APPENDIX 1.

1) Question Aiming at Description of Quadrilaterals:

A teacher asked his students the features of a trapezium. The answers of five students are as follows:

Student 1: The two opposing sides are parallel.

Student 2: The consecutive angles are complimentary.

Student 3: There are two types of trapezium. Right trapezium and isosceles trapezium.

Student 4: The high of a right trapezium is the one which is perpendicular to the paralel sides.

Student 5: The domain(alan) of each trapezium is the multiplication its height with the half of the total lenght of lower base and upper base.

When you look into the answers, which ones are correct and which ones are wrong? Why?

2) Question Aiming at Relations of Quadrilaterals:

Answer the questions below:

- a) What is difference between a sguare and a rectangle?
- b) What is difference between a rectangle and a parallelogram?
- c) What is difference between a sguare and a rhombus?
- d) What is difference between a trapezium and a parallelogram?

3) Question Aiming At Classification:

Below are five items about quadrilaterals. Which one is correct?

- a) All the features of a rectangle are the same for all squares.
- b) All the features of squares are the same for all rectangles.
- c) All the features of a rectangle is the same for all parallelogram.
- d) All the features of squares are the same for all rhombus.
- e) None of the choices above is correct.

PLANE GEOMETRY: DIAGNOSTICS AND INDIVIDUAL SUPPORT OF CHILDREN THROUGH GUIDED INTERVIEWS – A PRELIMINARY STUDY ON THE CASE OF LINE SYMMETRY AND AXIAL REFLECTION

Seval Yetiş, Matthias Ludwig

Goethe-University Frankfurt

Based on a detailed literature review, previous studies related to diagnosing and supporting (DS) children with mathematical learning disabilities are analysed with respect to the role of (plane) geometry. The results indicate that existing diagnosis and support instruments strongly focus on arithmetical topics while geometric contents are underrepresented or even non-existent. Then, first items DS line symmetry and axial reflection are implemented in 6th grades in the form of a test in order to specify children's understanding of these concepts and to find suitable items for the DS instrument. Finally, the test results are compared with findings through an individual interview conducted with a 5th grader beforehand.

Key words: diagnosis in geometry, axial reflection, line symmetry, figural concepts.

INTRODUCTION

Diagnosis and individual support has proved itself valuable to learn more about children's ways of mathematical thinking and to screen their misconceptions¹ and lacking mental models in order to contribute to a change for the better. A number of publications provide descriptions and lists of pupils' difficulties, error types and misconceptions, as well as suggestions how to foster particular mathematical issues. However, existing studies and commercial instruments for DS focus mainly on arithmetical issues. The field of geometry is either not being covered or only being minimally addressed. Consequently, it's even more important to develop a diagnostic instrument to assess children's geometric misconceptions and fields of difficulties in order to gain support points for the individual fostering. Thus, it is our aim to develop item-based interview guidelines suitable for detecting children's misconceptions and solution strategies regarding geometric issues and problems as well as to provide basic individual support rudiments. Our first investigations focus on line symmetry and axial reflection since there are a number of studies that describe pupils' misconceptions and error types (Küchemann, 1993; Xistouri, 2007; Bell, 1993) and are conducive to the development of DS items and interview guidelines. The purpose of this paper is to present the first outcomes of our study concerning line symmetry and axial reflection. It presents the items implemented in 6th grades in the form of a test and its analysis results regarding children's understanding and misconceptions of axial reflection. The overall aim is to develop task-based interview guidelines for the diagnosis and support of lower secondary students' figural concepts of line symmetry and axial reflection. This process will draw upon the theory of figural concepts by Fischbein.

THEORETICAL FRAMEWORK

The Concept of Line Symmetry and Axial Reflection

Hoyles & Healy (1997) investigated the processes through which pupils come to negotiate mathematical meanings for reflective symmetry by describing a micro-world, Turtle Mirrors. It is used “to help students focus simultaneously on actions, visual relationships and symbolic representations regarding reflective symmetry” (Panaoura, Elia, Stamboulides & Spyrou, 2009, p. 46). They also describe students’ primitive and intuitional variety of strategies for solving paper and pencil tasks on reflective symmetry. The reflection of objects in horizontal or vertical axis was easier for the students than in slanted axis. Hoyles & Healy (1997) describe how pupils use an approximate strategy derived from paper folding while reflecting in slanted axis – called ‘the strategy of imagining a vertical axis (IVA)’ in this paper.

Pupils face different problems when constructing plane reflections in a line and identifying the lines of symmetry in plane figures. Schultz (1978), Grenier (1985) and Küchemann (1993) identified the following factors as relevant: (a) direction of the axis (vertical, horizontal, slanted (45°), other); (b) complexity of the object being reflected; (c) presence or absence of a grid; (d) slope of the object and (e) size of the objects and distance from the axis of reflection. The first four were incorporated by Küchemann into a structured sequence of questions and the levels of response were identified as global, semi-analytic, analytic and analytic-synthetic. In *global* responses the object is considered and reflected as a whole with no reference to particular parts, angles, or distances. In *semi-analytic* responses, a part of the object is reflected first and the rest drawn from its matching the original shape and size. In *fully analytic* responses, the object is reduced to key-points, each reflected individually. These are connected and the result is accepted even though sometimes the image looks wrong. In analytic-synthetic responses, the global and analytic responses are coordinated so that the image is precise and also looks correct (Bell, 1993, p. 130). Küchemann indicated that students have some informal understanding of geometric transformations such as reflection and rotation. However, children experience difficulties when working on shapes which involve these transformations.

Bell’s study (1993) consisted of interviews and a diagnostic teaching experiment with students aged 11-12 years. This, too, revealed misconceptions. We take one example: children believe that horizontal/vertical objects have horizontal/vertical images or that horizontal objects have vertical images and vice versa.

There are several studies which deal with students’ conceptions of reflective symmetry and their difficulties in understanding the concept; however, there is more to be uncovered and explored. As an example, “[I]imited attention has been given to interrelations among students’ concept image of reflective symmetry and the use of different representations of the mathematical concept” (Panaoura, Elia, Stamboulides & Spyrou, 2009, pp. 47-48).

The Theory of Figural Concepts

Fischbein (1993) introduced the notion of *figural concepts*. He made an attempt to interpret geometrical figures as mental entities possessing simultaneously both conceptual and figural properties. According to the theory of figural concepts, the main objective is the development of the interaction between the figural and the conceptual aspect. Fischbein (1993, p. 160) stated that

[a]lthough a figural concept consists of a unitary entity (a concept expressed figurally) it potentially remains under the double and sometimes contradictory influence of the two systems to which it may be related – the conceptual and the figural one. Ideally, it is the conceptual system which should absolutely control the meanings, the relationships and the properties of the figure.

Various students' difficulties in geometrical reasoning can be interpreted in terms of such a rupture between figural and conceptual aspects of figural concepts – possibly even their difficulties in answering questions referring to axial reflection. The theory of figural concepts provides a powerful tool and offers a theoretical framework for our analysis of students' understanding of axial reflection and other geometric topics.

METHODOLOGY

The purpose of this study is to compile task-based interview guidelines for the diagnosis and support of lower secondary students' understanding of axial reflection, and thus for the development of the interaction between their figural and conceptual aspects of axial reflection. To achieve this, a pre-test was conducted and evaluated with Küchemann's methodology (Küchemann, 1993). Its results, that is, the solution rate of the items and emerging students' typical misconceptions while working with those items, will be examined in order to select suitable interview-items. The subjects were 195 6th graders who were chosen from nine classes and three schools. The students were given two invented tasks on line symmetry (including three items) and four tasks on axial reflection (including 13 items). The latter were adapted from the CSMS transformation geometry test restricted to an investigation of reflection and rotation (Küchemann, 1993). However, in order to focus on basic knowledge and save working time, both difficult items (e.g., object intersects the axis) and equivalent items of the CSMS transformation geometry test were excluded from the pre-test.

The items for line symmetry will give an overview about students' concepts of symmetry. The first item of the first task pertained to their associations with line symmetry and axial reflection; the second asked the students to draw images with one, two and no axis of symmetry. The second task provided eight flags of European countries for which the children should decide by marking with a cross if the given flag is symmetric or not, state and draw the right number of axis of symmetry.

The 13 items for axial reflection (tasks 3 to 6) included working on squared and blank paper with and without the use of the set square. Items of tasks 3 and 6 involved the drawing of the image. Task 4 (see fig.1) requires sketching the axis of reflection

between pairs of figures (4.1) or stating that and why this was not possible (4.2). Task 5 provided several points as possible reflections of point A. The students had to choose which of the given points was the image of A and explain their choice (see fig.1). Explanations encourage students to think analytically about the properties of reflection, even if they had originally made an intuitive choice.

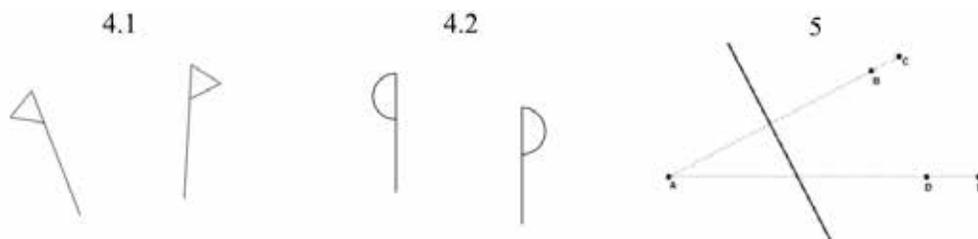

Figure 1: Items to tasks 4 and 5

In task 6 (see fig.2) students were allowed to use the set square; the remaining items required working without the use of the set square and other tools as well. In comparison, the equipment needed for the CSMS transformation geometry test was a ruler marked in centimetres; protractors and set squares should not be used for that test. The reason for our method lay in the fact that an individual interview with a 5th grader has shown that working with the set square provides wide support for the students. Many students have tendency to rely on procedural aspects of axial reflection, which is, e.g. positioning the set square in the taught way, measuring the distance of the object to the axis and finally transferring it to the distance of the image and the axis. This also became evident in the students' responses, especially in task 5. Since the students weren't allowed to use any tool for the test items – task 6 apart – and many of the questions involved drawing, regions had to be defined to delimit what was to be regarded as correct. For this, we used the marking scheme of Küchemann and the printed acetate sheets which he provides. He, too, defined regions by devising rules that took into account such factors as distance from the axis, the slope of the axis and whether or not a ruler was to be used. Thus, five codes were allocated to children's responses according to Küchemann's marking scheme. Code 1 includes responses which are correct and Code 2 those that are adequate, that is, not precise enough to be regarded as correct but also not obviously wrong. Code 3 refers to overt errors, e.g. reflecting horizontally or vertically when the axis is slanting or drawing the image parallel to the object. Code 4 refers to all other responses and Code 5 to unworked items. Two raters were involved in marking the students's responses and in assigning Codes to them. In order to perform reliability testing the Cohen's kappa coefficient was calculated. With $\kappa \approx 0,84$, it's safe to assume that a good inter-rater-agreement is present in this case.

Küchemann (1993) classified his reflection items into two types instead trying to discuss the effect on children's performance of the various combinations of the above mentioned features (a)-(d). These two types differ, generally, in terms of the strategies needed to produce Code 1 and Code 2 responses. Type A covers items where the axis is vertical (or horizontal) or the object is a single point (3.1, 3.2, 3.4,

3.5, 3.6). Type B includes items where the axis is slanting and the object is a line or a flag (3.3, 3.7, 6.1, 6.2) (see fig.2). So, type A items can be regarded as involving only one slope (of the object *or* the axis) because, having a vertical axis, the ability to reflect in a direction perpendicular to the axis requires merely the knowledge that the reflection takes the object to the other side. Type B items involve both the slope of the object *and* the axis.

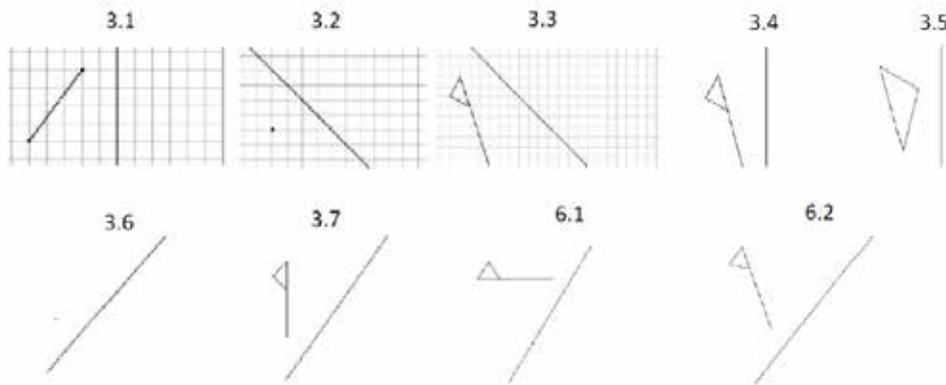

Figure 2: Items to tasks 3 and 6

Referring to the 13 items for axial reflection, each response to an item in each of the three reflection tasks was assigned one of the five codes. The percentages of success (Code 1) were calculated for each item. The items were grouped according to the percentages of success and item characteristics. The percentages were used *inter alia* for comparing the difficulties students experienced, both in Küchemann's test and in our sample, while working with the items, that is, for sorting the items by levels of difficulty. This is important because interviewed students will be provided with items also sorted by levels of difficulty. In order to intervene as a qualified professional, the challenging function of the interviewer will be to find out as much as possible about the student's figural concept of axial reflection or rather about the conflict between the conceptual and figural aspects generated by the given items. For this purpose, students' main strategies or error types in each item are worked out, which is useful for the interviewer to shed light on critical issues while interviewing the child.

RESULTS

The following tables 2 and 3 present the percentages of students' success in solving the reflection items. Since the items are grouped according to the percentages of success (Code 1), these tables also illustrate with which items students could cope more easily. The gradations in the tables are correlated to the item-levels of Küchemann (1993) with a factor of 0,90. A t-Test ($p > 0.86$) shows that there is no statistical difference among Küchemann's results of 1980 and ours of 2012. This implies, considering our sample, that there is no change in students' misconceptions and understandings of axial reflection since 1980.

The solution rates of task 4 reveal that students coped more easily with stating that it is not possible to draw a mirror-line between pairs of figures (4.2) than with finding

the mirror-line when it was possible (4.1) (see fig.1). A percentage of 66% of the students stated correctly in 4.2 that a mirror-line is non-existent. As for the results of table 1, 51% justified this statement by saying that the two figures are shifted or don't have the same height and 11% by stating that both figures are not parallel or don't face each other; 28% of the students drew vertical or diagonal axis between the two figures, which is again similar to Küchemann's results where 26% did so (Küchemann, 1993).

TASK	PERCENTAGE OF STUDENTS' (IN)CORRECT (-/+) & NO (/) RESPONSES			PERCENTAGE OF GEOMETRIC NOTIONS IN STUDENTS' RESPONSES				
	+	-	/	A is faced by B/D	distance	slanted axis	direction	⊥
5	78	15	7	13	52	15	9	11
4.2	66	28	6	shifted	face-	parallel-	other or no responses	
				51	5	6	38	
4.1	53	42	5	no reasoning demanded				

Table 1: Items grouped according to the % of success & item characteristic 'reasoning'

Task 5 was evaluated as correct if point B was chosen as the image of point A – independent of the explanations. In task 5 (see fig.1), 78% of the children chose B as the image of A whereas 9% chose D. 13% justified their choice with 'A is faced by B(D)', 15% chose B 'because the axis is slanted' and only 11% used the terms like 'perpendicular', 'right angle' or '90°'. 52% of the students gave explanations that referred to the distance and 9% to the direction. 21% of the responses referred to both the distance *and* the direction (e.g. "B/D is on the same line as A") or the distance *and* the perpendicularity. However, only 8% explained their choice correctly referring to the distance *and* the perpendicularity. In comparison, in the CSMS transformation geometry test, 21% gave explanations that referred to "the distance *and* the direction of the point in relation to the axis" (Küchemann, 1993, p. 141).

Considering the students' associations with the two topics in task 1, their tendency to rely on procedural aspects of reflective symmetry becomes obvious. 42% associated with axial reflection and line symmetry tools, with 24% mentioning the set square, 6% the ruler, 4% the compass and 8% the pencil. The terms 'right angle' and 'perpendicular' occurred only in 5% of the responses and 'sameness' in 9%. It is obvious that the properties are slightly associated with symmetry and reflection tools. Especially the set square (see fig.4), which assists students in solving symmetry and reflection items, seem to play a more prominent role in the students' associations than the conceptual aspects. Regarding students' explanations in task 5, the aspect of

distance seems to be more internalized than that of perpendicularity. One root cause may possibly be the broad use of the set square whereby students just have to measure the distances to the axis; the aspect of perpendicularity is hidden behind the center line of the set square (like in a black box) which is to be positioned onto the axis in order to draw perpendicular lines. Thus, many students do not realize which geometrical action is hidden behind this ‘positioning’.

The supporting role of the set square is also striking in a videotaped interview with a 5th grader who is struggling with drawing the image of a ‘modified’ triangle in a slanting axis without the support of any tool. After a couple of minutes the child produces the reflection of the given object –nevertheless the result is the image of a reflection in a vertical axis because the child ignored the slope of the axis and imagined a vertical axis (IVA) (see fig.3).

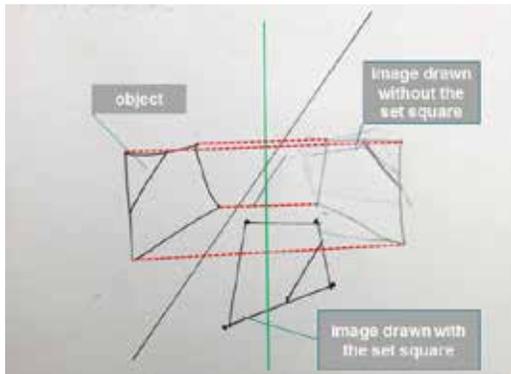

Figure 3: Students' strategy of imagining a vertical axis (IVA)

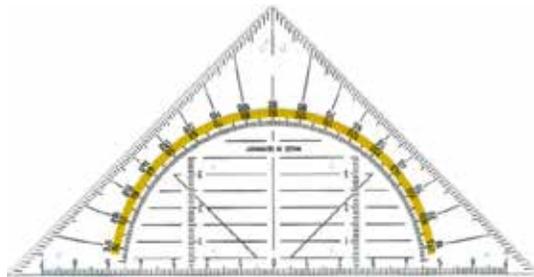

Figure 4: The set square

The child, still not aware of the answer's incorrectness, is asked by the interviewer to check her result with the set square. Within a few minutes the child produces the precise correct answer on the same sheet by relying only on procedural aspects. In this case study, the support of the set square is enormous and it is our future aim to investigate other cases concerning this matter through guided interviews. Does the set square inhibit or delay the development of the interaction between students' figural and conceptual aspects of axial reflection by providing too much assistance? Is the set square even a stumbling block for the internalisation of axial reflection?

The results of tasks 3 and 6 depict students' typical misconceptions. 3.1, 3.2 and 3.6 are items where the axis is vertical or the object is a single point. It is noticeable that 8% of the pupils who could cope with 3.1 couldn't do so with 3.2. Items 3.1 and 3.2 caused least difficulties for the students. In the former, 2% of the students' responses were assigned to Code 3, including 67% reflecting horizontally (RH) and 22% drawing the image parallel to the object (IPO). In the latter, 7% of the students' responses were allocated to Code 3, with all 7% RH. For the items 3.2 and 3.6 the percentage making overt errors (e.g. RH) was virtually the same. 8% of the responses to item 3.6 were Code 3 responses including 78% RH (see table 2). The presence of a

grid in 3.2 seems not to be a simplification for the students. The presence of a slanting axis in both 3.2 and 3.6 and of a slanting object in 3.1 seems to cause RH.

ITEM	PERCENTAGE OF CODE					PERCENTAGE OF ERROR TYPES (CODE 3&4)							
	1	2	3	4	5	RH/RV	IPO	IVA	D-	S-	T	ROT	Others
3.1	91	7	2	0	0	67	22	0	0	0	0	0	11
3.2	86	4	7	2	1	78	0	0	0	0	0	0	22
3.6	63	19	8	6	4	78	0	0	11	0	0	0	11
3.4	61	0	0	36	3	0	22	0	50	3	5	3	17
3.5	55	0	0	41	4	0	0	0	54	29	7	0	10

Table 2: Items grouped according to % of success & item characteristic ‘type A’

Responses to items 3.4 and 3.5 were assigned to Code 1, 4 and 5 (Küchemann, 1993). It is striking that in 3.4 50% of the error types related to the distance (D-). 22% drew the image parallel to the object (IPO). In 3.5 54% reflected failing the distance and 29% the size of the object. Both items involved a vertical axis and a slanting object – in 3.4 a flag and in 3.5 a triangle. Here, the complexity of the objects had effect on children’s performance.

3.7 and 6.1 are items involving a slanting mirror-line whereas the object to be reflected is horizontal or vertical. Working with items 3.7 and 6.1, the students experienced most difficulties. Virtually the same percentage of children made overt errors (e.g. IPO, RH/RV) despite the fact that the students were allowed to use the set square in 6.1. Code 3 and 4 responses to item 3.7 involved 31% IPO and 21% IVA; 10% translated the object and 17% confused reflection with rotation (see table 3). The percentage of students using the strategy IVA was even greater in 6.1: 47% imagined a vertical axis and reflected then. 18% drew the image parallel to the object and 20% rotated the object.

ITEM	PERCENTAGE OF CODE					PERCENTAGE OF ERROR TYPES (CODE 3&4)							
	1	2	3	4	5	RH/RV	IPO	IVA	IPA	O-	T	ROT	Others
3.3	45	18	20	8	8	18	26	7	12	14	5	0	18
6.2	40	29	15	4	13	19	15	8	0	0	0	35	23
6.1	39	20	35	2	4	0	18	47	0	0	0	20	15
3.7	25	29	32	4	10	13	31	21	0	0	10	17	8

Table 3: Items grouped according to % of success & item characteristic ‘type B’

Items 3.3 and 6.2 involve two slopes (object and axis), which implies that the slope of the object has to be related to the axis. Many children seemed to find the coordination that is required difficult and either ignored the slope of the axis entirely or ignored its effect on the slope of the image or didn’t work on the items. In 26% of the Code 3

and 4 responses to item 3.3 the image was drawn parallel to the object and in 18% the object was reflected horizontally. In 14% students confused the orientation (O-) and in 12% they draw the object parallel to the axis (IPA). Code 3 and 4 responses to item 6.2 included 19% RH and 8% IVA, 15% IPO and 35% ROT. In both 3.3 and 6.2, the percentage of IVA errors was low. The proportion of children answering both items correctly is virtually the same, also the proportion making overt errors even though in 6.2 the use of the set square was allowed. Here, the question which arises is why there is a low solution rate in 6.1 and 6.2 in spite of the fact that the set square was allowed. Did the work without the use of a tool in the first 11 items generate a conflict between the figural and conceptual aspects of students' figural concepts of axial reflection? And is this related to the fact that the students were confused when they had to use the set square in task 6? Additionally, about 45% of the students' total responses in the pre-test involved IVA more than once. However, there's no perceptible pattern since the majority didn't make this mistake more than twice. Even so, 45% of the students applied IVA systematically. Is this the controlling figural aspect of axial reflection? A prototype? A visual Gestalt?

CONCLUSION AND DISCUSSION

Appropriate test-items and the pre-test's results will be used not only to compile item-based interview guidelines aiming to *diagnose* lower secondary students' understanding of axial reflection, that is, to develop their figural concepts of axial reflection, but also to *support* children to revise them. Certainly, one has to consider that harmonizing the two components of figural concepts is neither spontaneous nor simple (Mariotti, 1995). Hence, in a next step, individual interviews will be conducted with 6th graders in order to help students to develop the interaction between the figural and conceptual aspects of axial reflection. An intervention or an attempt to do so could be made by generating a conflict between the two aspects. Destabilizing repeatedly a student's figural concepts and making him/her adapt conceptual aspects can possibly have positive effects in the development of *his or her* figural concept of axial reflection.

Based on the above analysis and results, several questions have been raised and need to be answered through further analysis and investigation. Future interviews may clarify the results of the quantitative part of this study. Among other issues, we will focus on questions regarding the role of the set square in the process of learning and understanding axial reflection as well as regarding the development of students' figural concepts of axial reflection: firstly, does the set square inhibit or delay the development of the interaction between students' figural and conceptual aspects of axial reflection by providing too much assistance? Secondly, is the set square even a stumbling block for the internalisation of axial reflection? Lastly, did the work without the use of a tool in the first 11 items generate a conflict between the figural and conceptual aspects of students' figural concepts of axial reflection? At this point, the study of Son (2006) must be considered. It reveals that a large portion of pre-service teachers has misconception and limited understanding of reflective symmetry.

Furthermore, “they have tendency to rely on procedural aspects of reflective symmetry when helping a student understand reflective symmetry correctly although they recognized a student’s misconceptions in terms of conceptual aspects” (Panaoura, Elia, Stamboulides & Spyrou, 2009, p. 47). Therefore, it is important that we attempt to answer the above questions since this has implications not only for the students, but also for teacher educators and teachers.

NOTES

1. The word “misconception” has been used instead of “conception”. This is because the German notion *Schülerfehlvorstellungen* (= students’ misconceptions) is common in the field of diagnostics in Germany. That is why we followed the perspective of (Son, 2006) and (Bell, 1993).

DEVELOPING SPATIAL SENSE: A SUGGESTION OF ACTIVITIES

Annette Braconne-Michoux, Patricia Marchand

Université de Montréal, Université de Sherbrooke (Canada)

This poster reports about two activities we tested with pupils in order to develop their spatial abilities. These activities are analysed within a specific framework: Berthelot-Salin's ideas about the development of spatial sense, Parzysz's "Knowing vs Seeing" and a generative structure of activities in construction (Marchand, 2006).

PROBLEMATICS

In some curricula (France, Québec), one can read that learning geometry and particularly 3D-geometry should enhance pupils' spatial sense. But the activities related to such objectives are rare or lacking. Here we present two activities we tested with students in order to develop their spatial sense and spatial knowledge.

THEORETICAL FRAMEWORK

Our research is based on

- Berthelot-Salin's ideas about the development of spatial knowledge: to recognize, to describe, to make or to transform real objects; to move, to find or to communicate the location (position) of an object; to recognize, to describe, to build, to transform a living space or a moving space.
- Parzysz's "Knowing vs Seeing": when representing a 3D-object, one has to deal with a loss of information, and to learn the rules for drawing.
- A generative structure of activities (Marchand, 2006) elaborated around five criteria: development, space, object, task and mental image. The key elements essential to all activities are: deprive of seeing, touching or intervene on the object during the first specific phase.

FIRST ACTIVITY: "TOWERS IN A ROW"

In the first phase of this game¹, a pupil has to organize a row of 5 towers aligned in such a way that the number of visible towers is given at each end of the row.

In the second phase, the same rule applies on a 3x3 grid and a 4x4 grid, with a new condition: two towers of the same height are not allowed in the same row.

This game was originally devised for kindergarten. We used it with secondary school students with learning disabilities. It proved to be quite challenging and we could

¹ Adapted from Valentin D. (2005) *Découvrir le monde avec les mathématiques ; Situations pour la grande section*, Cycle 2, éditions Hatier, Paris

witness an improvement as far as the strategies were concerned. In the end the students were able to anticipate correctly the location of a tower without any trial and error. The hidden towers were clearly identified. This activity proved to be an introduction to the drawing of plane views of a 3D-object.

Such an activity is at the same time a game but an opportunity to develop a pupil's spatial sense in Berthelot-Salin's meaning. Moreover, according to Marchand's framework, it has characteristics of a good learning activity.

SECOND ACTIVITY: "INSIDE THE BOX"

In this kindergarten activity ("boîte à image"), pupils are invited to build a landscape inside a shoe box and to look at it by a small hole in one side of the box. Different tasks can be performed from that point on. This activity was experimented with first and second grade pupils. We chose to make them represent their scenery on paper, then, to imagine what they would see if we were to make a hole on the tight hand side of the box. We also asked them to describe their box so that others could identify it (ex.: there is a cat at the front, a tree on the left...) and played "guess who?".

Choices were made according to our framework and this activity proved to be a rich one to include in a sequence of others aiming to the development of spatial knowledge. At first, we saw kids having a hard time building their boxes so that they could see all the objects through the hole. Afterwards they struggled with the drawings (perspective, orientation, position of the different objects), with the significant words to describe the position of each object in the box and in relation with the others, and finally when anticipating the view from another point of view.

CONCLUSION

This project exemplifies how we can create rich activities to develop spatial knowledge, from Kindergarten to High School students with learning disabilities. But, is the development of spatial knowledge enhanced in the curricula and for what purposes? Moreover how can a student benefit of the spatial knowledge developed outside of the school in the mathematical class?

ROLE OF SYMMETRY AXES ; UNDERGRADUATE STUDENTS' EXPERIENCE OF IMPOSSIBLE FIGURES AS PLANE SYMMETRY GROUPS

Özlem Çeziktürk Kipel, PhD

Namık Kemal University & Marmara University

Geometry teaching in the secondary grades asks for reasoning with various diagrams. Impossible figures are such kind of diagrams that enables students to see reflection with respect to one and many symmetry axes at once. This adds a new type of complexity to the geometrical thinking and reasoning. In this study, five types of impossible figures were used to gather data on students' number of corrections and the time asked for completing this. Used figure types were hexagonal symmetry I, II, III(p6), line symmetry(pm) and triangle symmetry-II(p3). The symbols in the parentheses were the classifications of plane symmetry groups by Schattschneider. One way MANOVA analysis of variance concluded many interesting associations regarding the model and the role of the symmetry axis on students' answers.

Introduction

Reasoning with various transformational geometry diagrams is a challenging issue for students. Concepts like translation, reflection and glide reflection flourish within impossible figure diagrams. Within these diagrams, reflection and rotation with many axes is a possibility.

Procedure

For the study, students redrew three type of impossible figures with variations; line symmetry (pm), triangle symmetry II (p3), hexagonal symmetry I, II, III(p6). They were classified with respect to the plane symmetry groups' classification of Schattschneider (1978). Students' number of corrections, as can be seen from the paper was counted as first dependent variable. The perceived time was second dependent variable. Research model included the effect of figure type on dependent variables; corrections and time. Some descriptive analysis on means and frequencies as well as one way MANOVA were tested on the model.

Results and Discussion

As a result, line symmetry figure required less time and fewer corrections than other figures. This was supported with the difference mean time of the figures with reflection axis or not. Among the figures, only line symmetry figure had the reflection axis. This was explained by conceived difficulty level among figure types. Rotational order and translational reflection with respect to rotation made the task more difficult. Existence of symmetry axis helped to the understanding of it.

As with the number of corrections, hex sym I and III required the highest mean corrections (4,00). Tri-sym II and hex sym II mean was around 3,00. The difference

between hex sym II and I /III can be explained with the existence of height feature in the former and nonexistence in the others.

In addition, dimension facet was added to the study by asking students an open ended question of what the figure made them to think of the dimension concept. Students' answers varied from many dimensions to fractal dimensions.

Hence, these kinds of figures may make the visual competencies of students on geometrical thinking visible but they may be facilitating for some students and inhibiting for others. How to understand which for whom is an issue with many facets as the WG4 group discussions suggest (WG4, Cerme 2013).

GEOMETRICAL ASPECTS OF GENERALIZATION

Marta Pytlak

University of Rzeszow, Poland

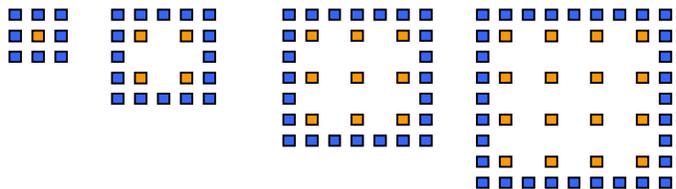

Generalization is considered one of the most important processes involved in mathematics. As Mason says: generalization is the heartbeat of mathematics (Mason, 1996). Whether it is viewed as part of higher level process, like abstraction (Dreyfus, 1991) or as the core process involved in a particular mathematics field, like algebra (Mason, 1996), there seems to be an agreement on its significant role in advanced mathematical thinking.

Discovering regularity and generalization are the kind of bridge between arithmetic and algebra. Looking on the historical development of algebra we do not omit the fact, that geometry have given many merits on this field. How could the geometrical aspects of generalization look like?

Methodology

The research, which was conducted among fifth-class students from primary school, aimed to find the answer to the following questions: How do the pupils from primary schools deal with a task involving discovering and spotting regularities? Are they able to make generalizations within some noticed rules?

The task that served as our research tool was an arithmetic-geometric and allowed a lot of different interpretations: there was given the sequence of four figures, each of them was built with two kind of elements. One is supposed to take how many elements we need for particular figures – not only those from the task, but also the next ones. The aim of the task constructed in this way was to check whether the students are able to discover the regularities occurring in the task in order to use them in their later work.

The research was conducted in school conditions, during normal classes. 38 students took part in this research. The students were working in pairs and their work was recorded. The atomic analysis of students' work and the atomic analysis of the video mentioned above were the research method that we used. Some additional information was obtained through the conversation with the teacher who was present during the whole experiment. The conversation took place not only after the finished work but as well during performing the task by the students.

Description of students' work

students started their work by counting the elements located in the pictures and then they filled in the table with the results of their work. Filling the first four lines took them comparatively little time. At this stage of solving the task any trials of

discovering regularities were spotted. They did not find any rules until they reached the fifth line of the table (to which no illustration was attached) which made them think about the task and looking for the proper solution. The quest followed different ways, and its analysis let us distinguish the following three types of reasoning:

- *arithmetic*: ignoring the pictures and paying attention to the numeric data taken from the table; finding and discovering arithmetic connections between number given in the table; students' work rely on an analysis the number column from the table filled to the fourth line
- *geometric*: paying attention mainly to the pictures, spotting geometric connections; strong visual aspect; students' work rely on an analysis figures' pictures and drawing the fifth figure and the next ones, work connected with drawing the next pictures of figures
- *arithmetic-geometric*: both the table and the pictures were taken into account at the same extent, finding geometric connections and combining them with arithmetic ones; replacing geometric connections with arithmetic ones; students' work rely on an analysis existing pictures of figures and then filling the table.

Results

The most frequently ways of work were generalizations within the limits of arithmetic dependences, which based on the number sequences. But some students started their work direct the figural property. Sometimes this approach did not end with success. In geometrical aspect student have to take into consideration much more factors. In this particular case the figural aspect have to be connected with the length of sides or an area.

The analysis of existing figures run in different ways: some students paid attention on the mutual position elements in the figure; some of them analyzed particular parts of the figures and the others analyzed connections between next figures Take as a whole. In poster I presented the examples of students work classified to emphasis category. Those example one could interpret in the light of geometrical paradigm or van Hiele levels of understanding geometry.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG 5: STOCHASTIC THINKING REPORT

Arthur Bakker, Utrecht University, the Netherlands
Pedro Arteaga, Universidad de Granada , Spain
Andreas Eichler, University of Education Freiburg, Germany
Corinne Hahn, ESCP, France

***Keywords:** Concept formation; context; probability education; statistics education; teacher knowledge; technology; statistical literacy; stochastic; uncertainty; variability*

OVERVIEW

Stochastic thinking refers to the combination of probabilistic and statistical thinking. This type of thinking is non-deterministic and leaves room for uncertainty.

WG5 was attended by 30 delegates; 19 papers and 5 posters were presented in this working group. To remind the audience, each paper was presented in 5 minutes, after which it was discussed for about 15-20 minutes. At the end of each session common themes were discussed.

There were three main themes: students at the school level, teachers, and tertiary education and theoretical issues. The discussion about each theme was instigated by a discussant (Per Nilsson, Andreas Eichler and Corinne Hahn).

Students

Andreas Eichler & Markus Vogel	Principles Of Tasks' Construction Regarding Mental Models Of Statistical Situations
Ayşe Yolcu & Cigdem Haser	8 th Grade Students' Statistical Literacy of Average and Variation Concepts
Susanne Schnell	Coping With Patterns and Variability – Reconstructing Learning Pathways Towards Chance
Ute Sproesser & Sebastian Kuntze	Statistical Literacy and Language – A Qualitative Analysis Of Needs Study

STUDENTS

Some of the papers reinforced the image that we know from the literature: student knowledge of probability and statistics is disappointing in many countries. Eichler and Vogel developed a framework for analysing tasks' potential to diagnose young students' intuitions or understandings. Sproesser and Kuntze emphasized the importance of language as a mediating tool in learning statistics. Their research suggests that students may have good intuitions but often not the statistical language to express these.

The discussant asked for more prescriptive research that would help us to improve probability and statistics education. There were indeed several papers and posters that presented promising ideas or evaluated interventions (Bakker et al.; Plicht; Schnell; Soto-Andrade).

TEACHERS

Compared to previous working groups on stochastic thinking, this one had a large set of presentations on teachers' knowledge and learning. We consider this encouraging, because the field has produced a lot of insight on student learning, instructional materials and innovative computer software but we still know too little about teaching. The discussant even flippantly wondered if teachers were ready to teach the probability and statistics curricula in most countries.

Again, many presentations underlined the existing image from the literature (which is mostly Anglo-Saxon), that teacher knowledge about probability and statistics is poor. Yet there are directions of research that are encouraging, for example the use of applets (Nascimento et al.) or *TinkerPlots* (Frischemeier and Biehler) in teacher

education. However, Arteaga et al. noted that teachers made more mistakes in graphing with Excel spreadsheets than without; the cause of this needs to be investigated further.

One striking observation is that there are many frameworks on teacher knowledge around. As a group we could hardly remember all the abbreviations concerning pedagogical content knowledge, mathematical and statistical knowledge for teaching. Apparently there is still a long way to go to understand what teachers need to know in order to teach the domain of stochastic thinking. It would be helpful to clarify the different emphases in the different frameworks and over time reach some convergence in terminology.

TERTIARY EDUCATION AND THEORETICAL ISSUES

Cañadas and colleagues highlighted students' problems with association – a topic that has so far received relatively little attention despite its importance in research.

The paper by Primi and Chiesi showed the importance of knowing mathematics for students self-efficacy in statistics education. The relation between mathematics and statistics is indeed one to investigate further.

Andra and Stanja addressed the thorny question of what characterizes stochastic thinking in terms of ideas, symbols and procedures.

GENERAL ISSUES

As commonly necessary in any working group, some time had to be devoted to the discussion of what we mean by particular *concepts*. Variability, statistical thinking, thinking and literacy are a few that returned in our discussions. It also struck us that we do not have conventional language to talk precisely about students' concept formation in flux. Depending on delegates' theoretical backgrounds, they preferred to talk about constructs or conceptions. We also discussed the difference between semiotic and cognitive conflicts.

Because of its applied and non-deterministic nature of stochastics, its link with *context* is crucial. Eckert and Nilsson showed how challenging it can be for a teacher to focus students' thinking on statistical ideas when tackling a contextual problem. Bakker et al. addressed vocational education, where the main focus seems work tasks rather than the statistical ideas behind them. Hauge proposed a more holistic approach to real-life problems that involve risk, which in itself combines probabilistic and contextual aspects. The latter two papers stress the interdisciplinary nature of stochastic thinking.

It was occasionally noted that statistics education is a younger field of research than mathematics education. Many of the issues raised have already been investigated in some related way in mathematics education. However, because of the differences between mathematics and statistics, we cannot always assume that findings from mathematics education research apply equally in statistics education.

FINAL COMMENTS

The group work was much appreciated. Delegates could make themselves well understood in English, even if they normally talked Turkish, Greek, Italian, Spanish, Portuguese, German, Dutch, Norwegian or Swedish. The size of the group was good and participation was not too skewed.

In the last sessions ideas were expressed for a European project and some joint effort in collecting data.

As a group we decided to change our name to *Probability and Statistics Education*. The main reasons are:

1. Though in German *Stochastik* refers to the combination of probability and statistics, stochastics has a rather narrow meaning in most other languages.
2. The new name better captures the broader issues addressed in the working group, not only thinking about also what is involved more generally in realizing better probability and statistics education.

WHAT DOES IT MEAN TO DO PROBABILITY? IDEAS, SYMBOLS AND PROCEDURES

Chiara Andrà¹, Judith Stanja²

¹University of Torino, Italy; ²University of Duisburg-Essen, Germany

We propose to adopt Rotman's terms of idea, symbol and procedure as a frame for characterizing probabilistic thinking. We present a qualitative analysis of a questionnaire given to a pre-service teacher and show how the apparent difficulties might be explained by the use of Rotman's frame. The questionnaire addressed the interpretation of artifacts that may be part of a probability course at primary school level. The result of the analysis suggests that the interpretation and usage of signs in probability is not self-evident and that probability requires a specific usage and interpretation of artifacts and signs. This usage and interpretation may be interfered with experience with the same artifacts or signs in other domains of mathematics.

Keywords: elementary stochastic, cultural semiotics, stochastic thinking

INTRODUCTION

In the last decades, the increasing importance of the role of probability in many areas (economy, business, science, politics, and so on) led several countries all around the world to include it in their curricula for early years at school. As a consequence, teachers' knowledge and understanding of probability has become a crucial point in the agenda of many primary school teachers' educators (Kvatinsky and Even, 2002). This had raised new issues concerning both the nature and the learning/teaching of probability. Several models were elaborated that *describe* probabilistic thinking (for an overview see Jones and Thornton, 2005) by taking particular conceptions into account and identifying existing or missing (partial) conceptions in students. Learners difficulties were *explained* in terms of misconceptions and/or missing or incomplete conceptions. The findings of these studies are bound to particular concepts. For example, Bar-Hillel and Wagenaar (1991) study intuitive notions of randomness by judgment tasks, such as “is this series likely for the rolling of a fair die?”, and production tasks, such as “give me an example of a series which is likely for the rolling of a die”. Falk, Falk and Ayton (2009) characterize such intuitive notions of randomness as “equal total frequencies” and “excess of alternation” (*ibid.*, p.203).

In this paper, we adopt a cultural (semiotic) perspective, and we question whether and how this perspective may contribute to research on probabilistic thinking. This is a huge endeavor and, in this contribution, we can only start. From a cultural (semiotic) perspective, we consider probability as a cultural product. We understand it as part of mathematics and therefore historically and culturally determined.¹ For

¹For a historical examination of the development of probability we refer the reader e.g. to Barbin and Lamarche (2004).

mathematics, Rotman (a philosopher and mathematician), proposed a characterization of mathematics “as a practice, as an ongoing cultural endeavor” (Rotman, 2000, p.3). In the next section we will present his ideas about mathematical activity and propose to adapt them for probability. Following his ideas, we will see that artifacts and signs play an important role in the mediation and communication of probability. In later sections, we will explore the potential of *Rotman's frame*. We will demonstrate, how Rotman's frame might be used to find new explanations for difficulties that learners face when dealing with tasks in probability.

ROTMAN'S FRAME: IDEAS, SYMBOLS AND PROCEDURES

In his work, Rotman (2003) investigates what it means *to do mathematics*, and states that “behind the various construals of mathematics as an activity [...] lie three distinct, fundamental theoretical discourses that enter into the subject, namely: idea, symbol, and procedure.” (Rotman, 2003, p. 1676). According to Rotman, for thinking mathematically all three – ideas, symbols and procedures - have to be coordinated, and there’s not a hierarchy among them. We give a brief description of the three components, connect them to other works, and discuss coordination of ideas, symbols and procedures.

Idea stands for the domain of human thought, as delineated by the individual’s narratives in natural language. Within the domain of probability, *Idea* can be understood as the domain of intuitive approaches to uncertain situations and fundamental ideas such as variability. According to Andrà and Santi (2011), a person intuits mathematical concepts when the access to the distinctive features of the mathematical object is self-evident, coercive, and global. Referring to Radford’s (2008) perspective, Andrà and Santi claim that self-evidence and immediacy can be traced back to “the spatial-temporal, sensorimotor and perceptive activity that semiotic means of objectification accomplish, support, foster” (p. 115). The domain of *Idea* concerning probability is situated in space and time, where intuitions arise and are accounted in narrative ways. The development of personal and collective practices in mathematics is closely connected to the productive use of artifacts as instruments in knowledge-building activities, which brings us to the *Symbol* domain. This is the domain of signs, as well as communication and semiotic practices from notational devices to entire linguistic systems. The importance of symbols in mathematics learning processes is expressed by Duval (2008) who states that there is no *noesis* without *semiosis*, namely that any meaning making process needs a system of signs to take place. This is in accordance with Sfard (2000), who states the crucial role of symbols in knowledge construction. Within probability, *Symbol* is the set of signs and symbols that are commonly used in probability (Venn diagrams, formulas, tables, histograms, and so on). A sign can be meant as an artifact that is connected with a meaning (or used as representation for a mathematical idea). In order to see an artifact as a mathematical sign, it needs to be related to a mathematical *idea* (see also Stanja, 2012). For elementary probability, we have to

consider the translation from the domain of artifacts (in space and time) to the domain of numbers and symbols. When an artifact such as a spinner is used, two cultural elements may emerge: the notion of probability as a ratio between favorable and possible outcomes, and the one of probability as frequency. The latter points out that “probability can be assigned only to an event that can be repeated” (Kvatinsky and Even, 2002, p.2), as it is the case with many, common artifacts (dies, cards, coins, spinners). Finally, *Procedure* is the domain of actions, processes, and operations on and with artifacts and signs. We can relate this to the ideas of Duval (2008), who identifies learning as becoming able to perform correct actions on mathematical signs. Actions in mathematics are transformations, which can take place within the same semiotic register (a *treatment*, e.g. transforming a formula into another formula), or between two different registers (a *conversion* e.g. from a formula to the graph). Procedures may be explained or justified by mathematical ideas, but they may be performed without reference to them.

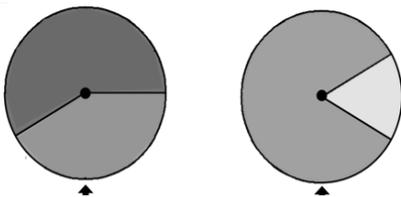

In the following, we elaborate on an example of a pre-service teacher to see what it means to integrate idea, symbol and procedure in probability.

MARTA'S EXAMPLE

Background Information

Marta, a pre-service primary school teacher, received a questionnaire (figure 1) at the very beginning of a course in probability in the Academic year 2011/12 at the University of Torino.

Imagine playing with this two spinners:

They pivot around their center. They are spun and, after several turns, they stop. The pointer at the bottom allows us to say if red or green is the outcome in the left spinner, and if yellow or blue is the outcome of the right spinner.

Question 1

If we turn each spinner 20 times, which possible outcomes would we get? Motivate your answers.

Spinner red-green:

Spinner yellow-blue:

Question 2

4 students have tried to turn the yellow-blue spinner 20 times, recording each outcome into an horizontal table:

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	

How would you comment the outcomes?

Question 3

Now, if you had tried to turn the yellow-blue spinner 20 times, which outcome would have you likely get?

Try to fill in the following horizontal table:

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	

And explain how have you acted, as much detailed as possible:

Figure 1: the English translation of the test given to the students.

Participants of the course were attending the third year of the undergraduate course in Primary School Education and had no previous school experience in probability (this is a quite common situation in Italy, since the introduction of probability in the curriculum is very recent). We were interested in how the pre-service teachers work on this kind of problems and how the domains of Rotman's idea, symbol and procedure emerge and interact with each other. We will describe how a pre-service teacher enters the world of random experiments with a spinner by dealing with the given problems.

The questionnaire was designed by Andrà and is based on interviews that had been carried out by Stanja in a different project in the school year 2010/11 with grade-3 students in Germany. In the first task (figure 1), the pre-service teachers were given an artifact, a figure showing a spinner, they were asked to give a prediction about the possible outcomes when turning the spinner 20 times and to give a justification. The students may have seen or played with a spinner before, but we stress that they had never engaged in a learning activity involving the meaning of the spinner in probability. The second task is a *judgment* task according to Bar-Hillel's and Wagenaar's (1991) taxonomy. There were four different sequences of 20 trials shown and the pre-service teachers were asked to comment on the outcomes. In the third task they were asked to imagine and draw a sequence that could be obtained by turning the spinner 20 times - a *production* task according to Bar-Hillel's and Wagenaar (1991), and to give an explanation of their action. We agree with Bar-Hillel and Wagenaar, that pure production tasks may hide the cases in which a student has "biased reflections of accurate notions of randomness" (*ibid.*, p.431). Therefore, it is important to ask the students to give a justification. All tasks had in common that they demanded the usage/coordination and interpretation of given socially constructed means the pre-service teachers were not familiar with, but that could be part of an elementary stochastics course (see e.g. Lopes and de Moura, 2002). The questions were open concerning the way of representing the outcomes and allowed to answer in more or less details. A similar task has been considered by Batanero, Godino and Roa (2004), in a study aimed at describing the knowledge needed for teaching probability at school. Specifically, the task pivoted around the concept of randomness, and the researchers observed that different students paid attention to different properties of the sequences (analogous to question 2 here).

We now present an interpretative analysis of Marta's answers to the questionnaire that focuses on her usage and interpretation of the given semiotic means. The analysis intends to understand how Marta made sense of the given means. Thus, it reconstructs a possible and plausible way in which Marta may have interpreted the given and her introduced semiotic means. We then discuss Marta's answers in terms of Rotman's Idea, Symbol, and Procedure. As an *a priori* analysis, we distinguish three cases. (1) The students carry out the task by means of symbolic operations and transformations, but their actions have poor spatial-temporal meaning, which is

conveyed by the natural language in the domain of the Idea, as well as poor probabilistic significance, given by the domain of Symbol. In a sense, we can trace this tendency back to the empirical vision of stochastic knowledge, as argued in Batanero, Godino and Roa (2004). (2) The students intuit the general sense of the activity, but they have neither the ability to perform operations, nor the possibility to access the inter-subjective meaning of it in the realm of probability. Given such a relationship with the mathematical theory, this case can be part of a formal vision of stochastic thinking (Batanero, Godino and Roa, 2004). (3) The students can access the inter-subjective, cultural meaning of the activity, but hardly perform actions and refer to the concrete artifact.

Analysis

Marta's answers to question 1 and 2 can be seen in figure 2.

Immaginiamo di giocare con due ruote colorate, come queste:

Esse ruotano attorno a un perno, posto al centro. Vengono messe in moto e dopo alcuni giri si fermano. In basso un puntatore ci permette di dire se sia uscito il rosso o il verde nella ruota di sinistra, il giallo o l'azzurro nella ruota di destra.

Domanda 1
 Se lanciamo ciascuna ruota 20 volte, quali saranno le possibili uscite? Motiva le tue risposte.

Ruota rosso-verde:

$$58,3 : 20 = 2,915 \quad \frac{2,91}{20} = \frac{29,1}{200} = \frac{29,1}{200}$$

Ruota giallo-azzurro:

$$16,6 : 4 = 4,15 \quad 83,4 : 1 = 83,4 \quad 16,6 : 83,4 = \dots$$

Maggior probabilità di uscita dell'azzurro

Domanda 2
 4 studenti hanno provato a girare la ruota giallo-azzurro per 20 volte, registrando ogni volta l'uscita su una tabella orizzontale. Ecco le uscite:

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
G	A	A	A	A	A	A	A	A	A	A	A	A	A	A	A	A	A	A	A

50 - 50 $\frac{10}{20} = \frac{1}{2} G = A$

Figure 2: Marta's responses to question 1 and 2.

For the first task we observe that she changed the representations of the spinners by including markers (dotted lines) and that she wrote arithmetic expressions for both spinners. For the second spinner she also wrote a sentence (“Maggior probabilità di uscita dell’azzurro”, that is “Greater probability of blue to come out”). In order to

reconstruct how Marta was possibly dealing with the tasks and how the domains symbol, procedure and idea interact, we have to interpret her writings and possible relations between them. Concerning the *procedure* component of Rotman's frame we can reconstruct from Marta's answers that she performs a *coordination* - an action - of the representations of the spinners and the symbolic system of percentages, which is supported by the marker lines: the components of the spinner representation (area sizes with the labels of the colors) are mapped in a 1-1 manner into the percentage system. The proportions expressed by percentages belong to the realm of *symbols* Marta uses. It is not clear whether she estimated/calculated the percentages or simply used a calculator (since there is no documentation of how she arrived at the percentages compared to her detailed writings elsewhere). Our interpretation, that Marta performed a spinner-percentages coordination is also supported by the writing of “G” (yellow) and “A” (blue) next to the percentages “16.6%” and “83.4%”. The “16.6%” is obtained or justified by the treatment (in Duval’s terminology a transformation within the same system of signs) in the symbolic system of percentages – the calculation “ $100-16.6=83.4$ ”. Here, Marta used the complement in the percentage system. Besides this coordination, Marta's way of searching for an answer differs for both spinners. For the first spinner, the writing “ $58.3:20=41.6:20$ ” supports the interpretation that Marta wanted to relate the proportions to the 20 trials (“:”) and to compare the two expressions. Here, the “=” sign is used in an unconventional way. The “=” sign can be seen as a statement about the action (comparison) that has to be carried out and not as the result of a comparison. This is particularly interesting since it gives insights about the initial *ideas* that Marta develops, namely that she wants to compare the spinners by using fractions and percentages and connecting this to the trials. Marta then performed a conversion from the system of percentages to the system of fractions (“ $58.3/20=41.6/20$ ”) and started another treatment - canceling - that she did not finish. For this spinner she did not write anything else. Why did Marta stop here? One reason could be that the “=” sign takes on a different meaning now and Marta realizes that both sides are not equal. Another possibility is that she realizes that her calculations did not lead her to answer the question. Either case, Marta is concentrating on the procedure to be carried out. For the second spinner Marta proceeded in a different way. She did not relate the proportions expressed by percentages to the 20 trials but she tried to compare them directly. This is supported by her writing “ $16.6:83.4=$ ” which could be understood as a *procedure* that has to be done, with a conversion to the language system “Greater probability for the outcome of blue” (translation).

For the second task, Marta performs a conversion from the first list to the symbolic system of percentages (equal frequency of yellow and blue \rightarrow “50 - 50”) and then to the symbolic system of fractions (“50 - 50” \rightarrow “ $10/20$ ”), where she performs a treatment (canceling: “ $10/20$ ” \rightarrow “ $1/2$ ”) and then converts this congruently to some idiosyncratic symbolic system of letters (“ $1/2$ ” \rightarrow “G=A”). For the other three lists, she performs similar conversions from the lists to the symbolic system of fractions

regarding the frequencies of yellow and then to her letter system. Here, Marta seems to have only limited access to the realm of *symbol* usually used in probability. She uses fractions but it is not clear what she associates with them. It is not clear what the unconventional writings in her letter system stand for. Possible interpretations are that they describe the relation of the frequencies of yellow and blue, or represent frequencies that for Marta could be seen as the same as probabilities or as estimates of the relation of probabilities from the frequencies that may refer to different spinners with different proportions. It becomes not clear at this point that Marta is aware of the difference between frequencies and probabilities and if she knows about the relations of them. When we look at the writing left of the lists the first interpretation gets supported since Marta added the absolute frequencies for yellow from all lists, related them to 80 trials, and connected this to the letter system (“→G”). In her writing, the “69” for blue may be a result of a reference to “100%” as the whole and the usage of the complement idea. There are no further comments or interpretations given by Marta.

The inconsistencies in Marta's answers may be an indicator for her trying to make sense of the given new situation by resorting to known (mathematical) actions. The use of symbolic expressions may come from her experience in other domains in mathematics. Marta related percentages, proportions of the spinner and fractions to each other and the word “probability” by performing *congruent* coordination and she performed procedures on the system of fractions. However, there is no comment from her on the possible outcomes and there is no interpretation of “probability”. The idea of variability also is not present in her writings. The intended meaning is accessed neither in intuitive terms nor in cultural and symbolic terms. However, Marta's answer to question 3 shows a leap: “I expect a majority of blue” (“Mi aspetto una maggioranza di azzuro.”). Here, she might start to access the cultural form of reasoning about the likelihood of a sequence of outcomes: she uses the verb “to expect”, which is historically related to the mathematical expectation, and the term “majority”, which is related to proportions. However, there is no explicit justification as a reference to the spinner and it is not clear whether these terms have the conventional meaning for Marta. Moreover, we did not find any evidence in Marta's written answers that she has used any out-of-school experience with random situations.

WHAT DOES IT MEAN TO COORDINATE IDEAS, SYMBOLS AND PROCEDURES IN PROBABILITY?

What does happen if idea, symbol and procedure are not coordinated, and only one is predominant? If someone, like Marta, relies mainly on procedures, then there is only a weak or pointless reference to the domains of Idea and Symbol. The student carries out the task by means of symbolic operations and transformations. The actions have poor spatial-temporal meaning, which is conveyed by the natural language in the domain of the Idea, as well as poor probabilistic significance, given by the domain of

Symbol. Sometimes it is possible to carry out a procedure without accessing the intended meaning and significance of it. In probability, this occurs when the student simply manipulates signs or when already known systems of symbols from different domains of mathematics are used which may lead to *substituting strategies* in solving probability problems (see also Stanja, 2012). This risk can be felt as very cogent, if we consider that the students generally tend to import their beliefs about the deterministic nature of mathematics into probability (Meletiou-Mavrotheris and Stylianou, 2003). When considering the coordinations that Marta did, we noticed that she performed only congruent coordinations (1-1-mappings). This would not be a problem, if the task would be to determine fractions or percentages from circular representations (a typical task when working with fractions or percentages in Italy). In the domain of probability, this is not sufficient: the interpretation and usage of the given means differs from other domains and is more complex in probability. In answering the tasks in the questionnaire, it was not only required to perform good conversions, but also to consider the spatial-temporal and sensorimotor domain, the intuitive world of ideas, and the culturally-given and socially-shaped world of the symbols, where the spinner changes from a real world object to a mathematical sign referring to probability. In fact, there is an underlying intended meaning when the students are asked to comment a given sequence of outcomes: the notion of likelihood, a historical concept that had been developed in order to model the extent to which experimental evidence (from one or many trials) supports the expected “ideational” outcome. The intended meaning of the activity is to shape a shift from the artifact of the spinner towards the signs embedded into the table. When the students are asked to predict an outcome at their turn, another underlying intended meaning is present: the notion of variability. Variability can be connected in this case to the notion of model Fit (Konold and Kazak, 2008). We refer the reader to Prodromou (2011) for an insightful study on the students’ ways of relating experimental and theoretical perspectives on probability. From Prodromou’s research it emerges that students have difficulties in coordinating the actual data and the ideational model. To know about this difference and to understand the relation between frequencies and probabilities, in fact, would mean to be able to perform non-congruent coordinations between represented probabilities and represented frequencies. As it has also been pointed out by Batanero, Godino and Roa (2004), the classical and the frequentist approach to probability are complementary in nature. In random experiments different outcomes may be obtained at each trial. Unlike arithmetic or geometry, random experiments cannot be reversed.

CONCLUSIONS AND DISCUSSION

This contribution is a first step to explore Rotman's frame to study probabilistic thinking. The novelty of this contribution consists in giving insights on Rotman’s frame and showing how it might be used to explain the difficulties that a learner might face when dealing with probabilistic tasks. Using this frame, we argue that the

coordination of semiotic means in probability differs from other domains and that there might be some interference between several domains of mathematics. We remark that our approach is different from Bar-Hillel and Wagenaar (1991), as well as from Falk, Falk and Ayton (2009), since we are not interested in how “bad” intuitions may impede the learning process, but our aim is to see what happens when intuitions/ideas, culture-symbol and procedure(s) are not coordinated, and thus which kind of difficulties the students may face.

Moreover, Marta's example illustrates that the signs used in probability are cultural products used by a community and whose usage is not self-evident and self-explaining. The inconsistencies in her usage of the means indicate that she did not answer the questions only with some pre-existing ideas in mind but that she was trying to make sense of the situation in front of her while interacting with it. It became clear that also the meaning and usage of known means (from arithmetic) need to be changed: it should be addressed deliberately and explicitly and therefore should be part of stochastics teaching. To our knowledge, this is not the case at the present, and there is a need for the design of suitable learning activities. Stochastics as cultural product implicates a different perspective on learning/the contents to be learned. Speaking in Rotman's terms this would mean that the links between the domains of Idea, Symbol and Procedure need to be supported. The meaning of interaction with cultural artifacts and signs, and with other persons is emphasized. Related to this is teachers' training. Following Batanero, Godino and Roa (2004), and with Rotman (2003), we maintain the importance for the teachers to integrate theoretical and empirical experiences in order to make sense of the activity, fostering the idea, the symbol, and the procedure in a coherent whole.

PROSPECTIVE PRIMARY SCHOOL TEACHERS' ERRORS IN BUILDING STATISTICAL GRAPHS

Pedro Arteaga, Carmen Batanero, Gustavo R. Cañadas y J. Miguel Contreras

University of Granada, Spain

We analyze the graphs produced by 207 prospective primary school teachers when comparing data collected by them in a statistical project. These graphs are classified according to their correctness, and the type of error in case of incorrect graph. The influence of using computers on the errors produced is also analyzed. Results show the prospective teachers' difficulties in building statistical graphs, in spite that they will have to teach these graphs, since many of them shared errors reported in previous researches with children.

Keywords: statistical graphs, errors, graph construction, primary school teachers' education.

INTRODUCTION

Nowadays we are surrounded by statistical information that is often presented through statistical graphs, and building and interpreting statistical graphs is an important part of statistical literacy (Watson, 2006; Ridgway, Nicholson & McCusker, 2008). Taking into account the relevance of the topic, this research was aimed to evaluate the formative needs of Spanish prospective school mathematics teachers in relation to their competence in building elementary statistical graphs. Below we describe the research rationale and background, method, results and implications for teacher education.

STUDY RATIONALE

In Spain, curricular guidelines (MEC, 2006) include statistical graphs since first level of primary school education (6 year-olds children). The success of this curriculum depends on the correct preparation of teachers, that, until now did not include statistics education.

Moreover, few studies have focused on teachers' knowledge about statistical graphs and most of them are related to prospective teachers (González, Espinel, & Ainley, 2011). In this study we continue our previous research (Arteaga & Batanero, 2011) where we analyzed the graphs produced by 207 prospective primary school teachers in an open statistical project where they had to compare three pairs of distributions. In that paper we classified the graphs built by the prospective teachers according to its semiotic complexity and the participants' reading levels in Curcio's (1989) categorization. Results showed that, although most participants produced graphs with sufficient semiotic complexity to solve the task posed, only a minority reached an adequate reading level to get a correct conclusion from the graph. In this new study we re-analyse the same data with a different perspective: The focus now is the correctness of the graphs built by these teachers and the influence of using computers on possible errors.

STUDY BACKGROUND

Errors in building graphs

Several studies evaluated the competence in building statistical graphs by students (see Friel, Curcio, & Bright, 2001; Tiefenbruck, 2007 for a survey). Li and Shen (1992) found the following errors: selecting a graph that is inadequate to the type of variable or representing not related variables on the same graph; using inadequate scales; omitting the scales in at least one axe; not specifying the origin of coordinates and not using enough divisions on the scales. Wu (2004) found the following errors by secondary school students when building and reading statistical graphs: (a) errors related to scales, (b) errors in titles, labs or specifiers (c) errors in pie charts, (d) difficulties with proportionality in a pictogram, (e) confusion between apparently similar graphs (for example, between histogram and bar chart), (f) confusing frequencies and variable values. Lee and Meletiou (2003) described four wrong reasoning when working with histograms: (a) Interpreting histograms as representation of discrete variables, assuming each rectangle refers to an isolate value instead to an interval of values; (b) Comparing frequencies in histograms using only the vertical axis (instead of areas) (c) Lack of appreciation of randomness in the data represented, and (d) Interpreting histograms as a bivariate graph.

