concept. In this sense, typical (prototype) sample are the key factor. Properties of concepts are key factors in the context of making relations between concepts, differentiating concepts, making generalizations of concepts and finally making classification.

Classification of quadrilaterals is regarded important in making relations between quadrilaterals and therefore in solving problems and proof studies in geometry. Because if a quadrilateral is in the same family with another quadrilateral than solutions, proofs, properties etc. raised for this quadrilateral would be valid for the other one as well. In this sense, De Villiers (1994) points out that individuals can make two types of classification of quadrilaterals. The first one is hierarchical classification which done by relating quadrilaterals under subset according to the properties they have. The other one is partition classification which means classification of quadrilaterals in separate sets individually according to the properties they have. According to de Villiers (1994), hierarchical classification was defined as

a type of classification which makes family relations of quadrilaterals more understandable. As various researchers have explained, making hierarchical classification of individuals and dominating education in this sense should be supported (De Villiers, 1994; De Villiers 1998; Fujita, 2012).

When the literature is studied, there are various studies about perception of quadrilateral nearly in every age group. In these studies it is seen that students are addressed questions about quadrilaterals, listing their properties, making separation and relation between them and making classification.

In the studies which are carried out for understanding of quadrilaterals by naming the drawn quadrilaterals or drawing the named quadrilaterals; different types of square, rectangle, rhombus and trapezium were asked to students in different age group who participated in the study. As a result of these studies, it was determined that quadrilaterals which have prototypical drawing in general were to a large extent marked or named correctly (Okazaki and Fujita, 2007; Fujita and Jones, 2007; Fujita, 2012; Clements, Swaminathan, Hanibal and Sarama, 1999; Monaghan, 2000).

The role of definition is very important for perception of quadrilateral. In the literature studies, personal definitions which were made free from academic definition were considered in understanding the perception so, the studies were focused on how the quadrilaterals were defined individually. In the study of Fujita and Jones (2007), it was found that the percentage of correct answer of prospective class teachers about quadrilaterals is quite low.

In the studies in which were asked to classify quadrilaterals, it was detected that great majority of the students make partition classification (Erez and Yerushalmy, 2006; Monaghan, 2000; Fujita and Jones, 2006; Berkün, 2011). The reason was stated as the images of quadrilaterals and the effect of these images on inclusion relations of quadrilaterals.

In the study of Okazaki and Fujita (2007) (with students aged between 15 and 18 and prospective class teachers) in which it was analyzed how the students make relations among quadrilaterals, it was determined that around 50% students gave correct answers for the question of whether rhombus and rectangle are parallelogram or not. Moreover, they have answered the view that square is rectangle and rhombus with quite a low percentage such as 35%. There are different studies which states that the relation between rectangles are defined correctly in low rates (Okazaki and Fujita, 2007; Elia, Gagatsis, Deliyianni at al., 2009; Heinze and Ossietzky, 2002; Fujita and Jones, 2007; De Villiers, 1998). In these studies it was found that not being able to make relation between square-rhombus and parallelogram-rectangle result from the fact that their angles are not 90^0 . Similarly, the relation between square-rhombus and parallelogram-rectangle could not be done since their edge lengths are not same and they were included in different family.

Perception and classification of geometrical shapes contribute solution of problems both in real life and in different fields of mathematics (NCTM, 2004; Martin and

Strutchens, 2000). As it's understood from the mentioned studies, it was observed that individuals belonging to different age groups don't have difficulty with the recognition of quadrilaterals, yet it was observed that they have difficulty with the classification of quadrilaterals and with the understanding of relations between them. However, the maths teachers and primary school teachers have great responsibility in the correct description of quadrilaterals by the individuals, and relating them to each other and classification of them by the individuals. Maths teachers have an important role in especially perceiving the relations of quadrilaterals and classification of them, which necessitates higher cognitive abilities. That's why, the knowledge of maths teachers about quadrilaterals must be checked in detail. Moreover, when the literature is investigated, there is no study showing the knowledge of maths teachers about quadrilaterals. For this reason, it is expected that this study will compensate for the loss in the literature.

THE PURPOSE OF THE RESEARCH

In this study it was aimed at determine how mathematics teachers comprehend the properties of quadrilaterals, how they construct the relationship between quadrilaterals and classify them.

METHOD

In this study, semi-structured interview was done with the method of qualitative research. In the interviews participants are asked seven questions five of them are open-ended and two of them are multiple choice questions. The interview questions were prepared based on the related literature. Questions were composed of three sections. In the first section teachers were asked how they define basic features of quadrilaterals, in the second section how they relate quadrilaterals in pairs, in the third section questions were about the family relations between quadrilaterals. Sample questions about each section are in the Appendix 1. Interviews were done with 9 middle school mathematics teachers who work at 8 different schools at a city in Turkey. Three of these teacher's teaching experience is less than five years, of the two between five and ten years, of the other two between twenty and ten and of the last two have more than twenty years of experience. According to the year of teaching experience the ages of the teachers range from twenty-five to fifty. The two teachers who participated in the research graduated from training institute, which had a two-year education and the others graduated from an education faculty, which has a four-year education years. All the interviews were recorded with audio recorder. Before the data was analyzed, each audio record was fully transcribed into verbal data. Content analysis technique was used in the analysis of obtained data.

FINDINGS

In this study, data were obtained by middle school mathematics teachers, analyzed under three main titles such as perceptions of quadrilaterals and understanding of the relations of quadrilaterals and classification of quadrilaterals.

Mathematics Teachers' Perceptions of Quadrilaterals

In the study, teachers' knowledge about the properties of square, rectangle, parallelogram, rhombus and trapezium was questioned.

It was determined that teachers correctly define properties of parallelism and diagonal of square and rectangle as well as properties of angle and vertices. Only one teacher was not sure in defining diagonal property of rectangle.

In data about parallelogram, the first perception of teachers was the parallelism of vertices. As it is understood from the statement of a teacher, *"if it is parallelogram, then their opposite vertices are parallel"* that since the name includes the term parallel, the first perception was parallelism.

It was observed that teachers' knowledge about properties of angle and vertices of parallelogram are mostly correct but they have doubts about properties of diagonals. This irresolution is related with the equivalence of lengths and angle bisector.

The first perception of teacher about rhombus is the equivalence of vertices due to the name of quadrilateral. The view of a teacher suitable about this condition was:

"We teach it as a quadrilateral whose all vertices are equal. Even when defining this quadrilateral, we reflect as it diamond shape colloquially." (T7)

As it is understood from the statement of T7, teachers identify rhombus with diamond shape. Similarly, it was observed that other teachers use same statements.

Moreover, similar to parallelogram, it was observed that teachers' knowledge about properties of angle and vertices of rhombus are mostly correct but they have doubts about properties of diagonals. This irresolution is related with the equivalence of lengths and angle bisector.

It was determined that teachers have two different views about the shape of trapezium. It was found that this diversity of views results from "parallelism of sides" and it was defined as the parallelism of "at least two sides" or "only 2 sides". Views of two different teachers:

"Only two sides of trapezium can be parallel" (T6)

"According to the property of trapezium (hesitates), at least two opposite sides should be parallel." (T8)

It was observed that teachers have problem with angle properties. However most of the teachers (7 teachers) stated that "side angles which are not parallel are supplementary angles" others (2 teachers) stated that "consecutive angles are supplementary angles".

It was determined that some of the teachers both know the properties of trapezium and have different perception about formal status of trapezium. Statements about this view are:

"Trapezium is the form of rectangle whose sides have different cut" (T2)

“Considering it as the divided form of triangle but right and left sides are not parallel like the sides below and above.” (T7)

When the explanations of Ö2 and Ö7 are analyzed, it is observed that they relate trapezium with the images of other quadrilaterals in the sense of form.