Technology does not facilitate the work with statistical graphs, because the students need to learn the software options in addition to the graphs features. Ben-Zvi and Friedlander (1997) analyzed the graphs produced by some students when working with computers and suggested that some of these students used the software in a non critical way, since they were unable to select the most adequate options of the software.

Teachers or prospective teachers' competence in building graphs

Bruno and Espinel (2005) described the following errors made by prospective primary school teachers when building a histogram: misrepresenting intervals, omitting null-frequency intervals, using non-attached rectangles with continue variables. In Burgess's (2002) study some teachers were unable to integrate the knowledge they got from the graphs produced in their reports with the problem context.

Tiefenbruck (2007) investigated fourteen primary school teachers' understandings of graphical representations of categorical data with a questionnaire, where only a few questions asked the participants to build a graph. The teachers had a basic knowledge of graphical representations of categorical data. However, some of them incorrectly suggested that the histogram and stem and leaf plot were adequate for categorical variables. They also were confused when defining the scale and in describing how to create a scale from data. In this study we continue all this previous research in analysing the type of errors the prospective teachers made when building graphs. Contrary to Espinel and her colleagues or Tiefenbruck, instead of using questionnaires we gave the

teachers an open-ended project; we also study the influence of computers on the possible correctness of the graph. Arteaga & Batanero (2011) is also a basis for this research.

THE STUDY AND METHOD

Participants in our study were 207 prospective primary school teachers in Spain who were enrolled in a mathematics education course; in total 6 different groups (35-40 participants per group). The participants studied statistics the previous academic year, including statistical graphs, which are an important component in the primary school curriculum (MEC, 2006). The data were collected as part of a practical activity where prospective teachers were encouraged to carry out an experiment to decide whether the group had good intuitions on randomness or not. The experiment consisted of trying to write down apparent random results of flipping a coin 20 times (without really throwing the coin, just inventing the results) in such a way that other people would think the coin was flipped at random (simulated sequence). Participants recorded the simulated sequence on a recording sheet. Afterwards participants were asked to flip a fair coin 20 times and write the results on the same recording sheet (real sequence). At the end of the session, in order to confront these future teachers with their misconceptions, participants were given the data collected in their classroom. These data contained six statistical variables: number of heads, number of runs and length of the longest run for each of real and simulated sequences from each student (part of the data are presented in Table 1; the total data consisted of 35-40 rows similar to those presented in Table 1. The prospective teachers were asked to analyse the data and produce a report with their conclusion (about the similitude or differences in the three pairs of distributions).

Student	Simulated sequence			Real sequence		
	N. of heads	N. of runs	Longest run	N. of heads	N. of runs	Longest run
1	10	14	4	11	9	4
2	12	9	4	11	16	2
3	11	12	4	11	16	2
4	10	9	4	8	9	4
5	11	11	3	7	11	4
...						

Table 1: Data collected by the students

RESULTS AND DISCUSSION

Although we did not asked the prospective teachers to use graphs in their analyses, 181 of them (87.4%) built some graphs to compare the number of heads 146 (70.5%) to compare the number of runs and 129 (62.3%) to compare the longest run in the real and simulated sequences. These high proportions of students who built graphs suggest they carried out a *transnumeration* process (Wild and Pfannkuch 1999) to obtain new information that was hidden in the raw data. These graphs were firstly classified into

basically correct, partially correct and incorrect graphs and secondly, according to the types of errors presented. Results are described below.

Categories of graphs

1. *Basically correct graphs.* Here we include *correct graphs* (correct title, axes, scales and labels) that are adequate to both, the problem posed and the variables being displayed (1.1). We also include unusual, but correct representations (1.2).

2. *Errors in the graph scale.* Watson (2006) warns about the need to be careful with the graph scales; however we found the following errors (Bruno & Espinel, 2005):

2.1. *Non proportional scales* where distances between different pairs of points that should be equal were different.

2.2. *Wrong representation of natural numbers on the number line*, for example, omitting null-frequency variable values.

2.3. *Titles or scale values missing or confuse* Although the title, labels on the axes and scales are essential part of graphs (Curcio, 1987) because they provide the contextual information needed to interpret the variables represented and the relationships between the graph different elements, Bruno and Espinel (2005) found many prospective teachers with difficulties to include a correct and meaningful title. In our study many students provided imprecise titles or labels, but only a few built graphs with no titles or labels.

2.4. *Not centred bars.* The variables in our study were discrete; however, many participants built histograms, which are used to represent continuous variables or when we need to group the variable values. Furthermore, some participants did not centre the rectangles in the class centre, although the variables only took integer values. This error was also reported by Bruno and Espinel (2005) and Espinel (2007)

2.5. *Wrong representation of intervals on the X axis.* Some participants made errors in representing intervals; for example they displayed intervals with a common point as disjoint. This error, also reported by Bruno and Espinel (2005) was more common between the participants who used Excel to produce their graphs.

2.6. *Inappropriate scales.* Li y Shen (1992) found some students who built a scale not wide enough to cover the range of variation of the variable represented. In our study we found this error as well as participants who built too wide scales, error described by Wu (2004).

3. *Incorrect graphs.* We found the following subcategories (See examples in figure 1):

3.1. *Lack of proportionality in the specifiers.* Participants did not take into account the conventions for each particular graph. For example in Figure 1a is difficult to read the frequency associated to each variable because the width of circular sectors is

not proportional to frequencies.

- 3.2. *Confusing variable values and frequencies.* In the distribution, each variable value is associated to its frequency. Some participants confused both and exchanged variable values and their associated frequencies in the graph (Figure 1b).
- 3.3. *Representing variable values and frequencies together.* Some participants built attached bar graphs, representing each variable value with its frequency in two attached bars, as if they were two different variables; they usually used Excel. Figure 1c shows an example of this category where a prospective teacher shows a limited knowledge about the software options; therefore, he makes an uncritical use of the software (Ben-Zvi & Friedlander, 1997).
- 3.4. *Representing variable values multiplied by frequencies.* A few participants working with Excel displayed in an attached bar graph both the frequencies and the product of frequencies by the variable value. These participants also showed an uncritical use of the software and misunderstanding of statistical of distribution.
- 3.5. *Inadequate graph.* Some participants selected graphs that were inadequate to the problem they had to solve. For example some participants did not form the distribution and displayed bar graphs were a too high number of bars to be able to interpret the graph (Figure 1d).
- 3.6. *Representing non-related variables in the same graph.* Some participants plotted variables non comparable together; for example representing in the same graph the three variables under study (number of heads, number of runs and longest run) or their averages (Figure 1e).
- 3.7. *Non comparable statistics displayed in the same graph.* In this case some participants displayed averages and measures of spread in the same graphs and therefore they confused the meaning of central tendency and spread (Figure 1f).
- 3.8. *Several errors.* Some students made several of the errors described before.

In Table 2 we present a summary of results. Basically corrects graphs had the highest percentage in each variable, although the percentage of incorrect graphs or graphs with errors in scales (partially correct graphs) was also very high. About half participants constructed basically correct graphs in comparing the variables at the project: 47% (85 participants) built correct graphs for the number of heads, 43.8% (64 participants) for the number of runs and 45.7% (59 participants) for the longest run.

About 20% of errors were related to scales (non proportional scales, wrong representation of numbers on the number line, etc...) in spite of Watson's (2006) claim that special attention should be paid to scales, because through them people can display

misleading graphs. Bruno and Espinel (2005) also indicated that these errors were widespread among prospective primary school teachers in their research.

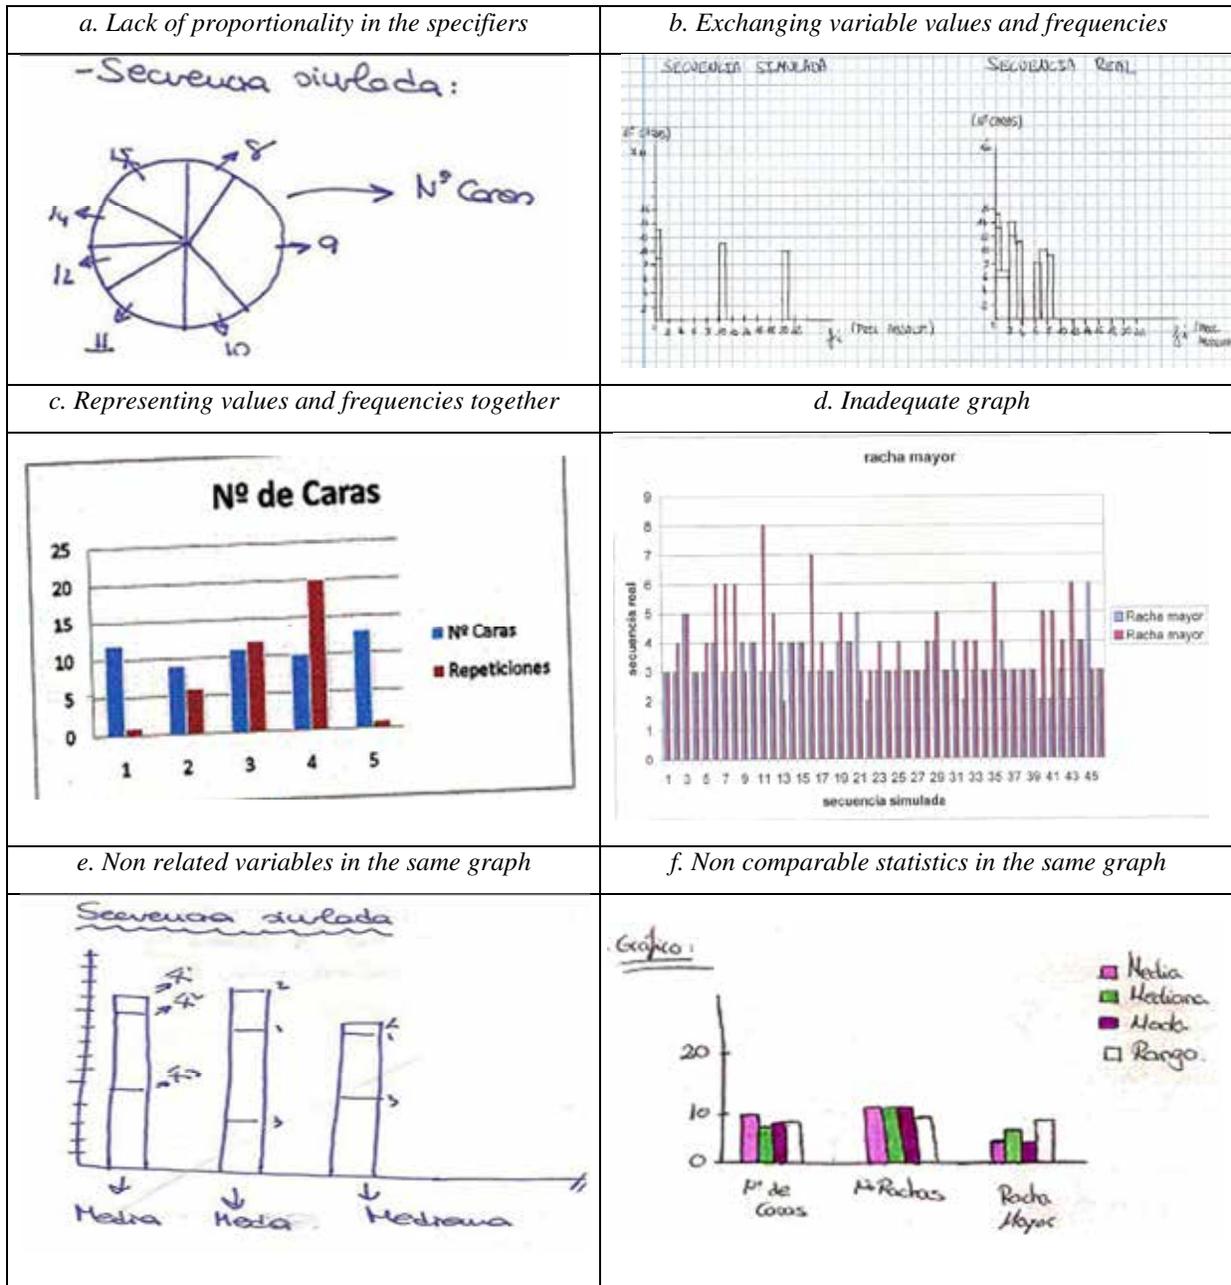

Figure 1. Incorrect graphs

The percentage of incorrect graphs was about 30%; adding the 20% errors in scales, this involves about half of the prospective teachers doing some kind of error. The differences in percentage of correct, mostly correct and incorrect graphs between the three variables posed in the project, were not statistically significant in the chi-square test of

homogeneity for the distribution of errors (Chi = 1.03, 6 degrees of freedom, $p = 0.9$). This suggests that the errors in the graphs did not depend on the variable represented but are due to lack of the necessary competence related to graph construction.

		Number of Heads	Number of runs	Longest run
Basically correct Errors related to scales	1.1. Correct	78(43.1)	57 (39.0)	53 (41.1)
	1.2. Correct and unusual	7(3.9)	7(4.8)	6(4.8)
	2.1. Non proportional scales	0(0)	2(1.4)	3(2.4)
	2.2. Wrong representation of numbers in the number line	4(2.2)	10(6.8)	5(3.8)
	2.3. Confuse titles or scales values	6(3.3)	4(2.7)	4(3.1)
	2.4. Non centered bars	8(4.4)	6(4.1)	7(5.4)
	2.5. Errors in representing intervals	4(2.2)	3(2.1)	3(2.4)
	2.6. Inappropriate scale	13(7.2)	8(5.4)	8(6.3)
Incorrect graph	3.1. Lack of proportionality in the graph specifiers	3(1.7)	4(2.7)	1(0.7)
	3.2. Exchanging variable values and frequencies	2(1.1)	1(0.7)	1(0.7)
	3.3. Representing variable values and frequencies together	3(1.7)	2(1.4)	2(1.5)
	3.4. Representing variable values multiplied by frequencies	2(1.1)	2(1.4)	2(1.5)
	3.5. Inadequate representation	7(3.8)	3(2.1)	1(0.7)
	3.6. Representing non related variables in the same graph	14(7.7)	14(9.6)	13(10.1)
	3.7. Non comparable statistics displayed in the same graph	2(1.1)	2(1.4)	2(1.5)
	3.8. Several errors	28(15.5)	21(14.4)	18(14)
Total		181(100)	146(100)	129(100)

Table 2. Frequency and percentage of participants according to the graph correctness

Influence of computers

Participants in our study were free to use computers or not to solve the task proposed. There were 50 prospective primary school teachers who did their statistical graphs using computers (all of them with Excel); around a fourth of the sample and less than a third part of those participants producing graphs.

An added problem when using computers is that, apart the statistical knowledge needed, it is necessary to know and manage the different software options. This provides an added difficulty to represent data using a graph; consequently many students simply accepted the output provided by the software without using the possibilities of changing the scale, graph type, etc., i.e. they made an uncritical use of the software that was also observed in Ben-Zvi (2002). This happened in our study, where, although a minority of students used computers (Excel), in general, these students had more errors than those who made graphs with only pencil and paper. Table 3 presents the results obtained in our study.

	Number of heads		Number of runs		The longest run		Total	
	Computer	No	Computer	No	Computer	No	Computer	No
Correct	18(36)	67(51.1)	16(40)	48(45.3)	17(42.5)	42(47.2)	51 (39.2)	157 (48.2)

Table 3. Frequency and percentage of prospective teachers according to the correctness of the graph and the use of computers

50 prospective teachers (27.5% of those who made graphs) used the computer to represent the number of heads in the real and simulated sequences, 40 (27.4% of those who made graphs) the number of runs and 40 (31%) the longest run. We note that the proportion of correct graphs was always higher if the participants did not use the computer. There were fewer errors in scales, possibly because the software automatically builds the scales, but there were much more significant errors when using the computer, such as choosing an inadequate graph or plotting frequencies and variables together.

When performing the chi-square test, to test homogeneity in the distribution of the three categories in the global data (last two columns of Table 3) among participants who performed the graph with or without a computer the test was statistically significant (Chi = 19.72, $p = 0.0001$ with 2 degrees of freedom). Therefore the use of software increased the participants' errors.

STUDY IMPLICATIONS

The strength of this study is that we provide specific information about the difficulties that prospective primary school teachers have when building statistical graphs. This is relevant, since graph construction is an important part of the graphical competence that a citizen should have (Wu, 2004; Watson, 2006) and because these teachers will have to teach this content in future. Consequently, we prove the need for these prospective teachers to have more education in working with statistical representations. In agreement

with Bruno and Espinel (2009) and Monteiro and Ainley (2007) our research suggests that building graphs is a complex activity for prospective school teachers. We agree with these authors in the relevance of improving the prospective teachers' levels of competences in both building and interpreting graphs (Arteaga & Batanero, 2011), in order that they later can transmit these competences to their own students.

A limitation of the study is that we did not analyse the pedagogical content knowledge about statistical graphs in prospective teachers. Since Espinel, Bruno, and Plasencia (2008) observed lack of coherence between the graphs built by participants and their evaluation of tasks carried out by fictitious future students there is also need to evaluate this pedagogical knowledge

PSYCHOLOGY STUDENTS' STRATEGIES AND SEMIOTIC CONFLICTS WHEN ASSESSING INDEPENDENCE

Carmen Batanero, Gustavo R. Cañadas, Pedro Arteaga and Maria M. Gea

Universidad de Granada, Spain

In this paper we analyse the strategies used in assessing independence in a two-way contingency table in a sample of 414 psychology students in three different Spanish universities. Strategies are analyzed from the point of their complexity level, their correctness, and the semiotic conflicts involved in the student's reasoning. Although there was perfect independence in the data, most students provided a moderate-sized association coefficient and a positive judgment of association. Few strategies reached the highest complexity level and a number of semiotic conflicts were identified.

INTRODUCTION

Although contingency tables are common to present statistical information and association judgment is a priority learning issue in statistics courses (Zieffler, 2006), little attention is paid to its teaching, in assuming that its interpretation is easy.

This paper describes part of a wider research that was aimed to assess the students' understanding of association in contingency tables before teaching and compare this knowledge with that acquired by the students after a teaching sequence designed for this research (Cañadas, 2012). In the initial assessment three different items corresponding to direct association, inverse association and independence were used. In this paper we only analyze the students' strategies in the item corresponding to perfect independence, because this was the item where students were less accurate in estimating the association coefficient and moreover, the majority of students considered there was association in the data (Batanero, Cañadas, Estepa & Arteaga, 2011). Strategies are classified according to the levels defined by Pérez-Echeverría (1990), and according to its mathematical correctness. Results are compared with those described by Batanero, Estepa, Godino and Green (1996) and students' semiotic conflicts that may explain their wrong strategies are described.

PREVIOUS RESEARCH

Research on association was started by Inhelder and Piaget (1955), who described the strategies used at different ages when judging association in tasks that were formally equivalent to a 2x2 contingency table (see Table 1).

Later psychological studies were developed with adults, and showed that subjects perform poorly, when judging association in these tables. For example, Smedslund (1963) found that some adults base their judgment only on cell a in Table 1 or by comparing a with b . Allan and Jenkins (1983) showed the tendency to base the association judgments on the difference between cell a and d in Table 1. Although Allan and Jenkins (1983) found that comparing the diagonals ($a+d$) and ($c+b$) was common in adults. Jenkins and Ward (1965) remarked that this strategy of is only valid

in tables that have rows with equal marginal frequencies. A correct strategy valid for all types of tables, according to Jenkins and Ward is comparing of the two conditional probabilities, $P(B|A)$ and $P(B|NotA)$, that is, comparing $a/(a+c)$ with $b/(b+d)$. Pérez Echevarría (1990) classified strategies that have been identified in psychological research until that time into 6 levels of performance. Levels 0 to 3 correspond to students who use 0 to 3 cells to perform the association judgment. In levels 4 and 5 the students use the four cells; the difference is that comparison between the cells are additive in Level 4 and multiplicative in Level 5.

	A	Not A	Total
B	a	b	a+b
Not B	c	d	c+d
Total	a+c	b+d	

Table 1: Format of a 2x2 contingency table

In a different perspective, Chapman (1967, pp. 151) reported a common bias that he called "illusory correlation": "*the report by observers of a correlation between two classes of events which, in reality, (a) are not correlated, (b) are correlated to a lesser extent than reported, or (c) are correlated in the opposite direction from that which is reported*". Many researchers have reported this bias and suggest that previous theories disturb the estimates of association (e.g., Wright & Murphy, 1984; Meiser & Hewstone, 2006). Batanero, Estepa, Godino, & Green (1996) analyzed the performance of 213 17 year-olds high school students and their strategies in association judgments and defined different conceptions of association: (a) *causal conception* according to which the subject only considers association between variables, when it can be explained by the presence of a cause - effect relationship; *unidirectional conception*, by which the student does not accept an inverse association, and *local conception*, where the association is deduced from only a part of the data.

Our research is aimed to go further in the analysis of strategies in the case where data show perfect independence, since this was the task in which students performed worse in Batanero et al. (1996) study, and in our previous study (Batanero, Cañadas & Arteaga, 2011). We also complement the type of analyses made in previous research in order to identify potential *semiotic conflicts* of students when assessing independence. This term is taken from, who adapted from Godino, Batanero, and Font (2007), who adapted from Eco (1979) the idea of semiotic function: "the correspondences (relations of dependence or function) between an antecedent (expression, signifier) and a consequent (content, signified or meaning), established by a subject (person or institution) according to certain criteria or a corresponding code" (p. 130). These authors also suggest that in mathematical practices different objects intervene: *problems, actions, concepts-definition, language properties and arguments*. For them "*the role of representation is not exclusively undertaken by language*": in accordance with Peirce's semiotic, they assume that "*the different types of objects can also be*

expression or content of the semiotic functions” (p. 103). The authors term *semiotic conflict*, any “*disparities between the student’s interpretation and the meaning in the mathematics institution*” (p. 133). This construct is weaker than that of conception, as stability is not required from the student, but only a misunderstanding or misinterpretation of a mathematical concept, property, language or procedure.

METHOD

The sample included 414 students in their first year of psychology studies from three Spanish universities: Almeria (115 students), Granada (237 students) and Huelva (62 students), all of them taking an introductory statistics course. The task given to the students (Figure 1) was adapted from Batanero et al. (1996), changing to a context of psychological diagnose, without varying the data. The samples included all the students enrolled in the course and attending the session; the difference in sample sizes was due to the size of the University. Though they had not yet studied association in the course they were following, the students had studied statistics in secondary education.

A researcher is studying the relationship between stress and insomnia. In a sample of 250 people he observed the following results:

	Stress disorders	No stress disorders
Insomnia	90	60
No insomnia	60	40

Looking to these data, do you think there is a relationship between stress and insomnia?

Please mark on the scale below a point between 0 (minimum strength) and 1 (maximum strength), according to the strength of relationship you perceive in these data.

Figure 1: Task proposed to the students

In part (a) of each item, students are asked to provide an association judgment. There are two categories of responses: (a) the student considers that the variables in the item are related (judging association); (b) the student considers the variables to be not related (judging independence). The estimation for the association coefficient estimation is deduced by measuring the exact position of the point drawn by the student on the numerical scale (0-1) in the second part of the item. Finally, a qualitative analysis was used to identify the strategies used by the students and their semiotic conflicts. The classification of strategies was performed by two different members of the team; in case of disagreement, it was discussed with the other team members until an agreement was reached.

RESULTS AND DISCUSSION

Association judgment and estimation of association

In Table 2 we present the percentage of students who considered (or not) the existence of association between the variables and the mean value of their estimation for the association coefficient. Most students indicated the existence of association although data in the item correspond to perfect independence. This judgment is consistent with their estimation of the association coefficient, which is moderate-sized in average. The differences in mean estimate (in the ANOVA test) or in the percent of students judging association (in the chi-square test) between the three universities were no statistically significant. This suggests that students' responses were similar, despite the difference in educational context. Results may be explained by illusory correlation (Chapman, 1967) since in this item data contradicts the students' previous theories (that stress is related to insomnia), as well as by the causal conception of association, reported by Batanero et al. (1996), who found 55.4% of students judging association in an item with the same numerical data and where the data also contradicted previous theories.

	Almería (n=115)	Granada (n=237)	Huelva (n=62)	Total (n=414)
Mean estimate	0.51	0.47	0.44	0.47
Number (and percent) of students considering there is association in the data	87 (75.7)	194 (81.9)	42 (67.7)	323 (78.1)

Table 2: Mean estimates of association and association judgment

Level of strategies

In order to explain the above results we analyzed the students' strategies, and the mathematical practices involved in these strategies. Firstly, the students' strategies were classified according to their correctness, in three groups: (a) correct strategies (that always produce a correct association judgement); for example, comparing the proportion of people with and without stress disorder in both groups of people with and without insomnia; (b) partly correct strategies that produces a correct response only for specific tables and involves some correct (although partial) ideas about association; for example comparing the sums of diagonals in the table; is only valid when the marginal frequencies in the table are identical; (c) incorrect strategies, when students use a procedure that is a priori wrong in all type of tables; such as for example, using only cell *a* to solve the task. This classification was crossed with the levels of difficulty proposed by Pérez Echeverría (1990), in the following way:

Level 0 Strategy. The student used no information from the table and only took into account his/her own previous theories about the association; the illusory correlation (Chapman & Chapman, 1969; Murphy & Medin, 1985) is shown in this case, for example: *Since when you do not sleep this cause some stress* (Strategy 0, Student 5).

Level 1 Strategy. When the student only used one cell in the table; usually cell *a* because this is the cell when both characters are present and has a higher impact on our

attention (Smedlund, 1963; Beyth & Maron, 1982; Shaklee & Mins, 1982, Yates & Curley, 1986): “*there is association, since 40% of the sample have insomnia and stress*” (Strategy 11; Student 111); other students used one of the cells *b* or *c* that contradicts the association: “*there is no relation since there are 60 people with stress and no insomnia and this is a big percentage*” (Strategy 12, Student 51).

Level 2 Strategy. Some students used two cells; for example, they compared *a* with *b* or *a* with *c*, so that they deduced association from only one conditional distribution, which is incorrect: “*If you look to the people with insomnia, there are more people with stress (90) than without stress (60)*” (Strategy 21, Student 21). Other students compared the cells with maximum and minimum frequency (Batanero et al., 1996): “*there are 90 people with stress and insomnia and 40 without stress and without insomnia; 90>40, but the relation is not too strong*” (Strategy 22, Student 61).

Level 3 Strategy: In this strategy students used three cells; for example, they compared cell *a* with *b* and *c*. In general, these students discarded cell *d* that correspond to the absence of both characters (Batanero et al., 1996): “*there is relationship as there are more people with stress and insomnia (90 people) and exactly the same number (60) with either stress and no insomnia or insomnia and no stress*” (Strategy 3, Student 153). All level 1 to 3 strategies are incorrect as the students only use part of the data and then show a local conception of association (Batanero et al., 1996), while part of the strategies in levels 4 and 5 are partly correct or correct. In Level 4 and 5 strategies students use all the cells; for example when they compare rows or columns. The difference is performing additive or multiplicative comparisons.

Level 4 strategies are based on additive comparisons of the four cells. One example is comparing the sum of diagonals ($a+d$) with ($b+c$): “*there are 130 people with both stress and insomnia or no stress and no insomnia, while there is only 120 with one of these symptoms.*” (Strategy 41, Student 176). This strategy was found by Allan and Jenkins (1983). This strategy could provide a good solution when the marginal frequencies (number of people with and without insomnia) were equal, according to Shaklee (1983); for this reason we considered the strategy to be partly correct. In another example, students compared two conditional distributions in additive way: “*In people with insomnia there is a difference of 30 having stress, while the difference in people without insomnia is smaller (20)*” (Strategy 42, Student 267) or else compared all the absolute frequencies among them: “*There are many with stress and insomnia (90) but the relationships is not strong, since having stress and no insomnia or insomnia and no stress (69) is also high, much higher than no insomnia and no stress (40)*” (Strategy 43, Student 156).

Level 5 strategies use all the four cells with multiplicative comparisons, but still may be incorrect or partly correct. For example, a wrong strategy is to compute all the joint relative frequencies and compared them: “*I computed the percent of each data and compare the results: $\frac{90}{250}100=36\%$; $\frac{60}{250}100=24\%$; $\frac{60}{250}100=24\%$; $\frac{40}{250}100=16\%$* ” (Strategy 51, Student 11). This procedure is incorrect, because the association should be deduced

from conditional distributions and not from joint distributions. An example of partly correct strategy is assuming that all joint relative frequencies in the table should be identical (that is, 25% cases in each cell). We considered this strategy partly correct because the student computed some “expected” frequencies, compared them with the observed frequencies and deduced that there was no association because these two types of frequencies were different. The strategy could have worked (and then was partly correct) in case the computation of expected frequencies were correct: *“I divided 250 between 4 (25%) to see the number of people we should expect in each cell, in case of no relationship. However, although the number of people with no insomnia and stress and no stress and insomnia are close to 25% there is a big difference in the other cells; more than 25% people with both insomnia and stress and less than 25% people with none of them (Strategy 52, Student 1).*

Finally, among the level 5 correct strategies we find students who compared two conditional distributions; for example, $a/(a+b)$ with $c/(c+d)$ or else performed a similar procedure in comparing columns: *“When we observe the table, 60% of people with insomnia have stress and also 60% of people with no insomnia have stress; the percentage is the same” (Strategy 53, Student 28).* Another correct strategy is comparing possibilities in favour and against B for each value of A; which was described by Batanero et al. (1996): *There are 90 people with insomnia for every 60 with no insomnia when you have stress; that is the odds are 3/2; the same odds 60/40 apply when you do not have stress” (Strategy 54, Student 21).*

	Incorrect	Partly correct	Correct	Total
Level 0	13 (100.0)			13 (3.1)
Level 1	73 (100.0)			73 (17.6)
Level 2	108 (100.0)			108 (26.1)
Level 3	27 (100.0)			27 (6.5)
Level 4	27 (26.2)	76 (73.8)		103 (24.9)
Level 5	20 (26.3)	10 (13.2)	46 (60.5)	76 (18.4)
No response	14 (100.0)			14 (3.4)
Total	282 (68.1)	86 (20.8)	46 (11.1)	414 (100)

Table 3: Frequency (and percent of total) of strategies by level

In Table 3 we present the frequency of responses in the above categorization. Only 11.1% of students used correct strategies and 20.8 % of them partly correct strategies. Students tended to use either level 2 or level 4 strategies none of which are correct, and moreover there were a big percentage of students who did not use all the cells information, since their strategies were level 3 or lower. At level 4, about 30% students compared join frequencies among them, an incorrect strategy described by Batanero et al. (1996) and about 60% used the four cells with additive comparisons, a strategy

described by Inhelder and Piaget (1955) in the concrete-operation level but that also was found by Batanero et al. (1996) in high school students. Finally most of level 5 strategies were correct as students either compared the odds ratios or compared conditional distributions a strategy proposed by Jenkins and Ward (1965) and also found in Batanero et al. (1996). The accuracy in the estimation of the association coefficient (true value is equal to zero) increases with the strategy correctness (Table 4) and the differences were statistically significant in the Anova test.

p value (Anova)	Incorrect strategy		Partly correct strategy		Correct strategy	
	Mean	Typical error	Mean	Typical error	Mean	Typical error
0.000	0.536	0.012	0.432	0.024	0.174	0.038

Table 4: Mean estimate of association coefficient in different type of strategy

Semiotic conflicts

The analysis of incorrect and partly correct strategies led to the identification of the several semiotic conflicts, which are classified below, according to whether they involve disparities in the meaning students assigned to association or independence (attributing wrong properties to these concepts) or other conflicts:

1. *Incorrect properties assigned to association:*

- (a) Identification of causality and association, which was called *causal conception of association* by Batanero et al, (1996) was found in level 0 strategies. Since we could not observe the stability of this belief, we just considered it as a wrong interpretation of a property of association (a semiotic conflict), because although causality always involves association, association does not always involves causality, students misinterpreted that this relation was symmetrical.
- (b) Assuming that association can be deduced from only a part of the data (which was called *local conception of association* by Batanero et al, 1996 and also appear in previous research, eg. Smedlund, 1963; Beyth & Maron, 1982; Shaklee & Mins, 1982; Yates & Curley, 1986; Pérez Echeverría, 1990). This conflict appears in all the strategies in levels 3 or below; again, we interpret this belief as a misinterpretation (conflict) as we could not observe its stability.
- (c) Assuming that it is possible to deduce association from additive comparisons, a strategy that should have been overcome, according to Inhelder and Piaget (1951) at the formal operations stage, but which, however, appeared in our sample in all the level 4 strategies. Students using this procedure only took into account the favourable cases (and not all the possible cases) when comparing probabilities; and therefore this strategy involves a conflict in understanding the idea of probability.
- (d) Assuming that association can be deduced from only one conditional distribution (Strategy 21), which was also described by Inhelder and Piaget (1951). Students here only used the conditional distribution of B given A and did not identify the relevance of the conditional distribution of B , given not A for the association.

- (e) Assuming that the difference in absolute conditional frequencies is enough to support association, an error which was found in Smedlund (1963) and Shaklee and Mins (1982) and appear in Strategy 43. The conflict appears as students misunderstood the important of relative frequencies in the study of association.
- (f) Assuming that the association can be deduced from the difference between the sums of diagonals in the table. That strategy was considered to be correct by Piaget and Inhelder, but Allan & Jenkins (1983) and Shaklee and Tucker (1980) suggested it does not work in the general case (for example, in the task given to the students). It appeared in strategy 53.
- (g) Assuming that $a > d$ in case of association, which appeared in Strategy 22. These students considered that only these two cells influence the association and consequently they did not understand that cell d , have the same value than a on the association. We did not find this strategy in previous research.

2. *Incorrect properties attributed to independence*

- (a) Expecting equal joint frequencies in case of independence, which involves confusion between the ideas of independence and equiprobability. It appeared in strategy 52 and was not described in previous research.

3. *Other conflicts*: Basing the association judgment in their own opinion, instead of considering the data, which appear in level 0 strategies, where students were guided by the illusory correlation phenomenon described by Chapman & Chapman (1969).

DISCUSSION AND TEACHING IMPLICATIONS

Most psychology students in our study judged association in a task where there was perfect independence, due to the illusory correlation phenomenon and their previous theories, which affected their accuracy in estimating the association coefficient. Results in our study were worse, as compared with Batanero et al. (1996) since a higher percent judged association. These authors did not inform about the estimate of association by their students; in our study the estimation was consistent with the association judgment. Results were very close in all participating universities. Regarding the conceptions described by these authors, we observed the causal and the local conception. Since we could not check the stability of these conceptions, we used instead the idea of semiotic conflict, which only involves a mistaken interpretation of a mathematical expression, a concept, property or procedure. Our list of semiotic conflicts is wider than the list of conceptions described by the authors, as new conflicts related to the ideas of association and independence were identified in our study. For example, in addition to assume that association may be judged from only part of the data, another frequent conflict was assuming that association can be judged from absolute frequencies (instead of relative frequencies). Another new conflict is assuming that the cells in the four cells in the table should have equal frequency in case of independence. Since semiotic conflicts do not assume a strong conviction on the part of the students, it is possible to change them with adequate instruction and then the

identification of these conflicts in the students is a first step in order to correct their wrong reasoning and improving their competence in judging association.

All these reasons and our results suggest the need for further research about teaching association, since the causal conception and the effect of illusory correlation does not seem to improve with traditional instruction (Batanero, Godino, & Estepa, 1998). Our purpose is to continue this work by designing an alternative teaching with activities that confront students with their conflicts and help them overcome them. This proposal will be tested and students will be assessed in order to compare their intuitive ideas with those acquired as a result of teaching.

CONTEXTUALIZING SAMPLING – TEACHING CHALLENGES AND POSSIBILITIES

Andreas Eckert

Per Nilsson

School of Computer Science, Physics and Mathematics

Linnaeus University, Sweden

The aim of the present paper is to shed light on mathematical knowledge for teaching probability. In particular we investigate critical instances when a teacher tries to keep track on the idea of sampling and random variation by allocating the discussion to an everyday context. The analysis is based on a certain episode of a longer teaching experiment. The analytical construct of contextualization was used as a means to provide structure to the qualitative analysis performed. Our analysis provides insight into the nature and role of teachers' knowledge of content and teaching. In particular, the study suggests the idea of a meta-contextual knowledge that teachers need to develop in order to keep track of the intended object of learning when allocating their teaching to an everyday context.

Keywords: Sampling, probability, descriptive statistics, mathematical knowledge for teaching, knowledge of content and teaching

INTRODUCTION AND AIM OF STUDY

This paper is part of a larger research project, which aims at investigating the nature and role of *Mathematical Knowledge for Teaching Probability* (MKTP).

Mathematical knowledge for teaching (MKT) (Ball, Thames, & Phelps, 2008) is a general knowledge framework which aims at structuring an understanding of teacher competences for teaching mathematics. The framework is divided in two main domains, *subject matter knowledge* (SMK) and *pedagogical content knowledge* (PCK). Both domains are viewed equally important for teaching mathematics. On an overall level, the notion of SMK implies that all mathematical content matter is similar in nature, following a certain mathematical logic and structure of axioms. However, there are reasons to consider specifics of MKT in relation to probability theory as this is considered different in nature to other branches of mathematics.

Steinbring (1991) argues that not even the basic concepts of probability theory fit into a logical deductive way of acquiring mathematical knowledge. For example, the concept of probability is used to describe chance but what is unique with probability theory is that the inverse is also true. In this way, probability concepts are self-referential, which implies that teaching probability requires a dynamic outlook on knowledge development. Stohl (2005) also recognizes that probability-laden situations could not be structured in a purely logical and deterministic way as for instance algebra and geometry. Since probability deals with modeling random dependent situations it operates within a non-deterministic paradigm and it is not possible, by certainty, to derive and predict a certain result.

Connected to the specific nature of probability, there are reasons to take a closer look at the pedagogical content knowledge teachers should develop in trying to make sense of probability in teaching. However, there are few attempts made to study in detail different aspects of PCK for teaching probability. Against this background, the present paper aims to contribute with insights on *knowledge of content and teaching*, a certain sub-category of PCK in the MKT framework, in relation to the teaching of probability. Knowledge of content and teaching is described by Ball et al. (2008) as a repertoire of forms of representations, techniques and examples and the interaction between mathematical understanding and pedagogical assets in relation to students' learning. In particular the paper focuses on the challenges a teacher might meet when contextualizing *sampling* in an everyday context through classroom discussion.

Described by Gal (2005), there are two overall reasons for teaching probability in school. The first is internal in that probability is part of mathematics and should be developed in its own right. The second reason is external in the sense that “the learning of probability is essential to help to prepare students for life” (Gal, 2005, p. 39). Elaborating on this duality, Gal (2005) suggests that teaching should put sufficient emphasis on probability-laden situations in the real world in order to help students to develop *probability literacy*. However, even if Gal (2005) proposes that the teaching of probability should, to great extent, stress real world applications of probability discussions, little is known about how such teaching should be structured and the nature of MKTP required in such teaching, for making details of intended probability content available to the students' learning.

The teacher's role is seen crucial for orchestrating a classroom discussion in ways that allow students to make sense of the mathematics (McCrone, 2005). To make a story of a mathematic content available to the students and to support their meaning makings of that story, teachers should make details of the content explicit in the discussions, in both explanations and questions asked (Franke, Kazemi, & Battey, 2007). In the present paper we intend to look at a teacher's explications or lack of explications, when the teacher tries to make the story of sampling available for a class of Grade 5 students in a Swedish school by allocating the discussion to an everyday context.

Aim of Study

The aim of the present paper is to shed light on knowledge of content and teaching probability (KCTP) required for *contextualizing* a probabilistic content in an everyday story. In particular we intend to investigate critical instances when a teacher tries to make sense of the idea of sampling by allocating the discussion to an everyday context.

FOCAL PROJECT, CONTEXT AND CONTEXTUALIZATION

The analysis reported in the present paper was based of the analytical construct of contextualization (Halldén, 1999; Nilsson, 2009). The construct of contextualization can be considered a constructivist reaction to constructivists' purported neglect of contextual aspects of learning.

Context plays a certain role in contextualization. In a sociocultural perspective, context refers to stable physical and discursive elements of a setting in which a learning activity takes place (Resnick, 1989). However, based on constructivist assumptions, in the present paper context refers to the cognitive context shaped by the learner's personal interpretations of an activity (Cobb, 1986). To speak about students' processes of contextualization is to speak about how learners struggle to render a phenomenon or concept intelligible and plausible in personal contexts of interpretation (Caravita & Halldén, 1994). This idea rests on the principle that we always experience something in a certain way, from a certain set of premises and assumptions (Säljö, Riesbeck, & Wyndhamn, 2003). Related to that, contextualization gives sense to learning mechanisms of how and why different knowledge elements make the activation of others either more or less likely (cf. Shelton, 2003). In other words, talking about how teachers and students contextualize a phenomenon is a way of organizing and conceptualizing their views of the phenomenon and what these views imply for their understanding of the phenomenon and their way of communicating the phenomenon.

To clarify how different contextual elements serve as points of reference in processes of contextualisation, it has shown fruitful to structure between elements referring to a *conceptual*, *situational* and *cultural* context. The conceptual context refers to personal constructions of concepts and subject matter-structures. The situational context refers to interpretations made in the interaction between the individual and the immediate surroundings, including interpretations of figurative material, possible actions and directly observable sensations. Third is the *cultural* context, referring to constructions of discursive rules, conventions, patterns of behaviour and other social aspects of the environment (Halldén, 1999).

It has also shown to be fruitful to structure between the *focal project* (FP) of a reasoning process and the *context* in which the FP is treated or contextualized (Nilsson, 2009; Nilsson & Ryve, 2010). To talk about a FP means that we pay serious attention to what a teacher or a student is actually trying to make sense of, or trying to work out. So, what constitutes the FP in a pattern of contextualization is the problem, goal or intention that a teacher or a student engage in and interpret as being their obligation to solve or achieve (Nilsson, 2009). Hence, viewing meaning making as a process of contextualization an analyst strives to account for agents' FPs and the way they contextualize these projects in order to understand how and why content elements are brought into play within a reasoning.

METHOD

Shaughnessy (2003) emphasizes the role of data experimentation in the teaching and learning of probability. He claims that, when trying to make sense of data, students are encouraged to develop probability questions. However, from research we know that it is not an easy task for students to make sense of data. Makar and Rubin (2009) report that students often disregard frequency data and also are struggling to connect conclusions to the data they have collected regardless of sample size (Makar & Rubin, 2009). The authors point to the need for teachers to make this connection more explicit to the learners. Also, Pratt, Johnston-Wilder, Ainley, and Mason (2008) highlight students' difficulties interpreting information in a data sample as they challenged students (10-11 years old) to infer, from data, the unknown configuration of a virtual die. Similar to Stohl and Tarr (2002), Pratt et al. (2008), show that what became critical for the students was the role of sample size, to understand the difference between drawing conclusions on the basis of the global (long-term) and local (short-term) behaviour of a data sample.

The rationale of a teaching experiment

The episode that will be presented and analysed in the present paper concerns how a teacher introduces a discussion on sampling and sample size through an everyday contextualization. The episode emerged within the frame of a teaching experiment in which a class of fifth graders had first been planting pumpkins and sunflowers. Since this is the first time these students encounter probability theory in the school environment, we find it important to give a brief overview of the teaching that took place before the episode that is in focus of our analysis in order to better understand our interpretations of the teachers' and the students' acts.

A developmental team, consisting of Maria, the teacher of the class, the second author of the paper and Torsten, a specialist on outdoor education, stood behind the design of the experiment. Maria did all the teaching. Ten students participated in the study, which was stretched over two lessons. Each student was assigned an individual box of one square metre during the first lesson in which they were planting 18 pumpkin and 18 sunflower seeds. Maria held a probability lesson about three week after the seeds were planted, which was based on the germination of pumpkins and sunflower seeds. The teaching rationale of the activity was, at the first place, to challenge the students on the idea of sampling and, specifically, on the role of sample size for making probability predictions. The teacher tackled this issue by confronting the students with the variations in growing outcomes between the students' individual boxes. For instance, in one box only one of the 18 pumpkins grew. This was compared to boxes where up to eleven of the 18 pumpkins grew. Based on this, the teacher led a discussion about how we have to combine more and more observations in order to get a more valid result of the chance for a seed to grow. The first part of the teaching ended with putting together all student results and dividing the resulting number by the total number of planted seeds to get an estimation of the probability

for a seed to grow. The same procedure was done for both the pumpkins and the sunflowers.

The rationale of the second part of the teaching episode was to represent the results of growing seeds in the structure of a two-way contingency table (Figure 1).

	Growing	Not growing	Total
Sunflowers	51	129	180
Pumpkins	67	113	180
Total	118	242	360

Figure 1: Two-way table of the growing of sunflowers and pumpkins

Not only the teaching but also the work of the developmental team were audio and video recorded. The developmental team made brief reflections on the teaching in immediate connection to the teaching. However, the detailed analysis presented in this paper was made by the authors of the present paper.

Data-analysis

This paper focuses on a certain episode of the entire teaching where Maria ends the lesson by telling an improvised story containing a sampling situation. The story is supposed to wrap up the discussions and introduce the coming lesson, in which the students were supposed to plan for and conduct their own probability-laden, statistical investigation. The third lesson was not actually supposed to be part of the teaching experiment. But implicitly it was, as the introduction of the lesson was included at the end of the second lesson.

In the analysis we are specifically looking for the participants FP and their contextualizations of their FPs. We account for this by attributing an intention to their behaviour. For example, a teacher does not assign a task to her students randomly. The teacher has an intention with this and by considering her behaviour as intentional, and continuously adjusting our interpretations of her intention, we create a model of her FP and the ways she is contextualizing the project.

RESULTS AND ANALYSIS

We enter the lesson when Maria portrays a picture where she waits outside a store for her husband to exit. While waiting, she keeps track of the number of each sex that visited the store. We have chosen to highlight certain transcripts from this episode as it helps us to illustrate and communicate our analytical points in relation to our research question.

The same context but competing focal projects

Maria portrays a situational context in which she is standing outside a store one early morning, reflecting on how many males that have visited the store. We ascribe to her the intended project, trying to contextualize sampling in a new way so the students get the opportunity to translate what has been discussed previously about samples.

Within this situational context Maria introduces a *genus context*, which is directed towards the distribution of men and women taking responsibility of shopping for groceries. Taking a close look at the way in which Maria is orchestrating the story, we note that she includes multiple FPs to her story, which we consider making it hard for the students to follow the storyline and the mathematical idea of it. We particularly distinguish two specific conflicting FP, dealt with within the same genus oriented context. First Maria has the intention of contextualizing sampling to the students and second she has the intention to convince her husband to more often do the shopping. Implicitly the story is also intended to create an interest for similar surveys since Maria is planning for an upcoming assignment on the topic of statistics and probability. She struggles to explicate the mathematical intention and give support to the students' meaning making process early in the story.

Maria: Another male, that makes three men, and it continued. I wondered, are men such early birds? My husband usually doesn't go shopping this early. I'm going to tell him that I stood here and watched. Then when I've counted ten people, seven of them were male. So I thought I would tell him that seven out of ten were male.

[...]

Maria: The worst part was, he [the husband] didn't exit. So I kept on waiting, and then a lot of women started to appear

Student 1: And then, when you looked out the window, you saw a girls' bus and a boys' bus.

Maria: No, but there were women and women and women. Eventually 20 men and 20 women had exit the store.

Our interpretation is that Maria's mathematical intention has not been made plain for the students so far. Instead they are subjected to the intention to reduce the disparity between men and women in typical household chores like shopping for groceries. Since this is a mathematics lesson, there are reasons to believe that the students are searching for a mathematical intention in the story of which they should make sense. We interpret that one student has caught on such a meaning and that there exists an unofficial game between Maria and her husband. If there are more men shopping in the morning, Maria's husband must do so more often as well and she wins. So the student tries to challenge the rules and prerequisites with a statement.

Maria: And do you know what I did then? I stopped counting.

Student 1: Coward!

Maria: You know, I didn't want there to be more girls than boys, right?

Student 2: You didn't have to tell him [Maria's husband] that you counted.

Maria: No, I actually didn't, since the outcome was what it was.

[...]

Maria: If I had stood there and counted a hundred, maybe 70% would have been women, right?

[...]

Maria: And if I would of stood there even longer I would of gotten an even better result. What the probability was for a man or a woman entering the store, right?

The teacher does not show any signs of recognizing the fact that there are competing FPs in the discussion. We note that more students seem to try to make sense of the story in terms of a game. They sense that Maria is about to loose, calling her a coward and offering her a way out, and she is admitting that fact from their point of view by not telling her husband about the result. To think of the story in terms of a game rather than whether men shop for groceries or not, might fit better with the students' expectations of probability application and their attempt of meaning making. In other words, since Maria's competing FPs appear confusing, the students contextualize the intended learning object of the story in a way that makes more sense to them.

Maria keeps on pushing her genus perspective combined with fairness. She does not want it to be more girls than boys shopping for groceries in an equal society. There is also a preconception on the teacher's behalf that the students share this view. But randomness does not have a genus agenda, making the two FPs conflicting, so she steps in and manipulate the result by keeping the sample size small. Her intuition tells her that more women shop for groceries, since that mental picture is more available to her. The session illuminates that Maria has a sound understanding of sampling and the role of sample size. Because of her knowledge of sampling she acknowledge that it becomes a risk to continue the thought experiment. She anticipates that the result will probably not differ much from the assumed true value in the long run, opposing her gender equality agenda.

There are more references to Maria's mathematical intention towards the end of the story. She eventually manages to explicate the mathematical content right at the end in a statement formulated with probability wording relevant to sampling by posing the question "What the probability was for a man or a woman entering the store, right?". The situational and cultural context seems to be the focus of Maria, instead of the conceptual context, for most of the episode. Next we will analyse what motivates the story.

Competing driving questions

At the beginning of Maria's improvised investigation outside the store, the driving question is implicit and could be interpreted in different ways. We find two, equally likely, possible interpretations. It could be a question about how many men shop for groceries early in the morning where the FP would be to contextualize aspects related to descriptive statistics. Or a more probability oriented question about the probability

for a man going shopping for groceries early in the morning, where the FP would be to contextualize aspects related to probability. Since the driving question is left unspoken, it is left up to the students to formulate a question that fits their individual meaning making of the story. We suggest that the close relation between statistics and probability when handling relative frequencies becomes an obstacle for teachers. It places great demand on teachers' subject content knowledge to be explicit about the driving question and how it corresponds with the teacher's FP with the activity, e.g., if the intention is to offer a description of a phenomenon or if it is to make a prediction of future behaviour of the phenomenon. More concretely, is the intention to describe differences between how many women and men that are shopping for groceries or is the intention to estimate the probability that the next person out of the store is a man? We interpret that Maria her self struggles between the two as she continues the story and right at the end of the story, Maria says the following:

Maria: If I had been there a whole day, I would of known if there are more women or men that goes shopping that specific day. And if I had been there for two days, I would of gotten an even better result. And if I would be staying there even longer I would have had an even better result: what the probability was for a man or a woman entering the store, right?

One way of interpreting Maria's words is to question her subject matter knowledge, that she is not sure her self about the difference between descriptive statistics and probability theory or even if there are any difference. But viewed from a perspective of mathematical knowledge for teaching we suggest that the classroom dialogue itself provides, probably unintentionally, the means for Maria to clarify the difference between a descriptive statistical and a probability-laden question formulation. The last turn of the last citation is actually the first time when she develops her contextualization of sampling in the story by including a question that is explicitly directed to probability to her context. It appears at the end of the discussion and we claim that it has not been explicit neither to the students, nor to the teacher from the beginning of the story. Hence, by contextualizing sampling as she did, we claim that also Maria developed her way of making sense of probability through the dialogue and the way she contextualized the question of sampling.

DISCUSSION

By taking this close look at a certain segment of the data gathered from the entire teaching activity, we are not in the position to make claims about the quality of the students' understanding of sampling and the role of sample size for making probability predictions. However, to make claims about the students' actual understanding has not been the issue of the present paper. The aim of the paper was to investigate aspects of teacher competencies in relation to the challenges a teacher might reach when trying to orchestrate the idea of sampling by allocating the discussion to an everyday context. Based on this we can reflect on the enacted object of learning (Marton & Tsui, 2004) in terms of how a teacher use everyday oriented

contextualizations to offer students opportunities to discern and learn concepts and ideas of probability theory.

Gal (2005) suggests that the teaching of probability should orient towards everyday situations in order to support the development of probability literacy. Even if we adhere to such a view of teaching, our analysis shows that this might not be an easy enterprise for teachers. Moreover, our analysis suggest that the problem of connecting to everyday situations should not only be considered as an issue of teacher's insufficient mathematical content SMK (Ball et al., 2008). We suggest that, what became crucial to Maria relates to her knowledge of content and teaching. What seem to be crucial for Maria in her attempt to create certain learning opportunities for her students by allocating the teaching to an everyday situational context, is to be aware of what contexts and FPs she is actually communicating. In that sense, our study extends the notion of KCTP to not only being a matter of a teacher possessing a repertoire of forms of representations, techniques and examples (Ball et al. (2008).

Based on the last lines of reasoning, our initial observations indicate that teacher education should challenge teachers to develop a kind of meta-contextual knowledge in order to learn to be explicit about their agenda in addition to developing SMK of probability. If a teacher uses an everyday contextualizing to make sense of probabilistic ideas and concepts, the teachers should be aware of that such a context might involve many items and variables that can obscure the intended ideas and concepts and sometimes even inhibit them from coming to the fore in the teacher's and students' reasoning. This implies the need to challenge teachers to be more aware of the implicit assumptions on which a reasoning rests and how explicit they are communicating the intended object of learning in a whole-class discussions.

Makar and Rubin (2009) emphasize the need of a driving question in the teaching of stochastic. In our analysis we note that the teacher communicates several different FPs in the discussion, mediated by different driving questions. So, there is no lack of driving questions as such. However, what we consider problematic is that there are several FPs and questions in play simultaneously, which the teacher seems to be unconscious of. We consider the teacher's difficulty to include a clearly defined probability oriented driving question as an important aspect. The students are supposed to become challenged to think about and propose predictions that contain degrees of uncertainty and that are based on frequency information. As claimed above, the analysis indicates that most of what Maria says stay within the context of descriptive statistics. As we can see in the last part of the last quote above, and from what we hear when we listen to the activity in its whole, we consider her to have sufficient subject knowledge to formulate probability oriented questions. Again, we believe that the critical element relates to a meta-level. She have to be aware of what FPs she mediates to the students and the ways in which the questions she poses direct the communication.

Our main conclusion from the analysed episode is the need for a meta-contextual knowledge amongst teachers that have the intention to allocate the meaning of

probability concepts to an everyday story. We also conclude that there is much left to do to define what a meta-contextual knowledge in probability constitutes of and what its consequences are for the teaching of probability. A more exhaustive teaching experiment, combined with qualitative analysis of interviews or focus group discussions with teachers would help to get further insight to these issues.

PRINCIPLES OF TASKS' CONSTRUCTION REGARDING MENTAL MODELS OF STATISTICAL SITUATIONS

Andreas Eichler, Markus Vogel

University of Education Freiburg, University of Education Heidelberg

In this paper we focus on the construction of tasks which is a specific topic within our on-going research into the development of a diagnostic tool for analysing young students' mental models when they act within simple statistical situations. For this, we discuss tasks from a theoretical perspective concerning statistical content, statistical thinking processes and – as the main aspect in this paper – the representation of tasks. We deduce principles of the tasks' development partly from statistics education research literature and partly from our previous research.

INTRODUCTION

The focus of this theoretical paper is on the development of tasks including simple realistic situations of uncertainty aiming to diagnose young students' perception of these situations. The development of tasks is part of a larger project (Eichler & Vogel, 2012), which aims to develop a diagnostic instrument for describing statistical situations' perception of students not having been taught in statistics and, further, to evaluate this perception of these students after a systematic schooling in statistics. Since in the mentioned research project a student sample was investigated using a first set of tasks involving simple statistical situations (ibid.), for a follow-up study, the existing set of tasks has to be extended. For this reason, we discuss theoretically both several principles of the tasks' development that can be deduced from theoretical constructs of psychology, and some empirical results of our previous studies. Thus, we firstly make some comments on well-known diagnostic tasks in stochastics education and analyse one well elaborated task of an intervention study of Bakker & Gravemeijer (2004). Afterwards we change this task step by step according to theoretical and empirical based prerequisites of a diagnostic task aiming to investigate non-schooled children's thinking in statistical situations.

DIAGNOSTIC TASKS IN STOCHASTICS EDUCATION

In their seminal work referring to children's development of thinking with probabilities, Piaget and Inhelder (1975; original 1951) used tasks that could be treated as diagnostic tasks to analyse the children's initial position of learning probability (Hußmann et al., 2007). The set of tasks which Piaget and Inhelder had used aimed to analyse the thinking of children of different ages, who were not schooled in probability. After Piaget and Inhelder, subsequent research also adopted diagnostic tasks to investigate young children's probabilistic thinking resulting in both replicating and modifying the findings of Piaget and Inhelder (Jones & Thornton, 2005). Fischbein and his colleagues diagnosed children's so called primary intuitions when working with probabilistic situations (e.g., Fischbein, 1975). They investigated instructional conditions that facilitate children to come from primary

intuitions concerning probabilistic situations to secondary intuitions (ibid.). Nowadays, in tradition of Fischbein's work most research on children's probabilistic thinking is based on an intervention design and, further, on students that are schooled in stochastics (Jones & Thornton, 2005). This is even the case for the research in statistics education that has increased considerably in recent years when statistics became a crucial part of the stochastics curriculum in many countries (Batanero et al., 2011). According to this research development we have a lot of knowledge about non-schooled children's thinking in probabilistic situations, but little knowledge about non-schooled children's thinking in statistical situations focusing on data (Mokros & Russel, 1995). This research gap motivates our research aiming to analyse the decision making of young students (without schooling) in realistic statistical situations (Eichler & Vogel, 2012). However, in the educational literature only very few tasks can be found that allow for analysing unschooled students' thinking or decision making concerning statistical situations. For this reason, we started to develop tasks representing statistical situations to provoke non-schooled young students' thinking about and decision making in statistical situations. After we had used these tasks in pilot studies we modified the tasks, used the modified tasks in further pilot studies again and so on. In this way our task development is taking place until now. We analyse this development in what follows.

FIRST STEP OF THE DEVELOPMENT OF A DIAGNOSTIC TASK CONSIDERING CONTENT AND THINKING PROCESSES

Using existing tasks as starting point for the development

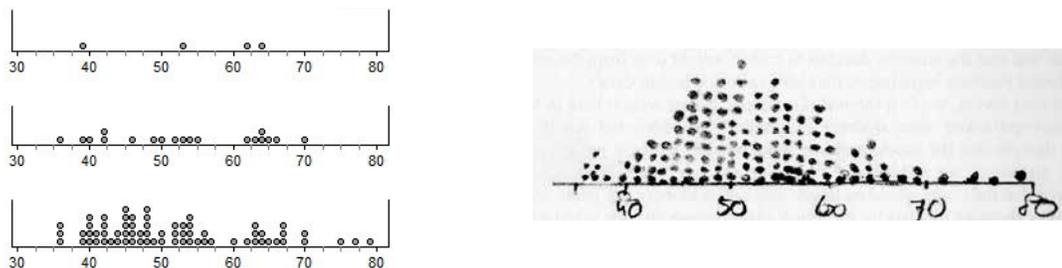

Figure 1: Collections of students' weight and students' prediction of a larger sample

We begin with a task from Bakker and Gravemeijer (2004, p. 158). The specific task aims to provoke students' thinking about variation, sampling and representativeness:

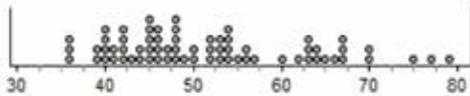

In a certain hot air balloon basket, eight adults are allowed [in addition to the driver]. Assume you are going to take a ride with a group of seventh-graders. How many seventh-graders could safely go into that balloon basket if you only consider weight?

Firstly, the students tried to estimate the average of the weight of both students and adults. Afterwards they collect data to students' weight in their class as basis to make a prediction for a larger sample. It seems obvious that non-schooled children would not be able to think about centre and variation in this task in a way using statistical concepts like range, average, median, and so on since they do not have systematic

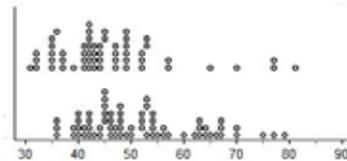

knowledge of these concepts. However they might be able to think about variation and centre in an informal way. Potentially these children might also be able to think about the sample in an intuitive way that a bigger sample would give more certainty than a smaller sample. However, we restrict our considerations to an informal way of thinking about centre and variation representing two main aspects of statistical thinking (Wild & Pfannkuch, 1999).

Provoking students' thinking

Given that non-schooled children are able to read the iconic representation of the data, they could be potentially able to describe the distribution in an informal way. However, research in stochastics education give a lot of evidence that a task involving a decision making in terms of both a comparison and a prediction would particularly provoke children's comments about a situation (e.g. Yost et al., 1962; Fischbein, 1975). Thus, a task involving decision making in terms of making a prediction – Bakker and Gravemeijer (2004) included a prediction in their task – could foster the students to think about a statistical situation (see figure 2, left side). As well, it is possible to enhance the given task leading to decision making process in terms of a comparison.

Another seventh-grader of your school will be weighted. Estimate his weight. Give a rationale for your estimation.

There are the sample of your school and a sample from another school. Which students are more heavy-weight? Give a rationale for your answer.

Figure 2: Variation of the task including decision making

Tasks in this way could serve as a diagnostic task to provoke students' informal thinking about centre and variation. However these tasks presuppose the students' ability to read the iconic representation of the data, i.e. the transnumeration of data into a graph (Wild & Pfannkuch, 1999), which is obviously not common for non-schooled children (e.g., Shaughnessy, 2007). At this stage of task development we expand our theoretical framework with regard to mental model theory. This theory allows for describing the perception and processing of statistical situations that were not represented by elaborated statistical methods like the dot plot.

THEORETICAL ESSENTIALS OF MENTAL MODEL THEORY

We reduce our theoretical focus on those aspects of mental models, which were fundamental for characterizing our task development.

Johnson-Laird (1983, p. 156) states: "A mental model [...] plays a direct representational role since it is analogous to the structure of the corresponding state

of affairs in the world – as we perceive or conceive it.” From the perspective of information processing Schnotz and Bannert (1999) describe mental models as being constructed individually according to a task and its requirements within a specific situation. By this, they conclude that a mental model represents *the structure* as well as *the function* of the modelled object in an *analogous relationship*. These are three essential characteristics of mental model theory which were important of being pointed out with regard to the task development:

- *Structure*: An essential process of mentally modelling a situation’s structure is recognising the physical objects of the situation, e.g. a die and its characteristics (or a student and his weight), as well as the relationship of these objects and their characteristics. Given data are also to be seen as being part of a situation’s structure because they represent results of a process having passed.
- *Function*: Concerning the dynamic aspect of mental models, i.e. the function, Seel (2001) suggests that, when coping with demands of a specific situation, an individual constructs a mental model in order to simulate relevant aspects of the situation to be cognitively mastered. Thus, here the term function is defined as mental simulation of a situation (in contrast by the mathematical construct of function). The function of mental models allows for deriving answers via mental simulation of systems by anticipating possible results given for example by throwing dice (or students becoming the weight they have when they were weighed). Mental simulations do not result in quantitatively exact conclusions but in qualitative ideas about the expected outcomes of such simulations (De Kleer & Brown, 1983). These “qualitative simulations” (De Kleer & Brown, 1983, p. 155) require sense making about the system or process that should be simulated, its constituent components and their relationships.
- *Analogous relationship*: This means, a mental model and the corresponding modelled situational object or process coincide structurally at least in some constituting elements. Thus, mental models can principally be inferred from observable information which represents mental modelling of a situation or task, the conditions of a students’ specific situation (experience, pre-knowledge), and students’ outcomes after working with tasks (written responses, videotapes).