Mathematics Teachers’ Understanding of the Relations of Quadrilaterals

Teachers who participated in the study were asked to make bilateral relations among quadrilaterals. Teachers making relations of between square-rectangle, rectangle-parallelogram, square-parallelogram, square-rhombus were determined. According to data, it was observed that most of the teachers focus on common properties and differences rather than classification.

For the common and different properties of square and rectangle, it was observed that they focus on angle, vertices and diagonal properties. Only one teacher make the relation that square is a special kind of rectangle. The statement of this teacher is as such:

“For example students are asked. Is square a rectangle or not? Most of the students say it is not. But I emphasize that square is a rectangle, specially.” (T6)

The statement of a teacher among 8 others who regard the relation between square and rectangle in the sense of common and different properties is as such:

“... there are short sides and long sides in rectangle as well. But all the sides of square are equal, yet opposite sides of rectangle are equal. Diagonals of rectangle do not intersect perpendicularly but diagonals of square do so. All the sides of rectangle are not equal but all the sides of square are.”(T3)

As it is understood from the statement of T3, they make relation between square and rectangle by focusing on the differences of sides and diagonals. Moreover, from this statement it can be concluded that teacher first of all visualizes rectangle as a quadrilateral which has short side and long side.

Properties of angle and diagonal were mentioned for the common and different properties of rectangle and parallelogram. However, properties of diagonal were stated wrong by most of the teachers. For example, a teacher pointed out a wrong property by saying *“diagonal length of both shapes is equal.” (T4)*

Apart from the answers which are based on common and different properties of rectangle and parallelogram, there are teachers who make family relation as well. One of these teachers gave this answer.

“... while teaching rectangle, we mention that it is a special kind of parallelogram. We make such a relation while teaching rectangle in order to show that we can obtain it out of a parallelogram.” (T8)

In addition to these relations, a teacher made a relation based on the image rather than the properties of rectangle and parallelogram. The answer of this teacher was:

“... think that we make a rectangle pattern from modeling clay, when we pull from opposite corners equally we obtain a parallelogram, so we can make a parallelogram out of a rectangle” (T3)

A teacher who participated in the study stated there would be no relation between rectangle and parallelogram with this sentence.

“All the properties of rectangle are different from parallelogram, they do not match with each other.” (T5)

Angle and side properties were mentioned for the common and different properties of square and parallelogram. There is one teacher who makes family relation for square and parallelogram. This teacher gave such an answer:

“... it is valid for parallelograms. Because it is parallelogram. Rectangle, square are parallelograms. We should give this message.” (T6)

3 teachers who participated in the study made no relation between square and parallelogram. One of these teacher stated that:

“All the properties of square cannot be valid for parallelograms, we cannot make a relation because there are too many incompatible properties.” (T3)

Angle and diagonal properties were mentioned for the common and different properties of square and rhombus.

For the relation based on angle properties, it was stated that if all the angles are right angle that the rectangle is square, if not then it is rhombus. There is one teacher who makes family relation (T6). In addition to these relations, two teachers made a relation based on the image rather than the properties of square and rhombus. Answers of these teachers are:

“the rectangle when you press one side of the square is rhombus.” (T1)

“If we pull the sides of square to one side equally then it is rhombus. We should pull the sides equally because opposite sides are equal.” (T3)

Mathematics Teachers’ Classification Of Quadrilaterals

Teachers were asked to classify quadrilaterals in the study. According to data obtained from teachers’ answers, there are 3 situations for quadrilaterals classification. These are:

1. Not making any relation among quadrilaterals (T1, T2, T5)
2. Partition classification of quadrilaterals: Making a relation with a table only according to common and different properties. (T4, T7)
3. Hierarchical classification of quadrilaterals: Making relation with specific family relations. There are 3 different schemes for this situation.