These three characteristics become crucial when we analyse the demands on mental modelling of tasks concerning decision making in simple statistical situations, when we construct a hierarchical model of tasks’ complexity and finally, when we construct new tasks on base of this model.

SECOND STEP OF THE DEVELOPMENT OF A DIAGNOSTIC TASK CONSIDERING MENTAL MODEL THEORY

Mental modelling of a situation represented in a task includes perceiving its *structure*, which is a precondition to conduct mental simulation adequately (*function* of the situation). This means that disclosing those elements which impact on a statistics problem situation in respect of its structure and its function would reduce the

complexity of a situation represented in a task, especially for young statistics unschooled students. For this reason, the development of tasks has to treat the visibility of a situation's structure as a matter of principle of tasks' representation. The visibility of those elements which constitute the *structure* as well as the *function* of a situation impacts on mental simulation. Such a mental simulation equals the process of data generation when a statistical situation is regarded – it could be seen as a qualitative mental data generation.

Changing the task according to demands of mental modelling

In the task of students' weight the result of data generation (*function* of the situation) is represented by the given data. Thus, the *function* of this situation itself is hidden because having passed as well as the situation's structure including those elements that impacted on the students' weight. Similar tasks, in which both the structure and the function are potentially visible, are the following:

Two students try to throw coins as close to the wall as possible. Who is the better player? Give a rationale for your answer.

Andrea lets a paper frog jump several times. Estimate, where the next paper frog will end. Give a rationale for your answer.

The two situations include a request for decision making as defined above. Further, the data as result of the situation's function (i.e. process of data generation) could be given in the same way as shown in figure 2. Taken into account that young students were potentially not able to understand the construction of a dot plot, we used a pictogram to represent the data, e.g. the frog jumps (figure 3; Eichler & Vogel, 2011) and changed the situation a little.

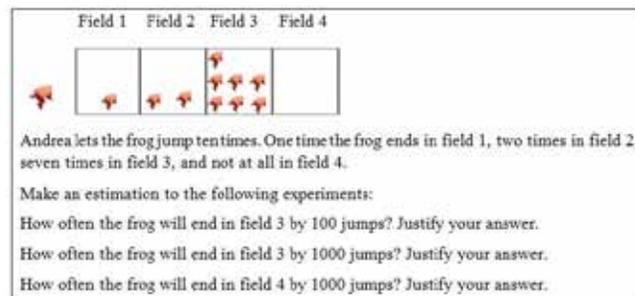

Figure 3: The frog task (early version)

However, a lot of young students confronted with this task in questionnaires and in interviews seem to misinterpret the situation. In particular, the equal arrangement of the frogs in the fields 1, 2 or 3 (fig. 3) led some students to the interpretation that those frogs being visible do not represent several jump results in reality. Those students were not able to match the descriptive representation (the text) and the depictive representation (the pictogram) to make inferences from the given information on base of an adequate mental model of the situation (Schnotz & Bannert, 1999).

An auxiliary change of the situation's representation in the task was to use a realistic picture of the situation in contrast to the more abstract representation using a pictogram (Vogel, 2006). Further, according to the findings in research into multiple external representations (Ainsworth, 1999; Mayer, 2001; Seufert, 2003), we combine for each step of the data generation a text with a picture. According to the cognitive load theory (Sweller et al., 1998), the text itself is formulated as simple as possible. Finally, we construct photos as pictures of the situation including all relevant objects representing the structure of the situation (cf. Schnotz & Bannert, 1999). We show in figure 4 only the changed representation of the situation since the task is the same as shown in figure 3.

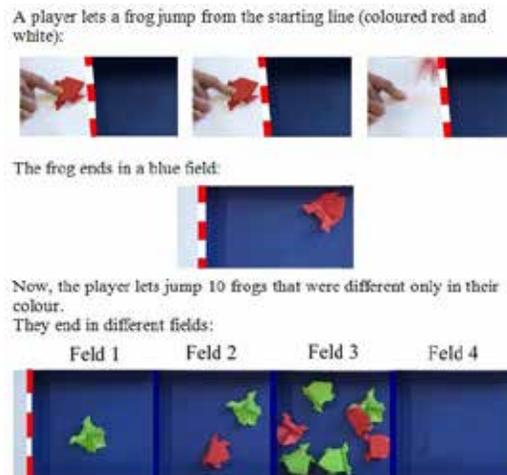

Figure 4: The situation of the frog task (final version)

Findings concerning the changed tasks

Using these special kind of “stochastics problem-storyboards” in an interview design (Eichler & Vogel, 2012) gave some evidence that even non-schooled students (referring to stochastics) were able to understand the situation in the intended way. Thus, after students have worked on the task given in the form described above, they were asked to conduct the experiments with real frogs and fields. In any case, the students were directly able to cope with both the structure and the data generation represented in the task.

Analysing the rationales that students gave in a paper and pencil test (students worked alone on several tasks like the frog task) yield amongst other results (ibd.) that students tend to identify different objects of a situation to be mainly relevant for the data generation. The consequence of this finding was to re-analyse the tasks in terms of characteristics of mental model theory using the terms *data*, *objects* and *mental simulation*. Regarding the frog task we can state with regard:

- to the *structure* of the problem situation that *data* representing the situation are given by the visualised results of 10 different frog jumps as well as the relevant *objects* of the situation. The objects include *human* objects, i.e. the jumper, and

non-human objects, i.e. the frogs, the fields, and the interplay of both sorts of objects;

- to the *function* of the problem situation that the process of *data generation* impacted by the objects and their interplay is visible and a prediction of future results of the data generation necessitates a *mental simulation* of the situation.

The distinction of given information in a task and a possible request to make a prediction to future data by mental simulation yield a model of a hierarchy of tasks' complexity that we could back up in a study based on eight tasks that are based on the same principles of construction as the frog task (Eichler & Vogel, 2012):

1. Lowest level: data given, human and non-human objects visible, mental simulation not requested (e.g. a task in which the results of coin throws have to be compared without making a prediction to future coin throws, see above);
2. Low level: data given, human and non-human objects visible, mental simulation requested (e.g. the frog task);
3. High level: data given, only non-human objects visible, mental simulation requested (this would be the case in the task concerning the weight of students, if it would be possible to develop a picture of the situation as described above);
4. Highest level: data not given, only non-human objects visible, mental simulation requested (e.g. a die task in which the students have to make a decision between two dice with different shapes to get a specific number).

Although we finished the development of tasks with identifying the levels of tasks' complexity, and used them with a bigger sample of non-schooled students, there were other aspects of the tasks that could be taken into account to develop a valid diagnostic tool for investigating young students' mental modelling of statistical situations.

FURTHER TASK DEVELOPMENTS

Our findings gave evidence that disclosing the impact of a human object on the data generation complicate a task for the students. However, our set of tasks includes one counterexample in which the visibility of a human object hinders the students' understanding of the situation, i.e. the so called car task (figure 5). According to the results of the interview study the car task is the only task with which situation not all students were able to cope when they were asked to conduct the experiment shown in the task.

Some of the students' responses gave evidence that they make inferences (Schnotz & Bannert, 1999) of both, the formulation "an automatically accelerated car" and the pictures being obviously contradictory in respect to the intended meaning. In terms of mental model theory underlying the principles of our tasks' construction: For these students, the objects of the car task might be given (human impact: starter holding the car; non-human impact: car with a spiral spring that accelerates the car automatically) but their interplay might not be captured clearly enough by the description. For example, some students seem to overestimate the impact of the human object on the

data generation: Some of the students' answers give reason for assuming that these students might have thought that the displayed hand causes at least partly accelerating because they cannot see the accelerating spiral spring inside the car. Thus, those students were not able to make inference from the text to one object (the spiral spring) that is highly relevant for the situation's structure and function.

Mark the position(s) where the next car (the next two cars) could stop. Give a rationale for your positions.

Figure 5: The car task

Based on these theoretical and empirical based considerations it is possible to change the situation's representation according to the underlying theory of mental models. Since the disclosed, but relevant non-human object (i.e. the spiral spring) could be the main reason for students' difficulties, we changed the situation's structure concerning the acceleration of the car: Instead of using an automatically accelerating car we use curves as accelerating distance of a toy car racing track (figure 6).

Figure 6: Use curves as accelerating distance of a toy car racing track in the car task

Thus, the assumed to be disturbing interplay between hand of the starter and car seems to be more clearly. Of course, this is a hypothesis which has to be proved.

According to our theoretical framework (founded by the theory of mental models and enriched by relevant aspects of theories of learning from multiple representations as well as of cognitive load theory) the principles of constructing new tasks in form of stochastics problem-storyboards could be applied concerning a considerable amount of existing tasks that potentially deal with centre and variation. Taking for example the question of design of paper helicopters (Ainley & Pratt, 2010) we could design a task, represent it comparably to the other tasks in a stochastics problem-storyboard and characterize it along our principles of task construction (figure 7).

The task is to test the stability of paper helicopters.

A player hold the helicopter at the starting height ...

... the player let the helicopter go ...

The helicopter ends on the floor. His position is marked.

situation

A player starts a paper helicopter several times beginning from a fixed starting height. Each time the helicopters' end position is marked on the floor.

request

"Mark the position where the next helicopter could land. Give a rationale for the marks."

Figure 7: Paper helicopter task represented in a stochastics problem-storyboard

CONCLUSION

In this paper we proposed principles of diagnostic tasks' construction aiming to investigate non-schooled young students' thinking within statistical situations. The aim of the paper was to discuss the interplay between theoretical models and empirical findings as basis for the tasks' development. The development of valid diagnostic tasks representing statistical situations is a crucial point of our on-going research program into young students' mental modelling within simple situations of decision making under uncertainty.

USING APPLETS FOR TRAINING STATISTICS WITH FUTURE PRIMARY TEACHERS

Assumpta Estrada*, Maria Manuel Nascimento** and José Alexandre Martins***

Universitat de Lleida, Spain*; Universidade de Trás-os-Montes e Alto Douro (UTAD) and CM-UTAD, Portugal**; Instituto Politécnico da Guarda (UDI/IPG) and CM-UTAD, Portugal***

In recent years, statistics has been recognised as a basic component of citizenship education and its incorporation into school curricula in various countries confirms the importance of learning statistics. Nowadays, several resources are available online, but their uses within classes may vary depending on the use a teacher devises for them, therefore a critical analysis of these tools is needed. In this paper, we present the Applemat model for the analysis of statistical applets that might promote training statistics among primary teachers, thus emphasising their didactical purposes. During this past school year (2011/2012), an applets selection – as statistical teaching tools – was used for training primary teachers and the model was introduced in their classes. We will only present the model and the report from one of the student groups in this paper.

INTRODUCTION

Primary teachers (teachers of pupils aged from 6 to 12) must be prepared to teach statistics from the official programmes and adequately educate their students. Realistically, this would create the need to include statistics education in the curriculum of future teachers, including contents and statistical literacy, in order to allow the development of students as fully literate citizens. In our own work (Estrada, Batanero, & Fortuny, 2004), we have already found conceptual errors in elementary concepts such as mean, median and mode, outliers, standard deviation and sampling. This brought to our attention the need to rethink teaching methods. Given that statistics is one of the subjects where technologies has a major impact (Contreras, Martins, Estrada, & Batanero, 2011) we thought that we may use some of the available Internet resources – the applets – in our classes. It was thought that, due to their characteristics, they may enable us to develop a different approach to the statistical concepts. Thus, we agree with Anderson-Cook and Dorai-Raj (2003) who state: “We believe that the applets will be an easily accessible tool (...) to help students gain a better working understanding of the concepts.” In our previous work (Nascimento & Martins, 2008), we have already used statistical applets with Portuguese university students, as homework, in order to make them reflect on the statistical use of their (mis)concepts and help them gain a better understanding of

how to work with them. Nevertheless, future primary teachers should have the opportunity to learn how to use applets as technological resources in statistical contexts, and attention should also be paid to the appropriate use of applets in the classroom.

In this work, we present the Applemat model version developed in the “Applemat Project” that enables future teachers to conduct a careful didactical analysis, with special emphasis on its utility in their future elementary classrooms. We also present an example of its use, devised by one group of students, as well as our own analysis of their work.

APPLETS AND TRAINING STATISTICS WITH FUTURE PRIMARY TEACHERS

In the professional development of teachers, ICT acts as a semiotic mediator that may change the epistemic configuration of the mathematics learning process (Font & Godino, 2006). However, Giménez (2004) states that teachers do not usually use these resources because they do not know their possibilities and limitations. The technological resources, namely the applets, also possess the conditions for a didactical suitability (Godino, Wilhelmi, & Bencomo (2005) later clarified by Godino, Batanero, & Font (2007) *apud* Godino, Batanero, Roa, & Wilhelmi, 2008) that defined it as the articulation of the following six types of suitability:

- Epistemic suitability: extent to which the statistical content is representative of the curricular content for a specific teaching level and whether its inclusion in the teaching is justified.
- Cognitive suitability: whether the content is adequate for the students’ previous knowledge and the extent to which the instructional goals can be achieved.
- Media/resources suitability: sound use of technical tools, resources and time.
- Emotional suitability: whether the teaching/learning process takes into account the students’ motivations, attitudes, affects and beliefs.
- Interactional suitability: whether the interactions between the teacher and the students and among the students themselves favour overcoming learning difficulties.
- Ecological suitability: degree to which the teaching/learning process is adapted to the social environment; possibility of establishing interdisciplinary connections.

Due to the availability of different statistical resources on the Internet, we think that teachers’ training should introduce and promote the use of these ICT resources, specifically the applets, to help future teachers in recognising their value and

applicability in elementary school classrooms. More generally, Tishkovskaya and Lancaster (2012) discuss the following:

Probably, the most common way to use information technology to enhance teaching materials in mathematics and statistics has been to add statistics applet illustrations letting students experiment with mathematical statements. Some of these illustrations are very sophisticated and valuable new elements in instruction (...) which can be accessed over the Web and used for the purpose of statistics education.

Most of the statistical applets found are devised to show contents. But Romero, Berger, Healy, and Aberson (2000) describe that “In [WISE] earlier applets (...), students interacted by pushing on-screen buttons with their cursor. In [WISE] most recent applets, students are also able to act directly on the distributions. (...)”.

Anderson-Cook and Dorai-Raj (2003) also reinforce that with the applets “[t]o answer the questions, students must interact with the applet, interpret and integrate findings, and explain and apply the concepts that they have learned”.

More recently DePaolo (2010) for her courses used the “four A’s for applet selection”: “Appropriate, Accessible, Attributes of high quality, Appealing visually”.

1. Applets had to (...) address topics and concepts commonly taught in these courses at introductory levels. They also had to have functionality (...);
2. Applets had to be accessible to undergraduate non-majors. They had to have an intuitive interface, explanation of purpose, and brief but helpful documentation on usage (...);
3. The applets’ attributes had to be of high quality. They had to have reasonable loading and running speed and be free of errors and misleading output. Applets chosen were clear in their purpose and successfully performed their intended function or demonstrated their intended concept;
4. Applets had to be appealing visually. They had to have effective (though not necessarily fancy) graphics and produce output that is easy to understand and interpret.

In our view this “four A’s applet selection” criterion (4AASC) adapted to the statistics curriculum of the prospective teachers or even of the elementary school one is a valuable guideline for choosing a “good” applet. Connecting with the didactical suitability components, the epistemic or mathematical suitability denotes the future teacher choice of a “good applet” using 4AASC adapted to the statistical contents of those elementary grades and also to the class kind of task for the pupils (either introductory, reinforcement or even test tasks). On the other hand, when the future teacher includes its adequate didactical use in the classroom work for that task we are referring to the cognitive suitability. “[T]eachers who are able to use today’s technology in the classroom will be prepared to learn and utilise tomorrow’s technology” (Powers & Blubaugh, 2005) stresses media/resources suitability. The emotional suitability, as pointed out by Díaz and de la Fuente (2005), determines that

using applets for teaching statistics and probability increases students' motivation for the subject because they present the concepts in a more attractive way and the interactional suitability also enables them to play a more active role in their own learning. Taking these aspects into account, it is important that the teacher considers how to use these resources effectively – emphasising epistemic and cognitive suitability. So, using the applets, as well as doing their didactical analysis, may help future teachers in the statistics learning process – ecological suitability. In prospective teachers' training, the methodological techniques should be implemented to give them the incentive to incorporate different types of practices into their training. In this paper we will only present the Applemat model and the analysis of one report from a group of students where we articulate the criteria for the applet's selection, its assessment and its adequacy for didactical analysis based on the six types of didactical suitability presented earlier. Further work with the other students' reports will be presented in the near future.

METHOD

The first approach to the model involved an answer to the question of how future teachers should conduct the didactical analysis of the applets – as a teaching tool. This approach was developed within the “Applemat Project” (2006–2007), as part of the “Teacher Innovation Group” (TIG). The TIG group was coordinated by J. Giménez from 2006 to 2007 and received funds from the Catalonia government. The TIG working group had experienced university teachers from different areas – analysis, geometry, statistics, etc. – that felt the need to improve the ICT use in the university classrooms of prospective teachers. The model was an attempt to standardise the didactical analysis for all the scientific areas that the university students are required to know. In the two years, TIG elements viewed the components described as conditions for didactic suitability and developed the model with three sections. In the first section, the resource is described and its possible use in elementary classes is discussed. In this section, the weight of the six components is higher regarding the epistemic suitability and the cognitive suitability. In the second section, the applet is devised as a teacher training tool in order to manage and use it during teachers' training university classes, so the weight of the six components is distributed amongst them. Finally, in the third section, the possible improvements and extensions of the applet are proposed and the weight of the six components is also distributed amongst them. The Applemat model's details are presented in Table 1.

Table 1: Applemat model details

In our research, this model was used in the Primary Teachers degree classes (3rd year) in a Spanish university 1st cycle (Bologna Degree) attending the Probability and Statistics Curricular Unit (course) in the school year of 2011/2012 (six credits from the European Credits Transfer and accumulation System, ECTS). In this course syllabus, besides the introduction to data analysis, probability and statistics contents, the didactics of probability and statistics are also present. The 123 students enrolled in this course were divided into two classes (58 and 65 students) and they presented a total of 32 works that were carried out in groups of three or four students.

Students using the Applemat model were not familiar with the didactical analysis of applets or any other ICT resources. Thus, the university teacher presented and subsequently practised the central tendency measures with the students, before using the Illuminations mean and median applet (retrieved from the NCTM Illuminations <http://illuminations.nctm.org/LessonDetail.aspx?ID=L452>) as the learning objectives, materials, the instructional plan with the task, the discussion and the questions for students were already available on the site. The students' task was then to search the Internet for different applets and select one to analyse using the Applemat model (Table 1). The basis for choosing their own applet must be one or both of the subjects: their course (at the university) syllabus topics, or the elementary curriculum topics on data analysis or probability. Once they had selected it, students worked as a team to apply the Applemat model. Finally, they had to present a written report of their work. This analysis was delivered at the end of the curricular unit and was assessed by the teacher, representing 25% of the final grade.

The assessment criteria are important in any course both for teachers and students, so the university teacher designed a first guideline evaluation document that included the 4AASC. The presented assessment criteria considered four groups: following instructions, presentation and style, statistical content and knowledge for elementary curriculum, and thinking and analysis. Firstly, following the instructions group

assessed the adequacy of the applet choice for the goals of this course, the prescribed parameters of the task, and those of the model, and of the learned statistical topics. Secondly, for the presentation and style criteria the graded items were the clarity of the report text (including spelling, grammar and punctuation), its visual presentation (also considering its creativity and illustrations that aid understanding, integrated within the text), and finally the key aspects of its precision and rigour using statistical terms, expressions and concepts and their meanings. Thirdly, in what concerns the statistical content and knowledge of the Applemat model, the reports were analysed considering the depth and awareness of the statistical and didactical knowledge focusing on: applet description; possible classroom uses and applications; previous and actual statistical knowledge contents required; techniques of the applet uses and their limitations; other possible applications, improvements or extensions; and alternative materials. Finally, the thinking and didactical analysis of the reports assessed the integration of a critical perspective along the report, as well as the significance of the proposed recommendations.

Lastly, this school year of 2011/2012 was the first year in which the guideline evaluation document was used. As written by Biehler (2005) in the students' project reports scope we consider having a similar situation with our guideline: "Our work on analysing students' projects, developing a new project guide, and developing an assessment scheme is still in progress."

AN EXAMPLE USING THE MODEL

From the 32 groups of future primary teachers, a didactical analysis using the model (Table 1) was chosen and is presented here as an example of its implementation. This work was selected based on the applet's characteristics – available for download to our own computers – and its good grade. We only translated the main lines of the students' analysis regarding the "Tables and Statistical Graphs" Spanish applet report (<http://www.edu.xunta.es/espazoAbalar/espazo/repositorio/cont/tablas-y-graficos-estadisticos>), and now we present it.

Section 1. Applet analysis and possibilities

1.1. Applet description: This applet is an attractive visual resource that allows students to use elementary statistical techniques to obtain information about children's daily contexts including data representations, graphics and numbers, and also allows for critical reflection of the results. This applet also helps to describe, extract and interpret the information presented in the tables or in the graphs (...) which is based on daily problem solving. Furthermore, this applet has six folders. Each one is about one statistical chapter and we enter it by selecting one of the six persons (characters). It also contains a glossary and a guide for teachers. During its use, there is a voice that explains the activities and these explanations are also written in the applet window. 1.2. Analysis and uses in elementary classes: a. How may we use it in the class? (...) this applet has six folders and each one is about one statistical

chapter: data techniques of collecting and classification (4 activities); building absolute frequency tables (4 activities) and relative frequency tables (3 activities); frequency polygons (4 activities); pie charts (5 activities); reading and interpretation of statistical concepts; b. Previous knowledge and contents required: reading double entry tables; reading coordinate axes; circular sector, including the concept of central angle measure; per cent, and the per cent value of a fraction; ability to use a calculator; c. Limitations: the applet does not have the possibility of error because if the answer is wrong, the student cannot continue the activity; the activities are not connected to each other; there is no way to change data; not all activities are for all elementary school levels; d. Techniques of use: choosing a correct answer; putting data into frequency tables; checking data; arithmetic operations like addition and subtraction; reading graphs; comparing graphs or data; completing a frequency table taking into account the added data; building a table from graph data; writing a legend; writing the title; e. Other contents that may be incorporated into the class: computations and measure.

Section 2. Management and use of class for teachers' training

2.1. Goals: explore the use of ICT in mathematics learning; learning to learn; development of manipulation and visualisation as a didactical procedure; (...) understanding of frequency tables; potentiate the study and the understanding of data graphs; development of the study and its interpretations using data; learn how to teach. 2.2. Developed professional skills: analysis skills; self-learning ability; critical thinking before the methodological procedures of learning; promote cooperative work; using, applying and creating manipulative resources to learn (...). 2.3. Transfer of learning: a. Initial problematic situation: if the user chooses chapter six – the baby with the bear – data information may have different graphic types, graphics may be compared or problems with statistical graphics may be proposed. (...) a chain of events is triggered when each character is chosen; b. Previous knowledge reinforcement: data techniques of collecting and classification; building absolute and relative frequency tables; frequency polygons; pie charts; reading and interpretation of statistical graphics; c. Using the applet: using interactive learning applets as a didactical resource; different ways of representing data; valuing different ways of data presentation, reading and interpretation.

Section 3. Applet improvements and extensions

3.1. Applet improvements or extensions: if the answer is wrong, the student cannot continue the activity, so this option should be changed and the student should have the opportunity to know what their mistake was. Since the activity folders are not connected to each other, some kind of connection may be implemented in the future; devise a way to allow data changing and provide a dynamic update of the graphic. 3.2. Other learning possibilities: in these students' work, another activity folder was proposed in order to connect all the contents in the other six folders already available; create activities in the folders in order to include some with percentages; include

pictograms; some more activities to reinforce students' training. 3.3. Alternative materials' advantages and disadvantages: 1. Building tables and graphics with a worksheet; Advantages: All computers have worksheets. Enables the discovery of how this survey tool helps students' use of statistics in their daily lives as well as in other subjects. Allows building any graphics type; Disadvantages: Activities must be guided by the teacher, at least in the beginning, since the software is not particularly accessible to younger students. The difficulty levels of learning are not easily controlled by the teacher; 2. Motivating element, Advantages: Activities are based on contents and are linked between them; Disadvantages: If the connection between pages is lost it is impossible to finish the activity.

From our analysis of these students' work, we think that the group had a good report since the students followed instructions, i.e., the proposed Applemat model and the main 4AASC. In our view, Section 1 of the model report shows that the students used/explored the applet in order to understand it fully. The report had a simple and clear presentation and style. The statistical content and knowledge for the elementary curriculum was adequate and without wrong definitions. Lastly, the item about thinking and analysis was good in this report as the group was able to present a first critical opinion about this applet, as well as considerations that allow a better understanding of its use in the classroom. Sections 2.1 and 2.2 were weaker, nevertheless the students attempted to offer a glimpse of the goals and a lighter view of the professional development. The topics of subsection 2.3 were good in describing the transfer of learning. In relation to Section 3 of the model, the report was good as it detailed improvements and extensions of the applet. Overall, the group report was good using the Applemat model for the applet's didactical analysis.

FINAL REMARKS

The availability of Internet resources enables statistical learning to be accomplished in a different way, using these resources as dynamic promoters. In this work, we reviewed some of the perspectives concerning the applet's uses and we presented a model that provides guidelines for the applet's didactical analysis, within future primary teachers' training scope. In our own view, applets – as technological resources – and the Applemat model with its three sections articulated the six components for the didactic suitability, as defined by Godino et al. (2005) and later clarified by Godino et al. (2007, *apud* Godino et al., 2008). Concerning the epistemic or mathematical suitability, the Applemat model described was suitable for the future teachers to use/explore the statistical concepts, for instance, in the tables and graphs presented in the students' example. They made use of their statistical knowledge choosing and exploring the chosen applet with this model. In general, the “statistical content in (...) primary school level (...) can be introduced and justified through [an

applet task] understood by the student” (Godino et al., 2008). With regards to the cognitive suitability, the Applemat model showed potentialities since the future teachers had to report the applet’s adequate didactical use in the classroom. Again we stress that using the applets, as well as doing their didactical analysis, may help future teachers in the statistics learning process – ecological suitability. According to the media/resources suitability, a single computer and an Internet connection for each group of students will be enough. Also, students may suggest different alternative materials as they did in Section 3 of their report. Since the interactional suitability mainly depends on how the teacher organises their work in the classroom, the future teachers were required to work in groups in order to encourage conflicts and verbalise their occurrence. A drawback of this year use of the Applemat model was the shortness of time to promote the class discussions. In this case, the emotional suitability was viewed as the students’ involvement (interest, motivation ...) in the study process by means of the Applemat model use. We consider that this was the most appropriate one and was the one that triggered the present work. Using the Applemat model, future primary teachers were able to value applets as a didactical resource based on their own observations and manipulations – with the detail given through the presented report of the group. To conclude, this school year of 2011/2012 was the first year in which the guideline evaluation document was used, so the assessment guideline is still in an improving stage. We are convinced that the university students’ work should continue to be carried out in small groups to promote opinions and discussion that will potentiate their critical thinking, which is essential in the building of an “almost real” didactical proposal. Following our analysis of the work done we propose a four-step approach in the future teachers’ classroom. Firstly, we will present them this year’s work so they will have a basis from which to explore the model themselves. Secondly, they will do this year’s work. Thirdly, after receiving the teacher’s feedback, the students will discuss their own work in order to clarify their own concepts. Finally, in order to enhance the future teachers’ didactical training for the elementary levels, they will prepare and simulate – for instance, for their colleagues – the didactical sequence in order to test it and improve it. With this approach, the applets will act as the semiotic mediator in order to change the statistics learning process, as already underlined by Font and Godino (2006). Although in the teacher analysis of this school year 2011/2012 almost all the reports got good grades, we intend to further develop their analysis in a qualitative and comparative way, detailing the differences between them, as well as any written conceptual (of probability or statistics) errors made. Finally, similarly to Contreras et al. (2011), we think that to promote an improvement of the statistical learning in

elementary schools, teachers should take all these resources into consideration, particularly the applets. Therefore, these resources should be implemented in future teachers' training in a similar way to the methods outlined in the current paper.

DESIGN AND EXPLORATORY EVALUATION OF A LEARNING TRAJECTORY LEADING TO DO RANDOMIZATION TESTS FACILITATED BY TINKERPLOTS

Daniel Frischemeier & Rolf Biehler

University of Paderborn

We investigate the reasoning of preservice teachers about uncertainty in the context of randomization tests. Last winter term (2011/2012), we developed a seminar about data analysis with TinkerPlots, where group comparisons have played a fundamental role. A typical task in this context was: “Is there a difference between two groups or could that difference have occurred at random due to the selection of our sample?” In the first part of this article we describe a possible method to answer such a question with the help of a randomization test (see Rossman, 2008) facilitated with TinkerPlots. In the second part we point out how the participants of our course conducted a randomization test in a statistical project work and which problems and (mis-)conceptions were observed.

Key words: Preservice teacher education, statistical education, group comparisons, randomization tests, TinkerPlots

INTRODUCTION

The preservice education of teachers of mathematics at the University of Paderborn consists of three domains: mathematics, didactics of mathematics and pedagogy. An obligatory course called “Elementary Statistics and Probability Theory” is part of the programme. In addition the student teachers can participate in a seminar which deepens the course “Elementary Statistics and Probability Theory”. The authors of this article have designed a seminar for preservice teachers in mathematics called “Developing statistical reasoning with using the software TinkerPlots” (Frischemeier & Biehler, 2012). In this course, the participants go through the whole PPDAC-cycle (Wild & Pfannkuch, 1999) which includes analysing data with the software TinkerPlots 2.0 (Konold & Miller, 2011) and writing down findings in a statistical report. Alongside describing and interpreting single distributions and exploring differences between them we wanted the participants to make conclusions about a wider universe and try to make generalizations of their findings. A typical task in connection with group comparisons was: “Is there a difference regarding a variable between two groups or could that difference have occurred at random due to the selection of our sample?” At the end, a statistical project work concluded the course. In the next part of this article we describe a possible method to answer such a question posed above with the help of a randomization test (see for example Rossman, 2008) facilitated with TinkerPlots. We focus on subject matter and knowledge of our students and do not discuss pedagogical content knowledge.

THEORETICAL FRAMEWORK

In general it is reported that pupils, students and pre-service teachers have a lot of misconceptions in testing hypotheses and using p-values (see e.g., Garfield and Ben-Zvi 2008, p.270). There we also get to know that most of the students have problems with questions concerning generalizing of a result found in a sample. An opportunity for emergent inferential reasoning, especially in connection with results from group comparisons, is a so called randomization test. For a detailed and formal introduction in randomization tests see Ernst (2004). Rossman (2008) recommends starting inferential reasoning with randomization tests. He introduces randomization test with the example “dolphin therapy”. For details see Rossman (2008). A big advantage according to Rossman (2008) and an important argument for a first step into informal inferential reasoning via randomization tests is that “...this procedure for introducing introductory students to the reasoning process of statistical inference is that it makes clear the connection between the random assignment in the design of the study and the inference procedure” (p.10). Rossman (2008) further points out that a randomization test “...also helps to emphasize the interpretation of a p-value as the longterm proportion of times that a result at least as extreme as in the actual data would have occurred by chance alone under the null model” (p.10). Furthermore, Rossman points to the problem of the “final” conclusion and the possibility that the null model is correct (although this is “unlikely” given a small p-value). Cobb (2007) emphasizes that, with randomization tests, students in introductory courses have a better opportunity to understand the “core logic of inference” converse to an approach based on calculations from normal-based probability distributions. This was also proposed by R.A. Fisher “but [...] was not realistic in his day due to the absence of computers”. Cobb (2007) also emphasizes his 3R’s: Randomize data production, Repeat by simulation to see what’s typical (and what’s not) and Reject any model that puts your data in its tail. The randomization of the data production (Cobb’s first “R”) is an important condition. However, we have decided to use randomization tests also in the context of observational studies comparing data to the hypothetical situation that a random assignment process has produced the data (see also Konold, 1994 for such an approach and Konold & Pollatsek, 2002 for the “process approach”). A bootstrap method would have been preferable if we deal with random samples, however, resampling with replacement seemed us too difficult for explaining it to students. If the data were produced by such a process (null hypothesis), it has to be judged whether a difference is likely to be due to random variation under the null model. A differentiation of methods and arguments for using a randomization test also with observational data can be found in Zieffler, Harring, & Long (2011). Rossman (2008) claims that teachers could use randomization tests to connect the randomness that students perceive in the process of collecting data to the inference to be drawn. He provides examples of how such a randomization-based approach might be implemented at tertiary level, while Scheaffer and Tabor (2008) propose such an approach for the secondary curriculum and provide relevant

examples. Which misconceptions of students occur when doing a hypothesis test? Vallecillos (1994) report that many students who thought (like in a deductive process) that the correct application of a test with a significant result implies the truth of the alternative hypothesis. Another misconception regarding p-values is that the p-value is supposed to be the probability that the null hypothesis is true, given the observed data (Garfield & Ben-Zvi, 2008, p. 270). In the following section we describe a method for conducting randomization tests with TinkerPlots as an instrument to make further conclusions beyond the data and try to antagonize the misconceptions described above. We assume randomization tests to be an adequate method for this respect and see this as a refinement of group comparisons in concrete informal terms being aware that our approach cannot solve all the problems students have with hypothesis testing.

RANDOMIZATION TESTS FACILITATED BY TINKERPLOTS

The sampler of TinkerPlots 2.0 can be used as a useful tool for simulations. At first we will describe a typical task handed out to the participants working with the so-called Muffins data (Biehler, Kombrink, & Schweynoch, 2003), which is a complex data set with 538 cases and about fifty variables of a questionnaire concerning media use and leisure time of eleven graders. “How much time do the girls read more than the boys on average?”. Exploring the Muffins data reveals that the girls on average read approx. 0.82 hours per week more than the boys. This motivates the question: “Is there a difference regarding the variable “Time_reading” between boys and girls or could that difference be due to the selection of our sample?” The 538 students are neither a random sample of a clear-cut population, nor do we do random “treatment assignments” However, we can just imagine a process, where reading time is independent from gender. If the data were produced by such a process (null hypothesis), we have to judge whether a difference of 0.82 hours can be due to random variation under the assumption of no difference. We imagine that we divide the group of 533 students randomly into a group of 301 pseudo-females and 232 pseudo-males. Then we can calculate the mean difference of reading time in these two random subgroups. When we repeat this process many times, we can estimate the probability to get a mean difference greater or equal to 0.82 just by random group selections. The advantage of Tinkerplots is that such a random selection model can directly be implemented in the software. We formulate our null hypothesis “The data were produced by a process where there is no difference regarding the variable *time reading* between boys and girls.” We estimate the probability that the difference between boys and girls is 0.82 hours or even higher under the assumption that the null hypothesis is true. This can be done in the following way by a simulation in TP - Figure 1 shows a screenshot with several steps of the randomization test in TP. We place 533 balls labelled with the 533 times of the variable “Time_reading” in our group of respondents in box 1 (see figure 1, upper-left corner, left urn) and construct another box 2 (see figure 1, upper-left corner, right urn) with 232 balls labelled with

(pseudo-) “male” and 301 balls labelled with (pseudo-) “female”. In the next step a ball from each box is drawn without replacement. This is repeated 533 times (because of 533 cases): The 533 values of the variable “gender” are randomly assigned to the 533 values of the variable “Time_reading”.

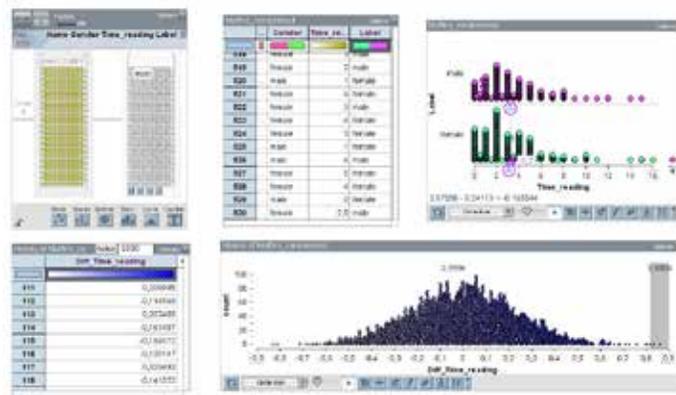

Figure 1: Screenshot of doing a randomization test with TinkerPlots

The results can be seen in the table and the plot “Muffins_randomised” (figure 1, middle and upper-right corner, see also the column “label” that contains the “pseudo-gender”). This whole process is repeated 5000 times and we collect the measure “difference of the means of the two groups” with the “History”-function in TinkerPlots. The table (see figure 1, bottom-left corner) contains the collected measures of 5000 simulated random assignments. In only three of the 5000 random assignments (see figure 1, bottom-right corner), the simulated result turns out to be as extreme or even more extreme than the observed difference in the Muffins data. With the divider-tool we can determine the number and the proportion of cases (measures) that are 0.82 hours and higher. This proportion is 0.0004, which is our p-value. The “result” of the randomization test is an estimated probability (estimated by relative frequencies) of 0.0004 that the difference between the means of the two groups equals 0.82 or is even higher under the assumption that there is no difference in the process producing gender and reading time. What can we conclude from these results? Due to this very small p-value there is a very strong evidence against the null hypothesis of no difference.

DESIGN OF THE LEARNING TRAJECTORY

In this paragraph we want to describe the learning trajectory we created for the introduction into randomization tests on the one hand and a so-called randomization test-plan we handed out to the participants while doing a randomization test on the other hand. The major goal was that the participants learn to perform randomization tests with TinkerPlots as we demonstrated in the paragraph above (although we have paid just few attention to teaching the logic of inference at this stage). At first the participants were introduced in the sampler of TinkerPlots by modelling and performing some simple chance-experiments. Our introduction into randomization tests began with the “Extrasensory perception (ESP)” - task (Rossman et al., 2001,

pp. 376), which the students had to do on their own in teams of two. In the working phase the first and second author gave support and feedback when problems occurred. Afterwards the results were discussed in the whole group. In the next step, our intention was to draw parallels between the simulation of ESP-task and the performance of a randomization test regarding the Muffins task: “Is there a difference regarding the variable “Time_reading” between boys and girls or did that difference occur at random due to the selection of our sample?”. The participants were handed out a randomization test-plan and then worked in groups of two on the muffins task described above. Before continuing with the description of the learning trajectory we want to give some arguments for handing out a randomization test-plan: Sweller (1999) have found out that the exploration of a complex learning trajectory such as the randomization test in our example, tasks the cognitive load of the learner very much. Due to the limitation of cognitive load he proposes to give the learner some help in form of structural aspects. With the randomization test-plan we give the participants a possibility to structure their thoughts and steps. With similar ideas to Biehler and Maxara (2007) we created the plan seen below (fig. 2).

Plan: How to do a Randomization Test

No	Step	ESP	Muffins
1	Observation Which difference do you observe between the means of the two groups in the dataset?	Number of correct answers = 20	<i>Mean of Time_Reading of boys = 2.685</i> <i>Mean of Time_Reading of girls = 3.503</i> <i>Difference = 0.818</i>
2	Hypothesis H_0 As said in the task, the difference of the means of the two groups could have occurred at random. Generate an adequate N-hypothesis for your investigation.	The person does not have any extrasensory perception (ESP). He/she guesses with a success rate $p = 0.25$.	<i>The difference of the means of Time_Reading of boys and girls has occurred at random.</i>
3	Simulation of H_0 How can you investigate the n-hypothesis with a simulation? Explain your procedure	Drawing 40times with replacement from an urn which is filled with 4 balls: 1 ball is labeled „r“ (right) and 3 balls are labeled „f“ (false)	<i>Place the 533 cases of Time_Reading in urn1. Construct urn2 with 232 balls labeled with “m” (male) and 301 balls labeled with “w” (female). Draw 533 times without replacement</i>
4	Test statistic Define the test statistic	$X =$ Number of correct predictions	$\bar{X} = \bar{X}_{\text{Group1}} - \bar{X}_{\text{Group2}}$
5	p-value Read of the p-value	$P(X \geq 20) = 0.0004 = 0.04\%$	$P(X \geq 0.818) = 0.0006 = 0.06\%$
6	Conclusions Which conclusions can you make regarding your n-hypothesis?	The p-value (=0.0004) is very small, so we have a strong evidence against our n-hypothesis. We assume that the fortune teller has not guessed. Another possibility is: he could have guessed but that would have been very unlikely.	<i>The p-value (=0.0006) is very small. So we have a strong evidence against our hypothesis “The difference of the means of Time_Reading of boys and girls has occurred at random.” Another possibility is: the difference occurred at random, but that is very unlikely.</i>

Figure 2: Randomization test-plan (with entries in “Muffins” – column, a task that our students had to do themselves)

In this “randomization test-plan”, the participants have a structure for the simulation-process on the one hand and can write down their findings on the other hand. On the left side of the plan, the participants get an overview of the structure of the randomization test, short instructions and leading questions for each (the forth column is without entries when it is handed out to the participants). A special feature of the plan is the third column “ESP”. The “ESP”-task is the exemplary task we used when introducing our students in randomization tests. To support the participants in step 6 to draw conclusions from p-values, we gave them further material in form of a hand-out which was supposed to give them hints how to evaluate possible p-values, as follows:

Hand-out: *We have a very strong evidence against H_0 , if $p < 0.1\%$. *We have a strong evidence against H_0 , if $p < 1\%$. *We have a medium evidence against H_0 , if $p < 5\%$. *We have a small evidence against H_0 , if $p < 10\%$. (Hand-out for the participants)

So after doing the “ESP”-task on their own with feedback of the first and second author as we have described above, the participants were handed out the “Muffins”-task which they had to do in teams of two. The results were discussed in the whole group afterwards. In reflecting on our “randomization test” sessions we found that there were two neuralgic points when doing a randomization test: First the correct formulation of the null hypothesis, second an adequate conclusion drawing from the resulting p-value. Finally the participants had to do a randomization test in their statistical project work, which was a requirement for completing the course.

RESEARCH QUESTIONS

In this paper, we will focus on the final randomization tests in the students’ statistical project reports. Three main research questions emerge: 1. How did the participants finally perform a randomization test with using of TinkerPlots in their project works? 2. Were they able to fulfil the six steps of the randomization-test plan? 3. At which stages/steps did problems (which?) occur?

DATA, PARTICIPANTS & METHODOLOGY

We have had a look at eleven statistical project reports that the participants had to do at the end of the course in teams of two. They were allowed to choose their own questions related to the data sets we provided. Due to this aspect it was possible that the level of difficulty differed from report to report and therefore from randomization test to randomization test. Doing at least one randomization test in their report was a requirement. 23 participants attended the course, 22 of them worked on the project reports in teams of two, so we have 11 project works (and 11 randomization tests) in total. The number of students’ semesters varies from 4 to 11, most (11 from 23) students were in their fifth semester. For a deeper analysis, we analysed all written extracts of the statistical project reports that dealt with the randomization test-task while focussing on the successful execution of the six steps of the randomization

test-plan and typical problems that occurred when going along these steps. So we have had a global view (cf. research question 1 and 2) and a local view (cf. research question 3) on the randomization tests of the project works. In the “global observation” we checked how well the participants performed the 6 steps of the simulation plan generally. If they accomplished a step as described in the example above, we called it “Step x successfully done”. We analysed the several steps with the background of our theoretical framework. We defined categories of typical problems with a focus on step 5 & 6. Furthermore we will also give typical examples for the categories in form of written extracts of students’ project works.

RESULTS

Let us have a look (table 1) how well the teams did in the several steps when doing a randomization test with TinkerPlots (Note, that every team have had an different topic, so some of them were confronted with p-values larger than 10%, others with p-values smaller than 0.1%, for example).

Steps successfully done	Number of teams (of 11)	%
Step1	11	100.00
Step2	8	72.73
Step3	10	90.91
Step4	10	90.91
Step5	5	45.45
Step6	5	45.45

Table 1: Overview-Randomization tests in project works

Almost every team was able to conduct and fulfil the simulation of the randomization test with TinkerPlots in form of accomplishing steps 1,3 and 4. Step 2 (formulating null hypothesis), step 5 (identifying and reading of the p-value) and step 6 (drawing conclusions from p-value) seemed to be problematic points as we mentioned above. So we want to have a closer look on that now.

Step 1 – Reading of the difference between groups in the dataset

As seen in the table every team accomplished step 1 successfully.

Step 2 – Formulation of null hypothesis

Regarding step 2 we can say that the majority of the teams (8 of 11) gave a correct formulation of the null hypothesis when doing the randomization test. Two teams formulated the alternative hypothesis instead of the null hypothesis. For example when comparing the reading habits of boys and girls in the muffins data and investigating the variable “Time_reading” the hypothesis of one of the teams was:

H. & P.: The Girls tend to spend more time on reading than boys.

Two other teams (three teams in total) showed the same problem when formulating an adequate null hypothesis.

Step 3 & Step 4 – Modelling the simulation process in TinkerPlots

As seen in the table nearly every team (10 out of 11) managed to model the simulation process of the randomization test in TinkerPlots.

Step 5 – Reading of the p-value

A notable problem which occurred in step 5 was a false identification of p-value in form of the mean of the collected measures. Two out of eleven teams identified the mean of the measures as p-value. Let us have a look on the case of Laura & Sarah. They wrote, when investigating the hypothesis “the gender-difference on the means of the variable `Time_phone_20min` (Number of phone calls per week that last longer than 20 minutes) did happen by chance”:

L. & S.: The mean of all means is approximately 0.000238873 after 5000 simulations und therefore smaller than 0.1%, which shows a strong evidence against the null hypothesis.

For them the mean of the 5000 collected differences is a very small value and seemed to turn out for them as a p-value.

Step 6 – Drawing conclusions from the observed p-value

In step 6 we found two phenomena: on the one hand “drawing premature conclusions from the p-value” such as “the p-value is smaller than 5%, therefore the null hypothesis can be rejected.” and on the other hand “drawing false conclusions from an observed p-value”. We will give an example for “premature conclusions” first. Alex and Kathrin concluded under the null hypothesis “the difference of the means of the variable “age” concerning the marital status of students is due to random effects”:

A. & K.: The statement can be rejected with a p-value of 4% (which is smaller than 5%). Therefore the null hypothesis [...] can be rejected.

We consider this as premature because we taught the students not to take a definite decision but express the uncertainty when a small p-value occurs as an amount of evidence. A more adequate statement in this case could be (relating to our hand-out which was supposed to support the learners when drawing conclusions from p-values): “Due to a p-value of 4% we have medium evidence against the null hypothesis”. An example of drawing false conclusions from the observed p-value is the following: The null hypothesis is seen as true, because the p-value is significantly high (> 10%). Victoria and Corinna were investigating whether a gender-difference of time spent on working (in hours per week) occurred at random and concluded:

V. & C.: “The result of the randomization test shown here (0.1033) is a probability. Here we have a relative frequency of 0.1033 or 10.33%. This value corresponds to our p-value. [...] The p-value is bigger than 10% which means that the evidence is not so strong and therefore the null hypothesis must be true. “

They made a typical mistake, which is also reported in Garfield & Ben-Zvi (2008, p.270). Having a “large” p-value, they concluded, that the null hypothesis must be true. It is noticeable that this problem occurred at every (precisely: 3 out of 11) team, who conducted a randomization test in which the p-value turned out to be larger than 10%. The problem may have occurred due to paying not enough attention to a p-value larger than 10% in our learning trajectory. We can conclude that the participants have several problems to make conclusions on their own. Summary: two of eleven teams have identified the p-value as the mean of the collected measures. Four out of eleven teams rejected their null-hypothesis (particularly due to a small p-value) in form of “drawing premature conclusions from a given p-value”. Three of eleven teams fell into the category “drawing false conclusions from a given p-value” concluded that the null hypothesis must be true, because of a large p-value (> 10%). All in all we can say that almost every team was able to deal with the technical process of the simulation in TinkerPlots, but they had partly problems with steps 5 and 6. They have acquired procedural knowledge of performing randomization tests in TinkerPlots, but some still fail to formulate an adequate null hypothesis or to identify a p-value or fail to draw adequate conclusions from it. When evaluating a p-value in the project reports, the participants seem to have the attitude either to accept or to reject a null hypothesis, instead of saying something like “...there is a small/medium/strong/very strong evidence against the null hypothesis”. Living with uncertainty obviously is something uncomfortable.

LIMITATIONS AND FURTHER RESEARCH

For evaluating the learning trajectory in the sense of design research approaches (see Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003) we plan a retrospective analysis and a redesign of the learning trajectory. Our aim was to give our students a method which allows them to make further conclusions from observational data. When using this method and conducting a randomization test, two crucial aspects arose: on the one hand the formulation of a correct null hypothesis, on the other hand drawing conclusions from a given p-value. Perhaps there is a need to revise our learning trajectory in order to improve students’ conceptual understanding of these aspects of randomization tests: how can they be better supported at major problems (for example the formulation of a correct null hypothesis; drawing conclusions from a given p-value)? We are currently (end of summer term 2012) conducting a qualitative interview study with the same participants, which is two-phased. In phase 1 they have to work on a group comparison (including a randomization test) exercise in teams of two. In phase 2 we interview them in form of a stimulated recall-method

to elicit the thoughts and strategies of them when working on the task. This will hopefully give further insights into the cognitive processes of the students while working with randomization test with TinkerPlots. The interviews are informed by our previous analyses of project reports that we presented in this paper and are also directed towards the levels of conceptual understanding of the null model that they implemented with TinkerPlots sampler. The difficulties we observed with formulating null hypotheses may have a deeper origin in understanding a “null model” of no difference in a process approach with no random treatment assignments in the data production process.

CONCEPTUALIZING AND ASSESSING SECONDARY MATHEMATICS TEACHERS' PROFESSIONAL COMPETENCIES FOR EFFECTIVE TEACHING OF VARIABILITY-RELATED IDEAS

Orlando González

Grad. School of Intl. Development and Cooperation, Hiroshima University, Japan

The importance of statistics education in secondary school has been emphasized in numerous mathematics curriculum reforms carried out recently in many countries, it being noticeable that variability may arise within all the statistical objects studied in such curricula. Despite this, there have been few attempts to conceptualize or assess empirically teachers' professional competencies (sensu Döhrmann, Kaiser & Blömeke, 2012) for teaching variability-related ideas. This article introduces a conceptual framework for examining teachers' statistical knowledge for teaching alongside teachers' beliefs and conceptions of variability, as well as a survey instrument developed based on it. Preliminary results of an ongoing exploratory study are reported, and implications for teaching and teacher training are discussed.

Keywords: Teachers' professional competencies, statistical knowledge for teaching, teachers' beliefs, teachers' conceptions of variability.

INTRODUCTION

In recent years, curricular reforms in many countries have brought into the secondary school mathematics curriculum topics related to statistics (e.g., NCTM, 2000), aiming towards statistical literacy. It is noticeable that variability—a property of an statistical object which accounts for its propensity to vary or change, which is considered by several researchers as a fundamental concept in statistics (e.g., Shaughnessy, 2007)—may arise in many different ways in such topics. Therefore, nowadays secondary mathematics teachers must instruct several variability-related ideas—such as the one of distribution, since through the lens of this idea statisticians examine data variability (cf. Pfannkuch & Ben-Zvi, 2011, p.326)—, and such work demands from them specific professional competencies, without which the aims of the mathematics curriculum regarding statistics education cannot be achieved.

Döhrmann, Kaiser and Blömeke (2012) point out that “successful teaching depends on professional knowledge and teacher beliefs” (ibid., p. 327), and, with this in mind, they framed mathematics teachers' professional competencies in terms of cognitive and affective-motivational facets (cf. Figure 1). In such framework—which is the theoretical basis of the international study Teacher

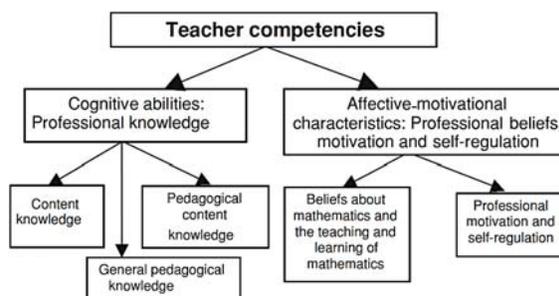

Figure 1: Conceptual model of teachers' professional competencies, according to Döhrmann et al. (2012)

Education and Development Study in Mathematics (TEDS-M)—, Döhrmann and her colleagues highlighted *subject matter knowledge (SMK)* and *pedagogical content*

knowledge (PCK) in the cognitive facet, and teachers' professional beliefs in the affective-motivational facet, as fundamental criteria for effective teacher education.

In the case of statistics education, scarce studies can be found in the literature focused on both the SMK and PCK entailed by teaching variability-related contents to help students achieve the aims of statistics education (cf. Shaughnessy, 2007), as well as on the beliefs held by in-service teachers on statistics teaching and learning of such contents. Hence, it is by no means surprising the urgent call for increasing research on these areas made by a number of concerned researchers, particularly for studies on teachers' professional knowledge and practices while teaching variability (e.g., Sánchez, da Silva & Coutinho, 2011, p.219), as well as for teachers' beliefs on statistics itself and on what aspects of statistics should be taught in schools and how (e.g., Pierce & Chick, 2011, p.160). Accordingly, the purpose of this paper is to respond to such calls by proposing a conceptual framework for secondary teachers' professional competencies to teach variability-related contents, which integrates *statistical knowledge for teaching*—henceforth SKT, the knowledge, skills, and habits of mind needed to carry out effectively the work of teaching statistics—, conceptions of variability, and statistics-related beliefs, aiming to identify indicators that could serve to examine such competencies, to help get a clearer picture about the level of competence to teach variability-related contents attained by secondary mathematics teachers, and also about the existence of any competence-related deficiency that might need to be improved.

THE MKT MODEL

Ball, Thames and Phelps (2008) developed the notion of *mathematical knowledge for teaching*—henceforth MKT—focusing on both what teachers do as they teach mathematics, and what knowledge and skills teachers need in order to be able to teach mathematics effectively. This model describes MKT as being made up of two domains—SMK and PCK—, each of them structured in a tripartite form (cf. Figure 2). Moreover, this model clarified the distinction between SMK and PCK, and refined their previous conceptualizations in the literature.

According to Ball et al. (2008), SMK can be divided into common content knowledge (CCK), specialized content knowledge (SCK), and horizon content knowledge (HCK). Furthermore, Ball and her colleagues presented a refined division of PCK, comprised by knowledge of content and students (KCS), knowledge of content and teaching (KCT), and knowledge of content and curriculum (KCC) (the interested reader should refer to the original article for a detailed discussion of these constructs).

Through this model, Ball and her colleagues made significant progress in identifying the relationship between teacher knowledge and student achievement in mathematics. However, as highlighted by some researchers (e.g., Petrou & Goulding, 2011, p.16),

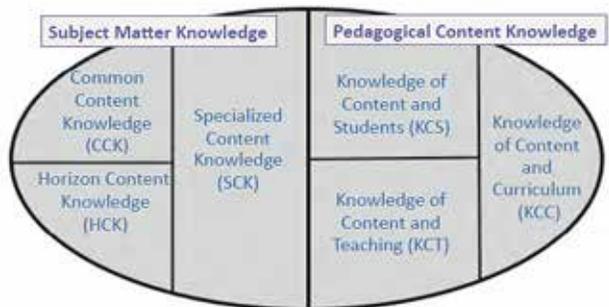

Figure 2: Domains of MKT (Ball et al., 2008)

the MKT model does not acknowledge the role of either beliefs or conceptions about the subject matter in teachers' practices, which could be a drawback, since it is well documented in the literature that beliefs and conceptions are important factors affecting the work of teaching (cf. Philipp, 2007).

CONCEPTUALIZING TEACHERS' PROFESSIONAL COMPETENCIES FOR EFFECTIVE TEACHING OF VARIABILITY-RELATED TOPICS

While several models have been developed in the literature aiming to conceptualize MKT, few have been done on SKT. All those few conceptualizations of SKT proposed to date are cognitive-oriented models that have assimilated some of the categories present in the aforementioned model for MKT (cf. Groth, 2007; Burgess, 2011; Noll, 2011), taking into account neither all the six components identified by Ball et al. (2008) and the role of beliefs in teachers' professional practice, nor the conceptions of variability held by the teachers, which could result in an inadequate picture of teachers' preparedness to teach statistical contents related to variability.

In an effort to fill such gaps, a conceptual model for secondary mathematics teachers' professional competencies to teach variability-related contents is proposed. This model is a two-faceted one: it includes a cognitive as well as an affective facet. The cognitive facet is a sixfold conceptualization of SKT, comprised by all the knowledge subdomains identified by Ball et al. (2008) in their MKT model, with the construct CCK—defined as the mathematical knowledge and skills expected of any well-educated adult—being adapted to meet the case of teaching statistics. In this regard, statistical literacy will be seen as CCK, since the acquisition of its related skills—e.g., identifying examples or instances of a statistical concept; describing graphs, distributions, and relationships; rephrasing or translating statistical findings, acknowledging the omnipresence of variability in any statistical context, or interpreting the results of a statistical procedure—is expected from any individual after completing school education (cf. Gal, 2004; Pfannkuch & Ben-Zvi, 2011).

The affective facet of the model proposed in this article is comprised by two components: teachers' beliefs about statistics teaching and learning, and teachers' conceptions of variability, since both beliefs—defined by Philipp (2007, p. 259) as “psychologically held understandings, premises, or prepositions about the world that are thought to be true”—and conceptions—the set of internal representations and the corresponding associations that a concept evokes in the individual, often explained in the literature as “conscious beliefs”—, have been widely regarded in the literature as factors influencing every aspect of teaching (cf. Philipp, 2007). A detailed discussion of the conjectures that informed the development of this conceptualization can be found in González (2012).

ASSESSING TEACHERS' PROFESSIONAL COMPETENCIES FOR EFFECTIVE TEACHING OF VARIABILITY-RELATED TOPICS

The Survey Instrument.

Based on the conceptual model previously outlined, a pen-and-paper instrument,

designed to be completed in one hour and comprised by tasks addressing variability-related concepts present in the secondary school mathematics curriculum, was developed, in order to elicit and assess each one of the eight components of teachers' competencies to teach variability-related contents identified by this study. Each question in the instrument was developed based on previous studies with similar aims reported in the literature (e.g., Ball et al., 2008; Isoda & González, 2012).

In order to provide a comprehensive framework for conceptualizing the cognitive aspects of teachers' competencies in the context of teaching variability-related ideas, twelve indicators were identified from the literature and selected for assessing SKT from teachers' answers to the designed instrument (see Table 1).

<p>A: Indicators associated to Statistical Literacy (CCK):</p> <ol style="list-style-type: none"> 1. Is the teacher able to give an appropriate and correct answer to the given task? 2. Does the teacher consistently identify and acknowledge variability and correctly interpret its meaning in the context of the given task? <p>B: Indicators associated to SCK:</p> <ol style="list-style-type: none"> 1. Does the teacher show evidence of ability to determine the accuracy of common and non-standard arguments, methods and solutions that could be provided on a single question/task by students (especially while recognizing whether a student's answer is right or not)? 2. Does the teacher show evidence of ability to analyze right and wrong solutions that could be given by students, by providing explanations about what reasoning and/or mathematical/statistical steps likely produced such responses, and why, in a clear, accurate and appropriate way? <p>C: Indicators associated to HCK:</p> <ol style="list-style-type: none"> 1. Does the teacher show evidence of having ability to identify whether a student comment or response is mathematically/statistically interesting or significant? 2. Is the teacher able to identify the mathematically/statistically significant notions that underlie and overlie the statistical ideas involved in the given task? <p>D: Indicators associated to KCS:</p> <ol style="list-style-type: none"> 1. Is the teacher able to anticipate students' common 	<p>responses, difficulties and misconceptions on the given task?</p> <ol style="list-style-type: none"> 2. Does the teacher show evidence of knowing the most likely reasons for students' responses, misconceptions and difficulties in relation to the statistical ideas involved in the given task? <p>E: Indicators associated to KCT:</p> <ol style="list-style-type: none"> 1. In design of teaching, does the teacher show evidence of knowing what tasks, activities and strategies could be used to set up a productive whole-class discussion aimed at developing students' understanding of the key statistical ideas involved in the given task, instead of focusing just in computation methods or general calculation techniques? 2. Does the teacher show evidence of knowing how to sequence such tasks, activities and strategies, in order to develop students' understanding of the key statistical ideas involved in the given task? <p>F: Indicators associated to KCC:</p> <ol style="list-style-type: none"> 1. Does the teacher show evidence of knowing at what grade levels and content areas students are typically taught about the statistical ideas involved in the given task? 2. Does the designed lesson (or series of lessons) show evidence of teacher's understanding and support of the educational goals and the intentions of the official curriculum documents in relation to the teaching of the statistical contents present in the given problem, as well as statistics in general?
---	---

Table 1: Set of indicators proposed to assess SKT through the answers to the survey items

In regard to the affective facet of the conceptual model proposed here, the conceptions of variability that might be distinguished in teachers' answers will be classified using the eight types of such conceptions identified by Shaughnessy (2007, pp. 984-985). In the case of teachers' beliefs about statistics teaching and learning, the limited research on this issue (e.g., Pierce & Chick, 2011, p.159) suggests that they could be identified through examining the features of the lesson plans that teachers produce, such as the tasks chosen to consider a particular statistical idea, and the types of instructional strategies teachers planned to use during the lesson. What teachers planned to do—which is related to the construct KCT—will be analyzed using the four categories reflecting on teachers' beliefs developed by Eichler (2008)—i.e., traditionalists, application preparers, everyday life preparers, and structuralists—, which will provide valuable information on teachers' beliefs about the nature of statistics, as well as about the learning of statistics (cf. Tatto et al., 2012, pp.154–156).

Profile of Item 1.

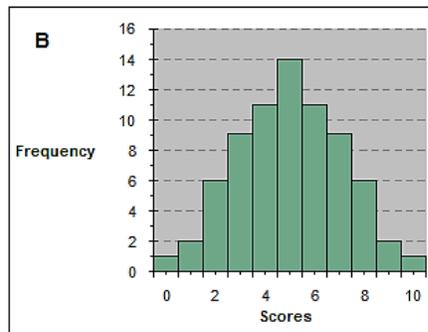

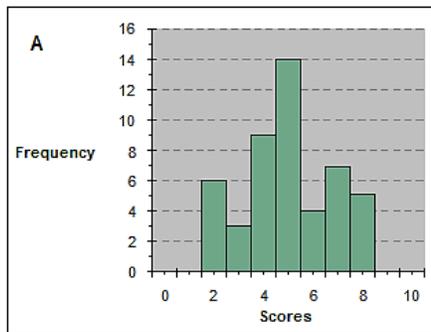

In a first stage of this study, a survey instrument comprised of one item—Item 1, which

is depicted in Figure 3, and deals with several ideas of descriptive statistics—was designed, and then sent by postal mail to three public secondary schools in Hiroshima Prefecture, Japan. The fact that the majority of the statistical contents present in the Japanese mathematics curriculum are ideas related to descriptive statistics was crucial in the selection of the task in Item 1. Two more stages of this study are planned in the future, each of them using a one-itemed questionnaire dealing with the ideas of probability and sampling, respectively.

ITEM 1

Please, read carefully the following task and answer the questions below:

Choosing the distribution with more variability. Look at the histograms of the following two distributions:

Which distribution (A or B) do you think has more variability? Briefly describe why you think this.