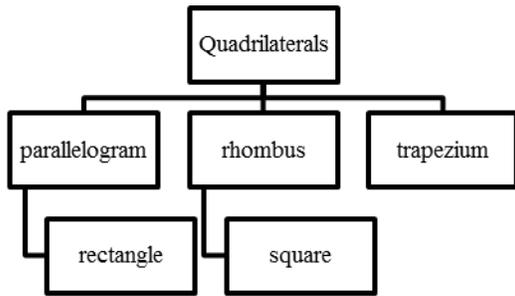

Figure 1: (T3, T8)

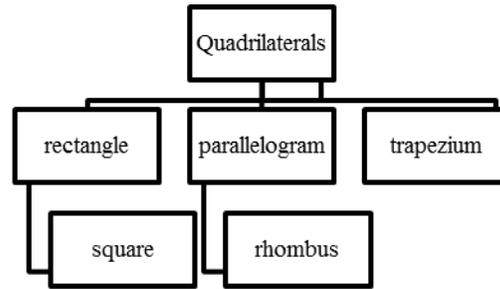

Figure 2: (T9)

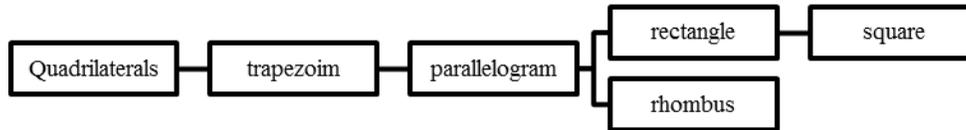

Figure 3: (T6)

In Figure 1, it is seen that teachers interpret square as a special kind of rhombus, but not a special kind of rectangle; interpret rectangle as a special kind of parallelogram but cannot interpret rhombus as a special kind of parallelogram. This results from the fact that teachers make interpretation based on side lengths. In this way, they could make relation between square and rhombus whose side lengths are equal and between rectangle and parallelogram whose only opposite side lengths are equal.

In Figure 2, it is seen that teacher interpret square as a special kind of rectangle and also interpret rhombus as a special kind of parallelogram but cannot interpret square as a special kind of rhombus. This condition results from the fact that teacher makes interpretation based on angles. In this way, they make relations between square and rectangle whose angles are 90° and between parallelogram and rhombus whose angles are not 90° .

When the figures for the third situation were analyzed, it is seen that teachers cannot make family relations totally. It was seen that teachers who have made Figure 1 and Figure 2 separates trapezium from quadrilaterals but teacher who made Figure 3 includes trapezium into the classification with other quadrilaterals. Since teachers generally do not consider property of parallelism, this causes them to ignore the fact that square and rectangle are parallelogram. It was stated that only 3 teachers interpret square or rectangle as parallelogram.

CONCLUSION

Generalization was not done in this study which was carried out with 9 mathematics teacher; yet in the light of data, specific profiles for the teachers' perception of quadrilaterals were put forward. It was determined that teachers who participated in the study correctly define properties related angles and sides of quadrilaterals but have problems with properties related diagonals. It was observed that although teachers have problems about properties related diagonals of quadrilaterals, they

focus rather on diagonal properties while establish relationship between quadrilaterals. However, it was seen that they define properties of diagonal wrongly. In Monaghan's (2000) study, in which he presented children's views (aged 11-12 years) of the differences between some quadrilaterals; he concluded that the images, properties related sides and the angles are focused on for differences between quadrilaterals, but not properties related diagonals.

The geometrical figures among mentioned quadrilaterals which is least known by participating teachers was "trapezium". It was observed that teachers have difficulty in identifying the image of trapezium. This condition was observed in the study of Berkün (2011) which was carried out with earlier ages.

While parallelism is not prominent for square, rectangle and rhombus in the findings, it was stated among the properties of parallelogram and trapezium. Similar findings were observed in the studies of Fujita (2012), Fujita and Jones (2007), Okazaki and Fujita(2007), Heinze and Ossietzky (2002).

Three of the teachers who participated in the study could not make classification. Contrary to most of the studies (Berkün, 2011; Monaghan, 2000; De Villiers, 1994), the some of the teachers (4 teachers) could make hierarchical classification. However, they could not correctly and fully establish family relations. The reason of this was that teachers focused on only angle and side properties, could not interpret and relate all the properties together.