- Answer this task in as many different ways as you can. Please, be sure to show every step of your solution process.
- What are the important ideas and concepts that might be used to answer this task?
- Suppose that, after posing this task to your students, three of them come up with the following answers:

Student 1: “Distribution A has more variability because it’s not symmetrical.”

Student 2: “Distribution A ranges from 3 to 14, while Distribution B ranges from 1 to 14. Then, Distribution B has more variability.”

Student 3: “The bars in Distribution A are clumped closer to the central bar than they are in Distribution B. Then, Distribution B has more variability.”

Dealing with each student separately, please comment briefly on each of these answers, focusing on whether the answer is correct or not, why you think so, and what reasoning might have led students to produce each answer.

- Suppose you pose this task to your students. What are the most likely responses (correct and incorrect), misconceptions and difficulties you would expect from them? Briefly explain why you think so. (Regarding to the most likely answers that you might get from the students, please do not include those mentioned in part (c).)
- Mathematically/statistically speaking, is any of the answers given by the students interesting or significant? If yes, briefly explain why and on what aspects. (Please, focus your response on whether there is a significant mathematical/statistical insight in the student’s answer, and whether there are forthcoming contents in future classroom subjects connected to the notions/concepts being said or implied in such answer.)
- Briefly describe how the important ideas and concepts involved in the solving process of the given task are addressed in official curriculum documents across the different grade levels of schooling.
- Suppose you want to plan a lesson (or a series of lessons) to introduce the meaning of variability in the context of the given problem to your students. Briefly describe as many instructional strategies, activities and/or tasks as you can think of that would be appropriate to use for this purpose, and sequence them accordingly, explaining why you chose to put them in such a particular order.

Figure 3: Item 1 – “Choosing the distribution with more variability” task

The original version of the task in Item 1—developed by Garfield, delMas and Chance (1999), and reported in the literature as an effective means of investigating teachers’ conceptions of variability in the context of histograms (e.g., Isoda & González, 2012)—was modified to facilitate the calculations that could be made while the respondent gives answer to the task, and was also enriched with questions aiming to

elicit all the facets of teachers' professional competencies to teach variability-related contents identified by this framework. A mapping between the components of SKT that would be elicited by each question in Item 1, as well as the indicators associated to each cognitive aspect considered by this framework, can be appreciated in Table 2.

The context of the task posed in Item 1—comparing distributions—requires from teachers the mastery of several variability-related concepts—e.g., distribution, measures of variation, frequency distribution table, and histogram. Therefore, the task in Item 1 was selected in order to see, among others, (a) whether by looking at the histograms of two distributions of scores, teachers could figure out which one has more variability, and then use data-based arguments to defend their answer; and (b) how the respondents conceptualize variability in the context of the given task.

Elicited Knowledge Component of SKT	Associated Indicator of SKT	Question
Statistical Literacy (as CCK)	A1	(a)
	A2	(a)
Specialized Content Knowledge (SCK)	B1	(c)
	B2	(c)
Horizon Content Knowledge (HCK)	C1	(e)
	C2	(b)
Knowledge of Content and Students (KCS)	D1	(d)
	D2	(d)
Knowledge of Content and Teaching (KCT)	E1	(g)
	E2	(g)
Knowledge of Content and Curriculum (KCC)	F1	(f)
	F2	(g)

Table 2: Knowledge components of SKT elicited by each of the questions posed in Item 1

About the Participants in this Case Study.

At the time of writing this article (September 2012), the survey process—which began in July 2012 in Hiroshima Prefecture, Japan—was ongoing, and expected to be completed by the end of September 2012. In this paper, a preliminary analysis of the data gathered from one of the schools participating in this study, comprised of the written responses to Questions (a) and (g) on Item 1 given by four senior high school mathematics teachers working in such school, will be reported. The respondents were between 28 and 56 years old; they had between one and thirty-four years of teaching experience—with three of them with at least 13—, and were the first group of teachers that voluntarily and anonymously responded and mailed back the survey booklets.

Results and Findings regarding Question (a).

Three out of four teachers answered this question. From those who answered, two teachers—Teachers 1 and 2—used three different approaches: Teacher 1 answered the task by comparing the range, variance and interquartile range of both distributions; while Teacher 2 answered the task by comparing the range, the shape, and the mean absolute difference from the mean of both distributions. Teacher 4 answered using only one approach: by comparing the largest data span from the mean in both distributions.

It is quite surprising that all these teachers made computation errors in every approach that involved calculations. Among all the calculation errors done by them, one was recurrent: although both Teacher 1 and Teacher 2 identified correctly Distribution B as the one with more variability via comparing the ranges, when computing them they used as minimum and maximum values 2 and 8 in Distribution A, and 0 and 10 in Distribution B, respectively; that is, they used the class marks instead of the lower and upper class limits, which are 1.5 and 8.5 for Distribution A, and are -0.5 and 10.5 for Distribution B. This might be understood as an indication that these teachers considered the variable

represented in both histograms as a discrete one.

In a similar way that Teacher 1 and Teacher 2 calculated the distribution ranges, Teacher 4 calculated the largest data span from the mean in both distributions. This teacher mistakenly argued that the largest data span from the mean is ± 3 and ± 5 units for Distribution A and B, respectively. Once again, it is noticeable that this teacher used for his calculations the class marks instead of the lower and upper class limits, possibly considering the variable represented in both histograms as a discrete one.

Regarding the conceptions of variability held by the respondents, the answer given by Teacher 4 indicates he holds the fifth conception of variability identified by Shaughnessy (2007)—“Variability as distance or difference from some fixed point”—, since this teacher points out deviations of the endpoints from some fixed value, such as the mean, when asked to consider the variability in both histograms. Reflecting a rather sophisticated recognition of variability, and at an even higher level, are the answers given by Teacher 1 and Teacher 2, which suggest that they hold the eight conception of variability identified by Shaughnessy (2007)—“Variation as distribution”—, since these teachers were able to use theoretical properties of the histograms to calculate numerically—although mistakenly—the measures of variation associated to each distribution in order to make their decision, exhibiting in such way an aggregate view of data and distribution, since they seem to be predominantly concerned with the variability of an entire data distribution from a center (cf. Shaughnessy, 2007, p.985). Unlike Teachers 1 and 2, Teacher 4 does not exhibit an aggregate view of data and distribution, since he is rather concerned with the variability of just the endpoints from a measure of central tendency.

Results and Findings regarding Question (g).

The purpose of this question is to elicit evidence of the indicators associated to KCT outlined in Table 1—namely E1 and E2. In order to determine the presence of such indicators in teachers’ answers, a criterion-referenced assessment rubric was designed, based on the characteristics of effective classroom activities to promote students’ understanding of variability compiled by Garfield and Ben-Zvi (2008).

All the four teachers answered this question (cf. Figure 4). In relation to Indicator E1, the answers given by Teacher 1 and Teacher 4 are the ones that seem to exhibit a higher level of knowledge on the key characteristics of effective activities that promote students’ understanding of variability identified by Garfield and Ben-Zvi (2008), such as the implementation of tasks involving comparisons of data sets, aiming towards describing and representing variability with numerical measures when looking at the given data, and promoting whole-class discussions on how measures of central tendency and variation are revealed in data sets or graphical representations of data (ibid., pp. 207-209).

Regarding Indicator E2, the answers given by Teacher 1 and Teacher 4 are also the ones that seem to evidence more knowledge on how to sequence activities and strategies intended to promote students’ understanding of variability. For example, in both answers is explicitly stated that the lesson must start by presenting students with some simple data, in order to

interpret it (Garfield & Ben-Zvi, 2008, pp.135-137). However, Teacher 4’s answer is at an even higher level compared to the others, since explicitly states that variability should be described and compared informally at first—e.g., by describing verbally how the data is spread out—, and then formally, through measures of variation (cf. *ibid.*, p.208).

Teacher 1	Teacher 2
<p>Task: 「Among 2 distributions, which one do you think has more variability?」</p> <p>Activities:</p> <p>① Check different ways (range, variance, standard deviation, interquartile range) for examining variability.</p> <p>② Place students in groups, asking to each group to use only one of the methods in ① to discuss about what things could be told about the variability of the given distributions.</p> <p>③ Each group will share with the rest of the classroom what they considered in ②.</p> <p>④ Depending on the method used, and while checking different considerations, think about how to look at variability.</p> <p>Students will experience personally the need of using several methods and finding out the appropriate one in order to consider data trends.</p>	<ol style="list-style-type: none"> 1. To make students think about which of 2 given histograms, A and B, has more variability. 2. To make students think about whether they can make their decision based only on the sample size. 3. To judge the variability using the variance. 4. To give practice problems to students.
Teacher 3	Teacher 4
<p>In mathematics there are a large number of approaches in many directions concerning “variability”:</p> <p style="padding-left: 20px;">Introduction of the formulas related to variability.</p> <p style="padding-left: 20px;">Studying variability through the use of computer technology.</p> <p>Based on the aforementioned approaches, bring up for discussion various topics in society and the corporate world, such as product development, among others, as well as their connections with practical applications.</p>	<ul style="list-style-type: none"> – Give 2 histograms, A and B. – To make students think about in which histogram the variability is larger, and to make them expose about what they think. <li style="padding-left: 20px;">...At this stage, a detailed explanation about “variability” has not yet been provided. – After their presentations, to explain about “variability”, and to make students think again about which histogram has more variability. – To explain, among other things, different terms besides “variability”, provide different histograms, and practice.

Figure 4: Translation of answers to Question (g) given by the four surveyed teachers

In relation to the beliefs about instruction of statistics held by the surveyed teachers, the answers given by three of them—Teachers 1, 2 and 4—provide evidence that they might be *traditionalists*—i.e., teachers more concerned about students gaining algorithmic skills, and less about context and applications—, with only one teacher—Teacher 3—providing evidence of being an *application preparer*—i.e., a teacher focused on teaching theory and algorithms, so the students could use them to solve real-world problems. Moreover, it seems that Teachers 1, 2 and 4 see statistics as a process of inquiry; that is, as a means of answering questions and solving problems. Furthermore, Teachers 1 and 4 planned lessons in which they encourage students to find their own solutions to statistical problems, while fostering the development of statistical discourse and argumentation in the classroom, which provide evidence that they might believe that statistics learning should be carried out as active learning. The answers given by Teachers 2 and 3 give evidence they might believe that statistics learning is a teacher-centered individual work.

CONCLUSIONS

Based on teachers’ performance in Question (a) of Item 1, some answer tendencies were identified; for example, calculating particular measures of variation considering the variable represented in both histograms as a discrete one. Only one teacher mistakenly used the shape of the histograms to answer, interpreting the variability in the given histograms as the differences in the heights of the bars, which is a common

misconception in this kind of problems (cf. Meletiou & Lee, 2003; Isoda & González, 2012). Despite of this, evidence of two teachers in this group exhibiting an aggregate view of data and distribution—i.e., holding the conception of variability known as “Variation as distribution”—is noteworthy.

Regarding teachers’ performance in Question (g) of Item 1, the one of Teachers 1 and 4 stands out from the others. Some of the characteristics identified in their answers are consistent with those of effective classroom activities to promote students’ understanding of variability made by the specialists (cf. Garfield & Ben-Zvi, 2008). Nevertheless, except for the answer given by Teacher 3, all the lessons planned by the respondents lack consideration of an explicit daily-life context, which is vital to internalize in the students that statistics helps solve everyday problems and tasks (cf. Gattuso & Ottaviani, 2011, pp.122-123, 129). Due to this fact, the majority of the surveyed teachers might be considered as traditionalists.

The fact that teachers’ answers showed, among others, a lack of knowledge about how to relate the given task to different data representations, such as boxplots and frequency distribution tables, and due to the importance of making an appropriate interpretation of variability for statistics, courses where Japanese senior high school mathematics teachers could learn more about developing intuitive ideas of variability and the interrelationship among variability-related concepts; describing and representing variability; using variability to make comparisons; being able to map the characteristics of a given histogram to alternate representations; and so on, could be required.

BRIDGING POLICY DEBATES ON RISK ASSESSMENTS AND MATHEMATICAL LITERACY

Kjellrun Hiis Hauge

Bergen University College, Norway

The aim of this paper is to generate discussions on why to develop mathematical literacy and critical thinking related to risk assessments and how. The paper presents ideas and key points from the academic literature on science for policy related to uncertainty and risk assessments. These are elaborated and exemplified. I further show that these match aspects of mathematical literacy and related literature on research in mathematics education. Perspectives from the two academic communities are then combined, resulting in a framework for increasing competences useful for public participation. The theoretical foundation of the framework constitutes the starting point for a series of future research questions and research projects.

Key words: risk assessments, societal issues, critical democratic competence, mathematical modelling, statistical literacy

INTRODUCTION

We are facing tremendous challenges in society, covering scarcity on food and energy supplies and pollution of various kinds and sources. Science is given an important role in finding solutions to these problems, yet ‘facts’ are occasionally disputed with scientific advice at the centre of debate. The academic literature on science for policy has responded to this situation, and increased attention is given to the handling of uncertainty in science for policy in situations characterised by high stakes and diverging interests. Experts’ common handling and communication of uncertainty through quantitative measures, as for example risk assessments, probability distributions, error bars or safety factors, are argued to be insufficient for sound decision making in such situations. In this paper, I will focus on risk assessments, often defined as the probability of an unfortunate event multiplied with its quantified impact.

From a democratic viewpoint, challenging policy issues benefit from an engaged public. Facts are often presented in numbers and thus require mathematical literacy. In the next section of the paper, I present some background information and research on mathematical literacy that is linked to active citizens and critical thinking. The proceeding section provides examples where risk assessments have been disputed. These are briefly discussed, demonstrating some key points from the academic literature on uncertainty in science for policy. The paper finally presents a framework for increasing mathematical literacy and critical thinking where perspectives from the two academic fields are combined. The ultimate aim of the framework is to

enhance mathematical literacy to strengthen public participation where risk assessments are at the centre of policy making. The framework is quite general, targeting students at any level of educational institutions, from primary school to teacher education institutions.

CRITICAL DEMOCRATIC COMPETENCE

UN describes literacy, including mathematical literacy, as a condition for critical awareness and which can stimulate participation and ensure increased influence on society. PISA 2003 and 2006 (OECD, 2003; OECD, 2006) defines mathematical literacy as: “ [...] an individual’s capacity to identify and understand the role that mathematics plays in the world, to make well-founded judgments and to use and engage with mathematics in ways that meet the needs of that individual’s life as a constructive, concerned and reflective citizen” (OECD, 2006, p. 72).

The Norwegian National Curriculum reflects the societal needs in terms of mathematical literacy. It highlights the competence to “understand and critically evaluate information, statistical analyses [...] to understand and impact processes in society” (Ministry of Education and Research, 2006). Further, the curriculum includes statistics, functions and graphic representation together with practical problem framing, of which all are relevant skills for risk assessments.

Mathematical literacy, including some definitions of statistical literacy (Ben-Zvi & Garfield, 2004), is closely linked to the development of critical democratic competence; the ability to criticize, evaluate and analyse applications of mathematics in society (Blomhøj, 1992, 2003). Blomhøj (1992, 2003) argues that mathematical modelling can increase the development of critical democratic competence. The modelling process can be described as consisting of the following cycle of phases: a) Framing the problem, b) defining the boundary (the choices of what to include and what not to include in the model), c) mathematization (developing the model by describing the system/situation with mathematical concepts and language) d) the mathematical analyses (the mathematical calculations or representation from applying the model), e) interpretation and evaluation of the model results, and f) evaluation of the model’s validity (Blomhøj, 2003).

Risk assessments are usually based on statistical enquiry to calculate the probability, and mathematical modelling to calculate impacts. However, the latter often requires data as well, and the estimated probability may also be based on mathematical modelling. This means that we need to add the following to the process list above, between b) and c): i) decisions on how and what to measure/sample and ii) structuring and displaying data (Lehrer & Schauble, 2004). The added phases require statistical literacy, including Watson’s third tier: *critical awareness* (Watson, 1997). All phases demand critical and skilful evaluation, as they all include some kind of choice with no officially “correct” answer. Mathematical modelling and statistical enquiry will often stand in contrast to the rather common perception that science and

mathematics produce an answer which is exact and correct. The acknowledgement of this is in itself a step towards critical democratic competence.

Research on school children working with aspects of mathematical modelling or risk assessments reveals children's development of critical thinking and critical democratic competence (see for example Hansen, 2009, 2010; Alrø, Blomhøj, Bødker, Skovsmose, & Skånstrøm, 2006).

Citizens cannot be expected to understand complex mathematical calculations, but insights in the modelling or sampling process may help understand uncertainty aspects in the process. I now turn to the academic literature on science for policy and present key aspects related to uncertainty and risk assessments. The purpose is to discuss how these perspectives can be utilised in developing mathematical literacy and critical thinking related to risk assessments in schools and in teacher educations, which is addressed in the last section of the paper.

UNCERTAIN SCIENCE FOR POLICY

Science is often seen as a key factor in solving societal problems and often plays an advisory role in developing policies related to environmental risks, for example related to greenhouse gas emissions or fisheries. While science has long been seen as 'truth' seekers, where science feeds the policy makers, we increasingly experience that scientific 'facts' are disputed. The discussions around whether global warming is real and whether it is manmade are examples of this. It is argued that the nature of problems science is asked to provide advice for has changed considerably. Now scientists have to deal with complex systems, of which knowledge and data may be scarce, and where the issue at hand is controversial with great values at stake (Funtowicz & Ravetz, 1993). A consequence of these challenges is that some policy processes have become more open, where cross-sectoral approaches, stakeholder involvement or public hearings have influenced policy making.

Risk assessments often play an important role in decision making, for example in fisheries management, managing permissions for petroleum exploitation and managing permissions for nuclear power plants. In such cases, risk is often defined as the probability of an unfortunate event multiplied with its effect. I now briefly present some discussions on existing risk assessments to demonstrate potential challenges with risk assessments in general.

Wild capture fisheries management is often based on risk assessments, where a management principle is to keep the probability of depleting a fish stock low. In general there are too many fishing vessels compared to the amount of fish, so that fishing needs to be restricted. Fisheries scientists provide risk assessments for this purpose. These are often disputed, and lack of trust between advisors, managers and the fishing industry is common. Several problems with calculating risk have been addressed (Hauge, 2011). The probability calculations are based on uncertain assumptions, ranging from the ability to predict what species fishermen catch to

assumptions on environmental conditions, which often vary from one year to another and may be impossible to predict so that it adds relevance. It is further argued that these uncertainties are downplayed by the science community, although this may indeed not be the intention (Hauge, 2011).

The question of opening Norway's northern offshore areas to petroleum production has been a long and heated political debate in Norway because the areas host some of the world's largest fish stocks and bird colonies. A central issue has been the development of risk assessments, which are defined by the probability of a major oil spill multiplied by its environmental impact. There has been disagreement between the petroleum sector on one side and the fisheries and environmental sector on the other side, on which of the previous blowouts are relevant for calculating the size of a major oil spill. Further, the relevance of these are questionable due to lack of data and the quite narrow scope of defining both the event and the impacts (focussing on birds, marine mammals and two fish species) (Hauge et al., 2012). The debates among experts and in the public have centred on the quality of the risk calculations rather than their scope and relevance. The existing risk assessments thus define what issues are plausible to discuss and criticize.

Similar problems are discussed regarding the risk calculations of meltdowns in nuclear power plants. The empirical basis for calculating the probability is argued to be weak since few power plants are based on comparable technologies. In addition, experience has shown that accidents are often initiated by a combination of two or more simultaneous events which in isolation are quite harmless. However, due to the complexity of power plants they have caused unpredictable occurrences, which have been challenging to interpret for the operators (Perrow, 1999).

IPCC (International Panel on Climate Change) uses the term 'likely' based on probability calculations: "Most of the observed increase in global average temperature since the mid-20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations" (International Panel on Climate Change, 2012). 'Very likely' refers to a probability assessed to be above 90% (IPCC, 2012). Sceptical proclamations to climate change are not uncommon, and for a non-expert it is challenging to weigh 'evidence'. Yet, the uncertainty in, for example, IPCC's temperature predictions should be apparent for an interested reader, as IPCC can inform us that these are based on emission scenarios and a "hierarchy of models". The latter implies that several research groups around the world produce temperature predictions, and that a weighted average is chosen as the 'most likely' one.

There are several similarities between these examples: i) they all represent great values at stake: monetary value, nature, life style and identity, ii) reputable scientific communities produce advice iii) scientific advice has great influence on public debate and/or on policy making, iv) scientific advice is associated with substantial uncertainty, and v) advice or predictions are presented with hyper-precision,

understood as numbers appearing much more certain than what the associated uncertainty would imply (Funtowicz & Ravetz, 1994).

Funtowicz and Ravetz argue that policy issues where stakes are high and ‘facts’ are uncertain require post-normal science, where quality in science for policy is defined as both high quality, peer-reviewed science and as fit for purpose. (Funtowicz & Ravetz, 1993). Although science may be ‘truth seeking’, traditional scientific questions and methods may not be relevant for a specific policy problem. Uncertainty should therefore be specifically addressed, and stakeholders, including the public, should evaluate the relevance of scientific input to policy and decision making (Funtowicz & Ravetz, 1993; Funtowicz & Strand, 2007). However, scientists and engineers are often not trained to address uncertainty in other ways than probability distributions, error bars or safety factors.

In response to this situation, several frameworks have been developed to enhance relevance in advice and assessments by articulating values and the qualitative aspects of uncertainties. The following list covers essential issues related to these:

- a. Mapping values at stake (van der Sluijs et al. 2005a, 2005b, 2008).
- b. Mapping potential risk bearers, which may depend on the final policy (van der Sluijs et al. 2005a, 2005b, 2008).
- c. Uncertainty in the translation from a policy problem to a scientific question: whether the scientific problem answers the policy question or only part of it, and whether it is neutral to values and risk bearers (Walker et al. 2003).
- d. The sources of uncertainty, referring to data, methodology, underlying assumptions, and the scope of investigation (Walker et al., 2003).
- e. Characteristics of the uncertainties: for example whether uncertainty can be represented by measurement error or whether it involves unknown aspects, implying that uncertainty cannot fully be quantified. Another characteristic would be whether the uncertainty is reducible (Funtowicz & Ravetz, 1990; Wynne, 1992; Walker et al., 2003).
- f. Extended peer-review (Funtowicz & Ravetz, 1993; van der Sluijs et al. 2005a, 2005b, 2008).

Uncertainty due to translating the policy problem to a scientific problem is a central issue. The relevance of scientific framings has been questioned in all four examples above: whether managing single stocks are possible when fishermen catch a mixture of species (Hauge, 2011), whether the developed risk assessments are adequate for giving permits for petroleum exploitation (Hauge et al., 2012), whether single event accidents are characteristic for nuclear power plant accidents (Perrow, 1999) and

whether all the efforts of reducing uncertainty in IPCC's temperature predictions will be helpful for policy making.

The purpose of addressing characteristics of uncertainties is that numerical results accompanied by error bars, or other quantified uncertainty measures, do not necessarily convey the soundness of the knowledge base. Appropriate data or knowledge may not be available, demanding more or less qualified guesses. Such choices have been made, for example, in modelling global temperature development: assessing historic temperatures, deciding data grids, deciding which physical processes to be left out in the model, etc. Uncertainty aspects like these cannot be reflected in quantified uncertainty measures and need to be addressed in addition. Frameworks are developed for this purpose (see for example Walker et al., 2003).

Scientists and experts often need to limit the scope of their investigations and make unsupported assumptions, having access to limited data, as the case was in the four examples above. The implied choices influence policy debates in ways people may not be aware of, which again can have political consequences. From a democratic viewpoint, such policy issues benefit from an engaged public. The public may not grasp the complex mathematics or science behind predictions or advice, but the public may be competent in raising relevant questions to knowledge production and understand the nature of associated uncertainties and its societal consequences.

CRITICAL DEMOCRATIC COMPETENCE RELATED TO RISK

A question imperative to the paper is how educational institutions can work with the concept of probability, modelling and risk in order to improve mathematical and statistical literacy related to societal questions where risk assessments influence policy making and decisions. I now present a framework for developing critical democratic competences, but which also can serve as a starting point for theoretical discussions on planned research projects. The framework consists of three rather complementary approaches. The first is to conduct risk assessments, the second is to practice with statistical and modelling concepts through issues presented in the media, and the third is to discuss risk assessments in light of the above list of value and uncertainty questions.

Conducting risk assessments requires and develops both statistical and modelling competences. Through first-hand experience on estimating probabilities of unfortunate events and on developing and applying models for calculating impacts, the student is trained in developing mathematical arguments. She further experiences that choices and evaluations need to be made in every phase of the process, and that mathematics is not necessarily about searching the one and only correct answer. Such experiences are crucial for developing critical thinking related to the use of mathematics in social life and are highlighted in literature on critical mathematics education, on modelling competences and on statistical literacy (Ernest, 2001; Blomhøj, 1992, 2003; Barbosa, 2006; Gal 2002; Watson, 1997, 2004; Lehrer &

Schauble, 2004). The ambitions on which parts of this process are to be addressed, and how, will vary, depending on age of the students and on the teacher's goals.

Practice with statistical and modelling concepts through media issues is valuable for linking classroom concepts to concepts used in the media. Media issues can be used as a basis for simple problem solving (Watson, 1997, 2004), or they can be used for searching and understanding concepts. Internet offers a rich spectrum of issues where relevant concepts can be found, such as probability, event space, stochasticity, risk, variable, stochastic variable, graphical representations etc. The student thereby gets experience with, and the habit of, discussing issues presented in the media. This also enables recognition that mathematical skills are relevant for media issues.

Discussing risk assessments presented in the media is the third approach. The calculations in such assessments are normally much too advanced to study for any lay person. But the exercise of exploiting a calculated risk through posing questions related to the list in the above section on Uncertain Science for Policy can enhance critical thinking. The list can be supplemented by Gal's (2002) "worry questions" about statistical messages. The purpose of this activity is less about concluding on correct statements about the risk assessment. Rather, by suggesting and discussing what choices the experts may have faced, the student can gain insight in what questions might be relevant to ask for increasing understanding about values and uncertainties associated with the risk assessment. The student can thereby act as an extended peer-reviewer. The introduction of socially relevant, real-life problems in its full complexity has been requested in the literature (Ernest, 2001). It also prepares for the role as consumers of mathematical or statistical information, which Gal (2002) points out is a more common role for adults than being a producer of such information. This last framework approach requires teachers that are inquiry oriented and feel comfortable with exploring unknown ground.

These three approaches to increasing critical democratic competence of students, specifically related to risk assessments, are partly complementary. Although all approaches seek to enhance critical thinking, they do so from slightly different angles. An aim is that a student is able to transfer insights related to what Wild and Pfannkuch (1999) call enquiry contexts to reading contexts. This can be facilitated through reference to the other approaches when working within one approach. Taken together, the framework aims at increasing the critical democratic competences to enable future adults in participating in societal issues. The last decade there has been an increasing global demand for participatory policy processes. Skills in asking the right questions concerning quantified information are crucial in this regard.

As a final remark, I find it important to emphasize that we wish to be critical to risk assessments, not necessarily because we expect scientists and experts to cheat or to perform badly, but because they are often required to give answers to problems to which solid conclusions cannot be expected. The scientists and experts involved are

often the best in their field, and they provide valuable knowledge, but you may need to be critical to the context in which this knowledge is used.

STUDENTS' INFORMAL INFERENCE REASONING WHEN WORKING WITH THE SAMPLING DISTRIBUTION

Bridgette Jacob and Helen M. Doerr

Syracuse University

Introductory statistics students struggle with the complexities of the sampling distribution, particularly when asked to draw a conclusion based on a sample of data. This study investigates the informal statistical reasoning of seven pairs of secondary students as they collect a sample of data in an attempt to draw a conclusion based on the related sampling distribution. We present analysis of this task and the results of a pre/posttest assessment of their informal inferential reasoning with the sampling distribution.

INTRODUCTION

Recent research efforts in statistics education have focused on informal statistical inference to understand how students begin to reason about data they encounter. Informal inferential reasoning is thought to develop as it brings together the underlying concepts of descriptive statistics, probability, and the sampling distribution to infer about populations before the procedures of formal inference are introduced. Makar and Rubin (2009) defined informal inferential reasoning as generalizing about a population using sample data as evidence while recognizing the uncertainty that exists. This focus on informal inferential reasoning as students take part in informal statistical inference tasks has been under investigation for the last decade (Ben-Zvi, 2004; Pfannkuch, 2006; Pratt, Johnston-Wilder, Ainley, & Mason, 2008; Watson and Moritz, 1999). While researchers are building definitions of informal inferential reasoning and frameworks for researching its development (Makar & Rubin, 2009; Pfannkuch, 2006; Zieffler, Garfield, DelMas, & Reading, 2008), exactly how informal inferential reasoning develops and how students demonstrate such reasoning across a range of contexts is still under investigation. This research was designed to add to the understanding of that development by investigating how secondary students demonstrated informal inferential reasoning at the end of a year-long course in introductory statistics in the United States. In particular, we were interested in two questions: (1) what knowledge of the sampling distribution do students exhibit and (2) could students make an informal statistical inference by situating a single sample in relation to the related sampling distribution.

BACKGROUND

Even with instructional activities designed to help students develop an understanding of the complexities of the sampling distribution such as those implemented in the study by Saldanha and Thompson (2002), students are likely to experience difficulty in drawing informal conclusions with the sampling distribution. The majority of secondary statistics students in Saldanha and Thompson's study compared a single sample statistic to the population parameter rather than to the sampling distribution

when asked to determine if it was unusual. Many of the difficulties students experience with the sampling distribution surround their misunderstandings of the effects of sample size and thus, the variability of the sampling distribution. Chance, delMas, and Garfield (2004) found this when using interactive software and paper-and-pencil tasks designed to assist students in making the distinctions between the population, samples, and the sampling distribution. For the introductory statistics students in their study, placing the sampling distribution in relation to the population and individual samples was problematic. The difficulties students have with the complexities of the sampling distribution and drawing conclusions with them have the potential to plague them further as they attempt to navigate formal statistical inference.

The definition proposed by Makar and Rubin (2009) was used to determine if students reported in this study were demonstrating informal inferential reasoning. The larger study, of which the sampling distribution task reported here is a part, was modified from a task framework for research on informal inferential reasoning developed by Zieffler, Garfield, delMas, and Reading (2008).

DESIGN AND METHODOLOGY

This research was part of a larger research project that examined the relationship between students' informal inferential reasoning and their formal inferential reasoning as this developed over a year-long course in introductory statistics at the upper secondary level. In this paper, we focus on students' reasoning about the sampling distribution as they completed a task designed to engage them in informal inferential reasoning. This task was the third in a sequence of four task-based interviews (Goldin, 2000) completed by seven pairs of students. We will also discuss their responses to the sampling distribution questions on a pre/posttest they completed as part of the larger study. The posttest included the same informal inferential reasoning questions as the pretest as well as formal inferential reasoning questions.

Setting and Participants

The students taking part in this study were enrolled in introductory statistics courses for college credit in their high schools. These students were either in their 11th or 12th grade year, 16 to 18 years of age, and had completed at least the first two courses of the three mathematics courses required for high school graduation. These students came from one of eight statistics classes taught by four different high school mathematics teachers from two high schools. These statistics classes met for approximately three and one-half hours each week for the 40-week school year beginning in September, 2011.

A pair of students from each of the eight classes was asked to take part in the task-based interviews; seven of the student pairs completed the study. The pairs of students represented a range of prior achievements in mathematics as judged by their classroom teachers.

Task-based Interviews

The structure of the task-based interviews followed the principles and techniques proposed by Goldin (2000). These included task-based interviews that (1) were designed specifically to answer the research questions, (2) included tasks with appropriate content for students' to grasp, (3) were structured based on key statistical concepts that gave students a variety of ways to demonstrate their understanding, (4) included an explicit interview protocol that allowed students to think about their responses without critiquing the correctness of their responses, and (5) involved students in free problem solving while they interacted with another student. The interview tasks were designed with multiple parts that increased in complexity.

Three classroom activities were implemented in each of the classes prior to the task-based interviews to provide the students with experiences in informal inferential reasoning. The three activities took place in the following order in conjunction with the progression of the class curriculum: (1) comparing distributions of data (Watson & Moritz, 1999); (2) a sampling and probability exploration (Konold et al., 2011); and (3) a sampling distribution activity.

Following each of these three classroom activities, the task-based interviews were conducted with the seven pairs of students. These interviews began with a recall of the classroom activity to gain insight into what the students learned from the activity. They were then asked to complete another problem in that same topic area to probe how their informal inferential reasoning was developing. A fourth task-based interview focused on formal statistical inference.

The focus of the research reported here involved the third task-based interview. This interview task was influenced by the work of Saldanha and Thompson (2002) who found that even after instruction on the sampling distribution, students tended to compare the results from a sample to the distribution of the original population rather than to the sampling distribution. The classroom activity and task in this study were designed to support what they called a "multiplicative" conception of sample where the distinction between the population distribution, the distribution of a single sample taken from the population, and the distribution of the sample statistics of many samples is understood. The interview tasks included a task used by Chance, delMas, and Garfield (2004) in which students identified sampling distributions based on a population distribution and answered questions about the variability of these sampling distributions. This interview task culminated with an informal inference task which required students to situate a single sample statistic in comparison to a related sampling distribution of many samples.

Pre/posttests

The study began with a pretest assessment to measure students' informal inferential reasoning. The study concluded with a posttest which contained both informal (identical to pretest) and formal statistical inference questions. There were two items

that specifically addressed informal inferential reasoning with the sampling distribution. Students' responses to these items are included in this analysis.

DATA ANALYSIS

The task-based interviews were video-recorded, transcribed, and coded for common themes in students' understanding of key statistical concepts. For the Sampling Distribution task-based interviews, we analyzed students' responses to determine the extent to which they (1) distinguished between the sampling distribution and the population distribution, (2) recognized the effects of sample size on the variability of the sampling distribution, and (3) drew an informal conclusion by situating a single sample in relation to the corresponding sampling distribution.

Students' responses to the sampling distribution items on the pretest and posttest were compared to determine if students improved on these items. Each item had two parts and students' responses to both parts were analyzed together to determine if students displayed consistent reasoning.

RESULTS

We will first report on the findings from the task-based interview on sampling distributions. This is followed by the results of the four pre/posttest sampling distribution questions for the seven pairs of students.

Sampling Distribution Task-based Interview

Part 1 of the third task-based interview involving sampling distributions had students predicting what sampling distributions would look like for a given population distribution and considering the variability of those sampling distributions. Given a tri-modal distribution and its mean (Chance, delMas, & Garfield, 2004), students chose the distributions that represented 500 samples of size 4 and size 16 from five possible graphs.

All seven pairs of interviewees chose sampling distribution graphs that were approximately normal in shape. Six of them also correctly identified the effect of sample size on the variability of the sampling distributions. Only one pair incorrectly identified the variability of the sampling distribution for a sample of size four; however, they did correctly identify the variability as less for the sample size of 16. This was an indication that these students had a base knowledge of the sampling distribution and its characteristics.

To begin the second part of the task-based interview, students viewed the Random Rectangle simulation in *Fathom*, shown in Figure 1. The population of rectangles, labelled with their corresponding areas, is on the left and the graph of the areas of the total population of rectangles is in the upper middle. The Sample of Rectangles graph below that in the center displays a single random sample of rectangles. The Measures from Samples of Rectangles graph in the lower right displays the sampling distribution of the mean areas. Students were able to watch a demonstration that

animated how each sample was taken from the population, graphed, and then the mean area from each sample was added to build the sampling distribution.

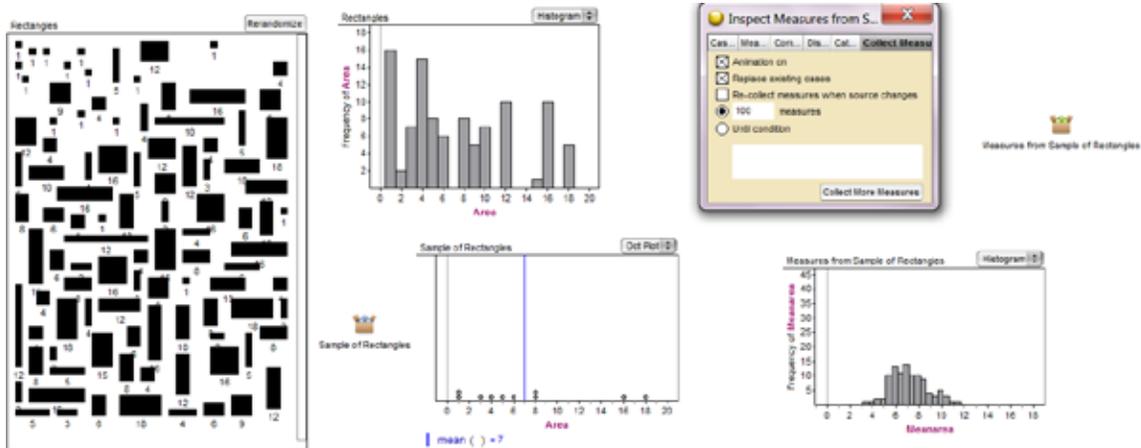

Figure 1: Screen shot of Random Rectangle simulation

Following this demonstration, the students were shown three sampling distributions generated from this simulation for 100 samples of sizes five, 10, and 25 rectangles. When asked about how all three distributions compared to one another, six of the pairs referred to these distributions as becoming more centered or having the same mean with five of them also referring to the decrease in variability as the sample size increased, as did this student:

Interviewer: So we went from a sample size of 5, then to 10, now to 25. So how about this one [of sample size 25]?

Student: This one's even more compact. The last one [of sample size 10] got all the way out to like 12. This one hasn't gone past 10 [referring to maximum mean area].

The remaining pair referred to the decrease in variability alone, mentioning the formula $\left(\frac{\sigma}{\sqrt{n}}\right)$ for standard deviation in support of this decrease.

Students were then asked what mean areas would be likely and which would be rare or unlikely for each of the sampling distributions. The students had no difficulty in identifying ranges of outcomes surrounding the peak of the approximately normal distributions as likely and those in the tails as rare. They demonstrated an understanding of the probabilities and variability associated with the normality of these sampling distributions of mean areas.

In an effort to bring the previous concepts of normality and variability related to the sampling distribution together to make an informal inference, the interview concluded with the sampling distribution in Figure 2. In the second interview of the larger study, students tossed small plastic houses to approximate the probability that a house would land upright when tossed. Students were shown this sampling distribution which was generated from 200 samples of 10 houses tossed, recording the proportion of houses landing upright. The interviewees were then asked if they

could determine whether the probability that a hotel would land upright was the same as that for a house. The hotels were slightly larger with a rectangular rather than a square base like the houses; and both the houses and hotels were available for students to manipulate.

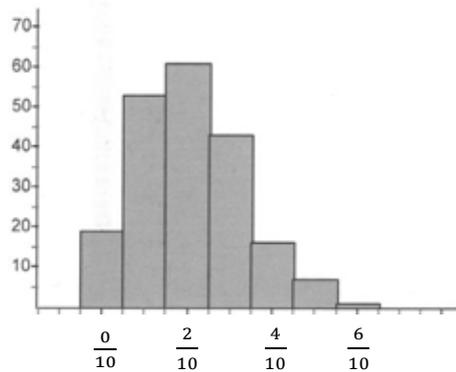

Figure 2: Sampling distribution for 200 tosses of 10 houses

Four of the seven pairs expressed that they would need to generate a sampling distribution exactly the same as the one they were shown for the houses with 200 tosses of 10 hotels. Another pair thought they would need to toss 32 hotels five times as they had with the houses in the second task-based interview.

Since time constraints did not allow for replicating the sampling distribution, all of the pairs tossed 10 hotels. Table 1 displays the number of tosses by each pair and some of their concluding remarks. Three of the pairs tossing 10 times averaged their 10 tosses to obtain a proportion for the hotels landing upright.

Number of Tosses	Students' Concluding Remarks
10 (averaged)	Like we had more two's and it looks like this one has more two's. So I feel like it would have the same probability as the house. I'm still doubtful. What we found was about 25%. So about a fourth of the time it'll land upright, if not a little bit more than that. And for this [the sampling distribution] we have like 20%, less than 20%, so that's just me doing math in my head and I just don't think it's likely. Plus we only did 10 trials.
2	I think you'd have to try probably more times, many more times, but, as it looks right now it's about the same. Maybe a little bit less.
1 hotel 10 times	Yeah, it was pretty similar. Between 1 and 2 [houses landing upright out of 10] so I think that [their results] still validates that that's relatively the same.
3	I'm figuring it's not going to be that far away. I think it's going to be roughly the same. It's maybe just a little bit less because it's weighted differently.
10 (averaged)	So it would probably look normal [sampling distribution for hotels] but not as variable as the other one [sampling distribution for houses]. I'd say they're very similar, the two, yeah.

10	We didn't do nearly enough. I mean you did this 200 times, we did this 10 times so like you can't really say like, oh look what we did really quick and that refutes that. Then I'd say it's different, but not by a lot.
10 (averaged)	You gotta take more samples. ...but with one trial, I think regardless of the outcome, you can't really compare that to what you got from this population [referring to sampling distribution]. It may fit into what you have seen. Like right here, this value right here, like 1, 2, [referring to peak in sampling distribution] ours was close so we could say yeah, it does compare similarly but I'm not going to bet my life on it.

Table 1: Number of tosses of hotels and students' concluding remarks

All of the pairs' tosses resulted in proportions that were at or close to the peak of the sampling distribution; however, their remarks demonstrated a variety of conclusions. At least one student from four of the seven pairs stated that the probability was slightly different. They were not taking the natural variability of sample proportions into consideration even though they had just identified likely and rare outcomes with the sampling distributions of mean areas of rectangles. Four of these pairs expressed their skepticism in the accuracy of their results due to their small number of tosses. The majority of these students were not yet ready to draw a conclusion from a single sample of data based on the variability of the sampling distribution. However, their statements, many expressing a degree of certainty or uncertainty, provided evidence that they were at a point in their informal inferential reasoning when they might be able to consider this next level of reasoning. This could be seen when we asked the following question of the pair who did three trials:

Interviewer: So is it [the results] enough less to say, do you think, that the probability is different?

Student: How far away would it have to be? Like, I mean, I don't know, I think it would be a couple percentage points. You know just a little lower.

This students' question lays the foundation for formal statistical inference. This may provide an opportune time to explore more deeply what it means for these sample proportions to be relatively the same or slightly different.

Sampling Distribution Questions on the Pre/posttest

There were two items on the pre/posttests involving drawing conclusions from a single sample based on the corresponding sampling distribution. The first item asked students to draw conclusions directly from a graph of the sampling distribution. For the second item, students were shown the population distribution and given the population mean. They were then asked to draw a conclusion based on the results of a random sample of size 50.

The first pre/posttest item had students drawing informal inferences based on a sampling distribution for the proportion of heads expected when a fair coin is

balanced on its edge 10 times. Marked on the sampling distribution in Figure 3 were the results of 0.7 heads and 0.9 heads from two different samples.

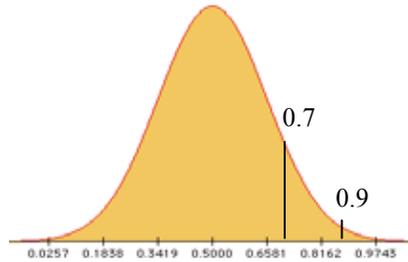

Figure 3: Sampling distribution for proportion of heads

In the first part of this item, students were asked if it was reasonable to conclude that the coin was fair with a sample proportion of 0.7 heads. Eight of the students answered correctly on the pretest that this result, which was between 1 and 1.5 standard deviations from the mean, was reasonable. This improved to 10 students answering correctly on the posttest; however, one student changed a correct answer on the pretest to incorrect on the posttest.

In the second part of the item, students were asked if it was reasonable to conclude that the coin was unfair with a sample proportion of 0.9 heads. Nine of the students answered correctly on the pretest and the posttest that this result, which was over 2 standard deviations from the mean, was reasonable. Two students changed their correct answers on the pretest to incorrect on the posttest.

Only six students answered both parts of this item correctly and one student answered both parts incorrectly. Of the seven other students, three concluded that both results indicated that the coin was unfair while the other four students concluded that both results indicated that the coin was fair. These responses are consistent with reasoning students displayed when working on the hotel task. This item, with the sample results of 0.7 and 0.9 clearly marked on the sampling distribution graph, provided further evidence that most of the students were not able to appropriately use that sample data as evidence as they were not fully considering the probabilities and variability associated with the sampling distribution.

For the second item on the pre/posttests shown in Figure 4, the students were shown a left-skewed distribution of exam scores for a particular exam. The average exam score for this population was 74 out of 100 points.

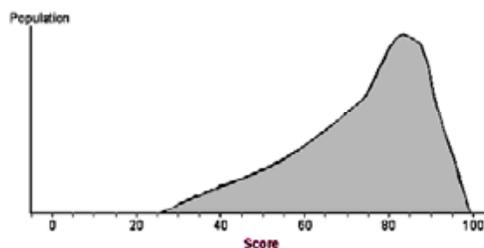

Figure 4: Population distribution of exam scores

In the first part of this item, the students were asked if a current group of 50 students with an average of 78 points did better on average than expected for this exam. Five students answered this part correctly on the pretest and seven answered correctly on the posttest. However, three students changed their responses from correct on the pretest to incorrect on the posttest.

The second part of this item asked the students if this higher sample average could just be due to chance. Nine students answered correctly that this higher score could be due to chance on the pretest and 10 answered correctly on the posttest. One student changed their answer from correct on the pretest to incorrect on the posttest.

Taking both parts of this item together, six of the students responded correctly and were consistent in their reasoning by answering that this score could not be considered better than what could be expected and that the higher sample average score was due to chance. Three other students were consistent in their incorrect reasoning by answering that this higher sample average could be considered better than what could be expected and that it was not due to chance. The remaining five students displayed inconsistencies in their reasoning. Four of these five answered incorrectly that this higher sample average could be considered better than what could be expected but also that it was due to chance. The incorrect and inconsistent responses to these two questions was further evidence that the majority of these students experienced difficulty in drawing conclusions based on the relationship between a population and the corresponding sampling distribution including the variability associated with it.

DISCUSSION AND CONCLUSIONS

Overall the students had general knowledge of the sampling distribution. They knew it took the shape of a normal distribution and they made references to the decrease in variability as the sample size increased. They also identified sample data values that would be considered likely and rare based on probabilities associated with the normality of sampling distributions. However, when it came to making a decision about the hotels in the last part of the interview, they were not completely prepared to reference what they knew. They were hesitant to compare a single sample or even a small number of samples to the sampling distribution. This was likely due to their knowledge of the Law of Large Numbers and their desire to eliminate variability in their sample(s) for comparison. This prevented the majority of the students from being able to use the probabilities and variability associated with the normal distribution in drawing their conclusions. Their responses to the posttest items provided evidence that these concepts were still creating difficulties for students at the completion of their introductory statistics course.

Referring to Makar and Rubin's (2009) definition of informal statistical inference, students were inferring informally; however, for the majority of them, the level of uncertainty they interpreted in the data they collected was preventing them from appropriately using their data as evidence. It would be worthwhile to investigate how

students would reason about the need for more samples in a task, like the one with the houses and hotels, if they were able to generate another sampling distribution or take more samples for comparison as many of the pairs initially wanted. Allowing students to explore their notions about taking more samples and the sampling distribution may help them to understand that this will not necessarily provide them with more certainty in their conclusions. Discussions about efficiency as well as accuracy in data collection could take place. Introductory statistics students likely do not have practical experience working within budget or time constraints for using data to draw conclusions. Therefore, taking many samples or creating another sampling distribution for comparison to make a decision may have seemed like the only certain methods. Students need experiences that will help them to understand that one sample can be enough to draw an inference with the sampling distribution. Developing activities that allow introductory statistics students to explore their notions regarding samples and comparing them to the sampling distribution may support their informal inferential reasoning that will, in turn, support their formal inferential reasoning.

ASSESSING STATISTICAL LITERACY: WHAT DO FRESHMEN KNOW?

Eugenia Koleza, Aristoula Kontogianni

Department of Education, University of Patras, Greece

While there are many studies about the statistical literacy of students, those that concern the statistical literacy of pre-service teachers are relatively few. In the present study we attempt to investigate the level of statistical literacy of pre-service teachers in their first year at the university and after the end of schooling. For the purpose of this study we adapted the framework of Watson (1997, 2003) and Gal (2002) for statistical literacy, while for the assessment of the participants' responses we used a modified model of SOLO taxonomy. Our findings indicate the low level of statistical literacy among pre-service teachers in their first year at the university.

Keywords: Statistical literacy, pre-service teachers, statistical knowledge, freshmen.

INTRODUCTION

Many researchers (among others Watson & Callingham, 2003; Budgett & Pfankuch, 2007) in the field of statistics education have emphasized the importance of statistical literacy for the effective participation of students in the society after the end of school. As the definition of statistical literacy is still being refined (Rumsey, 2002), in this paper we refer to it as 'the ability to understand and critically evaluate statistical results that permeate daily life, coupled with the ability to appreciate the contributions that statistical thinking can make in public and private, professional and personal decisions' (Wallman, 1993). Statistical literacy is a combination of abilities expected from citizens in information-laden societies, and is often considered as an expected outcome of schooling and as a necessary component of adults' numeracy and literacy (Gal, 2002).

Several studies have shown that teachers' knowledge is connected to what and how students learn and depends on the context in which it is used (Ball & Bass, 2000; Cobb, 2000). Consequently, it is important to inquire into the cognitive level of pre-service teachers in order to modify accordingly the content of the courses, which are relevant to Mathematics, at higher education.

While there are many studies about the statistical literacy level of students (e.g. Watson & Callingham, 2003), there are relatively few about pre-service teachers. Focusing on the dimension 'as an expected outcome of schooling' of statistical literacy, we designed and conducted a research which aims to identify at what level the students, who have just started their university studies (freshmen) in the Department of Education at the University of Patras, were statistically literate after the end of the schooling and the start of their university studies. In particular, our research questions were the following.

a) What is the level and depth of knowledge about fundamental statistical concepts held by pre-service teachers in their first year at the university? b) How do they use such knowledge in order to perceive and criticize information about the world around them? c) In other words, at what level pre-service teachers are statistical literate?

LITERATURE REVIEW

Statistical literacy is a major goal of several curricula of mathematics around the world (e.g. NCTM Principles and Standards, 2000; ACARA, 2010). According to the Australian Curriculum (ACARA 2010, p.2):

Students should develop an increasingly sophisticated ability to critically evaluate chance and data concepts and make reasoned judgments and decisions. They should develop an increasingly sophisticated ability to critically evaluate statistical information and build intuitions about data.

In the spirit of these ideas, several studies have been conducted in order to define statistical literacy (e.g. Watson, 1997; Watson & Callingham, 2003) and to investigate students' statistical literacy at different levels of education (e.g. Budgett & Pfankuch, 2007). Furthermore, the ARTIST Web site (<https://app.gen.umn.edu/artist/>) created by delMas and his colleagues provides and evaluates tools for the assessment of students' statistical literacy (for more details see delMas et al., 2007). In the field of adults' statistical literacy, the research by Gal (e.g. 2002) was a major contribution to the conceptualization of statistical literacy, while Moreno (2002) focused on the connection of statistical literacy with citizenship, and Shield (2006) in the W. M. Keck Statistical Literacy Project immersed statistical literacy in society. Recently, Kaplan & Thorpe (2010) applied to adults the framework of statistical literacy, proposed by Watson & Callingham (2003).

THEORETICAL FRAMEWORK

As “the research in statistical literacy has unveiled a very deep construct involving a myriad of types and skills and cognitive processes” (Shaugnessy, 2007, p.966), for the present study we have restricted ourselves to a framework based on a combination of the work of both Watson (1997) and Gal (2002) in relation to the kind of statistical knowledge students should have by the end of schooling.

Watson (1997) proposed a three-tiered Statistical Literacy Hierarchy, which is described as follows:

1. Understanding of basic statistical terminology.
2. Understanding of statistical language and concepts when they are embedded in the context of wider social discussion.
3. Ability to question claims that are made in context without proper statistical justification.

Respectively, Gal (2002) suggests that, for full participation in the society, students after the end of schooling should be able to:

- (a) ... interpret and critically evaluate statistical information, data-related arguments, or stochastic phenomena, which they may encounter in diverse contexts, and when relevant.
- (b) ... to discuss or communicate their reactions to such statistical information, such as their understanding of the meaning of the information, their opinions about the implications of this information, or their concerns regarding the acceptability of given conclusions. (Gal, 2002, p. 2-3).

For our research, we used a framework built on the combination of the above theories in order to define our assessment goals and to develop the respective items. A parameter also taken into consideration was the statistical contents found in the elementary mathematics curriculum that pre-service teachers will have to implement in the future. More precisely, we focused on: a. the average, b. the reading and the interpretation of tables and graphs and c. the critical questioning of claims embedded in a social context.

METHOD

In order to answer the research question, we designed and conducted a research project during the first semester of the academic year 2011-2012.

Participants

The participants were 166 students (pre-service teachers), 137 female and 29 male at their first year of their studies in the Department of Education, University of Patras. The students were taught Statistics in the 4th, 5th and 6th grade (ages 10-12) of primary education, the 2nd and 3rd grade (respectively 8th and 9th grade - ages 14-15) of Junior High School and the 3rd grade (12th grade - age 18) of High School. We will refer only to the content of the 3rd grade of High School (12th grade) as it was the most recent to the participants. Statistics is taught at the 3rd grade of High School as a part of the course "General Mathematics" for two hours per week and it is obligatory for all students regardless of their programs of study (Theoretical, Practical and Technological Direction) (Ghinis et al., 2009). The participants of our research were 134 (80.7%) of Theoretical Direction and 32 (19.2%) of Practical/Technological.

In their last year of High School (3rd grade), in the chapter of Statistics, students are taught how to process statistical data and interpret critically statistical conclusions. The Syllabus includes the following subjects (Pedagogical Institute of Greece, 2007):

Basic concepts: The students are taught basic statistical concepts such as population, variables (quantitative and qualitative), census and sample.

Presentation of Statistical data: The students are taught about frequency distributions and their graphical representations.

Location measures and measures of variation: The students are taught how to compute the arithmetic mean, the median, the mode (location measures) and the range, the variance, the standard deviation and the coefficient of variation (measures of variation) of discrete and continuous variables.

Questionnaire

The questionnaire items that we used for this study were either adapted from items used in previous researches (Aoyama & Stephens, 2003; Watson, & Callingham 2003; PISA, 2003; Harper, 2004; delMas et al., 2007) or developed by the researchers for the needs of the present study. The questionnaire included ten items, seven open-ended and three multiple-choice. The items were chosen and developed, according to our framework, in order to assess either the ability of the participants to understand fundamental statistical terminology or their ability to question statistical concepts embedded in real life problems.

Students (pre-service teachers) were requested to justify their answer for all items. Time given for response was about 1.5 hours. For the coding of the responses we adapted the SOLO model of Biggs & Collins (1982) as has been used by Watson & Moritz (2000). The complexity levels are described in the next table:

Code	Level	Description
4	Relational	Correct answer with correct justification.
3	Multistructural	Correct answer with partial justification.
2	Unistructural	Not able to interpret correctly the data or irrelevant use of data.
1	Prestructural	No justification. Justification based on irrelevant data or personal estimation.
0		No response or Yes/No answer without justification.

Table 1: Codes and description

Each item had a scoring rubric which was designed to identify increasing quality of response and these varied from 0-2 to 0-4, depending on the complexity of the item. The coding was done independently by two raters. An interrater reliability analysis using the Kappa statistic was performed to determine consistency among raters. It was found to be $Kappa = 0.736$ ($p < 0.001$), which indicates substantial agreement between the two raters (Landis & Koch, 1977).

RESULTS

Students' performance showed mixed results: on five- out of ten items - students' performance was rather low, while on the other five the majority of students' responses were at the relational level.

Due to space limitations we analyse only the low-performances' items.

Discussion on low performances' items

The next items involve contexts that may appear in the media, and their objective was to assess students' 'ability to question claims that are made in context without proper statistical justification' (Watson, 1997).

<p>Item 3</p> <p>In Zedland, opinion polls were conducted to find out the level of support for the President in the forthcoming election. Four newspaper publishers did separate nationwide polls. The results for the four newspaper polls are shown below.</p> <ul style="list-style-type: none"> • Newspaper 1: 36.5% (poll conducted on January 6, with a sample of 500 randomly selected citizens with voting rights.) • Newspaper 2: 41.0% (poll conducted on January 20, with a sample of 500 randomly selected citizens with voting rights.) • Newspaper 3: 39.0% (poll conducted on January 20, with a sample of 1000 randomly selected citizens with voting rights.) • Newspaper 4: 44.5% (poll conducted on January 20, with a sample of 1000 citizens with voting rights who responded the phone call.) <p>Which newspaper's result is likely to be the best for predicting the level of support for the President if the election is held on January 25? Justify your answer.</p>
--

Figure 1: Item 3

Code	Description	Examples
4	Choice of the third newspaper and correct justification based to the date and to the sample. Discriminating that the sampling that was based to phone calls isn't so accurate.	"The third newspaper because the date is closer to the elections' date and the sample is bigger. It is better than the fourth because the sample method is more reliable (examples why is more reliable)"
3	Correct answer with partial justification. (Referring only to the date or to the sample)	"The third newspaper because the sample is bigger"
2	Using arithmetic data in order to find how many people will vote for the president. Irrelevant justification.	By multiplying percentages with the number of the sample.
1	Choice without reasoning. Choice of the fourth newspaper considering the way of collecting data as more accurate.	"The fourth newspaper because it is more reliable the sampling method"
0	No response.	

Table 2: Codes and examples to the codes for Item 3

The third item (derived from PISA, 2003) concerned reasoning about samples and it was used in order to assess the participants' ability to question statistical claims embedded in a social context. Only the 40% of the participants' answers were classified at the relational level (code 4). The analysis of the students' responses revealed that they had some difficulty to understand why a sample cannot be representative of the population.

Student 65: The fourth newspaper because they used phone calls in order to gather the data.

Also, several students confused the poll's percentage with the sample size.

Student 18: Fourth newspaper because 44, 5 % of the voters is almost 500 people more than the others' newspapers population.

Item 7			
The state based its decision on the redundancy on the data table below, according to which 50 to 66 civil servants who belong to the age group 62-64 want to go out on redundancy voluntarily. Do you agree with this conclusion? Justify your answer.			
Reasons for retirement and retirement age			
	Retirement Age		
Reasons for retirement	Under 62	Between 62 and 64	65 or more
Age	10,5	21,6	64,6
Redundancy	10,5	50	14,6
Health problems	26,3	11,9	8,3
Close business	10,5	1,5	0
Privileges	10,5	3	0
Opportunity for the younger	2,6	1,5	6,0
Unhealthy labor	5,3	4,5	0
Family matters	7,9	0	2,9
In order to enjoy life	7,9	1,5	2,1
Other reason	7,9	4,5	2,1
	100%	100%	100%
Total	76	66	48

Figure 2: Item 7

Code	Description	Examples
4	Ability to discriminate and use correct the data of the table. Correct use of percentages.	"The conclusion is wrong because the 50% of 66 is 33".
3	Their reasoning is based on the complementary information. They realize that "the rest percentages" don't add to 50, but they cannot extend this reasoning to the rest 50%.	"If you add all the other reasons it is less than 50"
2	Not able to interpret correctly the table.	"I agree because it refers to 50 people in 66".
1	Choice without reasoning. No justification or justification based on irrelevant data.	"It is wrong, nobody would choose redundancy".
0	No response. Yes or No answer without justification.	

Table 3: Codes and examples to the codes for Item 7

This item was constructed and used in order to assess the participants' ability to question a misleading claim embedded in the context of wider social discussion. While this specific task was rather easy as it required only the reading of a table of data, only the 2% of the participants responded to the relational level. The majority of the participants' answers (43%) were at the prestructural level (code 1). Students justified their judgment by resorting only to their own beliefs (Budgett & Pfannkuch, 2007) rather than giving data-based justifications.

Student 11: It's a lie; nobody wants to go to redundancy.

Student 21: It is impossible so many people to be in redundancy.

The interpretations of this item indicates that, since Statistics is a social construct (Best, 2001), students' reaction is connected to their knowledge of real-life. This result is consistent with others researchers' (cf. Shaughnessy et al., 2004) who claim that when the context is familiar to students, they tend to rely on their personal opinions.

Student 11: It's a lie; nobody wants to go to redundancy.

Student 21: It is impossible so many people to be in redundancy.

Item 10

Two newspapers published articles about criminality and they used the next graphs. Which of these do you think that represents better the reality? Justify your claim.

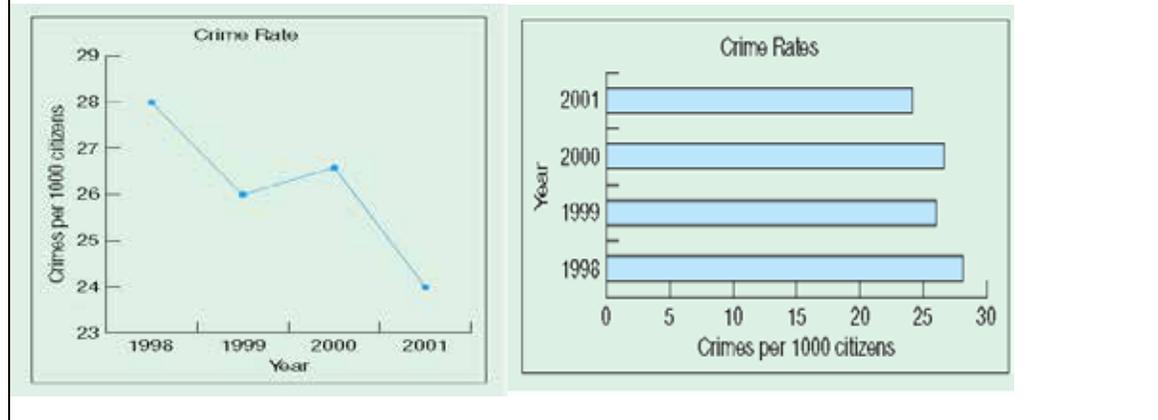

Figure 3: Item 10

Code	Description	Examples
4	Correct justification: ability to discriminate the wrong choice of the scale and the false affect that it creates.	<p>"The bar-graph is better because the scale starts form 0".</p> <p>"The time-graph is not correct, it is like an enlargement"</p>
3	Correct answer with partial justification.	"The bar-graph is better because it is more accurate"
2	Wrong justification based on personal estimations.	"The time-plot, because it is easier to read it, to understand it"
1	Response without justification	" The time plot is better"
0	No response.	

Table 4: Codes and examples to the codes for Item 10

This item, adapted from Harper (2004), refers to a misleading graph and its aim was to assess the ability of the students to discriminate the false effect that it creates. Only 1% of the participants were able to answer at the relational level, while the majority of them (59%) had chosen the time-plot as they considered it easier for interpretation.

Student 45: I believe that the 1st (the time-plot) is better because through it, it is easier to understand the decline of crime rates during these year.

It is a fact that graph interpretation cannot be effective, if the reader does not possess

basic graph reading skills. Among these skills we find the ability to recognize when the scale of a graph is truncated and the misleading impression that this fact creates, as in this specific item. While some students were able to recognize that the differentiation of the two graphs was due to the different scale, they could not understand why this fact created a wrong impression.

Student 41: As it is obvious at the 2nd graph the crime rates ranges from 23 to 29. So, the rest of the graph is useless. On the contrary at the 1st graph the given values are between 23 and 29, which make it more accurate.

DISCUSSION AND CONCLUSION

The goal of the present study was to assess the level of statistical literacy of pre-service teachers in their first academic year. The findings revealed that although students had been taught Statistics at all school levels and most recent in High School, their level of statistical literacy was rather low, especially when it comes to the questioning of statistical claims in a social context. These findings are consistent with those presented in other studies (Godino et al., 2008), which suggest that prospective primary school teachers in many countries enter the Departments of Education with a very limited statistical competence.

In sum, the participants were able to read and interpret simple graphs such as bar graphs, line-plots and pie-charts, and had knowledge of basic statistical notions such as the mean and the range. However, they had difficulties concerning sampling, graph evaluation and proportional thinking in a real life context. Also, they could not give proper justification to statistical claims in the context of a social discussion.

For the purpose of this study we used misleading tables and graphs and we asked the participants to question arguments based on them. For the answer of these specific items, most of the participants relied more on their experience of real world data than on their statistical knowledge. This fact indicates that even adults after the end of schooling, like students (Watson & Chick, 2004), are not able to detect the “unusual”.

According to Gal (2002) there are five interrelated “knowledge bases” that must be used to exhibit statistical literacy: mathematical knowledge, statistical knowledge, knowledge of the context, literacy skills and critical questions. The results of the present study show that items with low performance demanded more than plain mathematical or statistical knowledge. We argue that items demanding one or more of the last three “knowledge bases” (context, literacy skills and critical questions), turned out to be difficult for the pre-service teachers.

Consequently we suggest that a content of a Mathematics Course for pre-service teachers should further focus on these aspects by incorporating in the teaching, strategies of misleading graphs’ recognition and critical analysis and examples of real life statistical claims originating from the media.

ACKNOWLEDGMENTS

This research has been co-financed by the European Union (European Social Fund - ESF) and Greek national funds through the Operational Program "Education and Lifelong Learning" of the National Strategic Reference Framework (NSRF) - Research Funding Program: Heracleitus II. EVALUATING THE EFFICACY OF TRAINING ACTIVITIES FOR IMPROVING PROBABILITY AND STATISTICS LEARNING IN INTRODUCTORY STATISTICS COURSES

Caterina Primi and Francesca Chiesi

NEUROFARBA – Section of Psychology

University of Florence Italy

The aim of the present paper is to ascertain the efficacy of a training acting on both cognitive and non-cognitive factors in improving probabilistic and statistics learning in psychology students enrolled in introductory statistics courses. We previously tested the relationships between performance and students' general and mathematical background (cognitive factors), maths self-efficacy and attitudes toward statistics (non-cognitive factors). Results stressed the role of both factors. Thus we developed training activities focused on competences and self-efficacy and we verify that it helped students in improving probability and statistics learning as well as their confidence.

Key words: Probability Learning; Statistics Learning; Training Activities; Introductory statistics

INTRODUCTION

Being able to provide good evidence-based arguments, and to critically evaluate data-based claims are important skills that all citizens should have, as stated by the European Parliament and Council in defining the key competences within the Lifelong Learning Program (2006). Thus, from an educational point of view, it is fundamental to develop students' statistical reasoning, and to provide them with tools and knowledge to understand and use quantitative information. The ability to think statistically about uncertain outcomes, and to make decisions on the basis of probabilistic information is relevant in many fields (e.g., for businesspeople, physicians, politicians, lawyers), and an inability to make optimal choices can be extremely costly, not only at the individual level, but also for society in general.

Then, statistics has been introduced as part of a wide range of curriculum programs in many countries. However, the discipline is viewed as a difficult and unpleasant topic. At the university level, students often perceive statistics courses as a burden, encounter difficulties, experience stress and anxiety, and, eventually, many of them fail to pass the exams. It is also common for students to have low expectations regarding statistics classes, and to have negative attitudes towards statistics. Finally, as passing exams in statistics is a requirement for many degree courses, failing to achieve this might result in students' abandoning their chosen professions.

Starting from these assumptions, several researches have focused on the identification of models in which the role of non-cognitive factors, such as beliefs

and feelings, has been taken into account in explaining learning statistics. These factors appeared to be related to maths aptitude, previous maths knowledge, educational background and reasoning ability. Thus, statistics achievement might be the result of the interplay between cognitive and non-cognitive factors (Budé et al., 2007; Chiesi & Primi, 2010; Dempster & McCorry, 2009; Tremblay, Gardner & Heipel, 2000).

Starting from this premise, the present work aimed to assess the impact of both cognitive and non-cognitive factors on probability and statistics learning in psychology students enrolled in introductory statistics courses (Study 1). In light of the results of Study 1 we developed training activities and we verified its efficacy (Study 2).

STUDY 1

It was hypothesised that learning was related directly to students' general background and maths competence, as well as to their maths self-efficacy, beliefs about their own ability in dealing with statistics and feelings toward the discipline. Konold and Kazak (2008) suggested that some of the difficulties students have in learning basic data analysis stem from a lack of rudimentary idea in probability. For this reason, learning was operationalized including both probabilistic and statistical reasoning.

The causal paths among the mentioned variables were explored using structural equation modelling (SEM), a very powerful multivariate analysis technique. Among the strengths of SEM is the ability to construct latent variable: variables which are not measured directly, but are estimated in the model from several measured variables each of which is predicted to 'tap into' the latent variables. This allows the modeler to explicitly capture the unreliability of measurement in the model, which in theory allows the structural relations between latent variables to be accurately estimated. Thus, once the concepts used in the model have been operationalized and measured, the model is tested against the obtained measurement data to determine how well the model fits the data. In our model (Figure 1) cognitive and non-cognitive factors were considered as the latent exogenous variables (i.e., the independent variables) having an impact on learning considered the endogenous latent variable (i.e., the dependent variable). Each one was measured using respectively two, three and four observed variables (see details below).

Methods

Participants

Participants were 238 psychology students attending the University of Florence in Italy enrolled in an undergraduate introductory statistics course. Most of the participants were women (86%). This proportion reflects the gender distribution of the population of psychology students in Italy. All students participated on a voluntary basis after they were given information about the general aim of the

research (i.e., collecting information in order to improve students' statistics achievement).

Description of the Course

The course covered the usual introductory topics of descriptive and inferential statistics (including basic concept of probability theory and calculus), and their application in psychological research. It was scheduled to take place over 10 weeks, and takes 6 hours per week (for a total amount of 60 hours). During each class some theoretical issues were introduced followed by exercises. Students were requested to solve exercises by paper-and-pencil procedure, and computer packages were not used.

Measures

General Background Test (GBT). This is a scholastic assessment test consisting of 100 multiple-choice questions (one correct out of five choices) divided into five sections: Maths, Biology, English comprehension, critical reading and reasoning. The time for the test was 85 minutes. A single composite score, based on the sum of correct answers less the wrong answers (the score for a wrong answer was $-.25$) was calculated.

Prerequisiti di Matematica per la Psicometria (PMP, Galli, Chiesi & Primi, 2011). The PMP measures maths abilities needed by psychology students enrolling in introductory statistics courses. The scale is a 30-problem test. Each problem presents a multiple choice question (one correct out of four alternatives). A single composite score, based on the sum of correct answers, was calculated.

Survey of Attitudes Toward Statistics (SATS-28©, Schau, Stevens, Dauphine & Del Vecchio, 1995; Italian version: Chiesi & Primi, 2009). The scale provides a multidimensional measure of attitude. It contains 28 Likert-type items using a 7-point scale ranging from strongly disagree to strongly agree, assessing four components: *Affect* measures positive and negative feelings concerning statistics (6 items); *Cognitive Competence* measures students' attitude about their intellectual knowledge and skills when applied to statistics (6 items); *Value* measures attitudes about the usefulness, relevance, and worth of statistics in personal and professional life (9 items); *Difficulty* measures students' attitudes about the difficulty of statistics as a subject (7 items).

Solution of Maths Problems (Kranzler & Pajares, 1997). This is a subscale of *Mathematics Self-Efficacy Scale-Revised (MSES-R, Kranzler & Pajares, 1997; Italian version: Galli, Chiesi, & Primi, 2010)*. The subscale is composed of 18 problems with different levels of difficulty and it has been developed to assess the students' confidence to solve these problems.

Probabilistic Reasoning Questionnaire (PRQ, Chiesi, Primi & Morsanyi, 2011). This questionnaire contained 10 multiple-choice probabilistic reasoning tasks (one correct

out of three alternatives). Each task was scored either 1 (correct) or 0 (incorrect). The scores on the probabilistic reasoning tasks were summed to form a composite score.

Introductory Statistics Inventory (ISI, Chiorri, Piattino, Primi, Chiesi & Galli, 2009). This test consists of 30 multiple-choice items (one correct out of four choices) to evaluate learning at the end of an introductory statistics course. Half of the problems refers to descriptive statistics and the other half to inferential statistics. Each task was scored either 1 (correct) or 0 (incorrect) and a composite score was obtained.

Procedure

The GBT was administered before the beginning of the course. The SATS was presented during the first day. The PMP was completed during the second day, and the PRQ and the ISI at the end of the course.

RESULTS

As shown in the table (Table 1), significant correlations were found between Probabilistic and Statistic Learning with the other variables. These results support the hypothesised relationships. Concerning Attitude towards Statistic, only two scales Cognitive Competence and Affect were significantly correlated with Probabilistic and Statistic Learning. For this reason we did not introduce Difficulty and Value in the model.

	<i>M</i>	<i>sd</i>	1	2	3	4	5	6	7	8	9
1. General Background	44.43	10.32									
2. Maths Basics	22.70	4.20	.41**								
3. Maths Self-Efficacy	83.40	11.21	.28**	.38**							
4. Cognitive Competence	27.50	6.00	.08	.29**	.44**						
5. Affect	24.11	6.35	.02	.24**	.32**	.77**					
6. Difficulty	23.80	4.48	.04	.16**	.36**	.55**	.59**

Table 1. Means, standard deviations (in brackets) and correlations among the measured variables.

The final model included three latent variables and nine observed variables: Cognitive Factors and Non-Cognitive Factors were the exogenous latent variable that influenced directly the Statistic and Probabilistic Learning. Cognitive Factors were measured through the GBT (General Background) and the PMP (Maths Basics). The two scores of the SATS subscales (Cognitive Competence and Affect) and the score of the MSES-R (Maths Self-Efficacy) were used as indicators of Non Cognitive Factors. A covariance path was traced between errors of subscales measuring the attitude dimensions since the high correlation ($r = .77$) between the two subscales. Another covariance path was traced between Maths Basic and Maths Self-Efficacy ($r = .38$). The endogenous latent variable (Probability and Statistics Learning) was measured through two scores of the PRQ scale - obtained by dividing the test randomly in two parts with 5 items for each (Probability 1 and Probability 2) - and two scores of the ISI scale - obtained considering separately the descriptive and the inferential items (Descriptive and Inferential). Covariance paths were traced between the two indicators derived from the PRQ and the two indicators derived from the ISI.

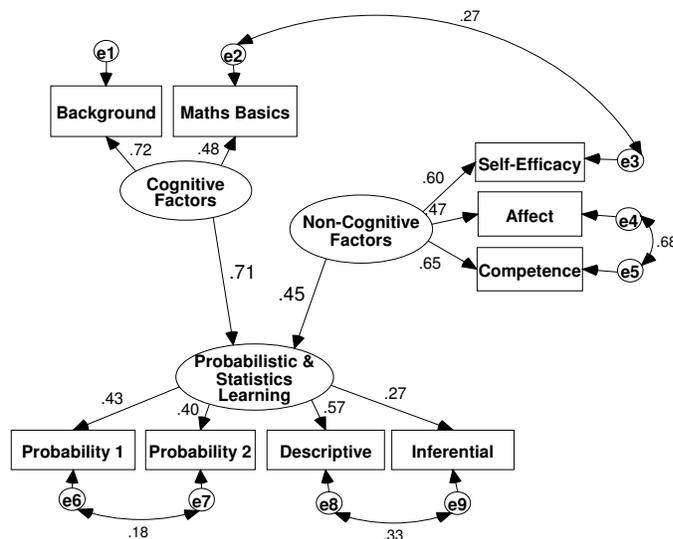

Figure 1. Final model with standardized parameters (paths are all significant at .05 level).

SEM analyses were conducted with AMOS 5.0 (Arbuckle, 2003) using maximum likelihood estimation on the variance-covariance matrix. Univariate distributions of all variables included in the model and their multivariate distribution were examined for assessment of normality. Skewness and kurtosis indices (ranging respectively from $-.78$ to $.26$ and $.57$ to $.47$) attested that the departures cannot be expected to lead to appreciable distortions (Marculides & Hershberger, 1997). The index of Multivariate Kurtosis (Mardia, 1970) ($\beta = 1.86$, $c.r. = 1.02$, $p > .05$) indicated that

there was not a significant departure from multivariate normality. That is, data met the assumption of multivariate normal distribution required by SEM. The model showed a good fit to data ($\chi^2/df = 2.45$; $CFI = .94$; $TLI = .90$; $RMSEA = .07$) and all the estimated coefficients were statistically significant.

As expected Cognitive and Non Cognitive factors had a significant direct effect on Probability and Statistics Learning. However, the relationship with the Cognitive factors was stronger.

DISCUSSION

In line with previous research, general background and mathematical knowledge acquired during the high school had a direct and strong effect on learning probability and statistics. It does not mean that the statistics learning depends solely on these math knowledge but they constitute a necessary tool to keep in touch with statistics. Indeed, at least at the introductory level, a basic mathematic skill such as understanding ratio (i.e., being able to *interpret* the results of the computation) may be important in *understanding* probability. For this purpose it might be useful to arrange training activities aimed at mastering the basic mathematical skills required during the course. Moreover, since perceived competences and affect concurred in determining learning, to help students enhance their confidence it might be useful to give exercise that allow students to experience mastery of the topics, and to provide feedback about their results to allow them to monitor their progress.

STUDY 2

Starting from this premise, we developed training activities for consolidating the basic mathematical skills required during the course. The training involved students in individual and group activities. The contents are some math basics deemed necessary to successfully complete the introductory statistics courses. In detail, exercises included: a) addition, subtraction, multiplication, division with fractions, and exponentiation, required in descriptive and inferential procedures; b) fractions and decimal numbers from 0 to 1 necessary to deal with probability; c) first order equations necessary in the standardization procedure and in the regression analysis; d) relations between numbers included in the range from -1 to 1, and the meaning of absolute value necessary for drawing conclusions in hypothesis testing. At the beginning students should solve exercises individually and after they interact within group to compare solution and to prepare a final report.

The aim of this second study was to verify the efficacy of the training activities for improving probability and statistics learning. For this purpose we compared the training group with a control group, i.e. students who were not presented the training activities but solved typical introductory statistics exercises such as computing means and standard deviations.

Methods

Participants

Participants were psychology students enrolled in an undergraduate introductory statistics course. One hundred twenty-four students were randomly assigned to the training group and 55 to the control group.

Training activities

The training consisted in two didactic units lasting two hours each. Students were divided into groups (about ten students for each group). In each unit each student received a booklet with a series of exercises about some maths basics deemed necessary to successfully complete the introductory statistics courses.

Each student had to perform individually reporting how he/she solved it. Then the groups discussed about the correct solutions and the more common errors producing for each exercise a report of the group's activities. At the end of each unit, students might have other exercises to do at home.

As for the training group, the activities of the control group were organized in two didactic units. Students were divided into groups (about ten students for each group) and requested to solve exercises by paper-and-pencil procedure referring to frequency distributions, graphs, means and standard deviations. They solved them individually and then a group activity followed to discuss about exercises' correct resolution and errors, and to produce a report. At the end of each unit, students might have other exercises to do at home.

Measures and Procedure

At the end of the training all students were administered the *Probabilistic Reasoning Questionnaire* (PRQ) to measure the probabilistic learning and the descriptive problems of the *Introductory Statistics Inventory* (ISI - Descriptive) to measure the statistics learning. We added for each problem of the ISI a scale to measure how self confident they were to solve it.

Moreover, we took into account an achievement measure. Since some students were unsuccessful in the final examination and therefore they needed several attempts to attain their goal, the number of failed attempts was registered.

RESULTS

Furthermore to measure the association between training and achievement we created two groups: one with the students who never failed (no failure group) and the other one with students who fails one or more times (failure group). As we can see from the graph (Figure 2), we found a significant association between the training and the failure ($\chi^2(1, N = 174) = 3.93, p < .05$) with a small the effect size ($\phi = .15$). In particular there is a higher possibility to pass in the training group than in the no training group (64% vs. 48%).

Significant differences were found between the training group and the control group. In particular, the training group improved in probabilistic learning, statistic learning, and confidence (Table 2).

	Training		Control		<i>t</i>	<i>d^a</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>		
Probability Learning	15.38	2.50	13.80	3.03	3.14**	.57
Statistics Learning	7.45	1.27	6.90	1.52	2.51*	.39
Statistics Learning Confidence	37.83	5.52	35.98	5.65	2.02*	.33

* $p < .05$, ** $p < .01$. ^a *d* is a measure of effect size. Cut-offs are the following: small $\geq .20$, medium $\geq .50$, large $\geq .80$.

Table 2. Mean scores compared with t test (and related effect sizes) for the Training and the Control groups.

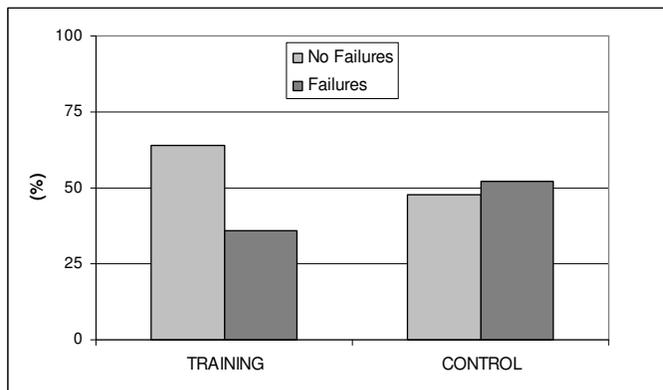

Figure 2. Percentage of failures in the Training and the Control groups.

DISCUSSION

The present study attested that students who participated to the training had positive changes not only in statistics and probabilistic learning but also in their confidence. Further the training seems to reduce the probability of failures. In sum, these results suggest that this training offers an example of an educational approach to introduce in introductory statistic course.

CONCLUSION

Teaching statistics with psychology students produces difficulties. Students are not primarily interested in statistics and dislike anything “mathematical”, often they do not have a strong background in Maths and they are not confident about their capabilities. The first aim of the present work was to investigate the impact of both cognitive and non-cognitive factors on psychology students’ probability and statistics learning. As expected, and in line with previous research (Leight Lunsford & Poplin, 2011; Tremblay et al., 2000) mathematical knowledge acquired during

high school had a direct and strong effect on achievement. Additionally, mathematics self-efficacy and attitudes toward the discipline (i.e., perceived competences and affect) concurred in determining performance in statistics (Dempster & McCorry, 2009).

The second aim was to develop and testing the efficacy of a training to strengthen basic mathematical skills and improve students' confidence in learning statistics. Individual and working group activities were proposed in which the students could perceive that they handled the basic tools to deal with an introductory statistics course. In this way they both consolidate their abilities and acquired more confidence. Students in the control group who solved statistics exercises without reinforcing before their mathematical skills showed worse performance and less confidence when compared to the training group. Indeed, math skills help in understanding and interpret statistical measures.

In conclusion, our findings suggest that maths competences are a necessary tool to keep in touch with statistics and to help students to believe that they have the capacity to cope with the demands of an introductory statistics course.

THE DIDACTICAL KNOWLEDGE OF ONE SECONDARY MATHEMATICS TEACHER ON STATISTICAL VARIATION¹

Sandra Quintas*

Hélia Oliveira**

Rosa Tomás Ferreira***

*Research Unit of the Institute of Education of the University of Lisbon **Institute of Education of the University of Lisbon ***University of Porto & CMUP, Portugal

This study aims to contribute to the comprehension of the didactical knowledge of the teacher who teaches statistics at the secondary level, looking at the classroom practices of one teacher regarding statistics variation. Results stress the intertwined character of the various domains of the teacher's didactical knowledge, giving evidence of a strong relationship between the teacher's knowledge of statistics variation and the level of depth by which she approaches this concept in the classroom.

INTRODUCTION

Recent research points out the emergency of a set of fundamental big ideas for the teaching of statistics, such as data, variation, distribution and representation, among other concepts, which every student should know at the end of secondary school (Burrill & Biehler, 2011). In fact, there is an increasing recognition that variability is a fundamental idea for the teaching of statistics (Shaughnessy, 2006; Garfield & Ben-Zvi, 2008). Wild and Pfannkuch (1999) emphasized its importance considering that it is “the reason why people have had to develop sophisticated methods to filter out the messages in data from the surrounding noise” (p. 236). However, it is a difficult concept for students to reason about (Garfield & Ben-Zvi, 2008). According to these authors, such difficulty does not rely on computing formal measures of variability (e.g. range, inter-quartile range and standard deviation), but rather on understanding different representations of the concepts involved in those computations as well as their relationships with other statistical notions.

Teachers should help students to build on their intuitive notions of centre and variability and integrate these concepts when addressing data and doing data analysis as suggested by Shaughnessy (2006). Teaching statistics requires a profound content knowledge of this area; however, this is not enough to ensure effective teaching (Ponte & Chapman, 2006). The specific knowledge held by mathematics teachers, which Ponte (2012) calls *didactical knowledge*, is essentially oriented towards the practical activity of teaching mathematics and is based on “knowledge of theoretical nature” (Ponte, 2012, p. 86) about mathematics, mathematics teaching, and general education; in addition, didactical knowledge is founded on “knowledge of social and experiential nature” (p. 86), namely about students, actions in the classroom, professional, scholar and surrounding communities, among others. Sánchez, Silva and Coutinho (2011) suggest the study of teachers' professional knowledge while teaching variation as an urgent matter. Thus, it is important to analyse teachers'

didactical knowledge in statistics, in particular of this topic, considering the ways it is evident in the practices of teaching variation in the secondary classroom. This study, which is part of a larger investigation, intends to make a contribution to this call.

BACKGROUND

Didactical Knowledge in Statistics

The model of teacher's didactical knowledge of Ponte (1999, 2012), particularly inspired in the works of Schön (1983) and Elbaz (1983), comprises four domains that orient directly the school practice. Each domain is here described in the realm of statistics, looking for enhancing its specificity.

The first domain is the *knowledge of the content* to be taught. It is essentially focused on teachers' interpretations of the discipline and it includes the understanding of concepts and procedures, statistical reasoning, argumentation and validation forms. It also includes the ability for epistemological reflection about the meaning of concepts and procedures and about the nature of statistical knowledge (Batanero & Godino, 2005). The teacher must be familiar with specific elements of this subject and develop insights toward a more formal understanding about them, namely concerning the fundamental aspects of statistical thinking, such as recognition of the need of data, attention to variation (Wild & Pfannkuch, 1999; Shaughnessy, 2006).

A second domain is the *knowledge of students and their learning processes*, which incorporates the knowledge of their difficulties, mistakes, obstacles and typical strategies in problem solving. Moreover, this domain includes knowledge of students as people, their interests and ways of acting and learning. In this domain, it is also important that teachers have a perception of the level of understanding that students have or will attain regarding different concepts (Ponte, 1999; Batanero & Godino, 2005). The *knowledge of curriculum* includes the knowledge of curricular goals and objectives, horizontal and vertical articulation/alignment of topics, and knowledge of materials and forms of assessment (Ponte, 1999; 2012). The current curricular framing enhances the active role of the students in building their mathematical and statistical knowledge (DES, 2001).

The fourth and last domain of teachers' didactical knowledge is the *knowledge of the instructional process*, which includes planning, teaching of lessons and assessment of practices. This knowledge is evident when teachers organize their own practice and give answers to the various situations of interaction with students (Ponte, 1999; 2012). It also encloses the capacity of adapting the subject matter to be taught along the various grade levels, of analyzing several methodological resources and of communicating with students (Ponte, 2012; Batanero & Godino, 2005). All domains of didactical knowledge are present, in some way, in the activity of the teachers when they teach (Ponte, 2012). Yet, the knowledge of the instructional process constitutes the fundamental core of the didactical knowledge model, since teachers' fundamental decisions that orient their practices and regulate their teaching processes are made in the scope of this knowledge (Ponte, 2012).

The Teaching and Learning of Statistical Variation

The fact that many mathematics teachers have a limited training in statistics and have not experienced data analysis makes it difficult to develop their statistical thinking, which has effects on their practices (Ben-Zvi & Garfield, 2004). Indeed, more often than not, teachers focus on computations and procedures rather than on data analysis and interpretation of results (Rossman, Chance & Medina, 2006). Sánchez and colleagues (2011) still add that teachers do not give enough attention to explanations and adequate use of terminology in statistics. Although acknowledging the usefulness of technical procedures, Scheaffer (2000) stresses the need for a genuine “understanding of analysis and communication of [statistical] results” (p. 158).

Wild and Pfannkuch (1999) assume that the *consideration of variation* is one of the main aspects of statistical thinking and describe it as the capacity of measuring and modelling variation and making decisions from data. It also involves looking for and describing patterns in the variation and trying to understand these with respect to the context. The term *variation* describes or measures the change in the variable, while the term *variability* refers to the phenomena of change (variable) (Reading & Shaughnessy, 2004). In this paper these terms are used indistinguishably.

Several studies state that students face serious difficulties in perceiving some measures of variability. In order to help them developing their reasoning about variability more efficiently, Garfield and Ben-Zvi (2008) suggest that their initial statistical activities should move from understanding informal ideas (e.g. differences in data values) to understanding and interpreting formal ideas of variability (e.g. standard deviation as measure of average distance from the mean; factors that can cause standard deviation to be larger or smaller). The concepts of distribution, mean and deviation from the mean are essential for reaching a meaningful notion of standard deviation (Sánchez et al., 2011) which, in turn, is important for understanding variation. It is crucial that teachers help students to build on their intuitive statistical concepts toward a more sophisticated understanding.

METHOD AND CONTEXT

This study is part of a larger ongoing qualitative research that focuses on Portuguese secondary mathematics teachers’ didactical knowledge of statistics. This communication refers to Estela, one of the three case studies of the wider research. In 2010/2011, they taught a 10th grade class and demonstrated interest in participating in this investigation. Estela has a master degree in mathematics education and she has been teaching mathematics for 23 years.

The data that informed the present study were collected using several instruments, namely: (1) participant observation, with audio and video recordings of eight lessons on statistics taught by Estela to a class of 25 students; (2) three semi-structured interviews to Estela with audio recording; and (3) documental collection of the resources used by the teacher in the observed lessons, especially working sheets. The data analysis was accomplished in a descriptive and interpretative way, pondering

and articulating the various collected elements. This analysis was guided by four assumed pre-categories that correspond to the four domains of the teacher's didactical knowledge of Ponte (2012, 1999).

The environment in Estela's class can be characterized as informal, with a good pace of work and a positive interaction between teacher and students and among students. The concepts or topics to be taught are often introduced through a task. Most of these tasks are selected by Estela from different textbooks and only a few are adjusted or created by her. Students usually work in pairs and the task's correction is mostly performed by the teacher in interaction with some students, once she realizes that most students have completed its resolution.

Estela followed the sequence of contents suggested in the secondary mathematics curriculum (DES, 2001), which is divided in three parts with the following order: (1) generalities about statistics (historical evolution, aim and utility; population, sample, sampling - some intuitive ideas; the statistical procedure: descriptive and inferential statistics); (2) organization of quantitative and qualitative data (process of summarizing data sets numerically and graphically); and (3) introduction to the study of two-dimensional distributions (graphical and intuitive approach).

RESULTS

According to Estela, the 10th grade mathematics curriculum regarding statistics focuses mainly on descriptive statistics, that is, on the summarization of quantitative and qualitative data through the use of multiple representations, giving little attention to inferential statistics and to interpreting results. Estela considers that the fact that statistics is not an object of assessment on national examinations and has no continuity throughout the remaining secondary grade levels contributes to a smaller importance given by teachers and students in comparison to other curricular topics.

Referring to the curriculum, Estela says that "There is almost no inductive statistics in here!", considering that it calls very little to making inferences and does not value the generalization over a population based on a sample. Furthermore, she says that:

That's why students tell me "Teacher, I can't wait to get started with statistics". Because they already know most of it [the contents]. What is really new about it? Maybe the spread measures and the two-dimensional variables (...) Also [the boxplot], but now in the new [basic education] curriculum it's there. It makes me wonder. (...) When the new generation in the 8th grade gets to 9th, there will be a new 10th grade curriculum because the boxplot won't be taught if they've had it in the 8th. Will this be a factor for a change? Will there be room for working more on inferential statistics?.

Through this excerpt, Estela enhances the need of a new statistical curriculum at secondary level that takes into account its inferential side, since the majority of the issues approached for the first time at this level were recently enclosed in the mathematics curriculum for basic education.

In her practice, the concept of (arithmetic) mean was mentioned for the first time in class by a student who referred to it describing its computation formula. And it was only in this way that the concept of mean, often targeted in the observed lessons when solving several tasks, was approached by students and Estela. It is a value that was most of the time computed by a graphical calculator (TI-84 plus) after students inserted the list of numerical data and followed the instructions: *Menu Stat* - choose *Menu CALC* - choose *select option 1: 1-Var Stats* with the corresponding data list.

However, in one of the interviews, while reflecting on some informal ideas attained by students concerning the mean, Estela mentions its visual representation, considering that the mean may be more difficult to be visualized by the students in some graphical representations (histograms, bar diagrams) than the median:

Since the mean is very influenced by outliers but I believe that they were able to more or less figure out if the mean was on the left or on the right of the median. (...) The intuitive idea is trying to approximate the mean and the median, but sometimes it is not [possible], just when the [data] distribution is symmetrical. This is the idea that I have about what they got [about the mean].

In this excerpt, when mentioning the visualization of the mean graphically, Estela seems to convey that the fact that there may exist outliers in the distribution may affect the symmetry, and that the visualization of the mean by the students, in this case, may not be so easy. However, she considers that students would not have difficulties in finding the mean in case the distribution of data was symmetrical.

Regarding the concept of standard deviation, students got used to see its symbol on the graphical calculator, when they obtained summary statistics for a numerical data set (discrete or continuous) before learning it in class. For Estela, knowing how to calculate the standard deviation by hand, besides being a lengthy procedure, is not a curricular goal. When talking about this concept in class, she shows its formula and mentions that it is “the positive square root of variance”. She defines it as a spread measure that “measures how far the data is from the mean” and exemplifies on the whiteboard how students should compute this measure with a set of numerical data. Yet, she also says that students must determine this value using the graphical calculator, following the instructions: *Menu STAT* - choose *Menu CALC*: choose *option 1: 1-Var Stats* and add *List*, whose corresponding value is found in S or in σ .

With the intention of showing a different way of interpreting standard deviation, Estela talks about the confidence interval “mean *plus* or *minus* standard deviation that contains approximately about 68% of data...”. She checks together with students the veracity of this statement, reaching the conclusion that in fact 71% of the data were included in the referred interval. Additionally, she alerts very quickly that this distribution of data should be of a “particular shape” in order for this property to hold, saying that it is something to be learned with much more detail in college.

In Estela’s opinion, the intuitive ideas that her students got about standard deviation could be summarized as: “given two sets of data values with the same mean... the

one that has larger standard deviation value is the one where data is more spread out [with respect to mean]”. This excerpt seems to indicate that this teacher considers that students take standard deviation as a spread measure. Her intuitive idea is correct, as long as none of the distributions have outliers.

Estela believes that statistics is a topic teachers do not fully master. For example, with respect to the concept of standard deviation, Estela only recently learned that after making the computation on the graphical calculator for obtaining the standard deviation value, she has to choose one of the two possible results. That is, this choice depends on whether the data set corresponds to a sample or a population. In her opinion, this issue is not highlighted in school textbooks and moreover is not part of teachers’ usual content knowledge. Having in mind the computation of standard deviation on a graphical calculator, she mentions that

Because sometimes it shows up in the graphical calculator... when I’m computing standard deviation S and Sigma appears on screen. You [may] remember that two or three years ago in a vocational mathematics exam there was a big issue because students were choosing the σ value [population standard deviation]... but since the task stated it was a sample then they [students] had to consider S [sample standard deviation]. And who were the teachers aware of it? None. (...) Do you know where I heard that? In my master degree, never in college [during undergraduate studies]! (...) And nowadays they [teachers] reach it [this distinction]. Textbooks didn’t.

Since the graphical calculator is a mandatory resource at secondary level, Estela thinks that one must take as much advantage as possible from this device, particularly useful in students’ learning, namely when working on a task with a lot of data, releasing them from the burden of extensive computations. In her view, this resource can also help to promote teachers’ statistical knowledge for those who lack preparation in this field, allowing them to develop some skills in statistics, as it generates additional questions about results and representations:

Since now they are not required to know how to compute those formulas with a lot of data, computing the mean is unthinkable, computing the median is unthinkable, the quartiles, the standard-deviation. (...) I’m still from a time when the graphical calculator wasn’t mandatory in school and of making huge handmade tables on the blackboard, it doesn’t make sense [anymore]... they [the students] found them very difficult and I thought it was the easiest part... I’d start with the mean, then would do x minus the mean... it was very easy and the calculator [nowadays] does it easily. And with the calculator we can have more data and even us teachers who didn’t have this teacher preparation [in statistics]... for us to learn and develop more ideas and skills about statistics [with the obtained representations]... it may generate more discussion and one can do more than trivial things.

Estela thinks that the statistics in the secondary mathematics curriculum emphasizes, above all, its descriptive side, where computation and procedure repetition prevail, with little space for carrying out interpretations and reaching conclusions. Thus, in

her practice, the tasks that she often asks students to work on contain several subsections, each of them very directed and with little focus on interpretation:

The questions [in statistics] have to be asking more [specific] things (...) and are very oriented to answer something, in Mathematics it is just that something, it is not for discussing... Since when? ... Mathematics is exact and it's over! ... and statistics is the same... it is for reaching that something and nothing more!

In one class, Estela proposed a task that she designated by “Properties of the mean and standard deviation” (see figure 1 below):

In a company the wages in the year of 2005 were the following:

Wages (euros)	600	700	800	1000	1500	2000	4000
Absolute Frequencies	20	50	15	9	3	2	1

a) Compute the mean, mode, median, quartiles and the standard deviation of this distribution;
 b) Supposing there was a 5% wage raise in 2006, what would be the wages in 2006?
 c) Compute the mean, mode, median, quartiles and the standard deviation of the 2006 wage distribution with the 5% raise. What do you conclude, comparing with the results from a)?
 d) Supposing there was a 50 euro raise in 2006, what would be the wages in 2006?
 e) Compute the mean, mode, median, quartiles and the standard deviation of the 2006 wage distribution with the 50 euro raise. What do you conclude, comparing with the results from a)?

Figure 1: Task about the properties of the mean and standard deviation

Estela thinks that this task, proposed in a working sheet, was very successful in promoting the study of those two concepts starting from the very same problematic set up, as opposed to the tasks she found in textbooks which presented separated contexts for analyzing the proprieties of each concept.

After reading the task, Estela asked students to make all the requested computations at once on the graphical calculator. Next, she reminded them that they should insert two different lists of numerical data (one corresponding to the wages and the other to their respective absolute frequencies). Estela showed how to proceed with the calculator. Several students revealed difficulties in understanding why they had to multiply by 1.05, instead of multiplying by 0.05, for wages to increase by 5%. Estela spent some time trying to clarify this issue. After having made all the initially requested computations writing them on the whiteboard – simultaneously with students – and having pointed out the influence of making a specific percentage or constant growth in the data values and their effect on each statistical measure, Estela concluded the task in the following way:

So, the story's moral: (...) if I multiply the values of the statistics variable by a number, all the statistical measures become increased by that number, increased..., I mean... multiplied. But if I add up a number to the statistics variable, all the values of the statistical measures become increased by that number, except for the standard deviation that remains unchanged. Is it understood?

The development of this task was quite centered on the computation of the statistical measures using the calculator and on the comparison of the different attained results, as the initial data were being changed. This task was not restricted to the properties of the mean and standard deviation since the mode and quartiles were also compared. Neither the teacher nor any student questioned any obtained result, in particular, why the behavior of the standard deviation was different from the other statistics measures when the initial data were increased by 50. This situation may suggest an overvaluation of the results from the graphical calculator, which may have hindered from wondering why the standard deviation remained unchanged. Teacher and students reached the right conclusions without interpreting and understanding deeply the formal ideas of variability of this task.

DISCUSSION

We now analyze the dimensions of Estela's didactical knowledge of statistics, with particular incidence in variation, emerging from her practice. Estela shows evidence of owning a *knowledge of the curriculum* restricted to some aspects with particular incidence on descriptive statistics. Such knowledge was noticed in her practice, for example, when working on the concept of mean, focusing mainly on its computational side (Rossman et al., 2006) and not mentioning explicitly others possible interpretations for the mean.

The *knowledge of the students and their learning processes* as a result of her statistics teaching experience gives her the conviction that students have more difficulties in seeing the mean graphically than the median. However, Estela thinks that in the presence of a symmetrical graph or an approximately one, students know that the values of the mean and the median are close. Also, concerning standard deviation, she considers that students are able to identify it as a spread measure, taking into account the residual values with respect to the mean value. Ponte (1999) and Batanero and Godino (2005) pointed out that teachers need to be aware of their students' reached level of comprehension of the concepts, as well as difficulties, in order to improve their teaching and assessment practices.

Estela's work in the classroom on an application of the standard deviation and the search for a confidence interval seem to indicate that, in her view, the topic of statistics should be expanded in terms of content, encompassing more inferential statistics. The same happens when she refers the need to develop the secondary curriculum given the recent curricular changes in basic education, which started to incorporate much statistics content currently addressed at the secondary level. However, in the task that she called "Properties of the mean and standard deviation", which had potential to help students to develop their reasoning about centre and variability, Estela ended up giving work orientation much centred on computations using the calculator, and in this interaction, neither the students nor the teacher questioned the obtained results. This situation suggests a certain overvaluation of the calculator results, since the need of reinforcing the interpretation and explanation of results was not observed. This is a commonly found phenomenon in mathematics

teachers (Rossman et al., 2006; Sánchez et al., 2011) and resonates with Estela's interpretation of the written curriculum. Furthermore, this interaction did not bring along any conjecture to be pursued. In fact, there are other properties, regarding variation, that could have been object of reflection in this or other tasks, namely that the median is a value located between the extreme values of the distribution, or that the residual sum with respect to the mean is zero (Garfield & Ben-Zvi, 2008). Nevertheless, these situations did not occur in Estela's classroom, raising important questions concerning her *knowledge of the instructional process* in teaching variation.

In her instructional process, Estela seems to give some relevance to the deepening of the mean and standard deviation concepts, since she proposed a task in this direction; yet, the understanding of formal ideas of variation as suggested in the literature (e.g. Garfield & Ben-Zvi, 2008; Sánchez et al., 2011) does not seem to be totally achieved. This situation may be related to Estela's formal comprehension of the standard deviation concept as noticed while presenting its definition in class or when reflecting on the informal ideas that students may hold about standard deviation. For instance, in the latter situation, she did not contemplate all the hypotheses that would make it always valid. Her *knowledge of the content in statistics* seems to affect the level of depth in which these concepts were developed in the lessons.

This analysis of Estela's practice gives evidence that the various domains of the teacher's didactical knowledge are interrelated, and consequently they must be taken into account in the study of the teachers' practices and also in teachers' preparation and professional development programs.

PROSPECTIVE ELEMENTARY SCHOOL TEACHERS' INTERPRETATION OF CENTRAL TENDENCY MEASURES DURING A STATISTICAL INVESTIGATION

Raquel Santos

Investigation Unit of the Institute of Education, University of Lisbon

João Pedro da Ponte

Institute of Education, University of Lisbon

The introduction of statistics as a topic of the elementary school curriculum makes it necessary to reinforce teachers' preparation in this area as well as to understand prospective elementary school teachers' statistical content knowledge. This paper aims to understand the meanings that prospective teachers give to central tendency measures during a statistical investigation. We observe innovative interpretations as well as interpretations based on the context of each question and showing real understanding of concepts. But we also notice that most groups do not interpret central tendency measures, just analyzing data by reading graphs and tables. For the future, we suggest that prospective teachers must work with tasks requiring the interpretation of different measures to understand the differences among them.

Keywords: Statistical investigation, Mean, Median, Mode, Teacher education.

INTRODUCTION

The Portuguese official curriculum documents for kindergarten and primary levels (ME, 1997, 2007) give emphasis to statistics. This topic has great importance nowadays since society depends more and more on results from statistical studies (Groth, 2006). With industry, medicine and other society sectors recurring to data to make decisions, statistics should be a focal part of the new information era (Wild & Pfannkuch, 1999). Statistical literacy, regarded as the “ability to interpret, critically evaluate, and communicate about statistical information and messages” (Gal, 2002, p. 1), is essential in the education of every citizen and naturally in the education of prospective teachers. Therefore, it is important to know how prospective teachers interpret and communicate statistical information.

Statistical investigations allow students to become active in the learning process. During these projects, students pick a theme of their interest, define goals, select instruments to collect data, choose samples, collect, analyze and interpret data to answer the proposed questions (Batanero & Godino, 2005). Additionally, during an investigation, they perform every step of the PPDAC cycle (Problem, Plan, Data, Analysis, Conclusions) described by Wild and Pfannkuch (1999), in an environment inciting meaningful learning (Ponte, 2007). Furthermore, students are able to appreciate the importance and the difficulty of the statistical work and the interest of statistics in solving real life problems (Batanero & Godino, 2005). Moreover, teaching through statistical investigations allows the identification of students'

difficulties in their mathematical knowledge and, sometimes, even to detect concepts and ideas that seemed well consolidated but are not (Ponte, 2007).

This article shows part of an investigation that aims to understand prospective teachers' statistical and didactical knowledge. Our specific aim is to analyze the ways prospective teachers (for Pre-K to grade 6) interpret central tendency measures (mode, mean and median), based on their reports of statistical investigations.

CONCEPTUAL FRAMEWORK

Teachers are a key element in the educational process (Ponte, 1994). They need to know in depth the content they teach, as this is true even for teachers of early years (Ma, 1999). A solid mathematical knowledge is essential to promote a learning environment where students want and can learn mathematics, and this must be addressed since preservice teacher education. Heaton and Mickelson (2002) state that teachers' statistical knowledge encompasses the ability to conduct statistical investigations, describe information using different methods and form conclusions. To Mulekar (2007), prospective teachers must have a deep comprehension of statistical concepts in order to give coherent meaning to results. Central tendency measures (mode, mean and median) have a particular interest as they are frequently found in daily life (Groth, 2006). To Groth, understanding of these measures is an important component of statistical literacy. Nevertheless, according to Jacobbe (2008), even grade 1 exemplary teachers do not have conceptual knowledge of the two most basic statistical concepts – mode and mean.

In Portugal, the mode appears in the official curriculum documents in grades 3 and 4 (ME, 2007) and teachers tend to consider it an easy concept to understand. However, some studies suggest a more complex picture. For example, Fernandes (2009), researching difficulties and errors in statistics from prospective teachers (for grades 1 to 6), refers gaps on the comprehension of this concept, especially when they select the biggest frequency instead of the corresponding value of the variable. In a study with 40 prospective teachers (for Pre-K to grade 6) in their undergraduate program it was frequent to find answers like “the mode is 9, since there is a bigger number of students that see television” (Martins, Pires & Barros, 2009, p. 7). In the interpretation of this measure it is recurrent to associate the mode to the biggest number on the results table, the biggest absolute frequency, the value that appears more times and the biggest frequency category or interval (Martins et al., 2009). Some of these interpretations reveal confusion, since the value that appears more times could be seen as the number on the absolute frequencies column that is repeated more often and not as the value of the variable that is repeated more times.

The concept of mean is introduced in grades 5 and 6 (ME, 2007). Research about this concept is vast, since it is very used in statistical studies. Leavy and O'Loughlin (2006) indicate that there are two types of understanding – conceptual and procedural: “Computationally, the arithmetic average is the score around which deviations in one direction exactly equal deviations in another direction” (Leavy &

O'Loughlin, 2006, p. 55); conceptually, the mean may be seen as a balance point or center of gravity, representing the data set. To the authors, interpretations of the mean as the fair share (the value that represents the data set as if all data were equal), or as the balance point (where higher values compensate lower values) show conceptual understanding of the concept. When computing the mean, a frequent mistake is to determine the mean of the absolute frequencies in qualitative variables (Martins et al., 2009). Students use several interpretations of the mean, just restating the algorithm (Chatzivasileiou, Michalis & Tsaliki, 2010; Fernandes & Barros, 2005), indicating it as the “sum of all results divided by the existing values” or “sum of numbers” (Martins et al., 2009). Others associate the mean to the notion of balance, the average value, the value that balance the highest and lowest values (Martins et al., 2009), the fair share value, the typical expected value (Chatzivasileiou et al., 2010; Konold & Pollatsek, 2004), the location measure (a close but not exact value) (Chatzivasileiou et al., 2010), a signal in noise (where the mean of different observations is a close approximation to the actual value, ignoring the errors) or a data reduction value (a value to reduce the complexity of all data) (Konold & Pollatsek, 2004). As incorrect interpretations, there are answers based on the maximum value, the minimum value, a specific value, the median and the mode (Chatzivasileiou et al., 2010; Leavy & O'Loughlin, 2006). On the latter cases, students lack recognition of the data set as a whole and tend to focus on individual values (Chatzivasileiou et al., 2010).

Concerning the median, concept of grades 7, 8 and 9 (ME, 2007), the scenario is also problematic. Research shows that there are difficulties on the understanding and interpretation of this concept on grade 12 students (Fernandes, 2009) as well as on prospective teachers (grades 1 to 6) (Fernandes & Barros, 2005). Computing it, several prospective teachers indicate the central value of the absolute frequencies, others confuse this concept with the mode, and the most frequent mistake is to determine the central value without ordering the data (Martins et al., 2009). Even some grade 1 experienced teachers calculate the mean when they are asked for the median (Jacobbe, 2008). Interpretations of this concept include associations to the point where the number of values above equals the number of values below (Konold & Pollatsek, 2004), to the central value (although not always on the most correct way) as well as to “the value in the middle”, the value that “divide in half”, the value that is “somewhere in the middle”, the second quartile (without more explanations), the value that “divide the sample in half and balance big values with small ones”, the “average number of all results” and the “mean value” (Martins et al., 2009). The last three interpretations show some confusion between the concepts of median and mean.

METHODOLOGY

Participants in this study are prospective elementary (grades 1 to 6) and kindergarten teachers in an undergraduate program of a Portuguese school of education that took a course on Discrete Mathematics, Statistics and Probability during the 2nd semester of their 2nd year of studies, in 2010/11. This is the single course in the program dedicated to the development of statistical knowledge. During the course, prospective

teachers worked statistical concepts through exploration and discovery, and strong emphasis was given to their interpretation in real contexts. Additionally, they worked with Excel to organize data and calculate statistical measures. Prospective teachers also carried out statistical investigations, individually or in groups (of 2-3), in themes chosen by them, with a look on their possible use with their future students. During such investigations, prospective teachers were asked to make records and do a written report to be presented to the class at the end of the semester, including data organization (indicating all relevant measures), analysis, interpretation, conclusion and a reflection about their work. Towards the end of the work each group received feedback from the teacher with questions to help them to reflect about what was done but never received simple corrections of it. After the presentation they received a final grade for all the process and final product. In this article we analyze these written reports to discuss their understanding of central tendency measures.

The 36 prospective teachers that attended the course were organized in 16 groups (6 groups attended day classes – D – and 10 groups after work classes – PL). 21 out of the 36 authorized the participation in this study. They were organized in 12 groups and chose themes such as recycling, food, water habits at home and routines. They undertook statistical investigations through questionnaires with 12 to 25 questions, with about 70% of the questions involving qualitative variables. When working the data, all groups used Excel, making use of the corresponding functions to determine the mean and the median. Regarding the mode, they realized it was more convenient to not use the Excel function “mode”, since this does not work when analyzing qualitative variables and also when the variable has more than one mode. Only two groups made a mistake determining measures of a variable, giving an absurd value for the mean in the particular context. All the other groups found correct measures, showing that Excel can be a useful tool to prospective teachers. Given the use of technology for computations, the focus of this paper was on the interpretation of such measures in the context of each question. This means that, for a single concept, a group may give different interpretations, depending on the questions, and, therefore, a group may be taken into account in different interpretations. Analysis of data was exploratory and involved the categorization of interpretations observed in these reports. Categorization was made according to definitions and cases of doubt were sorted out between the two authors. Codes are used to identify the written reports of groups (G1 through G10) and the class (D/PL).

RESULTS

Mode

There are a large number of interpretations for the mode concept in the written reports of statistical investigations (Table 1). Four groups associated the mode to something that happens “more times” like happened in previous studies (Martins et al., 2009). Example of that is the analysis of the question “What is your profession?” where the group stated “the mode of the profession group is ‘intellectual and scientific professions’, since it is the profession group that is repeated more times in

the sample” (G4D, p. 11). Interpretations made by five groups also associated mode to an answer that appears a large number of times, but made reference to “frequency” or related words, like “the number of accompanying people more frequent is 1 (mode)” (G3D, p. 23).

Appropriate interpretations	Number of groups
Value associated to the highest frequency	5
The majority of the sample.../most...	4
Value referred/repeated/verified/chosen/appears more times	4
Value associated to more/greater number of respondents	4
Other interpretation using “more”/“bigger” in context	2
Predominant value	1
Satisfactory value	1

Table 1: Appropriate interpretations of the mode

Four groups used expressions like “the majority” or similar that imply a correct idea: “the mode is 3, therefore the majority of students already went 3 times to the theatre” during the analysis of the question “how many times did you go to the theatre?” (G6D, p. 28). Also related to the size of the sample was the category of interpretations where the mode was associated to more or to a greater number of respondents. In that category were interpretations like “the greater number of respondents is from the feminine gender (mode)” (G3D, p. 6). A similar idea seems to be meant by a group that referred something that is predominant (“it is the feminine gender that predominates” – G6D, p. 23) and by another group that indicated “here we obtained a satisfactory answer of ‘yes’, being the mode of this qualitative variable ‘yes’” (G8PL, p. 8). Interpretations of the mode made by two groups were connected to the context, making use of the expressions “more” or “bigger”: “the television is the information method more used by the respondents (...). Hence, it can be concluded that the mode is television” (G2D, p. 17).

Table 2 summarizes the interpretation problems made by prospective teachers. Two groups did interpretations also associated to the size of the sample, but the expressions chosen were not as efficient as in the previous cases. For example, in the analysis of the question: “Since when do you recycle?”, a group used the expression “we noted that 36% of the people started to recycle between 2006 and 2008, where, because this is the mode interval, we conclude that the greater part of the sample started to recycle by that time” (G2D, p. 9). This response is problematic due to the fact that if something is happening to a large part of the sample that does not mean that that “part” is the greater and, consequently, is the mode.

Additionally, a group, in the analysis of the question “Where do you eat breakfast?”, refers “the mode (...) is home, since is the higher value in the graph and on the table”

(G1PL, p. 29). This statement, encountered also in previous studies (Martins et al., 2009), can be problematic when the variable is not qualitative, since in the quantitative case the highest value on the table could be from the variable and not from the frequency.

Problematic interpretations	Number of groups
A great part of the sample...	2
Highest value	1
Confusion	1
Without interpretation (quantitative variables)	7
Without interpretation (qualitative variables)	9

Table 2: Problematic interpretations of the mode

A group that made the following statement: “the ages to which we made more questionnaires were young people aged 19” (G1D, p. 8). We observe some confusion but it is unclear if it is in the comprehension of the mode or in the phrase construction in Portuguese. This statement conveys the idea that the questionnaires were made to ages and not to people, which can be confusing to who reads the reports.

It should be pointed out that, for the case of the mode, all groups who had problematic interpretations of this measure were also able to give correct interpretations. Therefore, the problems with some interpretations may be due to the fact that they tried to give an alternative description for the mode. Also important is the fact that in the case of qualitative variables, nine groups did not make any reference to the concept of mode and to what this measure represents and means when analyzing the data. The same happened to seven groups regarding quantitative variables. This means that, especially in the cases of variables where the mode is the only statistical measure that can be determined, some participants make only readings from graphs and tables, which seems to be easier to them, since they only need to extract data from the representations.

Mean

Table 3 summarizes the adequate interpretations of the concept of mean. A group argued the following expression “the average age is 3.4, which represents the age balance” (G1PL, p. 11). This response demonstrates that the group understands that the mean can be seen as a balance point (Leavy & O’Loughlin, 2006), but it is unclear the real understanding of the prospective teachers of the meaning of this measure. This interpretation may reveal conceptual comprehension (Leavy & O’Loughlin, 2006), but this is not evident, in this case.

Two groups used the fair share model when interpreting the mean, like the example of the analysis of the questions “How many favorite games do you have?” where the group wrote “it means that if every child had the same amount of favorite games,

each one had 13, 33 games" (G2PL, p. 21). This type of interpretation also found by others researchers (Chatzivasileiou et al., 2010) reveals conceptual understanding of the mean concept as suggest by Leavy e O'Loughlin (2006).

Appropriate interpretations	Number of groups
Value that represents the equilibrium (balance point)	1
Fair share model	2

Table 3: Appropriate interpretations of the mean

Problematic interpretations of the mean are associated with misconceptions regarding the distinction between this concept and other statistical measures (Table 4). The members of a group, both times they tried to interpret the mean, confused mean and spread measures, using the mean (and the median) to indicate whether the data was spread or not: "the values of the mean is 7.6 and of the median is 8, then we can conclude that the values are not very spread" (G6D, p. 28). We note that, in some quantitative variables, all groups made statements like "the mean is..." or "the sample, in average..." that do not represent an interpretation of the mean.

Problematic interpretations	Number of groups
Confusion between the mean and spread measures	1
Without interpretation	12

Table 4: Problematic interpretations of the mean

Median

There were several adequate interpretations of the concept of median (Table 5).

Appropriate interpretations	Number of groups
Value that divides the ordered data	1
Up to the median there is 50% of the sample...	1
50% of the respondents... or less...	3
50% of the respondents... at maximum	1

Table 5: Appropriate interpretations of the median

We observed the following interpretation of one group: "up to the median there is 50% of the sample, and after the median, there also is" (G5D, p. 13). This shows that these participants comprehend that the median divides the sample in half, 50% to each side of the median. Nevertheless, this can be problematic because of the non-inclusion of the median on the second half of the sample ("after the median").

Another group made the interpretation "the median is 7.5, which is what divides the ordered data" (G4PL, p. 11), revealing that the group understands that the median is a

number that divides the data when ordered, but do not reveal a real understanding of this concept in context.

Four groups make appropriate interpretations showing understanding of this concept in the context of the data, like: “50% of the people expect to return to the fair, in the same year, at maximum 2 times” (G3D, p. 31) or “50% of the children have 4 or less games” (G2PL, p. 21). This type of interpretation discloses understanding of the meaning of median in the context of the variable at study, making use of expressions that, in reality, make sense on data interpretation.

Nonetheless, not all interpretations were appropriate (Table 6). Three of the interpretations show that the median is a central value that divides data in 50% on each side, however without revealing the real comprehension of the concept. For example, one group wrote: “the Q2 is the median, which mean, the value that is in the center, equivalent to 50%” (G1D, p. 11). This interpretation shows confusion as it states that the median is equivalent to 50% of the data, which is incorrect. In the following example a group tried to make a statement like the one previously indicated as appropriate and very useful in context, however got confused, maybe because they do not really understand the concept: “50% of the people at maximum come to the fair with 3 accompanying persons” (G3D, p. 23).

Problematic interpretations	Number of groups
Value that is in the center	1
Value equivalent to 50%	1
Value to a maximum of 50% of respondents	1
Confusion between median and spread measures	1
Without interpretation	12

Table 6: Problematic interpretations of the median

Like in the case of the mean, one group used the median to make assumptions about the data spread, showing some confusion between the median and other statistical measures. In the case of the mean, contrarily to the previous measures, there are groups that only give adequate interpretations, groups that only give problematic interpretations, and also groups who are taken into account with both adequate and problematic interpretations. Moreover, it should be noted that none of the groups made the interpretation of the concept of median in all quantitative variables that they studied.

CONCLUSIONS AND IMPLICATIONS

The analysis of the written reports of the 12 groups highlights gaps on prospective teachers’ understanding of central tendency measures. Analyzing contextualized data, they interpret the measures in a way that demonstrates some confusion about their meaning, sometimes making no distinctions among statistical measures. Additionally,

they use interpretations not mentioned in previous researches maybe probably because they had to write a report with the analysis of several variables and try to not repeat the same interpretation all over. Example of that are the interpretations of the mode like something that happens to “the majority” and to “the greater number” of respondents (appropriate interpretations) or as a “great part” or “higher value” (problematic interpretations). Moreover, some groups gave appropriate meanings, like indicating the mean as a balance point (Leavy & O’Loughlin, 2006) or referring to the median as the center of the ordered data, but without showing a real comprehension of the meaning of the concepts. Additionally, we observe concrete and contextual interpretations like in the case of the mode as the value related to the majority, the mean as the fair share model and the median in where 50% of the sample is associated to this value or less. We suggest that interpretations related to the context of data are those that demonstrate stronger understanding of the concepts. Furthermore, an interpretation may be categorized as appropriate or not, depending both on the type of variable (quantitative or qualitative) and on the associated information (for example, if it is stated the relative frequency in the case of mentioning “great part”). Lastly, most or all groups do not make interpretations of central tendency measures, giving only readings of graphs and tables.

These results are important since they show a large variety of interpretations of central tendency measures, some appropriate and others not, that go beyond those mentioned in previous researches (e.g., Chatzivasileiou et al., 2010; Fernandes & Barros, 2005; Martins et al., 2009). Prospective teachers should experience and discuss all of them, in order to realize which ones better convey the information provided by data. Additionally, it is essential to make prospective teachers to compare and contrast the three central tendency measures to recognize their differences. Finally, this study shows the importance of emphasizing concrete interpretations of contextualized data, to consolidate the understanding of central tendency measures and to learn to distinguish them and grasp their utility.

COPING WITH PATTERNS AND VARIABILITY: RECONSTRUCTION OF LEARNING PATHWAYS TOWARDS CHANCE

Susanne Schnell

TU Dortmund University, Germany

Dealing with the phenomenon of chance in a mathematically sustainable way requires not only the prediction of outcomes using probabilities, but also taking into account the omnipresent variability as a constituent property of chance experiments. This paper investigates how students aged 11 to 13 make sense of random data from chance experiments by relating patterns and variability to one other. The empirical findings from design experiments are analysed using an interpretative framework. The presented case of two students illustrates how they gradually move from investigating and explaining single deviations to developing a conception of variability as a phenomenon which is especially visible for short series of repetitions.

Key words: *variability, patterns, knowledge construction, design research*

Probability education is widely reported as quite challenging for students, as pre-instructional conceptions seem to persist through school and beyond, even if they oppose mathematically sustainable ones (overview in Shaughnessy, 2007). One explanation of the impact of these initial conceptions is a constructivist perspective on learning: individual, active constructions of mental structures always build upon the existing mental structures by accommodation to experiences with new phenomena. Thus, initial conceptions have a major influence on substantial teaching-learning processes, which seems especially true for stochastics education (cf. Prediger, 2008). The reason for this may be the proximity of the everyday phenomenon of chance (in which the unpredictability of outcomes is often emphasised) and the related, but different, mathematical one (in which probabilities make predictions for patterns in the long run). The nature of chance itself thus seems to be counter-intuitive: patterns and variability are seemingly counterparts but only together do they constitute what stochastics is about.

Building on a previous CERME paper (Prediger & Schnell, 2011), this article focuses on the question of which conceptions students construct concerning variability and patterns when they are working on the experiment-based learning environment “Betting King”.

PATTERNS AND VARIABILITY AS COUNTERPARTS

Moore (1990) uses the interplay of variability and patterns as a defining element for the phenomenon of chance itself: “Phenomena having uncertain individual outcomes

but a regular pattern of outcomes in many repetitions are called *random*. ‘Random’ is not a synonym for ‘haphazard’ but a description of a kind of order different from the deterministic one” (p. 98, emphasis in original). This definition gives way for different insights that are crucial for stochastics:

Patterns and variability: While especially frequentist approaches to probability are concerned with identifying *patterns* in many repetitions of chance experiments (as estimations for unknown probabilities, see below), it is the omnipresence of *variability* (i.e. “the propensity for something to change”, Shaughnessy, 2007, p. 972), which is causing the uncertainty that stochastics deals with (cf. Moore, 1990, p. 135; Wild & Pfannkuch, 1999).

Short-term and long-term distinction: Even though variability is omnipresent, patterns (also called “signals”, Shaughnessy, 2007, p. 973) can still be identified, especially in the long run. This is well known as the empirical law of large numbers: While relative frequencies vary a lot for only a *few repetitions* of an experiment (short-term perspective), the variation of relative frequencies is smaller for a *larger number of repetitions* (long-term perspective) (cf. Fig. 1). The patterns identified in the long-term perspective are on the one hand an estimation for the theoretical probabilities. On

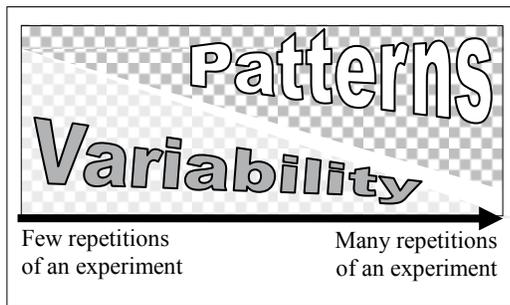

Fig. 1. Observability of patterns and variability in relation to the number of repetitions

the other hand, theoretical probabilities of an event (determined *a priori* by the ratio of the number of favourable cases to the number of all cases of the event when each case is assumed to have the same probability) serve as prediction of the patterns which will be observable in series of many repetitions.

Thus, when learning about probabilities in an experiment-based approach, students have to make sense of patterns and variability. To do so, the distinction between *short-* and *long-term contexts* is crucial (Prediger & Schnell, 2011).

Thus, when learning about probabilities in an experiment-based approach, students have to make sense of patterns and variability. To do so, the distinction between *short-* and *long-term contexts* is crucial (Prediger & Schnell, 2011).

PROCESSES OF LEARNING ABOUT VARIABILITY AND PATTERNS

There has been some research about how students cope with variability in statistics (especially in exploratory data analysis; overview in Shaughnessy, 2007). Results such as Ben-Zvi’s (2004) show how students gradually develop a sense of how to take variability in statistic samples into account: They use frequency overviews, address outliers and compare variation within and between distributions.

For probability education though, research on learning pathways of students coping with variability and patterns is still limited (cf. Jones et al., 2007, p. 928): For instance, Pratt and Noss (2002) investigate how students (aged 10 and 11) can successfully progress from a short-term context to a long-term context when working in a supporting learning environment. While initially conceptions such as

unpredictability of single events are dominant, new conceptions emerge in the learning process: Patterns are more stable for large numbers of experiments and expected or observed patterns can be linked to theoretical probabilities. These results give insights how students gradually develop a sense for the long-term context and sustainable patterns in the long run. The question remains how students build an integrated knowledge of both patterns and variability.

LEARNING ENVIRONMENT ‘BETTING KING’

To help learners gain experience with the phenomenon of chance, they have to be provided with opportunities to investigate data from random experiments, allowing them “to become aware of the underlying differences between short-term and long-term perspectives” (Prediger, 2008, p. 151). For this purpose, the learning arrangement ‘Betting King’ (to be published in Prediger & Hußmann, 2014) was developed as part of a textbook, introducing probability in grade 7 (students of age 12 to 13). The main activity consists of predicting results of a chance experiment: The players bet on the outcomes of a race with four coloured animals, which make a step forward when their colour is rolled with a coloured die with asymmetric colour distribution (red ant: 7/20, green frog: 5/20, yellow snail: 5/20, blue hedgehog: 3/20). The term ‘outcome’ (or ‘position’) refers to how often each animal was rolled. The game is first played on a board, which is later replaced by a computer simulation (Fig. 2). The differentiation between the short-term and long-term contexts is realised by the possibility to choose the number of throws of the die, after which the results of the game are determined (between 1 and 10,000 in the simulation). Furthermore, record sheets and written tasks are used to support the learning processes.

There are two consecutive game settings used to motivate explorations of the generated game results: In the first setting, “Betting on Winning”, students bet on the animal that will have the highest outcome and is therefore the winner of the game. Here, students usually soon discover the pattern that the red ant wins more often and can link it to the unfair colour distribution. Next, the security of this pattern is addressed in relation to the total number of throws: While for short games the winning animal varies a lot, but the red ant wins most often for large total numbers of throws such as 2,000.

The second game setting, “Betting on Positions”, motivates to more closely examine the generated outcomes: Students play one-on-one against each other and predict for

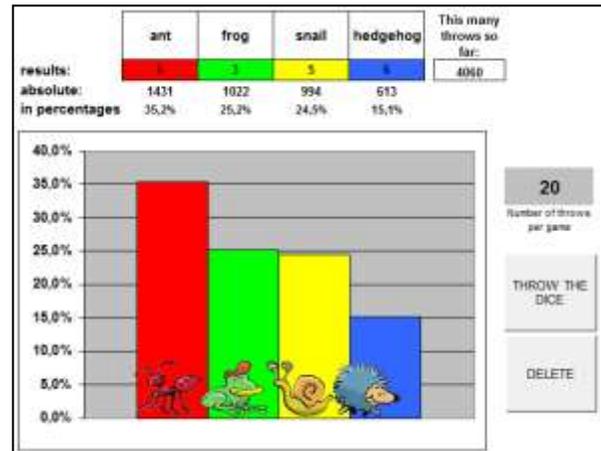

Fig. 2. Layout of the computer simulation at the end of the learning arrangement (translated and slightly rearranged for this paper)

each animal on which position it will land in relation to a pre-set (large) total number of throws. The bet closer to the result wins one point per animal. Soon, the game itself is left and students are encouraged to investigate patterns and variations of positions presented in different representations offered by the simulation (numerical and graphical). Here, the focus of the tasks first lies on comparing random outcomes (i.e. absolute frequencies) for series of games with the same total number of throws (cf. table 1).

Game number:	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.
Position of red ant:	681	692	706	709	682	738	747	670	698	713

Table 1. Series of randomly generated absolute frequencies of the red ant in a series of games with 2000 throws

Students can – for example – compare the (absolute and relative) range of results (as a measure for the variation) with the range of outcomes for a series of games with a smaller total number of throws such as 20 and thus gain deeper insight into the empirical law of large numbers. At the end of working on this learning arrangement, a dynamic perspective is introduced, where relative frequencies (presented as percentages) can be investigated when the total number of throws is increased gradually.

RESEARCH QUESTIONS AND DESIGN OF STUDY

Based on the previously elaborated theoretical perspective and the intention of the designed learning environment ‘Betting King’, the following questions will be addressed in this paper:

Which constructs of variability do students develop over the course of working on the learning environment and how are the constructs linked to an according pattern?

How do students develop an overall conception of variability over the course of the design experiments?

As the empirical data shows, the repertoire of different patterns observed by students is so rich (cf. Schnell, 2013) that this paper will focus on the scenes when students explicitly notice variability in the data in contrast to a related patterns.

Data collection

The foundation for this paper is a study in a laboratory setting, which was conducted to research the individual learning pathways in more detail (cf. Schnell, 2013; Schnell & Prediger, 2012, for the broader design research study). Here, the above presented learning environment was used in design experiments (cf. Cobb et al., 2003) with nine pairs of students (age 11 to 13). Each design experiment lasted between four and six consecutive sessions of 90 minutes. They were semi-structured by an experiment manual that defined the sequence of tasks as well as interventions for anticipated problems in crucial learning. The data corpus of the study includes

videos of all 40 experiment sessions, records of the computer simulations as well as all written products.

Data analysis

The *in-depth data analysis* is guided by an interpretative approach, identifying scenes in which new discoveries are made and integrated into the individual conceptions, here conceptualised as a network of *constructs* (cf. Schnell & Prediger, 2012 for the theoretical background of the analytical model). In these scenes, students' individual constructs are reconstructed with respect to four elements: the emerging insights (summarised by $\langle \textit{proposition} \rangle$), the *stochastic context* in which an insight occurs, the *situational context* to which it refers (such as the representation; due to page limitations this will not be addressed in this paper) and which *function* the construct has in the specific situation (e.g. explanations, descriptions of deviations). Due to the complexity of the “Betting King” game situation, the stochastic context was specified not only as short-term and long-term context: Students' constructs can relate to **One** or **Many** games (differentiation O-M), meaning single games or a series of (at least three) games in which the differences between the outcomes are addressed. Furthermore, the game(s) can have **Small** or **Large** total numbers of throws (differentiation S-L); in the learning environment, small numbers are usually represented by 1 to 40 throws and large numbers by 100 to 10,000. In the last phase of working on the given tasks, the continuity between these dimensions is investigated by looking at games with gradually increasing total numbers of throws. While patterns in accordance with the colour distribution of the die can be best observed for the context ML (Many & Long), variability is more visible for the context SM and single deviations (e.g. outliers of positions) in OS and occasionally also in OL.

In this article, the in-depth analysis of one pair of students (Ramona and Sarah) learning pathway is used to exemplify how learners cope with variability. For this, constructs with the function “description of deviations” were picked out and contrasted with constructs describing a related pattern. To show the development of how variability is experienced, the constructs are contrasted and differences regarding the stochastic context, the function and the influence of predictions are identified.

EMPIRICAL FINDINGS: RAMONA AND SARAH'S LEARNING PATHWAY

The case of Ramona and Sarah shows how students start with initial conceptions of variability which then get complemented when the focus is shifted from single games (OS context) to series of games (MS and ML context). Comparisons with other pairs of students will be made in the conclusion.

1. First encounters with variability: Constructs with function explanation (OS-context)

CONSTRUCTS EXPLAINING PATTERNS				CONSTRUCTS EXPLAINING VARIABILITY			
Short-title	Proposition	Sto. con.	Time	Short-title	Proposition	Sto. con.	Time
ANT-BEST	<Red ant is always best>	MS	1 ¹ ; 21:15				
COLOUR-DISTRIBUTION	<Red ant: 7, green frog: 5, yellow snail: 5, blue hedgehog: 3>	All	1; 28:05	HEDGEHOG-LUCK	<When blue hedgehog is lucky, it will get the blue faces a lot>	OS	1; 30:17

Ramona and Sarah identify the red ant as the best animal (ANT-BEST) already at the end of the second game (with 25 and 38 throws in total). When roughly seven minutes and two more games later the asymmetric COLOUR-DISTRIBUTION of the die is discovered, this is backing up the ANT-BEST pattern-construct (for more detail see Prediger & Schnell, 2011). At this point though, the girls notice that the order of the animals on the board game (with a total number of 28 throws) does not fit the expected order from the colour distribution: blue hedgehog is third and yellow snail is last. Ramona thus constructs HEDGEHOG-LUCK in order to explain the deviation in this one single game from the expected pattern:

Session 1; beginning 30:17;

After having played a game of 28 throws, the colour distribution is discovered

483f. Ramona: Blue has good chances, too, because- (...) Blue has sometimes a lot of luck and then it gets the three faces sometimes very often.

In this scene, variability is noticed as deviation from the pattern ANT-BEST. The discrepancy between the order of animals according to the COLOUR-DISTRIBUTION and the empirical result on the board is solved by building the construct HEDGEHOG-LUCK. Its function is to explain *why* this deviation occurred (i.e. the supposed “luck” of the blue hedgehog). In several other instances, LUCK is used again to *explain single deviations* of expected patterns, for example when blue hedgehog finishes on an unexpectedly high position in ‘Betting on Positions’.

2. Patterns versus absence of patterns (ML- and MS-context)

CONSTRUCTS ADDRESSING PATTERNS				CONSTRUCTS ADDRESSING VARIABILITY			
Short-title	Proposition	Sto. con.	Time	Short-title	Proposition	Sto. con.	Time
ANT _{100,1000}	<For series of 100 and 1000, red ant always wins >	ML	2; 52:20	DIFFER-ENT _{1,10}	<For series of 1 and 10 it is always different>	MS	2; 52:20
RANGES ₂₀₀₀	<For series of 2000, observed positions vary within certain ranges>	ML	3; 45:53	NO-RANGES ₂₀	<For series of 20, positions are always messed up and no ranges are observable>	MS	3; 46:16
HIGH-BARS-	<The higher the total number of throws, the less	ML	3; 87:39	LOW-BARS-	<For series of low total numbers of throws, bars	MS	3; 88:04

¹ The first number indicates the experiment session in which the construct was first verbalised.

LESS	move the bars in the diagrams >			MORE	move a lot>		
PERCEN TAGES- LIMITS	<Percentages have limits beyond which they don't change anymore>	ML	4; dyn 35:05	PERCENT AGES- CHANGE	<With steps of 20, percentages change a lot in the beginning>	MS	4; dyn 42:30

At the end of the first game type “Betting on Winning”, the students are asked to fill in an overview of all used record sheets, summarizing which animals won at least once for the total numbers of 1, 10, 100 and 1000 throws. After this, the girls are asked to verbalise their observation:

Session 2; beginning 52:15; after having filled in the overview table:

1079 Sarah: For 100 and 1000, [red] ant always wins. And for 10 and 1, it's always different-

In this statement, Sarah contrasts the stable *pattern* of the winning red ant for high total numbers of throws ($ANT_{100,1000}$; stochastic context ML) with the *absence of a pattern* of a specific winning animal for low numbers of throws ($DIFFERENT_{1,10}$; MS). Here, the function of the variability-construct is not an explanation of a single deviation, but a description of an observation Sarah made for a series of many games with a small total number of throws.

This contrasting of small and large total numbers of throws becomes a conscious strategy in the following, where Sarah first verbalises the construct RANGES: <Positions stay in certain ranges> and Ramona immediately projects this on the differentiation between small and large total numbers of throws:

Session 3; beginning 45:3; Predicting positions for games of 2,000 throws

769 Sarah: I was throwing the dice just like that, then I saw that 400 and 500-*points to screen*) mostly this gets 500 and sometimes also 400, this (*points to screen*) gets 700 and 600 and there 200 and 300.
(...)

772 Ramona: But that's only like that for 2,000. Ah yes, of course, right? Yes. Type in 20.
(...)

790 Ramona: (*After having looked at a series of games of 20 throws*) Ah, no, for 20, it's always mixed up.

Again, variability is constructed as the absence of stability ($NO-RANGES_{20}$). The idea of contrasting long-term and short-term contexts in the search for the existence of patterns is then also used for the bar-charts (constructs HIGH-BARS-LESS and LOW-BARS-MORE).

Furthermore, the influence of variability and patterns for finding a secure bet is made explicit in relation to the stochastic context:

Session 4, 73:30, at the end of playing 'Betting on Positions'

1057f. Sarah: [For 10,000] nothing moves, I think. No, not much. So it's easier to bet when you have these high numbers than the smaller ones.

Variability now seems to be a phenomenon which is actively addressed and influencing the security of bets.

This restriction, an absence of a pattern in games with small total numbers of throws, becomes a challenge when the girls encounter variability also for large total numbers of throws: When the game switches to percentages, a dynamic view of games' results is introduced and the results of every game are cumulated (which is discussed in detail with the interviewer at 33:15). While Ramona verbalises the construct <Percentages have limits beyond which they don't change anymore> (Session 4; 35:05) after a few games, the relation to the high total number of throws is not yet clear. Thus, the girls are asked to keep experimenting with the games.

Session 4; beginning 38:30; (Sarah keeps generating games of 20, so far 14 games of 20, i.e. a total number of 280 throws)

567 Ramona: The first digit [of the percentage, which are shown with three decimals, e.g. 35.0; cf. Fig. 2] always stays the same. And the last digit doesn't – never.

568 Interviewer: Hm.

569 Ramona: And in the middle, it stays the same, too. *(Sarah is generating more games of 20 throws; now roughly 3000 throws in total)* Yes, sometimes. But not always. For [blue] hedgehog it does- no it does not. Oh man!

While Ramona's initial reaction to percentages was to expect a stable pattern (PERCENTAGES-LIMITS), she is now struggling as the percentages keep changing. Maybe as a solution for this, she splits the percentages into the individual digits, for which she can find a stable pattern for the first decimal, the absence of a pattern for the last decimals, but then also encounters problems with the digit in the middle. Aside from the individual approach to percentages, this shows that for Ramona, the absence of patterns (and thus variability) means it *is* changing. A notion of changes that occur *more or less frequently* seems not yet established.

It takes four more minutes and generating several series of growing numbers before the girls can construct the variability observation as counterpart for PERCENTAGE-LIMITS and relate both to their stochastic context.

CONCLUSION AND OUTLOOK ON OTHER STUDENTS

When Ramona and Sarah start working in the learning environment, they perceive variability as the *deviation of a single game* from an expected pattern. This leads to building a construct which provides an explanation as to why this occurred — which is later used for outliers of all kinds. This initial conception of variability gets complemented when variability also occurs in series of games with small total numbers of throws. Here, the girls not only notice the *absence of a pattern* but keep

actively seeking for it when confronted with new representations. They are not giving explanations for these constructs but make use of the interplay of patterns and variability to evaluate the security of predictions in relation to a long-term and short-term context. Ramona's struggle with percentages shows, however, that the division of the two contexts (long term vs. short term) might be too rigid when it comes to a dynamic perspective. Since, up to this point, the students only addressed series of games with the same total number of throws, the contrast of patterns and no-patterns was sustainable. For the dynamic perspective though — and percentages specifically — the occurrence of occasional variations is posing a new challenge for Ramona.

The scenes presented here are snapshots from the learning pathways of two girls. Even though these pathways are highly individual, some common features of the pathways towards variability can be identified that appeared with all nine pairs of students: at the beginning of all design experiment series, constructs with the *function of explaining single deviations* could be identified. Their underlying conceptions are used less often over time when the *focus shifts to series of games* with a large total number of throws and are almost exclusively used for deviations of single games with small or large total numbers of throws.

While Ramona and Sarah find a meaningful way to deal with patterns and the absence of them by relating them to different stochastic contexts, the omnipresence of variability can also pose challenges of which patterns can be observed: Some students investigate how many of the four animals change their relative position to each other for series of small and large games (where green frog and yellow snail 'battle' for the second place) instead of focussing on the values of the differences of the outcomes.

Other students over-generalise the variability of outcomes per se: Even after having simulated many games with 10,000 throws in which only the red ant won, they explain this merely as an effect of "chance" and claim that another animal would win as often, if they played on another day or if someone else played the game. They deny the existence of (meaningful) patterns at all, before and even after discovering the asymmetric colour distribution.

Overall, most students from the empirical study managed to evaluate the security of predictions correctly in relation to short-term and long-term contexts. However, how they cope with encountering variability is highly individual. To understand these complex processes in more detail, further research focuses on a broader overview of the different conceptions of variability (cf. Schnell, 2013) and tries to identify types of processes of how conceptions develop when variation is encountered (cf. Schnell and Prediger, 2012; Schnell, 2013).

METAPHORICAL RANDOM WALKS: A ROYAL ROAD TO STOCHASTIC THINKING?

Jorge Soto-Andrade¹

CIAE and Department of Mathematics, Faculty of Science, University of Chile

We are interested in finding means to facilitating the access to stochastic thinking, especially for non-mathematically oriented learners. We argue that random walks are such means, since they allow a friendly visualisation of randomness, are amenable to experimental and enactive metaphorical study and provide “universal models” for a broad spectrum of stochastic problems. An explicit example of a didactical situation is given (Brownie’s walk) that has been tested with students and in-service teachers of various backgrounds since 2007. The findings suggest that this sort of approach significantly facilitates the access of non-mathematically oriented learners to otherwise cryptic mathematical notions, allowing them to construct them while solving situated concrete problems.

INTRODUCTION

We are concerned about facilitating the access to stochastic thinking. We are especially interested in approaches helpful for “general” non-mathematically oriented students in school, college and university. For instance, students majoring in humanities and social sciences or prospective or in-service elementary school teachers.

We claim that random walks provide such an access, indeed a “royal road” so to say.

Why random walks? Because random walks cross boundaries, appearing in the “natural world” as well as in the “cultural world”. They are a visual embodiment of randomness, that can be easily enacted and simulated, from primary school onwards. We can approach them in manifold ways: statistically, metaphorically, probabilistically... They provide “universal models” and metaphors for sundry phenomena. Indeed they facilitate the access of non-mathematically oriented learners to stochastic thinking, enabling them even to construct probabilistic notions while solving situated concrete problems. They show the way to a bottom-up approach to probability and statistics.

From the didactical viewpoint, it is crucial that the study of simple random walks may be undertaken “bare handed”, with practically no previous statistic or probabilistic tools or concepts. Students may tackle the paradigmatic question: *Where is the walker, after a given number of steps?* equipped with sheer common sense. Most important, they may realize that there are *several levels of answers* to this sort

¹ Supported by PBCT- CONICYT, Proyecto CIE-05

of question, the 0th level being: Nobody knows! For subsequent levels see the example of Brownie's walk below. Random walks also provide a propitious soil for the emergence of metaphors that make possible the construction of the concept of probability: for instance, the *probability* of finding the walker at given position at a given time appears as the *portion* of the walker found at that position and time.

Historically random walks appear rather late in science, as Brownian motion of pollen grains (Powles, 1978), although it might be argued that they were “anticipated” by Lucretius in 60 AD, who observed dust particles “skirmishing” under sunlight and thought this to be caused by “motions of matter latent and unseen at the bottom” (loc.cit). Contemporary examples include Brownian motion in metallic alloys (Preuss, 2002), foreseen by Einstein in 1905 (Einstein, 1956), besides fluctuations of stock markets! Interestingly, we find also instances of “cultural random walks”, quite motivating for humanists. Recall for example Saint Francis of Assisi's friars walking along the road network of medieval Italy to preach the Gospel, trying to be just an instrument of God's will. So they wanted to avoid choosing rationally their direction at each crossroad. Seen from the outside, their goal was to random walk in the road network, choosing at random at each crossroad. Saint Francis devised a clever method to implement this random choice: He told a friar to spin and whirl nonstop, in spite of dizziness or nausea. As a result (friars not being whirling dervishes) the friar finally collapsed and fell to the ground. Then the whole company would choose the road closest to the direction shown by the friar's head (Anonymous, ca. 1600).

In this paper, we describe a specific example of the use of random walks to introduce the students to stochastic thinking, that may be regarded as a first avatar of a fundamental didactical situation (Brousseau, 1998).

This approach has been tested with students and teachers with various backgrounds (ranging from scientific and humanistic students to in-service elementary school teachers and juvenile offenders). An a priori and a posteriori analyses were carried out, in the sense of didactical engineering. Finally, results obtained are discussed and some conclusions are drawn.

THEORETICAL FRAMEWORK: METAPHORS AND DIDACTICAL SITUATIONS.

Nature and Role of Metaphors in Mathematics Education.

It has been progressively recognized during the last decade (Araya, 2000; Bills, 2003; Chiu, 2000, 2001; English, 1997; Johnson & Lakoff, 2003; Lakoff & Núñez, 2000; Parzysz et al., 2007; Presmeg, 1997; Sfard, 1994, 1997, 2009, Soto-Andrade 2006, 2007, 2012, and many others) that metaphors are not just rhetorical devices, but powerful cognitive tools, that help us in building or grasping new concepts, as well as in solving problems in an efficient and friendly way: “metaphors we calculate by”

(Bills, 2003). See also Soto-Andrade (2012) for a recent survey. We make use of conceptual metaphors (Lakoff & Núñez, 2000), that appear as mappings from a “source domain” into a “target domain”, carrying the inferential structure of the first domain into the one of the second, and enabling us to understand the latter, usually more abstract and opaque, in terms of the former, more down-to-earth and transparent. We notice than in the literature the terms representations, analogies or models are often loosely used as equivalent to metaphors.

Recall that Grundvorstellungen (better translated as “fundamental notions” than “basic ideas”) for mathematical content, that are very often operationally equivalent to conceptual metaphors, have been developed for a couple of centuries in the German school of didactics of mathematics (vom Hofe, 1995, 1998). In the case of probability they are usually given in a more prescriptive way than we do here for metaphors (Malle & Malle, 2003).

Our approach regarding the role of metaphors in the teaching-learning of mathematics emphasizes their “poietic” role, that brings concepts into existence, described as “reification” by Sfard (2009).

Didactical Situations.

Instead of introducing first concept and tools that students will apply later to solving exercises and problems as in traditional teaching, in the spirit of Brousseau (1998), we aim at students constructing or discovering those tools and concepts, when trying to solve a problem or challenge, in the context of a didactical situation. The concepts or tools we intend to teach should emerge as “the” way to “save your life” in the given situation.

We describe the role of metaphors in didactical situations with the help of a “voltaic metaphor”: Metaphors are likely to emerge, as sparking voltaic arcs, in and among the learners, when enough “didactical tension” is built up in a didactical situation (Brousseau, 1998) for them. This requires setting up a suitable didactical situation and succeeding in having the students sustain and bear the necessary didactical tension. The notion of didactical tension deserves here further study.

OUR DIDACTICAL SITUATION: BROWNIE’S RANDOM WALK

Perhaps the most natural visual example of randomness is Brownian motion. So we begin by presenting Brownian motion to the students in an interactive form (using real time videos and also simulating applets). Then, the task of studying this phenomenon being complex, we try to settle for some “baby version” of it. Usually the students themselves have the idea of “simplifying” the phenomenon that we want to study, as much as possible, but without “throwing away the baby with the bath’s water”.

We consider here a specific “baby avatar” of Brownian motion: A 2D random walk, whose protagonist is a puppy, suitably called Brownie (as sometimes suggested by

the students themselves). Also an even simpler version, a 1D random walk may appear, that we do not consider here. We discuss below, somewhat halfway between “bricolage” (Gravemeijr, 1998) and didactical design (Artigue, 2009), how this random walk has been tackled by the students with the help of suitable metaphors and without a previous knowledge of probability or statistics.

Where is Brownie?

Brownie is a little puppy that escapes randomly from home, when she smells the shampoo her master intends to give her. At each street corner, confused by the traffic’s noise and smells, escaping barely from being overrun, she chooses equally likely any of the 4 cardinal direction and runs nonstop a whole block until the next corner. Exhausted, after 4 blocks, say, she lies at some corner. Her master would like to know where to look for Brownie and also to estimate how far she will end up from home...

Research background (the students)

- a) primary school teachers enrolled in a 15 month professional development program, at the University of Chile, aiming at improving their mathematical competences, from 2007 to 2010 and in 2012.
- b) 1st year University of Chile students majoring in social sciences and humanities, from 2007 to 2012 (1 semester mathematics course).
- c) University of Chile undergraduates majoring in mathematics and physics (one semester probability and statistics course) in 2009-2011.
- d) University of Chile prospective secondary school teachers (one semester probability and statistics course) in 2009 – 2011.
- e) Secondary school teachers enrolled in various professional development programs, in Chile, in 2006-2008 and 2011-2012
- f) elementary school students (6th to 8th grade), whose teachers were engaged in the professional development program described above (in progress).

Methodology

Learners were observed by the author and two assistants during work sessions (some of them videotaped), their written outputs were kept or scanned. They also answered questionnaires related to their use, appreciation and preferences regarding metaphors used in courses a) and b). Learners a) and e) did group work most of the time. Other learners participated in interactive lessons with a high degree of individual participation, horizontal interaction included.

We describe now the a priori and a posteriori analyses in the sense of didactical engineering or didactical design (Artigue, 2009) related to this experimentation.

A priori analysis.

The mathematical situation.

We have several approaches to the problem.

“Arid” theoretical approach: We calculate stepwise the probabilities of finding Brownie at the different crossings in the city map. We obtain in this way the probability distribution of the sequence of random variables $X_n =$ “Brownie’s position after n steps” and $D_n =$ “distance of Brownie to the origin after n steps”. To obtain a general expression for this distribution, a clever idea is to do harmonic analysis and synthesis of these processes with respect to the (non-commutative!) symmetry group of the random walk.

Statistical approach: To see what is going on, we can make a statistical simulation of the random walk, eventually using a worksheet.

Metaphorical approach: With the help of a “hydraulic metaphor” (Soto-Andrade, 2006, 2007), we replace the puppy’s random walk on the city map by a fission or sharing process on a grid. There we may see, for instance, the grid as a system of ducts and imagine a litre of water at the origin that flows symmetrically and fairly to the 4 next neighbours, each time. We have then to calculate stepwise with a deterministic process, which is equivalent to the original stochastic process, but has the virtue to avoid probabilistic language.

The didactical situation.

Working in groups, the teachers or students should realize quickly that there are impossible corners (street crossings) for Brownie, even close to her home. There might be divergent opinions on whether returning home is possible after 1 or 3 blocks, for instance. Then, after having spotted the corners where it is possible to find Brownie (after a 4 block run), some (up to one half of the) students or teachers will believe that they are equally likely. Others would have the vague intuition that some corners are more likely because Brownie can get there by several different paths.

Quite late, some will have the idea of experimenting, by simulating a good number of puppies, to try to settle the question. The majority of them will now be convinced that some corners are more favorable to find Brownie; her home for instance. They will not have much trouble in setting up a corner *ranking*. But they will have some trouble in quantifying their feeling of bigger or smaller likelihood. How to assign “weights” to the different corners? Some will usually think of counting paths to quantify their vague feeling.

It is likely that the “Solomonic metaphor” (cut the puppy into four pieces) or the “hydraulic metaphor” (the puppy flows equitably to the four immediate neighbours) will not emerge spontaneously. But this could happen under some minimal prompting like: *What, more concretely, could you imagine instead of this (rather abstract) fair random choice between the 4 cardinal directions?* (using some discrete gesture language).

The students or teachers should not have much trouble quantifying the likelihood of presence of the puppy at the different corners, with the help of the hydraulic metaphor. They will realize quickly the conservation law of the puppy: putting together her pieces at each step you reconstruct the whole puppy. The idea might also

emerge in the classroom to unleash a pack of puppies from home, that would spread out evenly, splitting into four equal groups at each corner (better begin with 16 puppies that will run 2 blocks each). We call this a “pedestrian metaphor”.

So we hypothesize that – eventually under some prompting – Solomonic, hydraulic and pedestrian metaphors may emerge, that will enable the students to solve the problem for a given (small) number of steps. Path counting will also emerge as a competing strategy to quantify likelihood, especially among students having being previously exposed to more mathematics.

A posteriori analysis.

Unexpectedly our primary school teachers had a strong tendency to see without hesitation the 9 possible corners for Brownie after a 2 block run as equally likely! Dissenting opinions emerged very slowly among them. On the contrary learners from groups b), c), d) quickly sensed that corners closer to her home were more likely.

We have witnessed the emergence in the classroom of metaphors like the Solomonic, hydraulic or pedestrian one (Soto-Andrade, 2006, 2007) right after the students or teachers were prompted to try to see the situation “otherwise”, while working in groups, with discrete support from the facilitator. Typically in a class of 30, one or two immediately “see” the puppy split into four pieces. These metaphors emerged more easily from learners in groups a) and b). Initially however many teachers seemed to have feeling that they were violating some (unspoken) didactical contract when allowing themselves to metaphorize.

In cases where this sort of visualization seemed out of reach, the hydraulic metaphor enabled us to act out the situation: 13 in-service elementary school teachers distribute themselves suitably on the nodes of a virtual grid on the floor, one of them holding a container with 1 litre water that she shares equitably with her immediate 4 neighbours, and so on... Each one of them could estimate the amount of water that

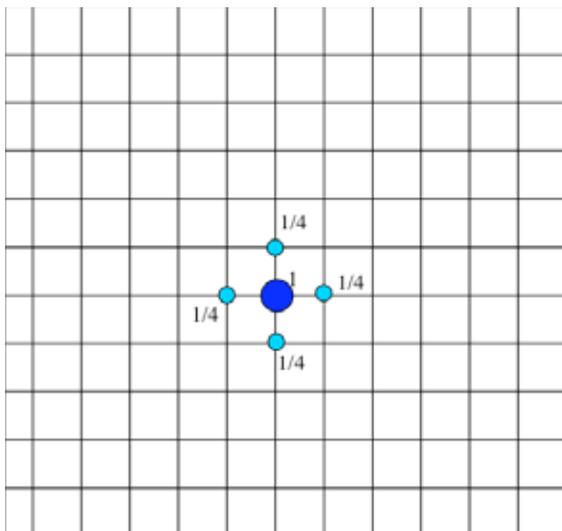

Fig. 1 Brownie’s splitting (0 and 1 block).

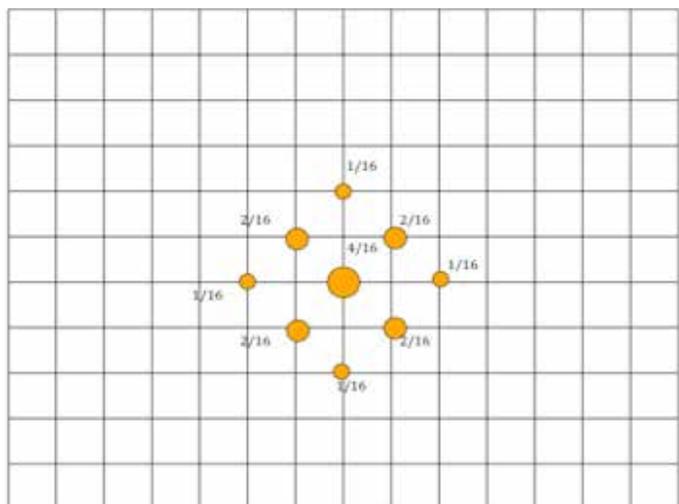

Fig. 2. Brownie’s splitting (2 blocks).

she will have after a given number of steps. Eventually they simulate this (more easily although less dramatically) with a square of board that they partition into four pieces and so on. See figures 1 and 2 above.

Results

As hypothesized, Solomonic, hydraulic and pedestrian metaphors did indeed emerged among our students, eventually with the help of some prompting. Path counting appeared also, among more mathematically literate students, leading to an assignment of probabilistic weights based in Laplace rule. One obstacle to the emergence of metaphors was the current didactical contract saying that metaphorizing is not good mathematical manners. Enacting the walk with the help of a hydraulic metaphor was a big help for most learners, especially for elementary school teachers.

With this course of action, most students and teachers succeeded in constructing the concept of probability at the same time that they solved the problem in context, with the help of suitable conceptual metaphors, in the sense of Lakoff and Núñez (2000).

Discussion

Our voltaic metaphor seems suitable to describe what happened in the classroom, regarding the emergence of metaphors that enable the learners to solve the problem they are tackling. To build up the necessary didactical tension is here crucial but not easy, especially when working with big classes (more than 50 students).

On the other hand, we remarked that in our hydraulic acting out of the random walk, each participant does something very simple, but the outcome is the analogical solution of a non trivial problem. This could be seen as just one simple example of application of “swarm intelligence” to the didactics of mathematics.

Also the role of the teacher in this sort of “mise-en-scène” turns out to be quite delicate. Definitely better than the metaphor “a teacher is a technician” emerges here the metaphor “a teacher is a tightrope walker”. In particular, experience shows that didactical micro-gestures of the teacher - tightrope walker may feed a butterfly effect in the classroom.

Notice that in our metaphoric approach the students are not given a “Grundvorstellung” (fundamental notion) for probability before they address the problem. On the contrary, they are prompted to tackle the problem “bare handed” first and eventually look for a friendly metaphor for the *concrete random walk* they want to study (e.g. “Brownie splits”). When trying to give pertinent answers to the questions asked, “poietic metaphors” may emerge that enable them to construct the abstract probability concept, like: “probabilities of finding Brownie at a given corner are pieces of Brownie”. This fits the framework of Brousseau’s didactical (better, adidactical) situations (Brousseau, 1998).

Brownie's walk seen from Google Earth (zooming out).

First, Brownie's walk can approximate efficiently Brownian motion: just make the grid denser and denser...If you zoom out, with the help of Google Earth, tracking Brownie with GPS, you will see the trajectories of pollen grains.

Second, the title of this section is also metaphoric: if we zoom out cognitively, we realize that Brownie's random walk is a paradigmatic example of a random walk (a metonymy, in fact) and that random walks play very often the role of universal models in probabilistic as well as statistical problems. For example:

1. The famous Italian unfinished tournament problem: Two players of equal strength compete in a tournament that consists of a series of games. The winner, who will get the one million euros prize, is the one who completes 10 wins first. Now, the tournament must be interrupted by "force majeure" when one player had won 8 times and the other 7 times. How should the prize be divided fairly between the two players?

This problem can be solved very easily by modelling or metaphorizing it by a random walk (a 2D one!) and solving the random walk metaphorically. This is friendlier than Pascal's classical solution (apparently he was not very fond of random walks). If we recall that "mathematics is the art of seeing the invisible" (Soto-Andrade, 2008) we would agree that students are doing real mathematics when they see the evolution of the tournament as a random walk on a 2D grid with absorbing barriers.

2. Evaluating screening tests (e.g. false positive problems) is a tough task for experienced physicians (Zhu & Gigerenzer, 2006; Gigerenzer, 2011). The typical question that physicians answer wrongly is: "I have got a positive HIV test, how likely is that I am really a carrier?"

Natural frequencies have been suggested (loc. cit.) as a means to get a correct answer without much toil, in a way a 10 year old could do. But if you look at this problem as a question about a (2 step) random walk, that you can solve with the help of a pedestrian metaphor, you recover exactly natural frequencies.

It is interesting to compare the relative popularity, among students in various levels and countries, of the hydraulic and pedestrian metaphors. According to Gigerenzer (loc. cit.), pedestrian metaphors (i.e. natural frequencies) should be much more popular, because you just manipulate whole integers and you compute a fraction only at the very end, or even you get your result in the form " m out of n ", as in pre-fraction days, that is all the same efficient for practical purposes. In the hydraulic metaphor however you need to manipulate fractions all the way. We have found experimentally however, consistently year after year, that 1st year university students majoring in Social Sciences and Humanities (group a) above) tend to prefer the hydraulic metaphor (8 out of 10 approx.), even if computing with fractions is not all that smooth for them. Apparently one reason for that is the *conceptual* impact of seeing one litre of grapefruit juice (or probabilistic fluid, if you like) draining downwards

through a graph of ducts, something that helps them tackle Zeno's paradox, for instance.

3. The classical fundamental didactical situation of Brousseau (1998) for statistics where 7th graders try to find out the composition of a bottle containing 5 marbles of 2 different colours by looking inside through a tiny opening (that lets them see just one marble at a time), can be modelled by a random walk in the plane that “ends up” engaging into *one* region out of four possible wedge-like regions (corresponding to the 1-4, 2-3, 3-2 and 4-1 compositions)

CONCLUSIONS.

We claimed that random walks are a means to facilitate access to stochastic thinking, especially for non-mathematically oriented learners. As grist to the mill of this claim, we described here an explicit didactical engineering for a concrete example of a random walk (Brownie's walk) whose bare handed study facilitates the construction of the concept of probability, thanks to the likely emergence of various helpful (mainly enactive) metaphors.

We have tested this didactical engineering with learners of several backgrounds, students as well as in service teachers across Chile. According to their performance (assessed by tests and group work) and answers to questionnaires and interviews, this approach (random walks metaphorically tackled) did help them to understand and even construct otherwise cryptic mathematical notions and to solve problems involving randomness in a friendly and efficient way (e.g. false positive problems). We noticed some initial resistance to metaphorizing, mainly among university students majoring in mathematics and secondary school teachers. University students majoring in humanities and social sciences and primary school teachers were more prone to metaphorizing, especially after being granted permission to do so (“you are not supposed to metaphorize in mathematics” seems to be the implicit current didactical contract). Among university students remarkable metaphorical capacities were detected in students coming from alternative schools, like Montessori or Waldorf. Otherwise it seems clear that traditional teaching in Chile, especially from grade 7th onwards tends to thwart metaphorizing. This suggests promoting this approach already at the beginning of elementary school and exploring related approaches emphasizing embodiment and enaction. Further research on this didactical phenomenon, quantitative as well as qualitative, seems commendable.

STATISTICAL UNDERSTANDING AND LANGUAGE – A QUALITATIVE ANALYSIS

Ute Sproesser, Sebastian Kuntze

Ludwigsburg University of Education, Germany

This paper presents results of a qualitative study based on data from 83 German eight-graders on the role of language for the understanding of a statistical problem. As competencies in the domain of statistics are necessary for social participation, communication skills related to basic statistical models appear as crucial. Language thus comes into play at various levels when learners make sense of situational contexts statistically or when they present solutions. Misconceptions might be connected to a development need of domain-specific language. The results of this study suggest that the development of the understanding of statistical problems is framed, i.e. enhanced or restricted, by a corresponding development of domain-specific language. Language-related knowledge thus could benefit from focused support in corresponding learning environments.

INTRODUCTION

Language plays a role for statistical thinking—not only abilities of data-related reading (e.g. Curcio, 1987) appear as crucial, but it is also important to be able to express statistical observations or ideas in an adequate language. Whereas competency aspects of data-related reading can be assessed with test instruments and have been integrated in competency models for statistical literacy (cf. Watson & Callingham, 2003; Kuntze, Lindmeier & Reiss, 2008; Kuntze et al., 2010), the area of data-related speaking or writing calls for more focused empirical research.

Consequently, this study investigates the relationship between students' understanding of a given problem and their ability to express their ideas in a statistically adequate language. Through this focus and on the basis of this problem, we try to get insight how secondary students' statistical understanding could be supported. The students were given problems related to statistical contexts and asked to give written answers. An analysis of these answers focused on the way students expressed their ideas and in particular on the role of language for the statistical understanding shown in the answers. The results of a case-based analysis indicate that some students have difficulties that appear to stem from the area of language use rather than from their pre-formal statistical understanding. Such pre-formal understanding could even be further developed by learning opportunities targeted on language.

THEORETICAL BACKGROUND

In moderate constructivist approaches to learning, there is an epistemological consensus that building up knowledge is closely linked with the development and re-

finement of language: This is not only the case for learning in the early childhood but also up to the contexts of domain-specific academic knowledge (cf. Reinmann-Rothmeier & Mandl, 2001; Vygotsky, 1986; Radford, 2003; Sfard, 2013).

For instance, when making sense from situations in which the interpretation of data is required, learners draw on their prior experiences and knowledge. Such knowledge is often pre-formal, like Fishbein's (1975) primary intuitions. The same appears to apply for language, which also develops from pre-formal to a more formal use of domain-specific language (Vygotsky, 1986). However, both of these development processes have shown to be far from 'linear': Neubert and colleagues (2001) describe the learning process by the terms of deconstruction and reconstruction which continuously frame the interaction of individuals with the surrounding socially influenced perception world.

In the domain of statistics, there is still little empirical evidence about the interplay of pre-formal statistical knowledge and language. However, language is considered to come into play when students have to decode a complex statistical situation or when they have formulate questions or conclusions from data (Shaughnessy, 2007). When passing through PPDAC cycles (Wild and Pfannkuch, 1999), language may frame the corresponding statistical thinking process. Gal (2003) identified the ability to express someone's opinion concerning statistical information as crucial for statistical thinking and statistical literacy. Gal as well as Watson (1997) emphasised the importance of the adequate use of statistical terms as well as the ability to (critically) communicate one's reaction to statistical information, which makes reference to the two areas of language and domain-specific knowledge introduced above. Even though Watson and Gal underlined the importance to use standard statistical language and although Biehler (1997) points out that some problems in data-related communication are caused by a lack of formal language, we see the need to focus also on pre-formal language use. In line with Makar and Confrey (2005), this study hence examines students' abilities to express their ideas and their understanding of a statistical situation regardless the level of abstraction of the language used. By accepting all stages in the development of domain-specific language in the analyses of cases of students' answers, we strive to access their statistical understanding of the situation, focusing also on elements of pre-formal knowledge. This corresponds to a research need, as questions such as how statistical understanding develops together with language or how statistical understanding can be fostered in learning environments focusing on language have not been answered fully in prior research.

Concerning our research interest related to language use and statistical understanding, we would like to recall that we keep distinct the (potentially non-verbal) statistical understanding of learners from the form this understanding may be expressed by means of language. It may appear as relatively obvious that a developed statistical understanding may coexist with a high statistics-specific language mastery, or that difficulties in the statistical understanding such as inconsistent pre-formal knowledge

can coincide with difficulties in statistics-related verbal expression. But there could also be the following cases: For example, a student might have a developed pre-formal statistical understanding of a phenomenon (in the sense of intuitions, cf. Fishbein, 1975) coupled with a low ability to express this understanding with domain-specific vocabulary. Conversely, a learner might have acquired a “language toolbox” related to statistics but as a consequence of a non-optimal statistical understanding, he or she might be unable to use this vocabulary adequately in a corresponding argumentation (cf. Makar & Confrey, 2005). Even if we assert that all four cases are basically possible, we expect based on Vygotsky’s (1986) general approach to thought and language that the development of specific language supports statistical understanding and that non-verbal statistical intuitions may promote the process of making sense of statistical vocabulary. Students’ abilities to express their statistical understanding as well as the role of specific language development for aspects of statistical thinking thus require in-depth empirical attention.

Consequently the study focuses on the following research questions:

How do students express their ideas and their understanding of statistical problems?

How developed is students’ statistical understanding and how adequate is their corresponding domain-specific language use?

DESIGN AND METHODS

This study was carried out as part of the project ReVa-Stat, (“Developing concepts of data-related reduction and statistical variation as a support for building up statistical literacy”). In the first phase of this research project, 83 students of grade 8 (39 girls and 44 boys, mostly 14 years old) were asked to work on tasks related to different statistical problems. These tasks addressed activities such as organizing and representing data as well as reflecting about variation or data. As the students had not attended any specific statistics course prior to participating in this study, they were asked to describe their ideas in their own words. We did not stimulate students to use a specific type of language. During four lessons, the students worked on this specific learner-centred material, which affords exploring their understanding, views and ways of expression. In the material, students were encouraged to first discuss the presented statistical problems in pairs and then to write down their answers. Data was gathered by collecting their written work. During the work phase of the students, a member of the research team observed the implementation and use of the material in the classrooms.

In the following, we focus on answers the students gave when working on tasks in a relatively early phase (first lesson) of their work with the learning material. The task (see Fig. 1) refers to the context of frequencies of colours in packages of chocolate lentils (cf. Engel & Vogel, 2005, and Eichler & Vogel, 2012, for the task context, Watson & Callingham, 2003, for the question format). Prior to this task, students had been informed that a sweets company produces the same number of chocolate

lentils of each of the 6 colours, they had then been given a package of 24 chocolate lentils as well as data about 9 more packages. The students had also been asked to calculate the average for every colour within the 10 given packages. The purpose of this activity was to give them hands-on experience that the mean is less variable than the original data. The students were asked to comment on their decisions for the three given diagrams.

- Some of Marie's classmates were asked to open several packages of Chocolate Lentils and to represent the numbers (of the different colours) in a bar graph. Marie, however, is sure: "A few of my classmates cheated! They didn't really count, but they just invented the numbers!"

What do you think: which diagrams have been invented? Justify your answer!

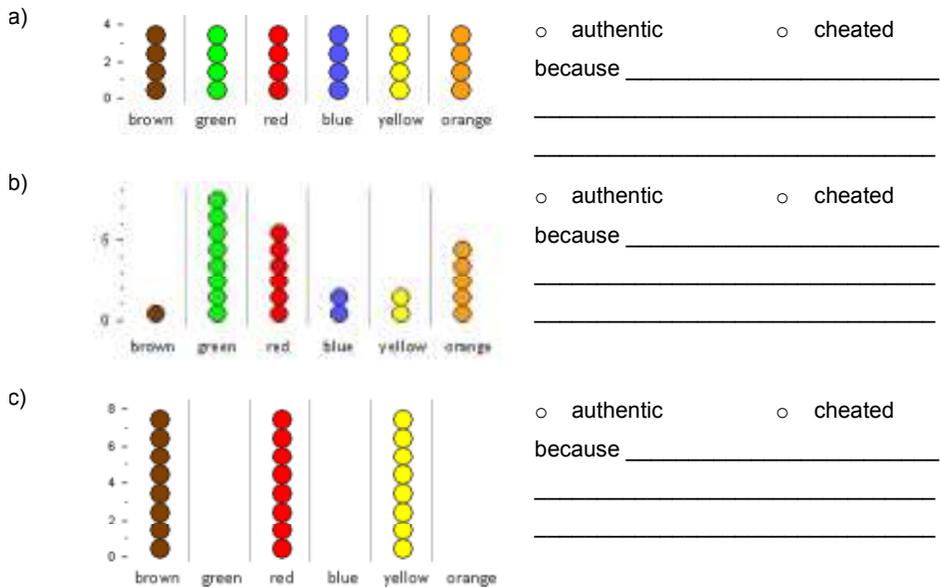

Figure 1: One of the “Chocolate Lentils“ tasks

The written results of the work of the students were analysed using a qualitative bottom-up methodology based on Mayring’s qualitative content analysis (2000). An interpretative analysis of the data was carried out by two researchers.

In this analysis, we were aware that also on the methodological level, examining whether a learner has a particular understanding of a specific situation is an interpretative and once again a construction process on the base of the learner’s expressions, in which her or his prior pre-formal or formal knowledge may be reconstructed through an interpretive process (Vygotsky, 1986; cf. also Neubert, Reich & Voß, 2001).

In a first step of the analysis process, particular cases of students’ answers were selected against the background of the research interest in order to identify types of answers inductively. In a second step, these cases were analysed in more depth so as to further develop categories. In a third step, the developed categories were used to obtain an overview of the whole sample. For this purpose two researchers rated all cases and were able to classify them according to these categories in a top-down coding procedure. To deliver insight in what we conceive to be the categories of “relatively high/low language mastery” and “relatively high/low understanding”, which were developed in the first and second steps of the analysis process, Table 1 shows the corresponding coding scheme for this third analysis step. Note that the term “understanding” is used to describe students’ ability to get into the core problem in the

sense of Fishbein’s intuitions (1975) whereas the notion “language” describes the students’ way to express the own thoughts concerning the given task.

Statistical understanding	
A: Relatively high statistical understanding / pre-formal knowledge	At least intuition visible that the core problem is to judge the regularity vs. the variation of the shown structure, Argumentation can be general or experience-driven.
B: Relatively low statistical understanding / pre-formal knowledge	The student did not realize that the regularity vs. the variation has to be judged; other irrelevant argumentation or lack of argumentation.
Language mastery	
1: Relatively high language mastery	Appropriate use of terms such as “distribution”, “(ir)regular”, “(non)uniform”, “(un)systematic”, “(un)equal”, ... ; description of probability / frequency with terms like: “seldom/rare”, “often”, “probable”, “randomly”, ...
2: Relatively low language mastery	No or inappropriate use of the terms above; description of the situation without generalisation (e.g. “There are differences.”); over-generalising way of expression (e.g. “In every package there are all colours.”)

Table 1: Overview of coding scheme for third step of analysis (top-down coding)

RESULTS

In the following, we will discuss the answers of three students referring to the above-mentioned coding scheme.

A sample answer of a student is presented in Figure 2 („Peter“). In his answer, Peter uses the word “distribution”. This notion is described as “uniform” and “non-uniform” in the case of a) and b). According to Peters answer in b), in “real”, the distribution is “fairly non-uniform” in his view. This expression appears to describe his understanding of statistical variation in this situation. The ways he uses the notion “distribution” in a) and b) enables him to characterise the data shown in the diagrams and to develop short and relatively dense argumentations.

Interestingly, Peter’s use of language in the answer to c) shows that he has made sense of the term “distribution” in an individual way: He argues that the distribution “is simply too big”. In our analysis, two possible interpretations have emerged: Peter either uses the term “distribution” in a different way here than in a) and b), which may suggest that the connection of the word “distribution” to a statistical concept is

still relatively loose, or he sees the word and concept of “distribution” like shifting balls between rows in the diagram, so that a perfectly uniform distribution would then be a ‘small distribution’ (because there would then be little concentration of balls in any of the categories), whereas an accumulation of all balls in one category would then be the ‘highest possible distribution’.

What do you think: which diagrams have been invented? Justify your answer!

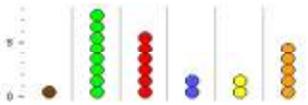

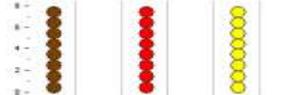

- | | | | |
|----|---|--|--|
| a) |  | [Geschummelt] weil „es sehr selten so [eine] gleichmäßige Verteilung“ [gibt] | [cheated] because “very rarely such a uniform distribution” [occurs] |
| b) |  | [Echt] weil „die Verteilung recht ungleichmäßig ist wie in echt.“ | [authentic] because „the distribution is fairly non-uniform like in real”. |
| c) |  | [Geschummelt] weil „die Verteilung der M und Ms einfach zu groß ist.“ | [cheated] because “the distribution of the M&Ms is simply too big”. |

Figure 2: Peter’s answers

In the case of Peter’s answer to question c), it is very probable that he has a correct statistical understanding of the situation without however perfectly mastering the language side in the sense that he would be able to share his thoughts using the domain-specific vocabulary adequately. Both interpretation alternatives further suggest that the language use in his answer not only points to a need of some further refinement of conceptual understanding related to the notion of ‘distribution’, but also that knowledge about the use of language itself should be supported in order to enhance his understanding.

The example of Peter’s answer also gives insight into the development process of domain-specific language together with conceptual understanding. Whereas Peter uses the notions of uniform and non-uniform distribution showing and applying corresponding understanding, his answer to c) (“big” distribution) shows that his domain-specific language concerning the term “distribution” still needs to be refined. In equal measure, he might not be familiar with the underlying concept, which supports the assumption that the development of conceptual understanding goes together with a development of language.

Anne (see Figure 3) answers question a) and b) by referring to her own experience with packages of chocolate lentils. She gets into the problem in a very elementary way—we do not know whether she has the statistical understanding related to the concept of probability, i. e. whether she sees that it is quite improbable to encounter a package with an exact uniform distribution without any variation like in the case of a). She might have an intuitive and experience-driven pre-concept in this area but is not able to express her ideas through more specific terms. Comparable to this example, she appears to have recognised a similarity between her package and the distribution shown in case b) but she lacks describing this phenomenon. Very probably,

she had not found identical frequencies in her package in the prior experiment, but the similarity she sees is a structural one, with frequencies showing statistical variation. Anne obviously has the language ability for describing her experience, however she might still not completely be able to express her thoughts beyond the specific experience.

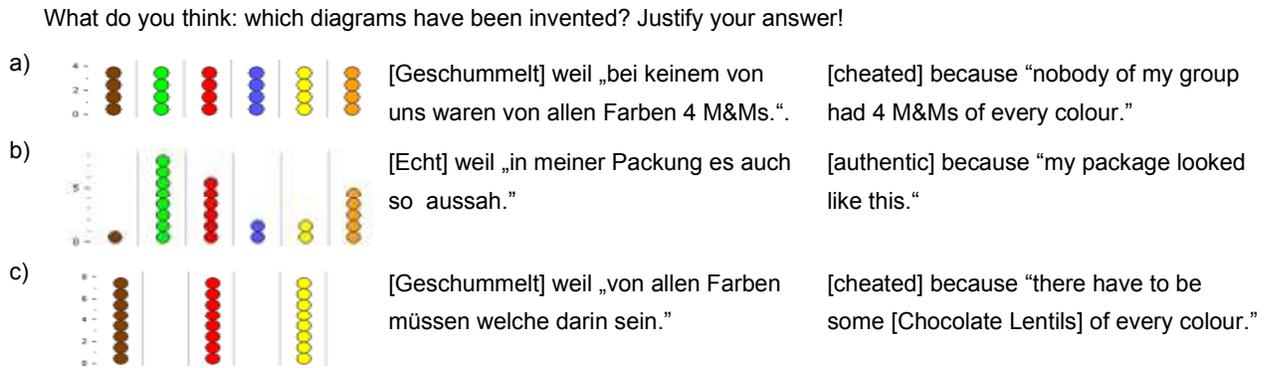

Figure 3: Anne’s answers

At the first sight, Anne’s answer to c) seems to reveal a lack of conceptual understanding, as she claims that all colours must be there in each package. In particular, prior to working on this task she had access to packages with missing colours. This makes it more likely to interpret her answer as an expression of irritation by the balanced distribution that might not have appeared “typical” to her. In contrast, in her written answer, she focuses on a different aspect. This utterance might hence be a case in which the statistical understanding diverges from the written answer, possibly as a consequence of a non-ability of expressing the statistical understanding in words. However, the analysis yielded this interpretation as one possibility among other possible interpretations.

Anne’s answers reveal a certain understanding (at least in the sense of intuitions, cf. Fishbein, 1975) of the statistical situation. However, she is not able to communicate her ideas neither using standard language nor using more general terms.

Figure 4 shows Tim’s answers. In contrast to the previous examples, Tim might have misunderstood the problem or have used an inappropriate logical structure. In case a) he argues that the distribution is authentic because the number of chocolate lentils in the shown package is 24, as stated previously in the learning material. His emphasis that “this corresponds to the truth” shows that this observation predominates over other possible considerations, so that he appears not to seek for other possible criteria for his judgement. Although he explains in a) his decision by the number of chocolate lentils, in b) and c) he changes his justification. However, again one single criterion is dominant, and Tim does not question whether the aspect is relevant. Now, his reason for the authenticity of the distribution is that “there is at least one chocolate lentil of every colour”. The order of the words in Tim’s answer (“at least” appears to have been inserted in the wrong place) indicates that he had later seen the

need of inserting the “at least”, probably because he saw that the frequencies were not all equal to one. In this case, Tim has obviously tried to make the language of his answer more exact, without however developing a more deepened understanding for example of statistical variation.

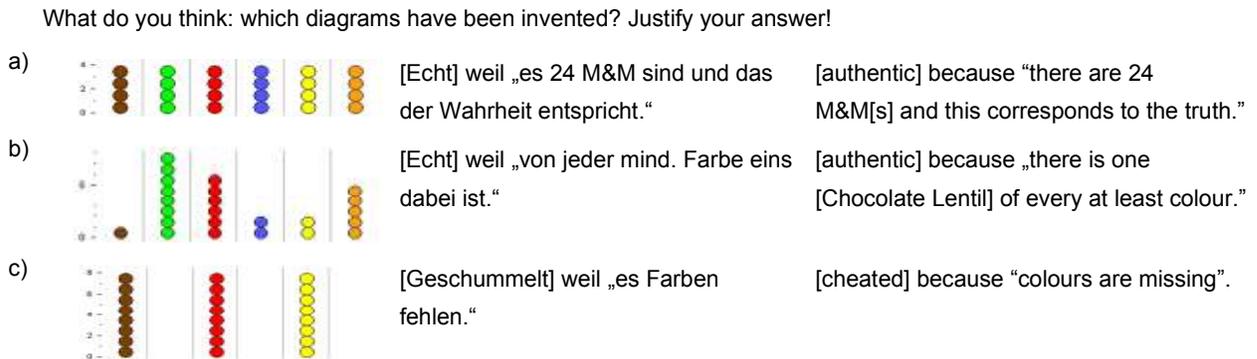

Figure 4: Tim’s answers

Finally, Tim justifies the decision that c) is invented with the statement that “some colours are missing”. We do not know if he thinks that the author made a mistake and “forgot” these colours or if Tim considers such a distribution as atypical.

Both from the point of view of statistical understanding and language, Tim’s answers suggest a need of further development. In this case, both the level of being able to communicate with statistical terms and the level of having corresponding conceptual understanding show deficits.

As a result of this case-based qualitative bottom-up analysis, we derived categories from the interpretation process of selected cases. Figure 5 gives an overview of these categories. In these categories, qualifiers like “low” and “high” refer to the sample of the cases in our study and hence will have to be adjusted in potential adaptations to other samples.

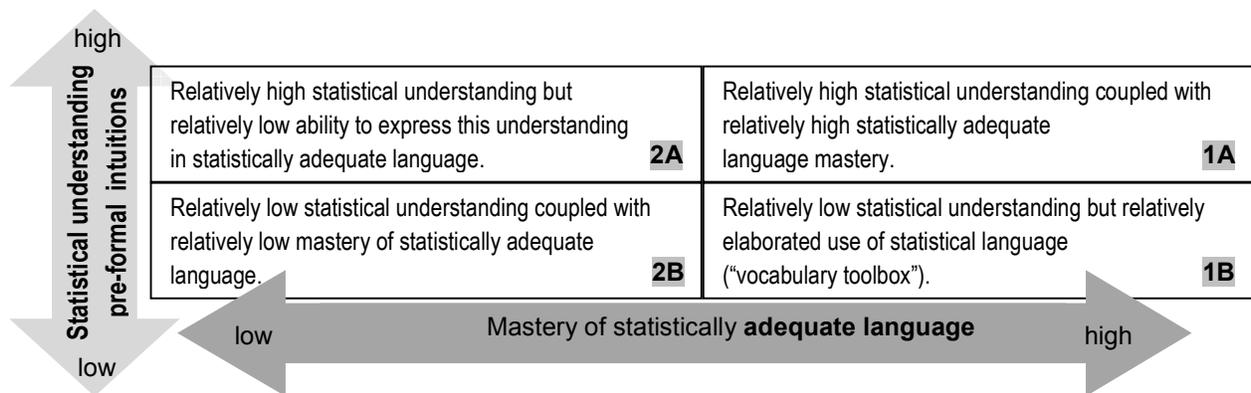

Figure 5: Bottom-up categories

In the third step of this study, a top-down coding procedure was done with all 83 cases of answers using the categories in Figure 5. The analysis was done by two

raters independently (inter-rater reliability: $\kappa=0.86$). In all cases with different codes an a-posteriori agreement of the raters could be reached in a subsequent joint interpretative analysis. The analysis yielded that 52 out of 83 cases were assigned to category 2A, which means that they have at least an intuitive understanding of the statistical situation, being however unable to express this understanding in adequate language. Fewer students were classified into the categories 1A (13 out of 83), 1B (1 out of 83), and 2B (17 out of 83). Whereas Peter's answers (Fig. 2) can be seen as a case illustrating category 1A, Anne's (Fig. 3) and Tim's answers (Fig. 4) have been classified into categories 2A respectively 2B.

DISCUSSION AND CONCLUSIONS

Consistent with the findings of Makar and Confrey (2005) the examples presented above as well as the results of the top-down analysis of the whole sample show that the students frequently use every-day language to express their ideas related to the statistical problem considered. Often, the non-availability of adequate notions affected the quality of their statements. Moreover, the use of appropriate language and the statistical understanding appear to be interrelated and both appear to play an important role for the ways students approach statistical problems, supporting Shaughnessy's (2007) assertions. In the sample of this study, the language development tended rather to have lagged behind the development of pre-formal knowledge or understanding. In more general terms, both areas—the refinement of statistical understanding on the one hand and the domain-specific language development on the other—appear as almost two sides of a medal, for their complementary importance for conceptual learning; the evidence appears to be in line with Vygotsky's (1986) thoughts, reflecting them in the domain-specific context of the given statistics problem. Figure 6 gives a schematic overview of this domain-specific complementarity.

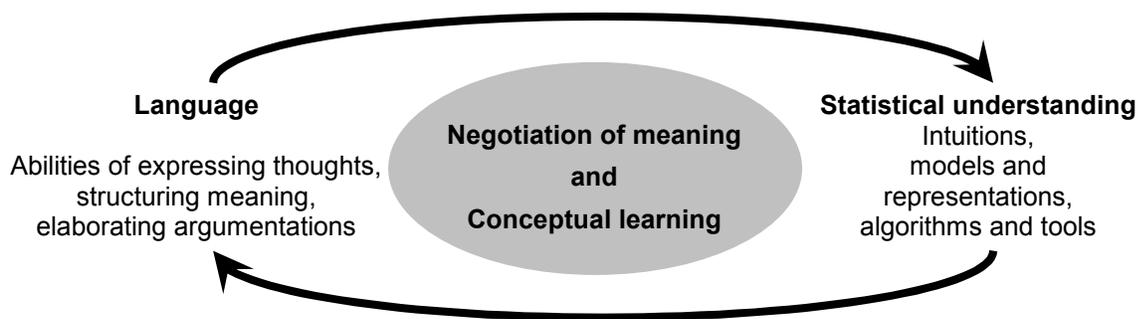

Figure 6: Language, statistical understanding and conceptual learning

Expressing statistical thoughts by means of written language often requires reorganising and deepening these thoughts—and it is hence a learning opportunity. In particular, misconceptions and incongruencies in statistical understanding often get apparent and can inform teachers and students about the stage of the ongoing learning process.

For building up statistical thinking in the classroom, the findings raise the question how a combined instructional focus on the development of statistical understanding and language can be implemented. We conclude that an explicit awareness of language can also foster the students' statistical understanding. In a follow-up study, effects of corresponding learning materials with an emphasis on language use will be examined.

8TH GRADE STUDENTS' STATISTICAL LITERACY OF AVERAGE AND VARIATION CONCEPTS

Ayşe Yolcu, Çiğdem Haser

Hacettepe University, Middle East Technical University

The purpose of this study was to investigate 8th grade students statistical literacy in average and variation concepts through Watson's (1997) three tiered framework. A total of 1074 eight grade students were surveyed with an instrument developed by researchers about statistics content in the elementary mathematics. Students' responses were examined through nine major questions in this instrument for this study. Descriptive analysis of correct and incorrect responses indicated that majority of students understood average and variation concepts though measures of central tendency and spread. Reasons of results and educational implications were discussed.

Keywords: Statistical Literacy, Average, Variation, Elementary Students

INTRODUCTION

Statistical messages have extensively been in the media through several types of arguments, advertisements, or suggestions (Ben-Zvi & Garfield, 2004). Therefore, the ability to understand, interpret, and critically evaluate statistical messages in daily lives of individuals which have been addressed as “statistical literacy” (Watson, 1997), has become important in information societies. Gal (2004) provides a statistical literacy conceptualization and its elements in a model for adults or “future adults”, in his term. In this model, communication with statistics, interpretation and judging of statistical claims are treated as the possible skills of statistically literate individuals. In addition statistical literacy plays a crucial role in public and private decision making of individuals where their daily life is full of data (Wallman, 1993).

Statistical literacy has also been a part of the school mathematics curriculum to prepare students to encounter the needs of society when they complete their compulsory education (Watson & Callingham, 2003). Understanding of average and variation is fundamental for statistical literacy as the words “average”, “variable”, or “vary” are a part of everyday language (Watson, 2006). Although there are studies in the literature examining statistical literacy from different aspects such as sampling (Watson & Moritz, 2000) or graphing (Aoyama & Stephens, 2003) in terms of grade level, research considering statistical literacy of average and variation concepts is scarce specifically in middle school context in Turkey.

Turkey has undergone through some revisions in the elementary mathematics curriculum considering the inclusion of statistics and probability as one of the five content areas of school mathematics in recent years. Statistics and probability domain of Turkish elementary mathematics curriculum consists of concepts such as sampling, measure of central tendency, graphs and tables, measure of spread, probability, and beginning inferences (MoNE, 2005). This study provided a brief reflection regarding

implementation of current elementary mathematics curriculum in Turkey with respect to students' capabilities in statistical literacy in terms of average and variation concepts. The results could point out further research in the context of both mathematics curriculum development and teacher education. Therefore, this study investigated Turkish 8th grade students' statistical literacy of average and variation concepts towards the end of their compulsory education.

THEORETICAL FRAMEWORK

Watson's (1997) three tiered framework is at the core of present study and used as a main analysis of students' statistical literacy. Statistical literacy has been addressed by Watson (1997) as the ability of understanding, interpreting, and evaluating statistical messages in various contexts. She presented statistical literacy in a three tiered framework:

Tier 1: Familiarity with and understanding of terminology used in statistical messages.

Tier 2: Interpretations of these statistical terms where they are contextualized in statistical claims which appear in the media or elsewhere.

Tier 3: The ability to question others' statistical reports critically; in other words, the critical evaluation of biased statistical information and posing possible critical questions to this statistical information.

More specifically, the first tier refers to the familiarity with terminology used in statistical messages in media. To illustrate, understanding the term "average" in context or defining "average" is a feature of Tier 1. For variation concept, the ability for Tier 1 includes expressing ideas of variation in daily life of individuals. The second tier includes the interpretations of these terms where they are contextualized in statistical claims. For example, interpreting or applying ideas of average in a variety of context is a characteristic of Tier 2. The last tier is the ability to question others' statistical reports critically; in other words, the critical evaluation of biased statistical information and posing possible critical questions to this information constitute the third tier of statistical literacy. For instance, examining whether mean or median is an appropriate average in a given statistical report or recognizing extreme values in distributions are basic characteristics of Tier 3 for statistical literacy of average and variation concepts (Watson, 1997; Watson & Moritz, 2000).

The compulsory education in Turkey addresses the elementary school period which comprises grades 1 to 8. It aims at developing informed citizens who possessed knowledge of statistics with an appreciation of the importance regarding the position of statistics in society (MoNE, 2005) through the National Elementary Mathematics Education curriculum. The elementary mathematics curriculum in Turkey is in spiral in nature and statistical topics including average and variation presented through measures of central tendency and spread across grades 6 to 8. At the end of the elementary school, students are expected to learn meanings of these concepts, how to

measure them and where to use them (MoNE, 2005). Therefore, investigating the level of statistical literacy of average and variation concepts that students have developed at the end of the compulsory education becomes important in order to understand the effect of elementary mathematics education. The present study investigated eighth grade students' statistical literacy in the average and variation concepts in terms of Tier 1, Tier 2, and Tier 3 which Watson (1997) have addressed and contributed to this framework from Turkish context.

METHODOLOGY

Participants

A total of 1074 eighth grade students from 48 classes in 9 randomly selected public schools in a district of Ankara participated in the study. Data were collected by the first author (except 7 classes who were surveyed by their own teachers) in participating students' classrooms during regular class hours.

Data Collection and Analysis

The data collection tool used in this study was prepared to investigate 8th grade students' statistical literacy in sample, average, graph, inference, chance and variation in terms of three tiers. The instrument was developed by the researchers, piloted with 292 8th grade students, and revised through mathematics education researchers', mathematics teachers', and students' comments. The Cronbach's alpha reliability measure in the pilot study was .72 and in the implementation was .75. The analysis of four items related to average concept (A) and five items related to variation concept (V) are presented in this paper. There were both multiple choice and open ended questions for these two concepts. A holistic rubric was prepared in order to classify students' responses in open-ended items and eliminating subjectivity based on their responses in the pilot study and related literature on statistical literacy. Students' responses were coded as non-statistical/incorrect, pre-statistical, and statistical for open-ended items. In addition, explanations of terminology with arithmetic procedures were coded separately. The responses of Statistical Literacy Test were classified according to the codes in the rubric. These codes were summarized as frequencies and percentages. Then, for descriptive statistics; mean, standard deviation, percentages, and frequencies were calculated.

RESULTS

Statistical Literacy of Average Concept

The first tier of statistical literacy of average concept gives indication of students' understanding of average concept. The item presented below intended to measure students' understanding of average in context.

“Last year, an average of 20 people had died due to traffic accidents.” What do you understand of the word “**average**” in this sentence?

The answers of students were classified through four categories which were blank or incorrect responses, pre-statistical responses, responses through measures of central tendency and statistical responses. The results indicated that majority of students either explained the term “average” through pre-statistical words (48.7%) or described through measures of central tendency (29.6%). The most notable response in pre-statistical responses was “almost” (34.8%) while “arithmetic mean” or “add them up and divide” algorithm were the most frequent descriptions (26.2%) for those who explained average through measures of central tendency. However, statistically correct responses constituted only 5.2% percent of total responses.

The analysis of students’ familiarity with methods for finding average or central tendency indicated that 36% of them labeled in a multiple choice item either “median” (18.1%) or “mode” (18.5%) as if these were not a method for finding average. This finding indicated that almost one third of the participants did not count median and mode as a measure of central tendency.

The second tier of statistical literacy of average concept requires students apply ideas related to average in context. The results showed that 40.2% of students correctly interpreted average in context whereas others (59.1%) chose the incorrect interpretations. It could be inferred that for average content in the second tier, only less than half of the participants had performed properly.

Evaluation of statistical claims which involves average concept constitute third tier group. There were two items related to this group. The findings indicated that majority of students gave incorrect responses or left this item blank (82.7%) which indicated that they were not able to critique a statistical claim in average context. The rest (16.4%) could correctly evaluate the appropriateness of this claim. The explanation for this evaluation was asked through another item. These items are presented below.

The number of problems solved in a math class is counted and represented in the following table.

Student	Number of problem
A	2
B	6
C	2
D	22
E	3
F	2
G	1
H	2

In order to summarize these data, the mean is calculated and found 5.

- a) Do you agree with this?
- b) Explain your answers with reasons.

The categorizations of explanations given by students for the second item are presented in Table 2.

Classification of Response	Students' Responses	Percentage
Blank/Wrong/Unrelated		93.1%
	Justification with arithmetic mean	52.4%
	Wrong explanations related to context	2.4%
	Other blank/wrong explanations	38.3%
Pre-Statistical		2.2%
	Notice the difference between numbers	1.3%
	Notice the outlier/extreme value	0.9%
Statistical		3.7%

Table 1: Descriptive Statistics for Item A4

Table 1 indicated that most of the participants provided wrong or unrelated responses (93.1%). These students accepted the statistical claim in average context without criticizing either providing wrong explanations related to context (2.4%) such as “Five questions can be solved in a class period” or justifying the results with arithmetic mean (52.4%). The rest of the participants gave pre-statistical (2.2%) or statistical (3.7%) responses. The statistical responses included either recognizing outlier in the data set or stating that getting average with median or mode is more appropriate. The difference between these statistical and pre-statistical responses was the appreciation of variability in the data set occurred in statistical explanations whereas recognizing outlier appeared in pre-statistical responses.

The detailed analysis of items revealed that majority of students had inadequate knowledge regarding average concept for statistical literacy. The most notable finding was that several students understood average which was a characteristic of the first tier behavior as “add them up and divide” algorithm which referred to the arithmetic mean and they did not consider median and mode as a way of finding average. In addition, only less than half of the participants were able to interpret average in context as a characteristic of second tier of statistical literacy. The majority of participants had failed to evaluate a statistical claim which was contextualized as third tier where they could not recognize outlier or justified this claim by providing evidence through arithmetic mean.

Statistical Literacy of Variation Concept

In the first tier of statistical literacy of variation concept, students were asked to select the data set which had more variability among others without context. Results revealed that majority of students (60.8%) were able to choose the data set with more variability. Students were additionally asked to provide explanations for their selections. These explanations were categorized as in the following table.

Classification	Codes based on Students' Responses	Percentage
Blank/Wrong/Unrelated		58.2%
	All numbers are same	6.5%
	Other blank/wrong explanations	51.8%
Pre-Statistical		12.1%
	Numbers are increasing	4.7%
	Numbers are different	7.4%
Descriptions via Measures of Spread		27.2%
	Range	23.1%
	Inter quartile range	0.1%
	Standard deviation	4%
Statistical		1.8%
	Larger variability	1.2%
	Away from average	0.6%

Table 2: Descriptive Statistics for Item V2

Table 2 indicated that majority of students (58.2%) either gave wrong responses or did not explain anything related to their answers in the first part. Of these, those who selected the data set which had the same numbers explained their responses through stating “all numbers are the same” (6.5%). Some of the participants (12.1%) provided pre-statistical explanations either stating that “numbers are increasing” (4.7%) or “numbers are different” (7.4%). A considerable percentage of students (27.2%) explained their responses through measures of spread. The most notable response in this category was “range” (23.1%) while “standard deviation” response was quite frequent (4%). Yet, very small percentage of participants (0.1%) explained their response through “inter quartile range”. Statistically correct responses constituted only 1.8% percent of total responses where they either indicated the large variability in data set (1.2%) or distance from the average value (0.6%).

The second tier of statistical literacy of variation concept required students to interpret statistical claims involving variability. Results related to this ability indicated that majority of students (74%) were able to interpret statistical claims involving variability. It could be inferred that variability in the second tier was accomplished by most of the participants.

The third tier of statistical literacy of variation concept demanded students to evaluate the data sets and chose the one had more appropriate variability among others. The task for this tier is shown below.

A group of students noted the highest temperatures in Ankara during one year. They find the highest average temperature in Ankara as 16° . Different from this group, three students predicted possible highest temperature for six different days in a year.

Students	Predicted Temperature
Seda	16, 35, 1, 5, 29, 10
Zeynep	16, 16, 16, 16, 16, 16
Umut	16, 15, 14, 26, 8, 17

a) Which students provide the data set regarding average temperatures with the most appropriate variability?

- a) Seda
- b) Zeynep
- c) Umut

b) Explain your answer.

The results revealed that majority of students gave incorrect response where only 23.6% of the participants did choose the data set with more appropriate variability which was spreading around center (Umut). Of the incorrect responses, 20.7% of students did choose “Seda” which had greater variability whereas almost one third of the students labeled “Zeynep” which consisted of the same numbers. The classification of the explanations regarding their answers is given in Table 4 below.

Classification of Responses	Codes based on Students' Responses	Percentage
Blank/Wrong /Unrelated		73.1%
	Same numbers in the data set	14.1%
	Equal to the average	8.9%
	Other blank/wrong responses	50.2%
Pre-Statistical		11.6%
	More difference between numbers	10.3%
	Different numbers	1.3%
Statistical		13.9%
	Appropriate variation	3.5%
	Different numbers but closer	3.5%
	Around average value	6.8%

Table 3: Descriptive Statistics for Item V5

Table 3 indicated that a high percentage of students (73.1%) either gave wrong and unrelated responses or left the explanation part blank. Those who picked “Zeynep” as data set which had the most appropriate variation explained their answers either as “the numbers were equal to the average” (8.9%) or “numbers were the same” (14.1%). The pre-statistical explanations included either more difference between numbers (10.3%) or different numbers (1.3%). Still, there were statistical explanations (13.9%) which consisted of responses such as “appropriate variation” (3.5%), “different but closer numbers” (3.5%), and “around average value” (6.8%).

The detailed analysis of statistical literacy of variation concept indicated that students obviously performed differently in different tiers. For instance, although it was possible to say that there were inadequate knowledge in understanding and evaluating variability, almost 75% of participants correctly interpreted variation in context. One of the interesting finding was that some (6.5% and 14.1% for separate items) of students, indicated that more variation was involved where the data set consisted of same numbers. In addition, very small percentage of students (1.8%) gave statistically correct explanation regarding understanding of variation whereas most of them (27.2%) described variation through measures of spread.

DISCUSSION

The aim of this study was to investigate statistical literacy of average and variation concepts of 8th grade Turkish students. The present study confirmed the previous findings that Turkish students tended to consider the average as the arithmetic mean or “add them up and divide” algorithm (Toluk-Uçar & Akdoğan, 2009) as a characteristic of the first tier of statistical literacy of average concept. Most of the students did not consider median and mode as other ways of finding average of a given data set. Only less than half of the participants were able to interpret average in context, which is a second tier ability. This might be derived from students’ poor understanding of average concept. Their performance in evaluation of a statistical claim involving average as a representative value, which was a Tier 3 skill, was poor as they could not recognize extreme values, or they explained this claim by providing evidence through arithmetic mean. These results confirm previous findings in which students did not consider average as a representative value for the given data set (Mokros & Russell, 1995).

Students’ understanding of average as a summarizing or representative value in this study might be related to Turkish elementary mathematics curriculum. Although Turkish curriculum has addressed average concept through measures of central tendency (mean, median, and mode), students have started to learn average through arithmetic mean, which may result in understanding average as “add them up and divide” algorithm. In addition, while teaching average concept, teachers may not focus on its characteristic of representative value of a data set; instead they may devote majority of instructional time for computational skills.

Students' performance in the second tier of statistical literacy of variation concept was relatively higher than the first and third tier, which could be attributed to objectives in the curriculum and statistics instruction in Turkish schools. Almost one third of the 8th grade students explained the meaning of variation through measures of spread, particularly range. These responses might be due to the emphasis on the computational skills in statistics content. Turkish elementary curriculum represents variation concepts through measures of spread (standard deviation, range, and interquartile range) and students might have conceptualized variation concepts through range because it was easier to calculate. Although majority of participants were able to interpret variation concept in various contexts, their responses in other tiers indicated that they considered that there were more variation where the data set consisted of the same numbers. These kinds of responses might be regarded as a sign of possible misconception about variation concept of 8th grade students.

The analysis of students' statistical literacy of average and variation concepts indicated that students conceptualize these contents through arithmetic mean and range which are measures of central tendency and spread. Since these two concepts are fundamental for statistical literacy and further statistics outcomes, understanding, interpretation and critical evaluation of them in various contexts should be emphasized both in curriculum and instruction.

The reason for relatively lower performance in the first and third tier of statistical literacy of average and variation concepts compared to the second tier might be originated from the item formats. Tier 1 and 3 items required students to explain the reasons of their answers; hence, these questions were in open-ended form whereas questions in the Tier 2 were in multiple choice formats. Since 8th grade students were more familiar with multiple choice items due to national placement exams, they did well on the second tier questions.

The findings of this study revealed that Turkish 8th grade students had performed lower in first and third tier of statistical literacy of average and variation concepts compared to Tier 2 which was interpretation of statistical claims. Since statistical literacy is an important feature for building active and critical citizens, elementary mathematics curriculum should aim at developing statistical literacy within statistics and probability content area in each grade level. Furthermore, objectives might be modified in relation to support for statistical literacy. There was only one objective regarding evaluation statistical messages in the context of graph concept. Therefore, curriculum makers or planners should identify and include objectives regarding critical evaluation and questioning of statistical claims to promote the development of statistical literacy within elementary school students. For instance, evaluation of arithmetic mean as a representative value or understanding variance within or between data sets should take place as objectives in the curriculum so that there would be the possibility of instructing those objectives.

UNDERSTANDING OF STATISTICAL GRAPHS IN PRIMARY: RESULTS OF A TEACHING UNIT¹

Ana Henriques

Instituto de Educação, Universidade de Lisboa, Portugal

Ana Michele Cruz

Agrupamento de Escolas D. João II, Portugal

This poster reports a classroom based study involving exploration tasks focus on the construction, reading and interpretation of statistical data represented in tables and graphs aiming to analyze grade 3 students' understanding of statistical graphs during a teaching unit as well as to identify their difficulties.

Statistical literacy, primary students, understanding of statistical graphs

In Portugal, the new mathematics syllabus for basic education underlines the importance of developing students' statistical literacy due to its recognized role in the general education of citizens and presents more demanding learning objectives for statistics. The major aspect of curricular orientations at primary level is the development of "the ability to read and interpret data presented in tables and graphs as well as to collect and organize them in order to solve problems in a variety of contexts related to students' everyday life"(ME, 2007, p. 26). However, there is plenty of evidence in literature and from our own experience that many students can read tables and graphs but they miss the conceptual abilities to interpret and draw conclusions from graphs (Shaughnessy, 2007). It is therefore necessary to promote classroom opportunities for students to contact with a variety of statistical representations developing their understanding of graphs. This study aims to analyse grade 3 students' understanding of statistical graphs and tables, before, during and after a teaching unit, as well as to identify their difficulties, with the purpose of improving the teaching and the learning of statistics. The study followed a qualitative and interpretative methodology and involved 25 grade 3 students of a primary school in Portugal. The teaching unit was conducted during the academic year of 2011/2012 and included a sequence of 7 structured and articulated tasks focus on the construction, reading and interpretation of statistical graphs and tables, assuming that students' understanding of statistical graphs involves those processes (Wu, 2004). During the exploration of each task, in the classroom, the students worked in pairs or small groups. Upon finishing the exploration, the students presented their work orally to the class. These discussions provided opportunities to answer students' questions, to ask them to explain their reasoning, to progressively introduce new representations and probing the students' understanding of graphs. Data collection methods included participant observation and the written documents produced by students (task explorations and tests). Concerning the reading and interpretation of statistical graphs we took Curcio (1989) levels - reading the data,

reading between the data and reading beyond the data - as a reference to analyse students' responses.

The preliminary results point to several difficulties regarding the construction of graphs which are consistent with those found in previous investigations (e.g. Lima & Selva, 2010). Major errors identified were related to title (absence or adequacy), labels and specifiers, scale selection, choice of an appropriate graphic to the situation presented. Concerning the interpretation of graphs it was found that students show few difficulties in level 1 questions (reading the data), but regarding levels 2 and 3 questions, requiring interpretation and inference, the students show they lack the capacity to explain their reasoning. As the teaching unit went on, the students evolve positively. Gradually they became aware of the several statistical representations that they could use to represent data, increased their level of responses to tasks involving the interpretation being able to better explain their reasoning and were attentive to all details of the graphs, developing, this way, their understanding of graphs.

The poster begins with a presentation of the study including the aims, framework, methodology and the teaching unit. The focus then is on examples of students' work in representing and interpreting statistical data to document the results of the study.

DIAGRAMS, GRAPHS AND CHARTS IN BIOLOGICAL COURSES A SYSTEM OF CATEGORIES IN THE OVERLAP OF MATHEMATICS AND BIOLOGY

Christine Plicht

University of Education Heidelberg

A main communication concept that can be found in everyday life and in different courses in school are representations like graphs, charts and diagrams. They are used for visualization, to show qualitative and quantitative connections between the data and its context. In our research program, we investigate statistic representations in the overlap of mathematics and biology. Statistical data always has a context and to read the data, it can require a basic knowledge of the applied topic. One main aspect of the project is to determine how students can read these representations and examine how they respond to the way they are designed.

Roth et al. (1999) investigated inscriptions in high school biology textbooks and scientific journals. Their research was mainly focused on graphs and scattered plots to determine out about their frequency and what practice is required to read them. A subsequent study about diagrams in a biological environment was presented by Lachmayer et. al. (2007). They proposed a model of cognitive abilities and their description of diagrams as depictional representations is based on the work of Schnotz (2001). To analyze how you can read statistical data in general, Curcio (1987) distinguished three levels how to read a graph. His model considers the context of the data: reading the data, reading between the data and reading behind the data. A fourth level that reaches further was added by Shaugyness (2007): reading beyond the data. In the current project these different competence levels are considered to include the biological component of the multiple representations.

To achieve an overview of statistical representation in biology courses, a sample of over 70 diagrams, charts and graphs was taken from schoolbooks designed for different types of secondary schools and levels. To acquire more multiplicity a textbook for university students was also investigated.

For a further and deeper analysis of these visualizations I developed a system of categories. The six categories are obtained on mathematical and biological motivation of the diagram, chart or graph. A commonly used distinction different from this is to categories reps in graphs, pie-charts, bar charts a.o. (Kattmann, 2006).

The poster suggested for presentation will focus on the system of categories and depict ways of presentation of data with biological context. Further analysis considered the different ways of the design and how the diversity of the mathematical correctness between the categories. Regarding also graphics in the representations based on the system of categories I found, a further classification can be made: diagrams that are mostly motivated by the biological content and diagrams that are

motivated by a mathematical approach. There can a transfer to Curcios competence-model be achieved. To read the biologically motivated diagrams knowledge of the context is required. Therefore you need to *read beyond* the data in order to *read* the data. That means that you need to know the biological subject behind the data to get all the information that are provided in the diagram or graph.

I will present a variety of ways how such diagrams and graphs are designed and then you see that a main aspect belongs to the used graphics. There are several levels how the graphics are integrative part of the representation (e.g. the bar of the chart are presented as milk cans or a picture of a cow is next to the graph). A tendency is visible, that with an increased number of graphics included and part of the syntax of the representation (like bars as a milkcan), the accuracy of numerical value represented decreases (then the volume of the cans don't correlate with the represented kilogram of milk).

The next step in progress after this theoretical observation is to find out how students actually distinguish between the categories of the representations and if they respond to the different ways of the included graphic. Is there a connection between the categories and the ability to read the data or beyond the data? Therefore students were interviewed interpreting some diagrams, charts and graphs to see how they cope with the data and their biological context. The results of the interviews are required for an intervention study, to promote the reading competence of graphs, diagrams and charts with biology as applied topic.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG 6: APPLICATIONS AND MODELLING

Thomas Lingefjärd, Sweden

Susana Carreira, Portugal

Gabriele Kaiser, Germany

Geoff Wake, United Kingdom

Keywords: Mathematical modelling; technology; theoretical perspectives

The starting point of the working group was a presentation of all the present authors (not all authors were at CERME), of which many were newcomers to this group and to the CERME conference. After that presentation it stood clear that the WG 6 consisted of many different approaches to modelling and applications. We also explained that this time the WG 6 would be organized the following way: The papers would be grouped and presented in a 10 minute talk each. When the presentations were finished we (the listeners) would divide ourselves in groups around the authors of the papers for a constructive critique, thereby helping them to improve their paper as soon as possible and in good time before the proceedings. Since CERME welcomed an inclusive attitude this time, many of the papers were rather non-theoretical.

The following meeting gave room for presentation of empirical research on lower secondary level where Bock & Bracke reported on real-world or realistic problems given to lower secondary students, Greefrath discussed solution plans which can aid the processing of modelling problems, Rafiepour addressed the levels of competency of modelling in grade 9th and 10th Iranian students, Rafipour also presented a poster, Albarracin & Gorgorio showed how Spanish middle school students approach Fermi problems, and Spandaw presented that Dutch students prefer modelling themes such as ‘electronic devices and computer games’.

The third meeting focused on empirical research on upper secondary level where Aerlebaeck described students’ use of average rates of change to construct, interpret and describe representations, followed by Doerr who examined the characteristics of teaching in a classroom setting where students created and interpreted models of changing physical phenomena. Eley reported on a study where students were enabled to question models and “optima” declared by others, Hamacher & Kreussler talked about how to merge educational and applied mathematics by engaging students in the location of bus stops. Sundtjoenn suggested that her students showed an inquiry approach in the work place related task she gave them and Laval and Almeida & Kato talked about their posters.

The fourth session gave room for a first summary and for open questions regarding topics for further research but also for papers regarding in-service-courses and practising teachers such as papers by Bautista et. al. implied that educational backgrounds of middle school teachers influenced their ideas about mathematical models and about their teaching of modelling. Hoff Kjeldsen argued that in order to facilitate teachers' use of theory in modelling it is important to develop intermediate representations and modes of collaborations. Mousoulides talked about the importance of parents supporting modelling activities in compulsory school. A very good session with good discussions.

The fifth meeting continued with papers concerning In-service-courses / Practising teachers by Borromeo Ferri who talked about attitudes and opinions of primary teachers towards implementing mathematical modelling in their lessons. Vorhölter and Grünewald investigated what kinds of interventions by teachers are adequate when allowing their students to do modelling and Frejd talked about his study of how professional mathematicians and modellers view mathematical modelling.

The sixth session we discussed research on teacher education with papers by Barquero who talked about the conditions that facilitate the life of mathematical modelling at educational institutions and the constraints that hinder the same to be carried out. Salett Biembengut talked about how a general and common style of thought with connection to mathematical modelling could become alive among educational institutions in Brazil. Benacka described the techniques of Excel with respect to modelling activities without data. Carreira gave a well organized description of how the two representation modes in GeoGebra facilitate students' understanding of linear functions, while Maltempi argued that the plasticity of the cybernetic world allow the creation of a space where imaginative aspects can be actualized, thus representing a differential for the practice of mathematical modelling itself.

The seventh session concluded a summary of the work in the WG 6 by a joint debate concerning prospects for further research led by Lingefjärd, Carreira, Kaiser, and Wake. One major conclusion was that many of the presented papers lacked a scientific or at least a theoretical perspective. Many papers were more of the kind: "this is what I do with my students". So the sessions closed with the following questions, rather identical with the ones from CERME 7 and still actual because of the outspread stack of papers in our group:

How do we move forward in the scientific debate on applications and modelling?
 How do we include applications and modelling in curriculum and school practice?
 What kind of empirical research is necessary?

What kinds of measures are necessary and can be constructed? Is the development of teaching units or learning materials sufficient? What is the role of comprehensive learning environments?

What can we say about the role of culture in the teaching and learning of mathematical modelling? Is it culture-free or what do we need to consider as cultural effects in our debate?

Universitat Autònoma de Barcelona

1 ABSTRACT

In this paper we describe a classroom experience based on the sequencing of Fermi problems related to estimating large quantities. The models used by a group of Compulsory Secondary Education (16 year-old) students are described herein. The variations the students apply to the models in order to adapt them to similar problems formulated in different contexts are shown. In the conclusions section, we reflect on this didactic proposal and the possibilities it offers to the students, so that they assimilate and internalize the models worked on.

2 INTRODUCTION

In this study we introduce Fermi problems oriented towards the estimation of large quantities. We understand that the modelling processes which appear in the solution of this type of problems with a realistic context cannot replace real-life decision-making, however their use in the classroom promotes attitudes which can be useful for everyday life (Jurdak, 2006). The problems presented in our study are based on the estimation of large numbers. We herein describe the way students adapt their modelling strategies to different problems with similar mathematical structures but which are formulated in different contexts. Seldom found as class problems, solving them demands the students to create their own strategies, adapt them and use them to solve different problems. This leads them to identify with and include these strategies in their mathematical knowledge base, which according to Schoenfeld (1992) may help students become competent problem solvers.

3 THEORETICAL REFERENCES

3.1 Modelling

One of the most relevant scientific activities involves creating models which provide an abstract recreation of objects, phenomena or processes we wish to understand. In recent years, there has been a strong tendency to attempt to approach model creation to the classrooms.

Lesh & Harel (2003) define model as follows:

Models are conceptual systems that generally tend to be expressed using a variety of interacting representational media, which may involve written symbols, spoken language, computer-based graphics, paper-based diagrams or graphs, or experience-based metaphors. Their purposes are to construct, describe or explain other system(s).

Models include both: (a) a conceptual system for describing or explaining the relevant mathematical objects, relations, actions, patterns, and regularities that are attributed to the

problem-solving situation; and (b) accompanying procedures for generating useful constructions, manipulations, or predictions for achieving clearly recognized goals. (p. 159)

According to this definition, a model can be understood as an abstract way of representing a particular phenomenon or reality. The way students elaborate models in order to solve problems is a matter of discussion and different views exist on this subject (Borromeo Ferri, 2006). However, in general terms, it is agreed to be a multi-cyclic process. According to Blum (2003), modelling processes can be structured into five main stages: i) Simplifying the real problem into a real model; ii) Mathematizing the real model into a mathematical model; iii) Searching for a solution from the mathematical model; iv) Interpreting the solution of the mathematical model and v) Validating the solution within the context of the real-life problem.

3.2 Estimation and Fermi Problems

When we intend to answer questions such as: how long would I take to get to the train station? How many 5kg paint cans do I need to paint the walls of my flat? Or, how many teaspoons of sugar do I need to cover the 250 grams indicated in the recipe? We need to make estimations. By estimation we mean a rough calculation or judgement of the value, number, quantity or extent of something. After revising the literature, three types of estimation can be found: numerosity, estimation of measurements and computational estimation (Hogan & Brezinski, 2003). This fact is due to the existence of a wide range of tasks which, although they don't share the numerical patterns which enable their execution, all require the concept of estimation (Booth & Siegler, 2006). Numerosity refers to the ability to visually estimate the number of objects arranged on a plane; measurement estimation is based on the perceptive ability to estimate length, surface area, time, weight or similar measurements of ordinary objects, while computational estimation refers to the process by which the value of a calculation, such as $13.2 \div 4.3 + 6.91$, is approximated.

There are yet two types of activities that are referred to as estimation for which we haven't found any relevant studies in the field of Mathematical Education. On the one hand, in a branch of Statistical Inference, estimation is known as the group of techniques which allow calculating an approximate value for a population parameter from the data provided by a sample. On the other hand, another mathematical activity regarded as estimation is the calculation of values obtained either from predictive activities or from approximating a reality by using a model which represents a situation. A good example of this kind of situations is directly reflected in what are known as Fermi problems.

Ärlebäck (2009) offers the following definition of a Fermi problem:

Open, non-standard problems requiring the students to make assumptions about the problem situation and estimate relevant quantities before engaging in, often, simple calculations. (page. 331)

Ärlebäck (2011) states that working with Fermi problems can be useful to introduce modelling in the classrooms for several reasons. Indeed, we have confirmed that they don't require any specific type of previous mathematical knowledge, the students are obliged to estimate several quantities by themselves (since the problems don't provide numerical data) and are encouraged to discuss the issue with their peers.

4 THE GOALS OF THE STUDY

Based on a class activity carried out with students in their 4th year of Compulsory Secondary Education, using a sequence of Fermi problems aimed at the estimation of large quantities, we study the models the students create to solve the problems as well as how they adapt the models to other similar problems. Thus, the goals of the study are:

1. To identify the models students use to solve problems
2. To identify the modifications they introduce to previously applied models when facing new problems

5 METHODOLOGY

The work dealt with in this paper is part of a wider study presented in Albarracín & Gorgorió (2011) where we research individual strategies for solving Fermi problems aimed at the estimation of large quantities. These types of problems are not currently included in the Spanish curricula and are not usually worked on in class, which means that students aren't being taught specific methods by which to solve them. Thus, students are obliged to create their own resolution strategies which include models of the situations proposed. By definition, the resolution process of Fermi problems can be based on breaking them into smaller problems, which should be easier for the students to approach than the original problem. Dealing with large quantities doesn't allow for simplistic approaches to the solution, and thus we expect the students to come up with strategies richer in mathematical elements, from the abstract representation of the studied reality.

The experience presented hereafter was carried out on a group of 22 pupils in their 4th year of ESO (compulsory secondary education, 16 year-olds) with no previous instruction in modelling. This time we asked the students to solve a set of Fermi problems in teams, which required estimating the number of objects distributed over a surface area in contexts initially familiar to them. The first problem refers to the school itself, while the following four problems require information which isn't directly available to the students, and which they would have to obtain from an external source. The problems are the following:

- Problem A: How many people fit in the school playground?
- Problem B1: How many people fit in a concert at the Palau St. Jordi¹?

¹ Palau St. Jordi is a pavilion built for the Barcelona'92 Olympic Games

- Problem B2: How many people fit in a demonstration held in the town hall square of your city?
- Problem B3: How many people fit in a demonstration held in Plaça Catalunya (Barcelona)?
- Problem B4: How many trees are there in Central Park?

The problems were worked on in several sessions. In the first session, the students were set problem A and asked to write an individual resolution proposal. Afterwards, the students were arranged into work teams of 3 or 4 (6 groups in total) which had to come to an agreement on a group resolution proposal and determine the actions and resources required to estimate the number of people that fit in the school playground. In the second session the students executed the previously planned work and started to write their reports. In the third session, the reports were completed and they shared the results and methods used.

In the fourth session, the students were presented with the following four problems (B1, B2, B3 and B4) and were allowed to access the internet if necessary. The purpose of the fifth session was to complete the different resolutions and produce a second results report. The sixth session was carried out as a conclusive activity in which the results were compared with information obtained from external sources.

The data used in this study are the reports created by the students and the observations collected by the first author during the experience. We herein present some of the data collected. Fig. 1 shows the resolution of some students who propose estimating the amount of people that would fit in the high school playground by counting the number of them that would fit in it if arranged into rows and columns.

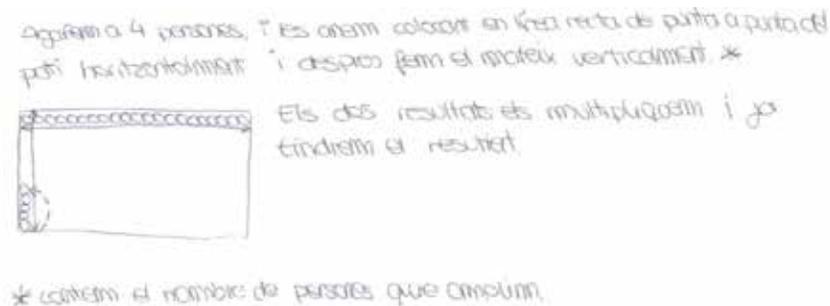

Fig. 1. An example of the resolution of problem A.

The abovementioned proposal reads “ We would take 4 people and place them in a straight line from one end to the other of the playground crosswise and lengthwise, counting the number of people that we fit into it. We would then multiply both results.” As displayed in Fig. 2, the students have made their calculations and obtained 26 and 82 people respectively for each dimension of the courtyard, for which they give a result of 2,132 people.

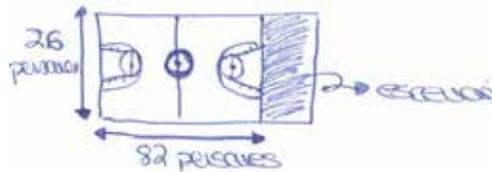

Fig. 2. Data collected for the resolution to problem A.

In Fig. 3 we present some students' resolution of problem B2, which requires estimating the maximum amount of people that would fit in the town hall square during a demonstration.

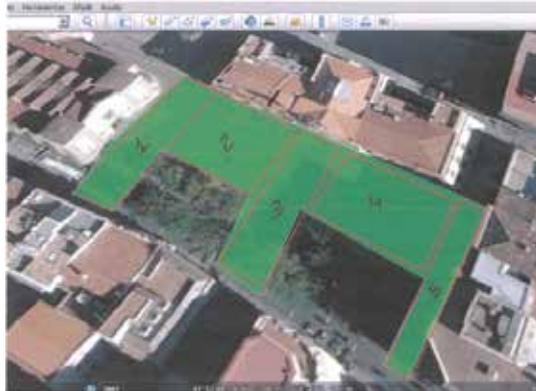

Fig. 3. Available space in the town hall square.

The caption of this picture is the following: "We searched for the town hall square on Google Earth and marked the areas where people could be in with the polygon drawing tool. We assumed they wouldn't tread on the green areas. We afterwards divided the shaded area into rectangles to make it easier to find out their surface areas. We assumed 3 people could fit in a square metre." After that, the students calculated the number of people that could stand in each of the separate areas with their previously-obtained surface data. Figure 4 shows the calculations for zones 4 and 5, as well as the final result.

Dades del recuadre numero 4:
 $20 \text{ metres} \cdot 16 \text{ metres} = 320 \text{ m}^2 \cdot 3 = 960 \text{ personas}$
 Dades del recuadre numero 5:
 $32 \text{ metres} \cdot 4 \text{ metres} = 128 \text{ m}^2 \cdot 3 = 384 \text{ personas}$
 Si sumem totes les persones dels diferents recuadres obtenim
 el nombre de **3801 personas**

Fig. 4. Calculations done for the resolution of problem B2.

The data was analyzed following the model presented in Albarracín & Gorgorió (2012), which identifies the resolution strategies proposed by ESO students for several Fermi problems which require estimating large quantities. Within the scope of

our research, we understand a resolution strategy as a plan of action or policy designed to achieve a major or overall aim.

The analysis is centred on describing the specific actions the students propose and placing them in more general settings. For instance, some students propose counting the number of people attending a demonstration one by one, by asking all of them to write down their name on a list, or suggest recording video footage of a leakage in order to count the number of drops falling throughout the recording by hand. Both of these proposals to different problems portray different plans of action but show the same intention, which is to carry out an exhaustive count of the entirety of objects in the problem. Therefore, these proposals show different actions with the same kind of plan, which we interpret as adaptations of different problems to the same type of strategy.

By using the quantitative data analysis software NVivo 8, we established different analysis categories corresponding to the strategies detected. These categories are: lack of strategy, exhaustive count, use of an external source of information, reduction of the problem to a smaller one, comparison with a real-life situation and breaking the problem into different parts to be solved separately.

The latter strategy contains elements of modelling. The way the students break up the main problem into different sub-problems is determined by how they represent the situation studied. Several models have been identified for each situation, which portray different ways into which the problem can be broken up. Some of these models coincide with those identified in this study, and will be explained in the following sections.

6 MODELS DETECTED FOR THE FIRST PROBLEM

We will firstly focus on the resolution of the problem of estimating the number of people that fit in the school playground (problem A).

Not all the individual proposals included a resolution scheme that enabled the required estimation to be made, but we however observed that the teamwork yielded suitable work plans for all groups. The students' proposals described the situation by means of mathematical concepts and their relationship to the studied reality as well as the procedures required to reach a solution, which means they modelled the problem following Lesh & Harel's (2003) definition.

It is worth noting that the high school playground has a rectangular plan view.

In the following we present the mathematical models created by the different teams to estimate the amount of people in the high school playground, which has a rectangular plan view.

Four of the teams used a strategy based on the idea of population density. The students measured the length and width of the playground in order to obtain its surface area. On the other hand they carried out experiments to determine the number of people that would fit on a small surface area. Using the experimental data, they

obtained a value for the density of students that would take up one square metre and then multiplied it by the surface area of the playground in square metres.

One of the teams based its strategy on the iteration of a reference point. The students measured the length and width of the playground in order to calculate its surface area and carried out experiments to determine the area a single person would occupy. Using this value, they divided the total surface area of the playground in square metres by the surface taken up by one person. This process is equivalent to the iteration of a reference point, which is a length estimation strategy which consists of mentally counting the number of times and object (reference point) may be placed on top of the object to be measured (Joram, Gabriele, Bertheau, Gelman & Subrahmanyam, 2005).

One of the teams based its strategy on a grid distribution. The students in the team lined up one after the other. In order to move the line forward, the last person in the line would advance to the position in front of the first person in the line. While moving forward they counted how many people would be needed to occupy the length and width of the playground. To find out how many people would fit in the playground, they multiplied the two experimentally calculated values. This model responds to a similar idea to the product rule used to obtain the surface area of a rectangle.

We would like to stress that the previous three models are based on a type of resolution which establishes different sub problems that must be solved separately: What's the surface area of the playground? How many people fit in a square metre? Or: how many people can we line up along the length of the playground? This way of proceeding corresponds to Ärlebäck's (2009) definition of Fermi problems.

Once they completed the activity, the students reported their results, as well as the methodology used to obtain them. This idea-sharing session succeeded in getting the students to compare their methods and adopt the models their classmates had used. They also discussed their results, since the values obtained ranged between 1200 and 2200 people for a playground of 350 square metres. The students accepted the idea that there couldn't be just one single correct result, but a suitable interval including all possible solutions.

Afterwards the results were compared with capacity data from concert venues and the students realised their density values were rather high. This triggered discussions in which they tried to clarify the points in which they disagreed (surface area occupied by an adult versus that occupied by a teenager, comfort, safety rules). This allowed the students to connect the model used and the decisions taken with the reality being studied.

7 ADJUSTMENT OF MODELS TO THE FOLLOWING PROBLEMS

In the second session the students solved the remaining 4 problems. This time they weren't allowed to go to the locations referred to in the problems to take any

measurements, and they therefore decided to search for the required information on the internet. Given that the formulations of the problems contextualized the estimation in public spaces, the students were faced with the difficulty of deciding how to adapt the models they had built for the previous problem to the new problems set. Given that the data we are working with is the students' output, this study cannot analyze the cyclical process of modelling for a specific problem. However, we can study the modifications made to adapt certain models for their use on different problems.

The first notable fact is that the teams generally used the population density model for the new problems, possibly because they considered this model more versatile and adaptable to any situation. Only two of the teams used the iteration of a unit, the space taken up by a tree, in order to solve the problem on Central Park. They considered that the density of trees expressed as units by square metre wasn't a manageable number.

After analysing the resolutions presented, we detected several variations in the models used by the students.

The students identified unavailable spaces when devising the resolution strategies for problems B2, B3 (squares in an urban centre) and B4 (trees in Central Park). Contrarily to the case of the school playground, it's not possible to cover the whole extent of a public space, since some of it taken up by street furniture or roadways. Considering this constraint, the students looked for an aerial photograph of the areas to be studied in Google Maps, delimited inoperative areas and marked them. Then they made some measurements with a tool from Google Maps in order to calculate surface areas.

The students identified spaces with different densities when embarking on the resolution of the problem which refers to the Palau St. Jordi, a large pavilion where concert attendants can either sit on the tiers or stand in the arena. They were unable to find an aerial photograph of the pavilion interior because it is indoors. They needed to approximate the surface area of each of the two parts by educated guesses. Once estimated the surface areas, they applied different population densities to them.

In problems B1 (population density of the steps), B2, B3 (population density in a demonstration) and B4 (density of trees) the students realised that the density of the objects may vary according to the circumstances. When estimating the population density of trees in Central Park, the students collected information regarding types of trees and their ages. They also determined that the density of people seated on one of the tiers in Palau St. Jordi is different from that of the people standing in the concert. They also distinguished between the population density in a concert from that of a demonstration. When the students completed their estimations using methods they had created themselves, the activity ended up in a discussion on the validity of the results obtained. They used information from different sources on the web (Wikipedia and several online newspapers) in order to contrast the results and even

discarded some of the statements made by the media. Therefore, the students validated their results and established direct links between the studied reality and the models they had created and adapted to different situations.

8 CONCLUSIONS

Based on the collected material and data analysis, we can state that all the working teams in this study solved the problems presented to them as Fermi problems, by establishing small sub problems they solved separately by means of calculations or estimations. For the problem on the number of people that would fit in the playground, the students' proposals included different types of models. This suggests that working with different Fermi problems may help and encourage students to generate a wide range of strategies and models, which agrees with Ärlebäck's (2011) statements on the possibilities offered by Fermi problems.

Using an initial problem to be worked on at school followed by list of similar problems that require researching information in external sources has allowed the students to discuss how the previously created models adapted to the different problems (Ärlebäck, 2011). This discussion has driven the students to generate new models which adapt to the new situations to estimate the amounts required in each of them.

When working with problems which pose new difficulties, the students adapted their models to the represented reality, developing more complex versions of the proposed models. Since the work was carried out in teams, we ensured that all the students in class took part in the discussion on the different key aspects of decision-making for generating the models used. This allows the students to adopt these models and include them in their knowledge base (Schoenfeld, 1992). Therefore, the proposed sequence of problems has led to a higher level of understanding of the methods and concepts used; connecting those to different situations which have similar approaches but differs in some content details. It is worth noting that students started their project using the models suggested by their own team but easily adopted ideas proposed by other teams, which implies that the different idea-sharing sessions of methods and results were crucial to the whole process.

Finally, we observe that students are able to compare some of their results with information gathered from different sources. This comparison provides information which they may include when elaborating future models, such as the need to decrease the population density for safety reasons. On the other hand, some of the data found on the web did not agree with some of the results the students had obtained using their most perfected models, accepted by the whole class, which lead them to question the truthfulness of this information. Manifestly, the process reached its most relevant point when the students realised that their own analysis of a situation may disprove information provided by the media. In conclusion, by means of these resolution processes the students have given meaning to the concepts worked on in class and compared their output with real information, as described by Jurdak (2006).

STUDENTS' EMERGING MODELS OF AVERAGE RATES OF CHANGE IN CONTEXT

Jonas B Ärlebäck, Helen M. Doerr & AnnMarie O'Neil

Linköping University, Syracuse University, Syracuse University

This paper describes a model application activity in the context of how light intensity varies depending on the distance from a point light source within a model development sequence focusing on developing students' understanding of average rate of change. Students' early models were found to be linearly decreasing functions and they did not distinguish between the light intensity and changes in light intensity. Most students were able to draw on several representations (most notably tables and graphs) to represent, describe and distinguish between the light intensity and changes in light intensity. Some students encountered difficulties when describing change when the rates were negative and understanding how the graphical representation of average rates of change depended on the interval width.

The difficulties encountered by students when reasoning about and interpreting rates of change are well documented in the research literature (Carlson et al., 2002; Monk, 1992; Thompson, 1994). The covariational reasoning students need to simultaneously attend to both the changing values of the outputs of a function and the changing values of the inputs to the function, is foundational for understanding average rates of change in pre-calculus and instantaneous rates of change in calculus (Johnson, 2012; Oehrtman, Carlson & Thompson, 2008). However, relatively little research has attended to the particular challenges students encounter when reasoning about negative rates of change, the role of context in the tasks involving change, and students' construction and application of representations. Many studies investigating aspects of average rates of change use different representations (graphs, tables, figures, symbols, written language, simulations, enactments) to create tasks on which students' work is then analyzed (e.g. Johnson, 2012; Herbert & Pierce, 2012). Often, the use of different contexts provides a background situating the representations, and students are asked to extract contextual meaning from a given representation.

Whitney (2010) investigated students' initial understandings of rate of change and their preference for using different representations (tables, graphs, equations and contexts) in the context of linear functions. The students tended to use tables as tools for organizing information and "graphs were not students' first choice in representing information" (p. 186). Along the same line, Herbert and Pierce (2012) found that the rate-related information understood by students through different representations was highly individual, and that "understandings of rate in one representation or context are not necessarily transferred to another representation or context" (p. 455). This is consistent with the findings of Ibrahim and Rebello (2012) comparing student work with different representations in the subject matter areas of kinematics and work.

In this study, we examined students' use of average rates of change to construct, interpret and describe representations of the relationship between measurements of light intensity and distances from a light source. We focused our attention on students' descriptions of how the light intensity varies with the distance from the light source and on the students' interpretations of the graphs that they created to represent the average rates of change. The questions guiding this investigation were: How do students interpret and describe their constructed representations of average rates of change? How do students attend to context when interpreting and describing their constructed representations of average rates of change?

THEORETICAL BACKGROUND

We used what Kaiser and Sriraman (2006) call a contextual modeling perspective on teaching and learning mathematics (cf. Lesh & Doerr, 2003) and a design-based research methodology (Cobb et al 2002; Kelly et al. 2008) to design and implement a sequence of modeling tasks aimed at supporting the development of students' understandings of average rates of change.

Model development sequences

Model development sequences (Doerr & English, 2003; Lesh et al., 2003) begin with model eliciting activities where students are confronted with the need to develop a model in order to make sense of a situation familiar to the students. When the model is elicited, the purpose of successive model exploration activities and/or model application activities is to help the students extend, revise and refine their emerging models. The focus of model exploration activities is on the underlying structure of the elicited model and especially on the strengths of various representations as well as on how to productively use these different representations. In model application activities the students apply their model to new situations, which in turn can lead to the model being further extended, revised and refined and to further understandings of the utility of the representations.

METHODOLOGY

The model development sequence designed to support the development of students' understandings of average rates of change formed the basis for a six-week course taught by the third author for students who were preparing to enter their university studies. Throughout this sequence, students were engaged in the processes of iteratively revising and improving their models of average rates of change while interacting with other students and participating in teacher-led class discussions. A total of 34 subjects (10 female and 24 male) participated in the study; 21 students had studied calculus in high school and 13 had not studied any calculus. The students worked in small groups to complete the different activities. The model eliciting activity used motion detectors to elicit the notion of negative velocity with motion along a straight path. To explore changing negative rates, multiple model exploration activities were used based on computer simulations (Kaput & Roschelle, 1996) and structured exercises (Watson & Mason, 2006) focusing on different representations of

negative rates. Two model application activities in the sequence were carried out as lab projects where the students spent several days on the activities and wrote final reports. One model application activity focused on creating a model of the intensity of light with respect to the distance from a light source (the Light Lab), and the other aimed at modeling the rate at which a fully charged capacitor in a resistor-capacitor circuit discharged with respect to time. Each activity included class discussions focusing on the relationships among different representations of negative rates of change and students' interpretation and descriptions of change in different contexts and settings. The work reported on in this paper is the analysis of the students' work on the Light Lab, which took place at the beginning of the fourth week of the course.

The Model Application Activity Design

The Light Lab task was designed and carried out in six phases as illustrated in Figure 1. Prior to the Light Lab, the students' work on the model eliciting and exploration activities almost exclusively involved different representations of one-dimensional motion along a straight path. The aim of the Light Lab was manifold; it was originally designed as a model application activity in that it provided the students with an opportunity to apply their emerging models of average rate of change elicited in the context of linear motion in a new context. However, the iterative design process inherent in the design-based methodology led to the successive inclusion of elements of exploration focusing on the graphical representations of the average rate of change in non-linear contexts.

Figure 1. The six phases of the Light Lab

The first pre-lab task aimed at making explicit the students' intuitive and initial models about the relationship between the intensity measured at different distances from a point source. The students were asked to consider a one-dimensional scenario of an approaching car and to sketch a graph of how the intensity of the car's headlights varied depending on the distance you are from the car. The students were also asked to describe how light is emitted from a point source in terms of how the light rays emitted from it are dispersed, and what implications this might have for their emerging intensity model. The students' work on this task was collected and discussed in class.

In the second task, students collected light intensity data using a flashlight with the focusing cap removed, a meter stick, and a light sensor connected to their graphing calculator. They collected 15 measurements of the intensity at one cm intervals from the light source and transferred the data to their computers. The light sensor measured light intensity in a relative and arbitrary unit called "light intensity units" (LIU). Due

to physical limitations of the light sensor, the first two or three data points gave a maximum reading of one LIU on the light sensor.

In part one of the lab, the students were asked to make a scatter plot of their data and to write descriptions of how the intensity of the light changed with respect to distance from the light source. They were encouraged to compare this relationship to their predictions from the first pre-lab. The students were also asked to calculate the average rates of change of the data in one cm intervals and to (1) describe the average rate of change of the data as distance from the light source increases; (2) to graph the average rates of change in a scatter plot; and (3) to create a separate rate graph of the calculated average rates of change.

In the second pre-lab task, the students were given four images representing light intensity at different distances. The number of dots per square inch indicated the intensity, and the task for the students was to determine the intensity in dots per square inch at a given distance from the light source. The second pre-lab introduced an inverse square relationship as a model for how the intensity varies with distance from the light source, and familiarized the students with finding such a functional expression fitting a given data set. This task was given as homework and subsequently discussed in class.

In the second part of the lab, the students were asked to determine a function fitting their collected data, explain their work, and analyze the average rates of change of their function using the difference quotient. Due to the limitations of the sensor, students needed to construct a piecewise function, consisting of a horizontal linear piece for the first two or three data points and an inverse squared piece for the remainder of the data set. More specifically, the student were asked (1) to calculate the average rates of change of the function at integer x values and an interval width of 0.5 cm; (2) to show these average rates of change in a function plot; (3) to create a rate graph for the average rates of change values; and (4) to describe how the average rate of change of the function changes as distance from the light source increase.

Data analysis

In this paper, we report on the analysis of the student data from pre-lab 1 ($n=34$; done individually) and the lab reports ($n=18$; all written by pairs of students with the exception of one student writing alone). The analysis was done in two phases following the principles of grounded theory (Strauss & Corbin, 1998). First, codes were developed to categorize the students' reasoning and answers on each of the questions for pre-lab 1. This initial analysis focused on capturing the students' initial models of how the light intensity varies with distance from the light source and how light disperses from a point source. In the second phase of the analysis, the students' final lab reports were read and coded, focusing on interpretations and descriptions of how the intensity varied with the distance from the light source and its average rates of change, the graphs the students produced, how they attended to the context throughout their writing, and how the students' used their ideas from the pre-labs.

RESULTS

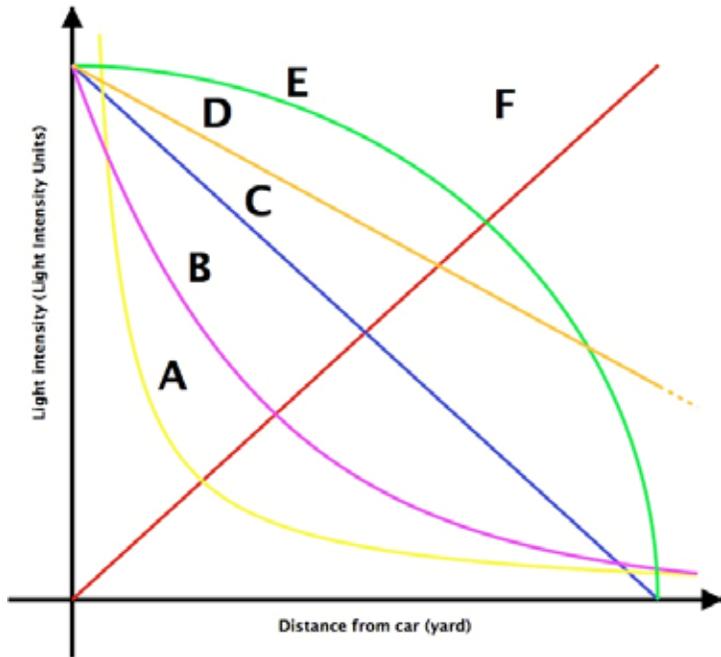

Our analysis yielded three sets of results. First, we found that most students' early model of changing light intensity was a linearly decreasing function and did not distinguish between the light intensity and changes in light intensity. Second, as students' models of light intensity with respect to distance developed, most students were able to draw on several representations (most notably tables and graphs) to represent, describe and distinguish between the light intensity and changes in light intensity. Third, some students encountered difficulties when describing change when the rates are negative and understanding how the graphical representation of average rates of change depends on the interval width.

Students' initial models of variability of light intensity at different distances

The students' initial models of the relationship between light intensity and the distance from the light source are shown in Figure 3, which illustrates the different types of graphs the students constructed to describe how the light intensity from a car's headlights varies with the distance to the car. The table displays the number of students' graphs in each category; the cut off between the C and the D graph was a slope of -0.7 . Nearly all of the students ($n=28$, 83%) drew a linear relationship between the intensity of light and the distance from the source. All but one of these linear graphs (shown as C and D in Figure 3) correctly show the intensity decreasing, but incorrectly at a constant rate. This is likely due to the students assuming that the speed of the approaching car is constant (c.f., Doerr, Arleback & O'Neil, submitted) and confusing the constancy of speed of the car with the constancy of the decrease in light intensity. The one student who drew graph F incorrectly reasoned that the light intensity increased as the distance from the car increased. The four students who drew graph A, with its asymptotic behavior at the y-axis, were likely drawing on their formal physics and/or mathematical knowledge of the inverse square law for light intensity. We note that all students had taken a prior course in physics. Since graph B shows a maximum intensity at the instant the distance is zero, the one student who drew graph B may have attended to his perception of the context as well as his formal previous knowledge.

Nearly all students ($n=26$, 76%) provided a qualitative description of the intensity at 1000 yards compared to at 2000 yards, using vocabulary like "greater" and "less". The remaining 24% of the students, on the other hand, made a quantitative statement describing the intensity at 1000 yards to be exactly twice the intensity at 2000 yards. This was done exclusively by students drawing a C graph in Figure 3. While it is possible that this could be the case, this reasoning is more suggestive of exponential decay (whose change is multiplicative in structure) than a linear function, whose change is additive in structure.

When asked to "Compare the rate at which the intensity is changing at 1000 yards and 2000 yards", 17 of the 34 students described or calculated the rate of change their graphical representation. One student, referring to his C graph, wrote: "The rate at

Graph	Number of students
A	4 (12%)
B	1 (3%)
C	22 (65%)
D	5 (15%)
E	1 (3%)
F	1 (3%)

Figure 3. Students’ initial models of intensity vs. distance from light source

which the intensity is changing at 1000 yards and 2000 yards is the same”. However, 16 of the 34 students compared the values of the function at the two distances rather than the rate of change at those distances. For some of these students, their description did not mention the rate of change at all (for the C graph: “The intensity doubles from 2000 yards to 1000 yards”); other students explicitly confounded the function’s values with the rate of change values (C graph: “The rate of intensity is doubled”). The remaining one of the 34 students simply gave an equation of a linear function that did not correspond to his graph.

When asked to “Draw some representative light rays leaving the light source” the students drew figures of light dispersing either as cones, perpendicular rays or waves

A. Light rays “cone-like”	B. Light rays perpendicular	C. Light disperse as waves
28 students (82%)	5 students (15%)	1 student (3%)

Figure 4. Students’ initial models of intensity vs. distance from light source

(see Figure 4). Students drawing a cone-like model have a potential rationale for why the light intensity decreases when distance increases, whereas the perpendicular model implies a constant light intensity, independent of distance. One student, likely

drawing on previous knowledge from prior coursework in physics, drew the light dispersing as waves. However, regardless of their model in Figure 4, all students concluded that the light intensity would decrease as distance increase. This illustrates the compartmentalization of conflicting ideas in the students' emerging models that the students have still not resolved and pulled together.

Students' descriptions of the light intensity and its average rate of change

All students used tables to organize and summarize their raw data and various calculated quantities. Scatter plots of the data were included in all reports, either as separate graphs, together with graphs where the average rates of changes were drawn in, or, in graphs showing how their symbolic piece-wise function fit the data. Nearly all (89%) of the reports included correct descriptions of the values of the data drawing on the context of light intensity. Some descriptions tended to be short and close to strict mathematical statements: "The intensity of the light source decreases as the distance increases." Other descriptions were more closely situated and connected to the lab setting: "As the distance from the light source increased, the light intensity decreased. The farther away the sensor was away from the light sensor the smaller the light intensity became." These two sentences convey the same information using slightly different language: the first is a general sentence about the behavior of how light intensity varies with distance from the light source, similar to the more mathematical description in the previous example. This relationship is then expressed in terms of the context of the lab. One can also note the use of the word "smaller" in the last sentence, which does not quite capture the notion of light intensity, pointing at the complexity of trying to make precise and meaningful interpretations of mathematical statements and relationships in context.

In some cases, the students made explicit references back to their data to support their descriptions. In the following example, the description accompanied a table listing the light intensity values and the calculated average rates of change values as well as a scatter plot of the data with the average rates of change drawn in, connecting all consecutive points (as shown in Figure 5A): "As the distance from the source increases the intensity of the light decreases. For example, at 3 cm the light intensity reads .832 LIU [Light Intensity Units]; at 4 cm the light intensity reads .637 LIU; and at 5 cm the light intensity reads .463 LIU. It is also noted that rate at which the data changes as the distance from the light source increases changes." This description also includes a correct conclusion about the long run behavior of the average rates of change of the light intensity. Over half (56%) of the students constructed and correctly interpreted a similar graph of the average rates of change. In this particular case, the students continued to elaborate their description of the behavior of the average rates of change: "Although the majority of the average rates of change are increasing, the absolute value of average rates of change are decreasing which tells us that as the distance from the light source increases the intensity of the light decreases quickly at first and then decreases more slowly." In this statement, the students argued from the graph of the average rates of change values (Figure 5B), and

articulated that these values are increasing. But the students then considered the absolute values of the negative average rates of change to provide the qualitative statement about the rate that is “decreasing quickly at first and then decreases more slowly.” All reports but two (94%) included the correct rate graphs of the average rate of change over the 1 cm intervals similar to the one in Figure 5B and 44% of the student made it explicitly clear how to see the average rates of change in the scatter plot (see Figure 5A) by referring to the slope of the line segment connecting two consecutive points.

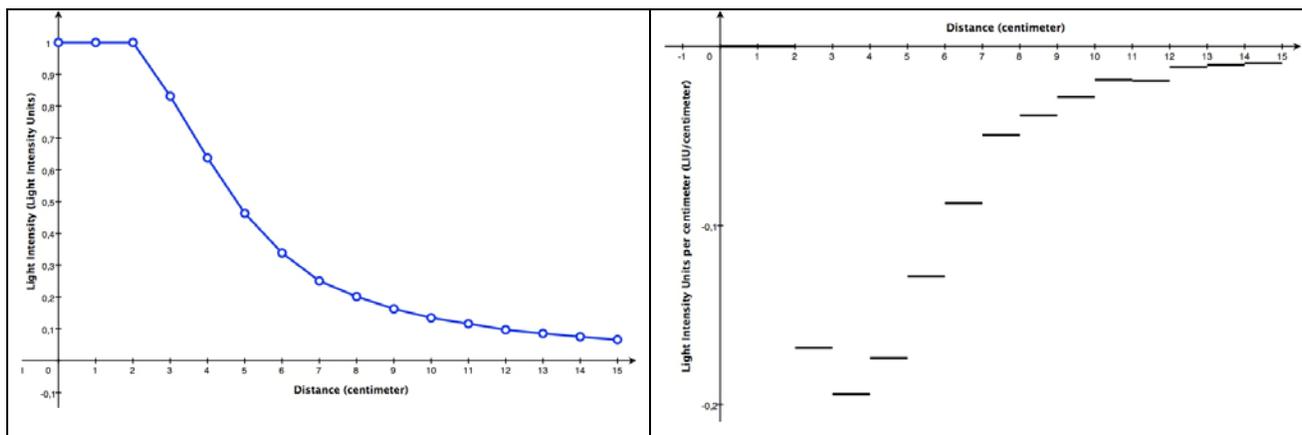

Figure 5. (A) shows the scatter plot and (B) the corresponding rate graph of typical data the students collected

Students' difficulties describing and representing change

For some students, their descriptions of the behavior of the light intensity contradicted their description of the average rate of change of the light intensity. For example: “The intensity of the light decreases at a decreasing rate with respect to the distance from the light source, as predicted earlier. The average rates of change increase at a decreasing rate as distance from the light source increases.” This points to the complexity of the ideas involved in reasoning with negative rates and their different representations, especially when cast in an applied context.

Some of the mathematical demands of the model application activity were challenging for the students. For example, when using the difference quotient to create a rate graph for the average rates of change of the derived function at integer x values and interval length 0.5 cm, many (78%) of the students plotted the interval width as 1 cm. This indicates that the key idea that average rates of change are always calculated over an interval was not yet fully understood by the students. The students had broad guidelines as to what to include in their reports. Hence, there were aspects of their models that were discussed by some students, but simply not addressed by others. For example, only some students (56%) provided arguments for why the first few data points had a measurement of 1 LIU; some students (22%) discussed sources of error that might have distorted the data during the measurement.

DISCUSSION AND CONCLUSIONS

The analysis shows how the students' diverse emerging models of how intensity varies with the distance from the light source converged as the students worked through the phases of the Light Lab. In line with the results of Whitney (2010), the students extensively used tables, but they also created contextually based graphical representations, from which the majority could successfully describe the data they collected within the context of the flashlight and light sensor. More than half of the students could meaningfully describe how the average rates of change of the light intensity varied. Using a meaningful context and actively engaging the students in the model application activity seemed to support some of the students in developing their models of changing phenomena.

The results of this study also suggest a number of issues, such as the meaning and importance of the interval width in the difference quotient and the validation of developed models, need to be addressed to support the continued development of the students' emerging models of average rate of change. Some of these issues could be addressed through a re-design of the activity. However, it should be emphasized that this model application activity was not the end of the model development sequence. Rather, it was followed by another model application activity that engaged students in examining the rate at which a fully charged capacitor loses its charge. The next step in our analysis of the development of students' emerging models will be an examination of that data. This study points to the potential value of examining the development of students' emerging models over sequences of modeling activities.

CREATING THE NECESSARY CONDITIONS FOR MATHEMATICAL MODELLING AT UNIVERSITY LEVEL

Berta Barquero*, Lúdia Serrano** & Vanessa Serrano**

*Universitat de Barcelona , ** IQS–School of Management. Universitat Ramon Llull

This paper focuses on the study of the ‘ecology’ of mathematical modelling in the teaching of mathematics at university level. Using the framework of the Anthropological Theory of the Didactic, we introduce the notion of study and research courses as an ‘ideal’ didactic device for integrating mathematical modelling into current educational systems. We explore some of their essential characteristics or principles that can help with their design, testing and analysis in order to face and overcome some of the constraints that hinder the development of mathematical modelling activities.

1. RESEARCH BACKGROUND: THE ECOLOGICAL DIMENSION IN THE MATHEMATICAL MODELLING PROBLEM

The starting point of our research is the problem of teaching mathematics as a modelling tool in first-year university courses. More specifically, we focus on the intricate problem of studying the ‘ecology’ of mathematical modelling practices in these institutions, that is, the set of *conditions* that favour and the *constraints* that hinder (or prevent) its large-scale development as normalised activities in current educational institutions (Barquero, Bosch & Gascón 2008 and 2010, Artaud 2007, Blum et al. 2002 and Doerr & Lesh 2011). We postulate that the integration of modelling activity needs an in-depth analysis of this ecology.

We use the framework of the Anthropological Theory of the Didactic (ATD) and its conception of mathematical modelling. The ATD uses the notion of mathematical praxeology (MP) as a fundamental tool to describe and analyse mathematical activity. In accordance with García et al. (2006), we consider modelling as a *process of reconstruction and articulation of MP of increasing complexity*. This process can start with the study of a question arising in an extra-mathematical situation, that we call the ‘initial system’, and leads to the construction of a MP that can act as a ‘model’ of the considered initial system. This work usually creates new questions, which require the construction of new models, the previous model thus acting as a ‘system’ of this new modelling process (Serrano, Bosch & Gascón 2010). From this perspective, intra-mathematical modelling—that is, the process of modelling a mathematical system—appears as a particular case of mathematical modelling and allows considering it not only as a way to make the functionality of mathematics visible, but also as a key tool for the construction and connection of mathematical contents. Thus, *mathematical modelling cannot be considered only as an aspect or modality of mathematical activity but has to be placed at the core of it*. This

integration constitutes an essential aspect of our research problem. We will refer to it as the *ecological problem* of mathematical modelling:

What *limitations* and *constraints* in our current educational systems prevent mathematical modelling from being widely incorporated in daily classroom activities? What kind of *conditions* could help a large-scale integration of mathematical modelling at school? What kind of *didactic devices* would make large-scale integration of mathematical modelling possible?

In order to face this problem, from the ATD we propose to use the notion of *study and research courses* (SRC), introduced by Yves Chevallard (2006), as a didactic device to facilitate the inclusion of mathematical modelling in educational systems, and, more importantly, to explicitly situate mathematical modelling problems in the centre of teaching and learning processes (Barquero et al. 2008 and Winsløw et al. 2012). In this paper, we will introduce some of what we consider the main traits of SRC. They can be understood as working principles (or assumptions) that can be taken into account for a design, implementation and analysis of a SRC. We postulate that they are necessary to create appropriate *conditions* to face some of the most important *constraints* to the ‘normal’ life of mathematical modelling at university institutions (Barquero et al 2012).

2. TOWARDS A NEW DIDACTIC PARADIGM: RESEARCH AND STUDY COURSES

Chevallard introduced the notion of SRC (Chevallard 2006) as a general model for designing and analyzing study processes. Its main purpose arose from the need to introduce a new epistemology to replace the still dominant ‘monumentalistic’ epistemology (where mathematical contents appear as monuments to visit) for one which could (re)establish the ‘raison d’être’ and the functionality of mathematics at school. In Chevallard’s words, a change of paradigm at school is completely necessary: from the paradigm of *visiting works and its shortcomings* towards the new didactic *paradigm of questioning the world* (Chevallard 2012).

2.1. General conditions and research methodology for the testing of the SRC

During the academic year 2006/07, our research group started implementing SRC with first-year university students of the business and administration degree (4-year programme) at the IQS School of Management of Universitat Ramon Llull in Barcelona (Spain). Since then, they have been implemented year after year with some variations and improvements. A special device, called the ‘mathematical modelling workshop’, was introduced in the general organisation of the mathematical course. It consisted in weekly sessions of 90 minutes in which one third of classroom time was devoted to students’ work. More than half of their personal work was done outside the classroom. The instructor of the course was also responsible for the workshop sessions. Said sessions ran in parallel to the two-hour weekly lecture sessions, which

included problem-solving activities. Its attendance was mandatory for the students and it constituted forty per cent of the final grade.

In the general organisation of a workshop the students (around 50 in the class) are organized in teams of 3 or 4. They work under the supervision of the instructor responsible for the course and, if possible, of a researcher who acts as an observer. In most of its implementations, the workshop focuses on a single initial problematic question Q , to which students have to provide a complete answer during the entire academic year. It can also consist in three linked questions, one for each term. Once the initial question is presented, two kinds of workshop sessions are combined every week: teamwork and presentations. In the first ones, each team has to look for ‘temporary’ answers to partial questions derived from Q and prepare a ‘partial’ report with these answers. Then, the reports are orally defended on the subsequent sessions by some selected working teams. A discussion follows to state what progress has been made and to agree on how to continue the study process. During the presentation sessions, one member of the class (named the ‘secretary’) prepares a report containing the main points in the discussion and the new questions put forward to be studied in the following sessions. At the end of each term, every student has to individually write a final report of the entire study (evolution of problematic questions, work with different models, relationship between them, etc.).

At this stage of the process, the collected data of the implemented SRC comprises the students’ team and individual reports, the teacher’s written description of the work carried out during each session, the worksheets given to the students and a brief questionnaire handed out to the students at the end of the each term. It constitutes the empirical base upon which the *analysis a posteriori* of the SRC rests.

2.2. Development of the SRC implementation: How does the population of users of a social network evolve over time?

We here focus on the most recent experimentation of the SRC, during the academic year 2010/11. On this occasion, the implementation of the SRC focused on the generative question (Q_0) about *the evolution of the number of users of a social network* called *Lunatic World* (see figure 1). The initial question led to consider different kinds of mathematical models depending on the assumptions made about the initial system.

This initial question was divided into three sub-questions, one of which was approached in each term. The division was made based on the necessary tools for their resolution. For instance, the initial and generative problematic question Q_0 was partially approached using discrete models and assuming independent generations of users during the first term of the course. It was then approached using functional models, so as to fit the best continuous function to real data during the second term. The third branch, developed during the third term, came from the use of discrete models, assuming that all users belonged to different groups. It led to reformulate Q_0 as Q_3 (see figure 2). We will refer to this case in the following section.

www.LunaticWorld.com

What is a social network? A social network is a social structure made up of a set of actors (such as individuals or organizations) and the dyadic ties between these actors. The study of these structures uses social network analysis to identify local and global patterns, locate influential entities, and examine network dynamics.

We will focus on studying the evolution of the number of user of a social network, which is called *LunaticWorld*. It was created in 2004 by 18 users. One of its main characteristics is that a person can become part of it only if another user invites him/her. In the following table you can find information about the evolution of the number of users of this network over some years. With this information, it is proposed to look for responses to the following initial question (Q_0):

Year	Number of users
2004	18
2005	56
2006	151
2007	447
2008	1034
2009	3143

Given the size of population over some time period,

- Can we predict its size after n periods? Is it always possible to predict the long-term behaviour of the population size?
- What sort of assumptions on the population and its surroundings should be made?
- How can one create forecasts and test them?

Figure 1. Introductory worksheet to the workshop:

Presentation of the social network and of the initial question Q_0

MATHEMATICAL MODELLING WORKSHOP – 3rd term

The social network *Lunatic World* has recently introduced important changes. From now on, all users will be distributed in three different groups: **Basic**, **Medium** and **Premium**. After one month, a user can remain in the same group, be promoted to another group or leave the network. Moreover, the only type of users that are allowed to invite other users to join the following month are 'Medium' and 'Premium' groups.

CASE 1 [One of the 16 cases that were distributed to the different teams]:

- 15% of 'Basic' users remains as 'Basic' one month later and 75% of 'Basic' changes to 'Medium';
- 25% of 'Medium' changes to 'Premium' the following month and 50% remains as 'Medium'. Each 'Medium' user invites on average 4 new users that enter as 'Basic' users the following month;
- 90% of 'Premium' remains in the same group. Each 'Premium' user invites on average 3 new 'Basic' users.

Figure 2. Introductory worksheet to the third branch of the SRC:

Discrete models with users distributed in different groups

The different phases of the design, application and analysis of this SRC were similar to those developed in a SRC on population dynamics (Barquero at al. 2008 and 2009)¹. After the implementation of SRC with first-year university students for more than six academic years, we can talk more concretely about the main traits of SRC that seem important to create appropriate *conditions* for the 'real' development of mathematical modelling at university institutions. As mentioned earlier, they can be understood as working principles (or assumptions) for the design and carrying out of SRC.

3. CREATING CONDITIONS FOR MATHEMATICAL MODELLING

3.1. A generative question is the starting point of functional study processes

The starting point of a SRC should be a ‘lively’ question with a genuine interest in the community of study. We call it the *generative question* of the study process, and denote it by Q_0 . It should not be a question imposed by the instructor to cover certain didactic needs fixed a priori. That is, obtaining answers to Q_0 has to become the main purpose and an end in itself. The study of Q_0 , together with the derived questions that can appear along the study, is the *origin, engine* and ‘*raison d’être*’ of all the study process. In this sense, Q_0 should be present during the entire study process and acts as its articulating axis.

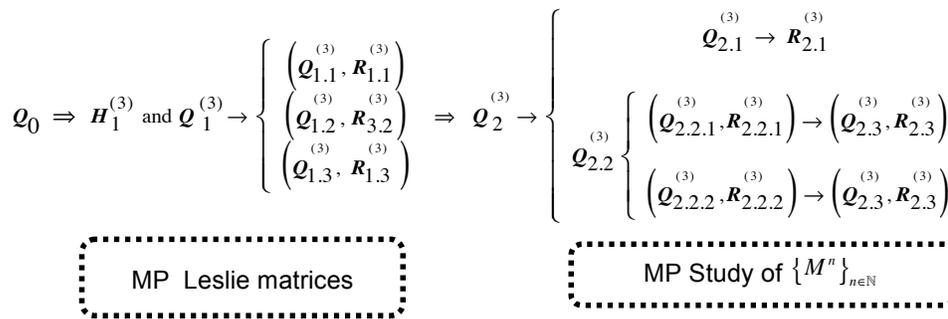

The case of the SRC on ‘*How does the population of users of a social network evolve over time?*’ provides a good example of the power of its generative question Q_0 . With its implementation, we verified how the sequence of questions arising from Q_0 led the students and the teacher to consider most of the main contents of the entire mathematics course (see Barquero et al. 2008). In each term, different aspects that revolve around the initial situation were analyzed. They required the mobilization of various types of mathematical models: forecasting the number of users in the short and long term, considering time as a discrete variable (first-order sequences models, *1st term*), the same forecast considering time as a continuous variable (differential equations, *2nd term*), and the forecast in discrete time distinguishing three user groups with different privileges (models based on matrix algebra, *3rd term*). However, during the SRC, these contents appeared in a very different structure from the traditional organisation. Instead of the classical ‘logic of mathematical concepts’, the workshop was more guided by the ‘logic of the problematic questions’ and ‘types of models’ that appeared progressively.

Another important outcome consists in the necessity to break the rigidity of the classical structure ‘lectures - problem sessions - exams’, based on the sequence ‘introducing new contents - applying the contents’. It can be considered as an important constraint to the integration of mathematical modelling. However, it was still important to ensure that both lectures and problem sessions were taken into account during the workshop. As a result, there had to be a bidirectional relationship between all these didactic devices. On the one hand, ‘lectures and problem sessions’ are used to provide students with some of the necessary tools to be able to follow the workshop. And, vice versa, the workshop motivates and shows the functionality of the main content of the course.

3.2. SRC have a tree structure, as a consequence of the search for answers to Q_0

During a SRC, the study of the generative question Q_0 evolves and opens up numerous other ‘derived questions’: Q_1, Q_2, \dots, Q_n . One must constantly question whether these derived questions are relevant. The fundamental criterion to decide whether they are indeed relevant is to ensure that they are capable of providing answers R_i that are helpful in elaborating a final answer R^\heartsuit to Q_0 .

As a result, the study of Q_0 , and of its derived questions Q_i , leads to successive temporary answers R_i which would be tracing the possible ‘routes’ to be followed in the effective experimentation of the SRC. We claim that the work of production or construction of R^\heartsuit can be described as a tree of questions Q_i and temporary answers ($R_i = MP_i$) related to each other during a modelling process that is both *progressive* and *recursive*. For instance, in the following diagram we can see, in terms of questions and their successive answers, the structure of the 3rd branch of the SRC concerning ‘Discrete models with users distributed in different groups’. Its study led to the consideration of two MP: the first one is based on the construction of models based on Leslie matrices and its use in the short-, medium- and long-term forecast of users’ distribution and the second one focuses on the study of powers of matrices, with Leslie matrices being a particular case.

Some examples on the formulation of questions that appear in the structure of the third branch of the SRC:

$Q_{1.1}^{(3)}$: How can we describe the evolution of the distribution of users in groups under the new conditions of *Lunatic World network* (see figure 2)?

$Q_{1.2}^{(3)}$: Will it be always possible to forecast the future distribution of the users after some periods of time? Which will be the long-term distribution of users? [...]

$Q_{2.2.2}^{(3)}$: In the case of Leslie matrices (L) of 2nd order, what are the main properties of L^n ? What can we say about $\lim_{n \rightarrow \infty} \{L^n\}_{n \in \mathbb{N}}$? Can we generalise their properties to the case of a Leslie matrix of n -order?

Figure 3. Structure of the 3rd branch of the SRC in terms of questions and answers

Let us stress the importance and utility for students/teacher/researchers of what we have called the *mathematical a priori design* of the SRC to guarantee that the generative question is sufficiently ‘fertile’ to lead to many other derived questions. The design also gives a detailed description of the possible evolution of the study of Q_0 in terms of potentially derived questions and their successive answers (Q_i, R_i), which would be tracing the possible routes to be followed in the effective experimentation of the SRC.

3.3. Promoting the role of the study community: The dialectics between individuals and the community

A ‘real’ integration of mathematical modelling needs to *promote the role of the study community* along with that of the *director* of study. This study community has to be in charge of ‘collectively’ studying Q_0 and producing an appropriate answer R^\heartsuit . In

contrast to the ‘dominant pedagogy’ where there is dominance of ‘individual’ work under the orders of teacher, the group of students and the teacher have to share the set of tasks and negotiate the responsibilities that each of them has to assume.

This displacement going from the individual to the community has numerous important consequences to enable the existence of mathematical modelling. On the one hand, the collective study of questions provides the opportunity of *defending answers* produced by the community, instead of accepting the *imposition of official answers*. On the other hand, this work required students to take on a lot of new responsibilities that the ‘traditional didactic contract’ exclusively assigns to the teacher, for instance: addressing new questions, creating hypotheses, searching for and discussing different ways of looking for an answer, comparing experimental data and reality, choosing the relevant mathematical tools, criticizing the scope of the models constructed, writing and defending reports with partial or final answers, etc. The teacher thus has to assume a new role of acting like the leader of the study process, instead of lecturing the students. And it soon appeared that the teaching culture at university level did not offer a variety of teaching strategies for this purpose.

3.4. The dialectics of questions and answers as the engine of the SRC

An important dialectic that is integrated in the SRC is the task of posing questions and that of the search for answers. In the ‘traditional’ didactic contract, the responsibility of posing questions generally falls on the teacher, while students only come up with doubts or questions that the teacher can answer quickly.

As we saw in the experimentation of the SRC, the mathematical modelling process required the entire community to focus on the study of a single question for a long period of time (the whole year!). This question had to remain ‘alive’ and ‘open’ session after session. Furthermore, the relevance of the derived questions and the opportunity of its consideration must appear as yet another gesture of the study process. It had to be negotiated between the teacher and the students.

This situation is rarely seen under the ‘dominant’ pedagogy. For instance, the teacher is only attributed with the ability to ‘teach’ certain contents, the value of which nobody questions. In order to overcome the constraints that appeared during the experimentation of the SRC (students’ passiveness, their request for a close supervision by the teacher, etc.), the teacher introduced some relatively new didactic devices. For example, the teacher asked the students to pose at least one new question that arose from the work carried out when they handed in their weekly team report. Moreover, at the beginning of the following session those new questions were brought together and students—under the teacher’s watchful eye—agreed on the way to continue. It was an excellent way to compare and discuss the work done during the entire process, and more particularly, a way for the study community to formalise all the questions approached as well as their successive temporary answers.

3.5. The dialectics of the diffusion and reception of answers

Against the temptation of imposing some answers that are acceptable within the educational institution, the group of students needs to be invited to *defend* the successive answers R_i they provide, although they may still be of a temporary nature.

In the case of our experimentation, as we mentioned before, we introduced a device named ‘Report of results’, which was relatively foreign to the mathematical teaching culture. Each week, in groups, the students had to elaborate a written text in which they gathered both the documents provided by the teacher, and the partial results of the work done in the workshop session. They complemented it with their personal comments and the information on the subject they were able to gather. They had to hand in the report to the teacher. These dossiers thus contained the answers that each group would defend in class at the beginning of each session. At the end of the workshop, each student had to hand in their own ‘final report’ that no longer contained the chronicle of the study process but focussed on presenting and defending a final answer to the question initially posed. Undoubtedly, the students did not easily accept elaborating, reading and defending the reports due to the difference compared to other study devices used in other subjects. Despite all the resistance put up by students to the changes introduced during the implementation of SRC—working in groups, scheduling the study on their own, formulating questions, selecting mathematical contents, using a computer and bibliographical resources, writing and defending temporary answers, etc.—all these responsibilities (traditionally assumed by teachers) were progressively accepted by them. This increasing autonomy assumed by the students during the SRC seems a necessary condition to carry out the activity of mathematical modelling.

3.6. The dialectics of ‘media’ and ‘milieu’

The implementation of a SRC can only be carried out if the students have some pre-established answers accessible through the different means of communication and diffusion (that is, the *media*), to elaborate the successive provisional answers R_i . These *media* are any source of information such as, for instance, textbooks, treatises, research articles, class notes, etc. However, the answers provided are constructions that have usually been elaborated to provide answers to questions that are different to the ones that may be put forward throughout the mathematical modelling process. They have to be ‘deconstructed’ and ‘reconstructed’ according to the new needs. Other types of *milieus* will therefore be necessary to put to the test and ‘check’ the validity of these answers.

In our experimentations with SRC, this dialectics was crucial for mathematical modelling. When constructing a model from a certain system, it was essential for the student to have access to answers that were not reduced to the ‘official’ answer of the teacher (or textbook), as well as to the means to validate them. Students were systematically asked to look for information in the *media* about the types of models they provided. In particular, they had to check whether said models already existed and whether they were important enough so as to be assigned a specific name, and so on. The validity of the models constructed or provided was carried out from data –

which in our case the teacher had provided – and through numerical simulation with Excel or the symbolic calculator Wiris (www.wiris.com). We find good examples of this in the 3rd branch of SRC based on Leslie’ matrix models (see figure 2 and 3) where, for example, to be able to forecast the short- and long-term distribution of users into groups or to simulate the n -power of a Leslie matrix, the numerical simulation provided by Excel or Wiris could work as *media* to formulate some conjectures about their pattern but also as *milieu* to check or refuse the conjecture they could have formulated.

4. DISCUSSION AND FURTHER RESEARCH

Using the ‘ecological’ metaphor, we can say that for mathematical modelling to be able to ‘live’ normally in a teaching institution (more specifically at university level), an in-depth study of the *conditions* that facilitate and the *constraints* that hinder the type of mathematical activities has to be carried out. In our research, we have used the notion SRC as a reference model of didactic organisations, which are proposed to allow mathematical modelling to ‘live’ in educational systems. In this paper, we have introduced some of what we consider as their main characteristics that can be used as principles for their design, testing and analyses. Far from being closely-characterised, what it is important to highlight is that most of their traits appear to face some constraints that generally come from the dominant ‘epistemological’ and ‘pedagogical’ models and that make the life of mathematical modelling difficult (Barquero et al. 2010 and 2012). We have mentioned several of them throughout the paper: coming from ‘monumentalistic’ school epistemology, from the classical organization of mathematics following the ‘logic of mathematic contents’, from the ‘traditional’ didactic and pedagogic contract, from the rigidity of the classical structure ‘lectures – problem sessions – exams’, from students’ passiveness, etc.

Given the fact that the origin of most of these constraints is located at the generic levels of ‘school’ and of ‘society’, it seems obvious that they are not to be directly modified only through changes introduced by the teacher in the classroom. We therefore propose a different way, which, in a sense, is the opposite approach. We suggest beginning by proposing and changing the *gestures of the study*, which requires the introduction of *new didactic devices* which make the carrying out of gestures possible. After more than six years of implementation of SRC at university level, we can say that SRC have become more and more consolidated as a normal didactic device. Despite their initial difficulties, our present research moves forward towards a progressive and generalized introduction of certain ‘*study gestures*’ and the appropriate ‘*didactic devices*’ that could make it possible to effectively transform the type of scientific activity carried out in university classrooms.

DIVERSITY IN MIDDLE SCHOOL MATHEMATICS TEACHERS’ IDEAS ABOUT MATHEMATICAL MODELS: THE ROLE OF EDUCATIONAL BACKGROUND¹

Alfredo Bautista, Michelle H. Wilkerson-Jerde, Roger Tobin, & Bárbara M. Brizuela

Tufts University

The purpose of this study was to explore the relationship between mathematics teachers’ educational backgrounds and their ideas about 1) what constitutes a mathematical model of a real-world phenomenon, and 2) how models and empirical data relate. Participants were 56 United States (US) in-service mathematics teachers (grades 5-9). We analysed teachers’ written responses to three open-ended questions through content analysis. Results show our participants do not hold a unitary understanding of mathematical models. Teachers with backgrounds in Mathematics Education and Science Disciplines especially stressed the usefulness of models to show general relationships, whereas those with backgrounds in Other Disciplines stressed the importance of producing exact results.

INTRODUCTION

In the United States, and elsewhere, mathematics teachers across grades K-12 are increasingly required to include modelling in their teaching. In fact, mathematical modelling is one of eight practices standards proposed by the Common Core State Standards for Mathematics (2012). Considerable research has been devoted to exploring how mathematics teachers from different grade levels solve modelling problems (Blum & Borromeo Ferri, 2009; Verschaffel, De Corte, & Borghart, 1997), and to describing their beliefs and conceptions of the role of modelling activities in the classroom (Kaiser & Maaß, 2007). However, little is known about how teachers understand what a “mathematical model” is, and about the relationships between models and real-world phenomena.

Defining modelling in the context of mathematics education is a complex task (Blum, 2002). Most researchers and policymakers agree that mathematical modelling involves using the tools of mathematics to distill key elements of a real-world situation and articulate the relationships between those elements. This distillation enables the learner (or the model creator, more generally) to further explore the situation using the tools of mathematics, with the ultimate purpose of mobilizing those findings toward accomplishing further goals in the original situational context (Lesh & Doerr, 2003). By definition, then, model creators themselves must decide what particular mathematical representations, tools, and methods are appropriate to

¹ This study was funded by the National Science Foundation (NSF), Grant # DUE-0962863. The ideas expressed herein are those of the authors and do not necessarily reflect the ideas of the funding agency.

use when modelling a given situation. What constitutes a mathematical model, therefore, varies across situations and contexts, as well as users and audiences.

This study explores how middle school mathematics teachers think of mathematical models, considered as the external *objects* produced during the modelling process. Several definitions of the term “mathematical model” have been proposed by educational researchers. For example, Niss (1989) defines mathematical model as a combination of one or more mathematical “entities,” whose relationships are chosen to represent aspects of a real-world situation. In a similar vein, Lesh and Doerr (2003) argue that models are conceptual systems expressed using external representations, serving as tools to construct, define, and explain other systems.

These definitions elaborate on models’ representational nature, and emphasize how models embody the decisions modellers make during modelling process (Janvier, 1987). Mathematical models consist of one or more representations purposely chosen and displayed in a way that allows modellers to highlight what they identify as the most important variables and relationships of the phenomenon under study. Deciding what is and is not important constitutes, in fact, one of the main tasks to be completed in modelling activities. Thus, mathematical models themselves may substantially vary depending on the final goals, preferences, and/or biases of their creators. It is perhaps for that reason that the above definitions do not specify which particular representations can be considered as the “components” of mathematical models. In a nutshell, mathematical model is a “slippery” concept, open to numerous interpretations.

In this study, we use the variable “Educational Background” to explore the diversity of teachers’ ideas about models as external objects. Existing literature has not yet focused on investigating the relationship between mathematics teachers’ educational background and their ideas about mathematical models. In the field of science education, the interview study conducted by Justi and Gilbert (2003) explored the “notions of model” held by 39 science teachers with different disciplinary backgrounds – holding degrees in Chemistry, Physics, Biology, or Primary Teaching Certificate. The ideas of these science teachers tended to differ according to their educational backgrounds. For example, most teachers holding a Primary Teaching Certificate strongly subscribed to everyday views of the notion of model, according to which a model is a reproduction of something or a standard to be followed. Teachers with a degree in Biology expressed similar ideas, although they referred to broader variety of *uses* of models. Finally, teachers with a background in Physics or Chemistry discussed the notion of model in more comprehensive ways, consistent to perspectives currently held by scientists and philosophers of science. Moreover, they emphasized the usefulness of models for making predictions. These results suggest that the use of mathematical models might in fact differ across different disciplines.

PURPOSE AND JUSTIFICATION

The purpose of this study is to provide evidence that middle school mathematics teachers with different educational backgrounds tend to have diverse sets of ideas regarding 1) what constitutes a mathematical model of a real-world phenomenon, and 2) the relationships between models and empirical data. Drawing on the assumption that teachers' ideas about mathematical content are crucial mediators for the way they teach such content to their students (Sánchez & Linares, 2003), the evidence presented in this paper can be taken as an indicator that teachers with different disciplinary backgrounds might be addressing the teaching of models and modelling activities in very different ways. A better awareness of this diversity of ideas can inform teacher educators as they design programs to prepare mathematics teachers (both pre- and in-service) for an increasingly modelling-focused curriculum. Our study is also relevant for cognitive researchers interested in teacher thinking, as it shed light on the role that educational background plays in teachers' ideas about subject matter.

METHOD

Participants

Data for this study were gathered during the third week of a professional development program carried out in the Northeast of the US. Participants were 56 grade 5 to 9 mathematics teachers from nine school districts. There were 49 female teachers and 7 male teachers, ranging from 26 to 63 years of age. When data were collected, their professional experience as mathematics teachers ranged from 2 months to 28 years. The teachers had a variety of educational backgrounds, which we grouped into four categories:

- Mathematics: when the teachers earned their bachelor's or master's degree in mathematics (13 teachers);
- Mathematics Education: when teachers' bachelor's or master's degree was in mathematics education and they did not hold a bachelor's or master's degree in mathematics (8 teachers);
- Science Disciplines: when teachers' bachelor's or master's degree was in any science discipline (such as physics, engineering, or chemistry) and they did not hold a degree in mathematics and/or mathematics education (8 teachers);
- Other Disciplines: when teachers' bachelor's or master's degree was in other disciplines (such as Special Education, History, English, or Literature) and they did not hold a degree in any of the above-mentioned disciplines (27 teachers).

Modelling Problem and Target Questions

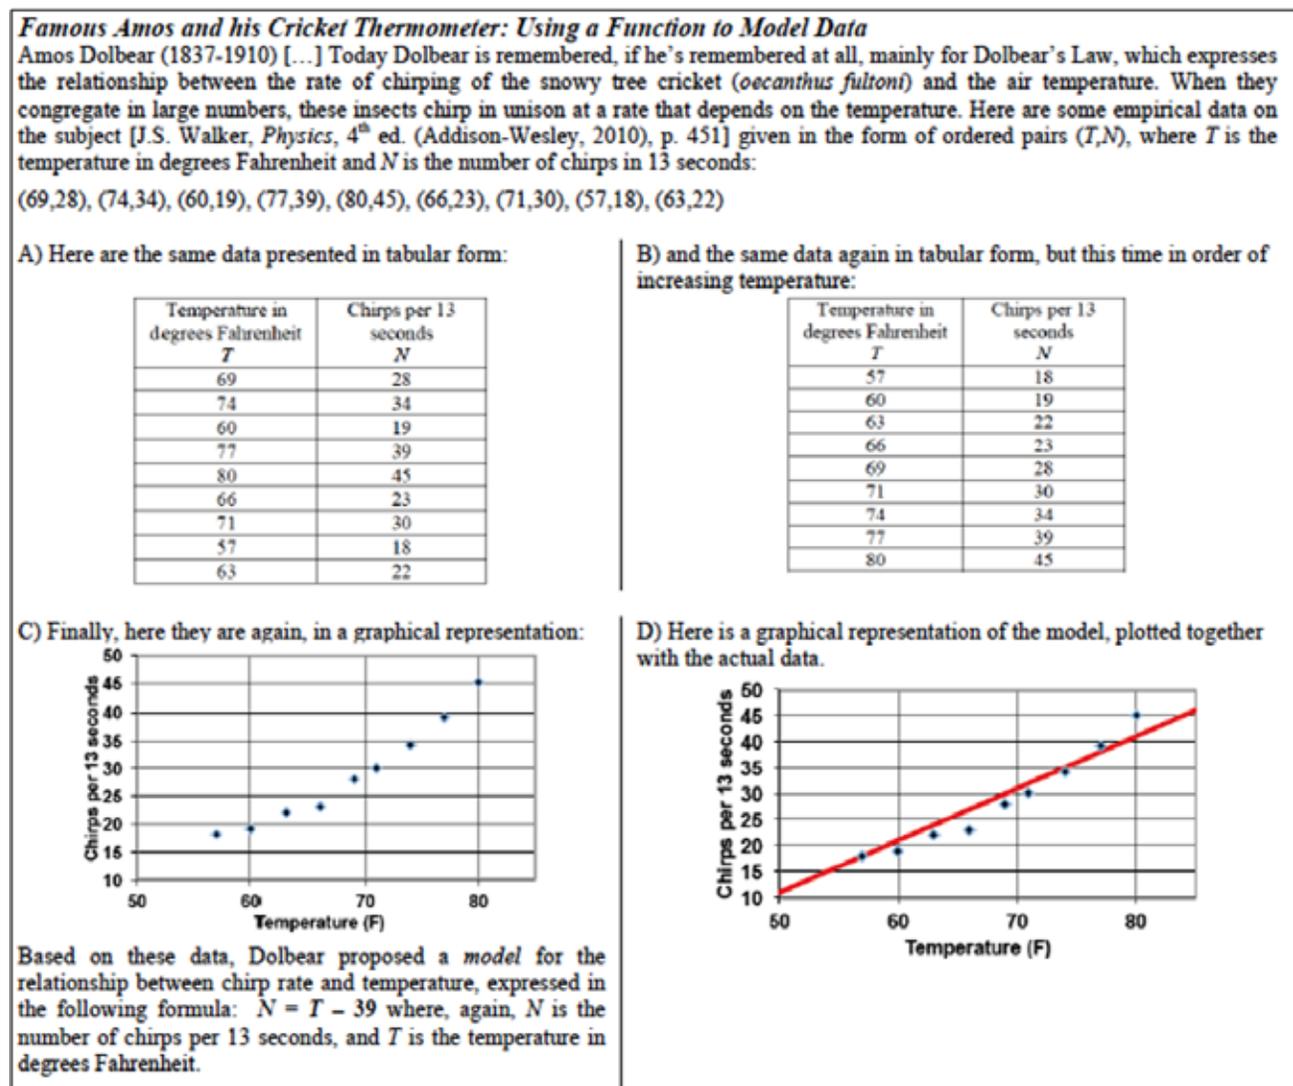

The modelling problem used (see Figure 1) presents Dolbear's Law, which expresses the relationship between the rate of chirping of the snowy tree cricket (N) and air temperature (T). A linear relationship between these two variables is proposed by the model creator. To explain Dolbear's Law, different representations of this relationship were shown to the teachers. Notice that the problem explicitly

characterized the equation ($N = T - 39$) as the *model*. The list of ordered pairs, tables, and graphs were characterized as *representations*. The nine data points presented in these representations were referred to as *data*.

The teachers were asked a set of 12 open-ended questions. Several questions focused on the advantages and disadvantages of some given representations over others. Other questions focused on the similarities and differences among these representations. For this study, we analysed only those questions involving the ideas of “model” and “data,” which were the following:

- Question 1: *How would you characterize the relationship between the model and the data?*
- Question 2: *Could you extract the data from the model?*
- Question 3: *Do you think the model conveys more or less information than the data? Why?*

Figure 1: Problem used in the study

RESULTS

Teachers' responses to the three target questions were analysed using sets of non-mutually exclusive categories. In this section, we first focus on the content specific to each question. Then, we analyse some additional ideas that systematically appeared throughout the three questions. Tables containing the frequencies and percentages obtained by each group are presented.

Question 1: How would you characterize the relationship between the model and the data?

Teachers with different educational backgrounds tended to refer to different representations when characterizing the notion of “mathematical model” (Table 1). Recall that all sets of categories used in this study are non-mutually exclusive in nature. This is why counts in many columns of the tables presented go over 100%.

	EDUCATIONAL BACKGROUND			
	Mathemat N=13	Math Ed N= 8	Science N=8	Other Disc N=27
<i>The model is referred to...</i>				
As an Equation	6 (46.1%)	5 (62.5%)	1 (12.5%)	3 (11.1%)
As the Data Points	1 (7.7%)	1 (12.5%)	3 (37.5%)	9 (33.3%)
As the Line of Best Fit	8 (61.5%)	4 (50%)	7 (87.5%)	17 (62.9%)
Doesn't specify / Unclear	2 (15.3%)	0	0	0

Table 1. Frequencies and percentages obtained by Question 1 analytic categories*

* Values equal or higher than a third of each subsample (33.3%) are bold. Categories are non-mutually exclusive

Teachers from all educational backgrounds frequently referred to the line of best fit as the model, especially the group Science Disciplines. The groups Mathematics and Mathematics Education tended to express that the model was the equation provided ($N = T - 39$). They referred to it using the terms formula, algebraic expression, and/or function. In addition, a number of teachers from the groups Science Disciplines and Other Disciplines referred to the original data points as being part of the model. Interestingly, other representations provided such as the ordered pairs, the tables, and the written description of the scenario were never referred to as the model.

Question 2: Could you extract the data from the model?

We found opposite ideas regarding the viability of extracting the original data points from the model (Table 2). Whereas the groups Mathematics and Mathematics Education provided us mostly with negative answers (i.e., the data points *cannot* be extracted from the model), the groups Science Disciplines and Other Disciplines showed more diverse views, providing both affirmative and negative responses. These findings make perfect sense if we consider that the data points were regarded as part of the model by groups Science Disciplines and Other Disciplines, but not by the groups Mathematics and Mathematics Education.

	EDUCATIONAL BACKGROUND			
	Mathemat N=13	Math Educat N= 8	Science Disc N=8	Other Disc N=27
Affirmative answer	2 (15.3%)	1 (12.5%)	4 (50%)	10 (37%)
Negative answer	11 (84.6%)	5 (62.5%)	2 (25%)	14 (51.8%)
Elements of both	0	1 (12.5%)	0	0
Unclassifiable / Unclear	0	1 (12.5%)	2 (25%)	3 (11.1%)

Table 2. Frequencies and percentages obtained by Question 2 analytic categories*

Values equal or higher than a third of each subsample (33.3%) are bold. Categories are non-mutually exclusive.

Question 3: Do you think the model conveys more or less information than the data? Why?

This question also elicited different responses among our participating teachers. Most teachers from all backgrounds think that the model conveys more information than the data, although the justifications given present interesting differences (justifications are not presented here due to space limitations). In addition, the opposite idea (the model conveys less information) was also identified among some teachers (Table 3).

	EDUCATIONAL BACKGROUND			
	Mathemat N=13	Math Educat N= 8	Science Disc N=8	Other Disc N=27
More information	10 (76.9%)	5 (62.5%)	5 (62.5%)	13 (48.1%)
Less information	0	2 (25%)	0	5 (18.5%)
It depends, Different, More and Less	3 (23.1%)	1 (12.5%)	2 (25%)	5 (18.5%)
Unclassifiable / Unclear	0	0	1 (12.5%)	4 (14.8%)

Table 3. Frequencies and percentages obtained by Question 2 analytic categories*

* Values equal or higher than a third of each subsample (33.3%) are bold. Categories are non-mutually exclusive.

An analysis across Questions 1, 2, and 3: Exactness vs. Relationship

Content analysis led us identify the existence of two ideas that recurrently appeared in most teachers' responses throughout the three questions analysed here: the ideas of "Exactness" (or lack thereof) and "Relationship." This finding is interesting to us because the questions posed did not explicitly ask about these issues.

As can be seen in Table 4, most teachers from the groups Mathematics Education and Science Disciplines consistently referred to the usefulness of models to show relationships or general patterns in the data. This result was consistently found across the three questions analysed. Very few references to the idea of exactness were identified among these two groups. Teachers from the group Other Disciplines, in contrast, tended to stress the idea of exactness very often. For them, models should be able to provide exact/precise approximations to empirical data. Teachers from the group Mathematics did not show a clearly defined tendency. Interestingly, Question 3 triggered responses focused on both ideas (exactness and relationship), although specially that of relationship.

	EXACTNESS			RELATIONSHIP		
	Question 1	Question 2	Question 3	Question 1	Question 2	Question 3
Mathematics (N = 13)	5 (38.4%)	5 (38.4%)	6 (46.1%)	5 (38.4%)	3 (23%)	8 (61.5%)
Math Educat (N = 8)	0	2 (25%)	3 (37.5%)	6 (75%)	5 (62.5%)	5 (62.5%)
Science Disci (N = 8)	1 (25%)	3 (37.5%)	2 (25%)	7 (87.5%)	6 (75%)	8 (100%)
Other Discipli (N = 27)	17 (62.9%)	16 (59.2%)	20 (74%)	8 (29.6%)	11 (40.7%)	12 (44.4%)

Table 4. Exactness vs. Relationship: Frequencies and relative percentages*

* Values equal or higher than higher than a half of each subsample (50%) are highlighted. Categories are non-mutually exclusive.

DISCUSSION AND CONCLUSIONS

Researchers have proposed that mathematical models consist of one or several mathematical entities purposely chosen and displayed to describe, predict, and/or explain phenomena (e.g., Lesh & Doerr, 2003; Niss, 1989). Consistent with that idea, the first conclusion of this study is that middle school mathematics teachers also understand and think of mathematical models as external tools of representational nature (Janvier, 1987). In the context of “The Cricket Problem,” most teachers cited several external representations as constituting the model, including the line of best fit, algebraic notation (equation, formula, and/or function), and to a lesser extent, the raw data points. Teachers associated these representations with the model even though the text of the problem explicitly defined the equation as the model and characterized the others as representations. Other external representations available – such as the list of ordered pairs, the written description of the scenario, the unordered table, and the ordered table – were never explicitly referred to as part of the model, even though some of them contained precisely the same information as the data points.

Our second conclusion entails two ideas: a) middle school mathematics teachers in the United States do not hold a unitary understanding either of what a mathematical model *is* or of what such a model is *for*; and b) teachers with different educational backgrounds understand mathematical models in systematically different ways (Justi & Gilbert, 2003). This study illustrates the extent to which the notion “mathematical model” can be interpreted differently by different audiences. Even though all teachers were provided with the same materials, they spontaneously focused their attention on different representations and analysed the situation using different criteria. While teachers from all backgrounds tended to include the line of best fit in the model, teachers with backgrounds in Mathematics and Mathematics Education were more likely than those in the other two groups to mention algebraic expressions, and to state that the data could not be extracted from the model (those with Mathematics degrees were most emphatic on this point). In contrast, those with backgrounds in Science or Other Disciplines were more likely to consider the data points themselves

as part of the model, and thus to consider it possible, if perhaps difficult, to extract the data from the model.

A somewhat different pattern emerges, however, when the teachers' reasoning is considered more closely, with attention to the recurring themes of "exactness" and "relationship." Teachers with backgrounds in Mathematics Education and in Science Disciplines strongly stressed the important role of the model in illustrating or clarifying the general relationship between the two quantities (temperature and number of chirps). For them, models are powerful tools to show general patterns in the data and to be able to generalize beyond the particular set of data at hand to the natural phenomenon under study. Teachers from a Mathematics background tended to take a more formal approach, viewing the data and model as mathematical objects to be compared, with less concern for the real-world phenomenon being described. Teachers with backgrounds in Other Disciplines were most concerned with exactness – whether the model could precisely reproduce the original data.

An educational background in Mathematics seems to be associated with understanding models as an "idealization" of the data, as abstract representational tools whose main work is to *predict*. In addition, teachers with this background are concerned with formal aspects of models. For example, they frequently expressed the importance of clarifying the domain and range of the function, and referred to the tensions between mathematics and the natural world (e.g., crickets would die under extreme temperature conditions). Finally, these teachers focused on the question of how the model and data are related as "abstract entities" (Kaiser & Maaß, 2007), with less reference to what the user might want the models for.

Teachers with educational backgrounds in Mathematics Education and Science Disciplines demonstrated some similar ideas to each other. They focused on what the model is good for, as well as what the user can do with models. In addition, they described models as powerful tools not only to *predict* but also to describe the general relationship between variables and to help us see patterns and generalize (Justi & Gilbert, 2003). Exactness of models is not an important issue for these teachers, as it is for the Other Disciplines group. Teachers with a Mathematics Education background extensively referred to the advantages of having a model (e.g., to visualize patterns, estimate unknown data, see trends in the data). However, they did not describe in detail the specific conceptual information of the problem at hand, as teachers from Science Disciplines did. Indeed, having a background in Science Disciplines is associated with focusing on the specific characteristics of the model (specific kind of functional relationship, strength of the relationship, presence of outliers, etc.). Moreover, it was primarily the Science Disciplines group who tended to see the model presented as just one of many possible models, and who discussed other possibilities (i.e., an exponential model).

Formal education received by teachers from the Other Disciplines group was focused neither on mathematics nor science content knowledge. The preoccupation of these teachers with the exactness of the model suggests that they might conceive of

mathematics as an abstract, authoritarian discipline (Kaiser & Maaß, 2007). Like many college students, teachers from the Other Disciplines group tend to view models as either exactly right or else completely arbitrary, in which case the choice of a model becomes entirely subjective. The characterization of the “degree of exactness” of models along a *spectrum* is a more sophisticated idea than just dividing them into “exact” and “non-exact” (or “right” and “wrong”), as teachers in the Other Disciplines group did. Similar to the Mathematics Education group, these teachers did not pay much attention to the conceptual/contextual information of the modelling scenario at hand. In contrast, they tended to refer to the model in the abstract (Verschaffel et al., 1997).

EDUCATIONAL IMPLICATIONS

Given the diversity of potential educational backgrounds among middle school mathematics teachers, it is crucial to develop a better understanding of the ways in which these diverse backgrounds might influence their ideas about mathematical models, and subsequently their teaching of modelling. The findings of this study can inform the design of units on mathematical modelling for both pre-service and in-service mathematics teachers. For example, it would be enriching for teachers with backgrounds in Mathematics and Mathematics Education to deal with situations of exploration and analysis of the different every-day constraints that might affect mathematical models. Similarly, teachers with backgrounds in Other Disciplines would benefit from experiences in which the exactness of models is not an essential issue. This would allow them to explore the advantages of visualizing general trends in the data. More generally, the evidence presented here shows that there is room for all teachers – regardless their educational background – to expand the range of representations they consider as, or include in, mathematical models, and the goals and purposes of generating, analysing, and evaluating such models. Our findings further suggest that one way to do this might be to encourage teachers with different backgrounds to collaboratively engage in modelling activities, in order to better understand the role of perspective, available tools and skills, and sense-making play in modelling activity.

LIMITATIONS AND DIRECTIONS FOR FURTHER RESEARCH

This study is clearly exploratory and suffers from a number of limitations. First, the evidence comes from a single source of data —i.e., written responses to open-ended questions. The present analysis constitutes the first step in our research agenda on middle school mathematics teachers’ modelling ideas and approaches. Other data sources should be included to validate our claims. This is precisely our next goal. We are currently in the process of interviewing a subset of the teachers who participated in this study. Among the goals of our interviews is to clarify some of the findings presented here. Another limitation is that the sample of participating teachers was uneven regarding the four educational background groups, and some of the groups were too small for robust statistical analyses. This imbalance roughly reflects the current backgrounds among middle school mathematics teachers in the United States,

where teachers with a Mathematics or Mathematics Education background are outnumbered by teachers with backgrounds in Other Disciplines. The fact that this study was conducted in the context of a professional development program did not allow us to select the sample having the educational background criterion in mind. Therefore, further studies should be conducted to determine whether the differences identified here are also observed in other samples of mathematics teachers. It would be also necessary to study mathematics teachers' responses in other types of modelling situations (e.g., probabilistic simulation situations, theory-driven models).

EXCEL MODELLING IN UPPER SECONDARY MATHEMATICS – A FEW TIPS FOR LEARNING FUNCTIONS AND CALCULUS

Jan Benacka & Sona Ceretkova

Constantine the Philosopher University in Nitra, Slovakia

The paper brings a few tips to using spreadsheets for teaching and learning functions and calculus at gymnasium (grammar school) in a constructionist way when the learner develops the application by himself. A questionnaire survey was conducted with 34 gymnasium students in four 90 minute lessons to find out if they found the lessons interesting, understood the mathematics and learned new spreadsheet skills.

INTRODUCTION

Mathematical modelling and applications has been in the focus of research in mathematics education for several decades (see Blum & Niss, 1991; Beare, 1993; Blum, 2002; Borromeo Ferri & Blum, 2011; Lingefjärd, 2011). Connection of mathematics to other sciences, its relevance to the outside world, learning concepts in context and connecting them through applications, teaching conceptually through helping students construct their own meanings grounded in real-life experiences – these are some of the basic ideas that underpinned this new vision of mathematics education at the pre-college level (Abramovich, 2003).

A powerful tool that enables easy access to ideas and concepts through a computational experiment are spreadsheets. The tool represents a most popular general-purpose software used by educators to promote the spirit of exploration and discovery by integrating experiment in teaching.

Educators discovered the educational potential of spreadsheet in mathematics and sciences in the early 1980s. Spreadsheets allow using problem-solving and heuristic methods that are close to the talented pupils. Only applications developed in special programming environments offer such ability of analyzing scientific problems.

Baker and Sugden (2003) gave a detailed account on spreadsheets in education from 1979 till 2003. They prove on a wide range of research papers about spreadsheets in teaching mathematics, physics and computer science that

"... there is no longer a need to question the potential for spreadsheets to enhance the quality and experience of learning that is offered to students. Traditional barriers (...) need to be removed, either by ensuring that access to computers is improved or by changing assessment methods. Further expansion is needed of the types of topics that can be effectively covered by spreadsheet examples ..." (also see (Sugden, 2007)).

The paper was written on the occasion of launching the electronic journal Spreadsheets in Education. The goal of the journal is to create a forum for scholarly research into the use of spreadsheets at all levels of education, in which ideas on the use of spreadsheets can be exposed, explored, and reported to a practising audience to enable to adopt a technology for life to which all students should be exposed. Many

articles has been published in the journal on spreadsheets in upper secondary mathematics (Abramovich, 2003, 2012), (Sugden, 2005), physics (Benacka, 2009), informatics (Lovászová & Hvorecký, 2003), (Benacka, 2008), etc. There are many articles in other journals and books on spreadsheet modelling in upper secondary mathematics and sciences (Neuwirth & Arganbright, 2004), (Benacka, 2011).

While developing the spreadsheet application, students project their mathematical knowledge into a tangible form and gain another view of mathematics. Spreadsheets offer to the students the power of dynamical discovering, which is an important element of inquiry based learning (IBL) in mathematics and science. Spreadsheets enable the students to develop applications that satisfy his/her specific requirements (the cells can be formatted conditionally; the parameters can be controlled by scrollbars and other components, etc.). These all are powerful motivating factors. When the application is ready, it can be saved and used again; if necessary, it can be modified or improved. A great advantage of Excel[®] is that it is a common equipment of computers at school and home; it is accessible almost everywhere.

In this paper, we bring a few tips to using spreadsheets for teaching and learning functions and calculus at gymnasium (grammar school; age 15–19) level. The aim is to learn the concept in a constructionist way when the learner develops the application from “nothing”. The topics are graphing functions, finding extremes, solving systems of linear equations, and calculating area by the idea of the Riemann integral and Monte Carlo method. Some of the applications can be implemented in a short time provided the user is skilled in spreadsheets; however, as the authors' teaching practice has shown, most of graduates of secondary schools and even upper secondary teachers are not familiar with the skills used. A questionnaire survey was conducted with 34 gymnasium students. The research questions were if the students found the lessons interesting, understood the mathematics and learned new spreadsheet skills. The results are discussed.

GRAPHING FUNCTIONS

Functions are a significant part of mathematic curriculum at upper secondary school. Students study the properties of the graphs, the relations between the parameters and the graph, etc. The knowledge is essential for studying STEM (see Michelsen, 2006).

The application on the left side of Fig. 1 graphs functions if the definition domain is \mathbb{R} . The graph is of xy line type made over 100 points in range B17:C117. Cell C13 contains the formula $=(C12-C11)/100$. Cell B17 contains $=C11$, Cell B18 contains the formula $=B17+\$C\13 . Cell C17 contains $=\$C\$5*(B17-\$C\$6)^2+\$C\7 . The formulas are copied down as far as row 117. The application on the right side of Fig. 1 graphs functions if the definition domain is not \mathbb{R} . The graph is made over 10000 points in range B17:B10017, M17:M10017. Cell C13 contains the formula $=(C12-C11)/10000$. Cell C17 contains $=(\$C\$5*B17+\$C\$6)/(\$C\$7*B17+\$C\$8)$. Cell M17 contains $=IF(ISERROR(C17),NA(),C17)$. The points that are out of the definition domain are skipped due to function NA().

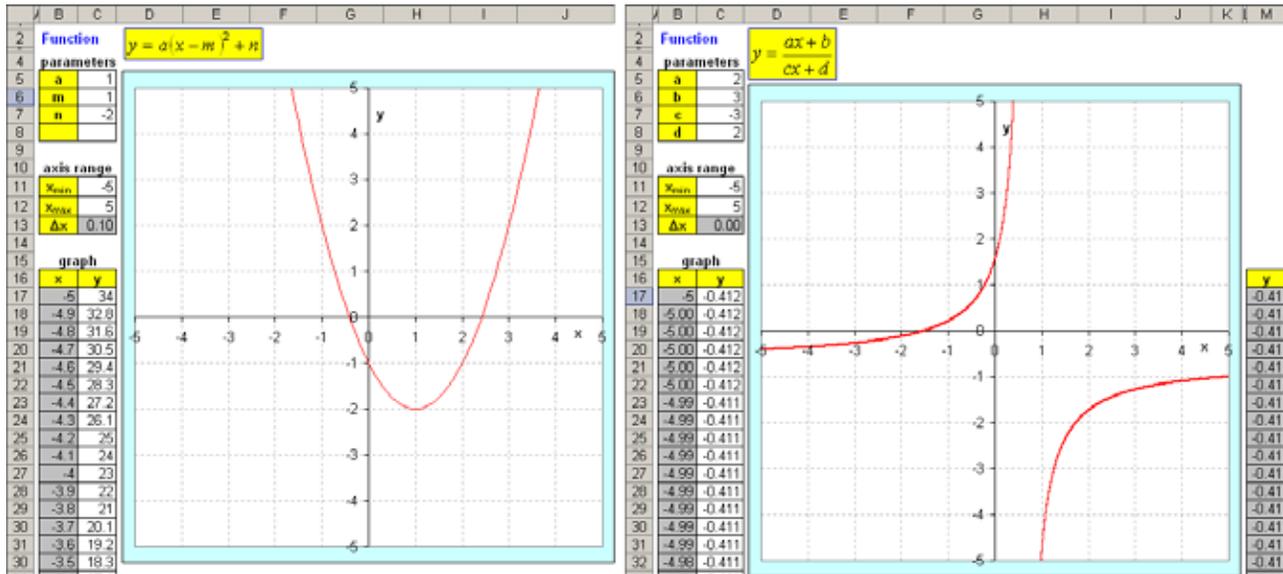

Figure 1. Graph of a function with $D = R$ (left) and $D \neq R$ (right)

The trajectory of a projectile moving in a vacuum is depicted in Fig. 2 as a practical application of graphing functions. The topic is taught at Slovak gymnasium in the optional subject Physics seminar. The projectile moves in accordance with the physics formulas after clicking and holding down the spinbutton next to cell Q4. The application is an example of modelling in interdisciplinary teaching (see Maass & Mikelskis-Seifert, 2011). The details can be found in Benacka (2009).

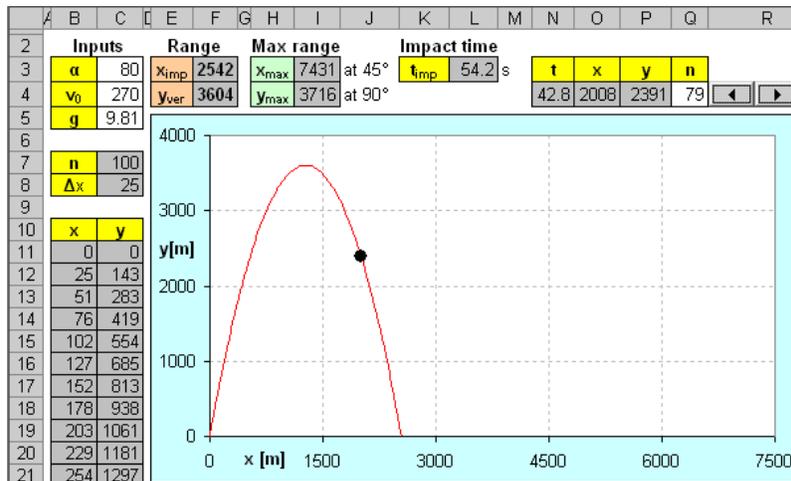

Figure 2. Projectile moving in a vacuum

FINDING EXTREMES

Tasks with extremes are traditionally solved within calculus. However, they can be solved in Excel[®] without using derivatives. The problem of finding the maximum volume of a box made of a square paperboard of 1m side length is solved in Fig. 3. After inputting the function $V(x) = x(1 - 2x)^2$ in range C17:C117 and adjusting the ranges of the axes, the maximum clearly appears on the graph. It can be found by enlarging the axes ranges (Fig. 3, right side) or by using Solver (range J4:K4).

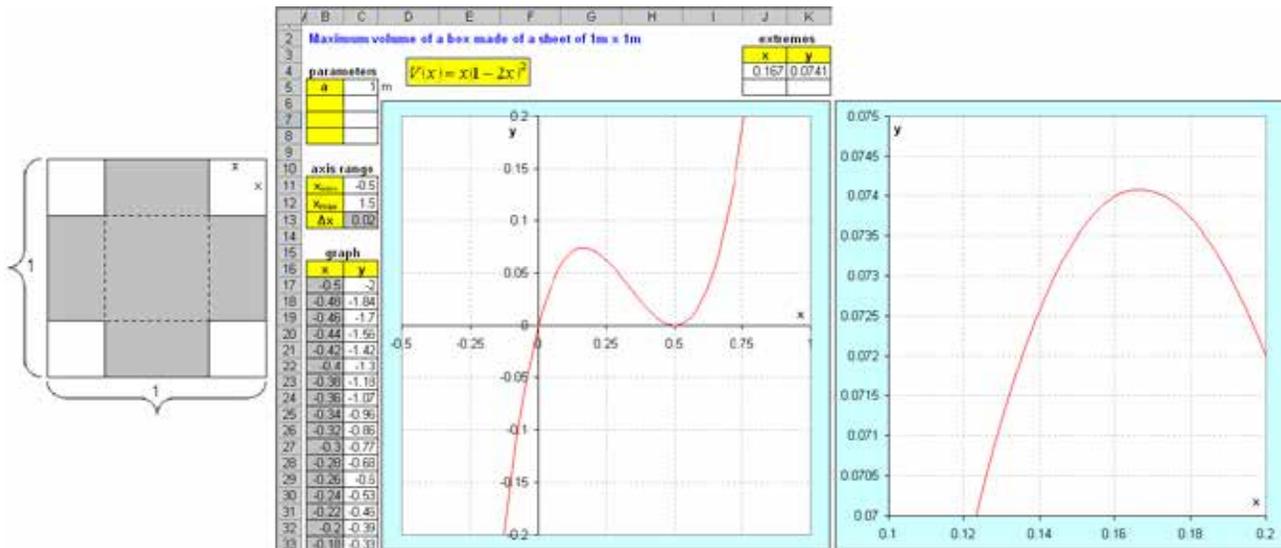

Figure 3. Maximum volume of a box made of a square paperboard

SOLVING SYSTEMS OF LINEAR EQUATIONS

Another possibility of using Solver is to solve systems of linear equations. The problem of finding the parabola that is going through 3 given non-collinear points is solved in Fig. 4. Point A, B, C are given in range L6:M8 and added in blue into the chart. The system is solved in range L12:P15. Cells L12, M12 and N12 contain the formulas =L6^2, =L6 and =1. They are copied down into rows 13 and 14. Cell O12 contains the formula =M6, which is copied down, alike. Cells L15, M15 and N15 contain the estimated values of a , b , and c ; it is enough to input 1, 1, 1 at the beginning. Cell P12 contains the formula =L12*\$L\$15+M12*\$M\$15+N12*\$N\$15, which is copied down into rows 13 and 14. Cells O14 and P14 contain the formulas =SUM(O12:O14) and =SUM(P12:P14). They are necessary for Solver. The Solver constrains are \$P\$12 = \$O\$12, \$P\$13 = \$O\$13 and \$P\$14 = \$O\$14. After clicking button "Solve", the values of a , b and c appear in cells L15, M15 and N15. Then, the formulas =L15, =M15 and =N15 are inserted in cells C5, C6 and C7.

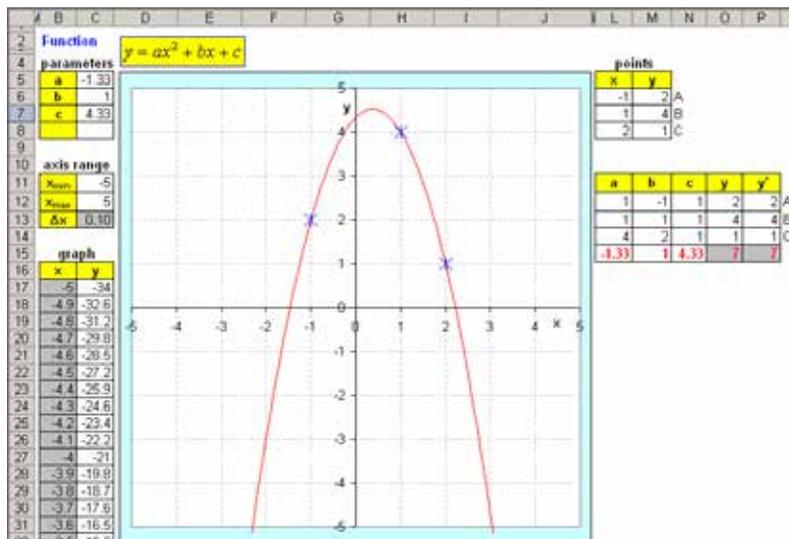

Figure 4. Finding the parabola that is going through 3 given non-collinear points

CALCULATING AREA – THE RIEMANN INTEGRAL

The application is in Fig. 5. The maximum number of subintervals is 1000. Cell N6 contains =COUNTA(L11:L1010). Cell N8 contains =(N5-N4)/N6. Cell M10 contains =N4. Cell M11 contains =M10+\$N\$8, which is copied down as far as cell M20. The equation of the function is copied from cell C15 into cell N10. Cell N10 is copied down as far as cell N20. Cell P11 contains =IF(N10<N11,N10,N11), cell Q11 contains =IF(N10>=N11,N10,N11); the formulas are copied down as far as row 20. Cell P10 and Q10 contain =SUM(P11:P1010)*N8 and =SUM(Q11:Q1010)*N8. Cell Q4 contains =(P10+Q10)/2, which gives the result – the average of the lower and upper integral sum. Cell Q5 contains =(Q10-P10)/2, which is the maximum possible error. To get a more accurate result, it is enough to select range L20:Q20 and pull down, e.g. as far as row 20 (Fig. 5, middle). To reduce the number of subintervals, e.g. to 5, it is enough to select the redundant range L16:Q30 and delete (Fig. 5, right).

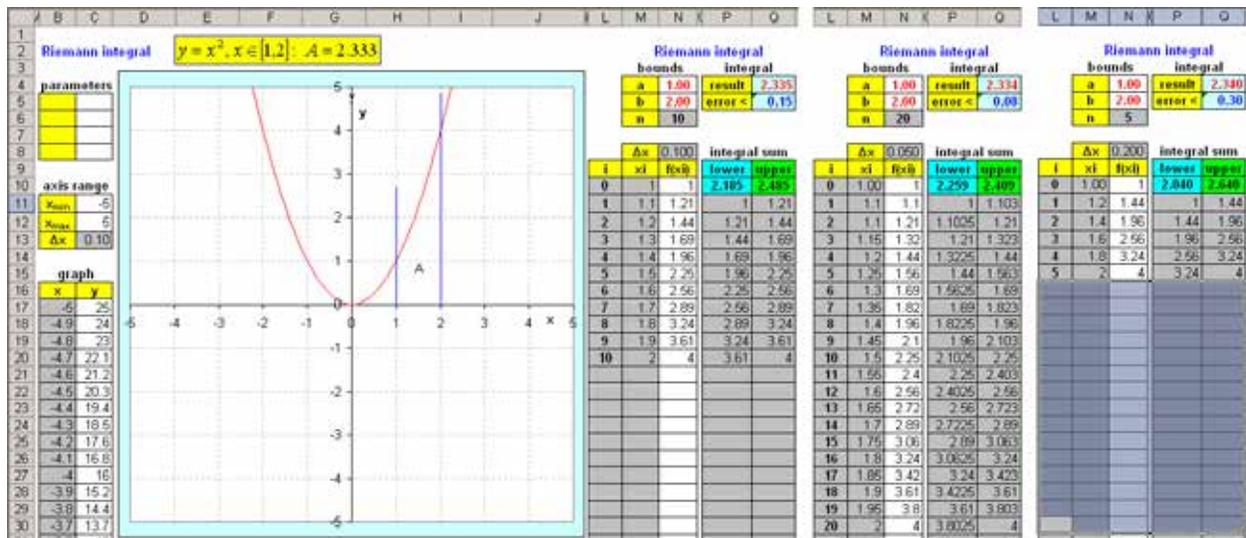

Figure 5. Calculating area by the Riemann integral

CALCULATING AREA - THE MONTE CARLO METHOD

The application is in Fig. 6. Bounds a and b are inputted in cells C3, C4. Maximum M of the function on the interval is inserted in cell C5. The area S of the rectangle between a , b , M and axis x is computed in cell C6. Cell F2 contains the number of the generated numbers. Cell C9 contains = $\$C\$3+(\$C\$4-\$C\$3)*RAND()$. Cell D9 contains = $1/C9$. Cell E9 contains = $\$C\$5*RAND()$. Cell F9 contains the formula that gives 1 if y_i is on the graph or below it otherwise it gives 0. The formulas from range C9:F9 are copied down as far as row 1008. The (x_i, y_i) pairs from ranges C9:C1008, E9:E1008 are graphed as xy point graph (the red points). Cell F3 gives the number of the points on the graph or below, which are the "good" ones. Cell F4 gives the result. The calculation is based on the fact that the ratio of the number of the "good" and "all" points equals the ratio of the area below the graph and the rectangle that comprises it. Cell C2 contains = $LN(2)$. Cells F5 and F6 contain = $C2-F4$ and

=F5/C2*100. If 10000 points are generated instead of 1000, then the error is smaller about ten times (Fig. 6, right side).

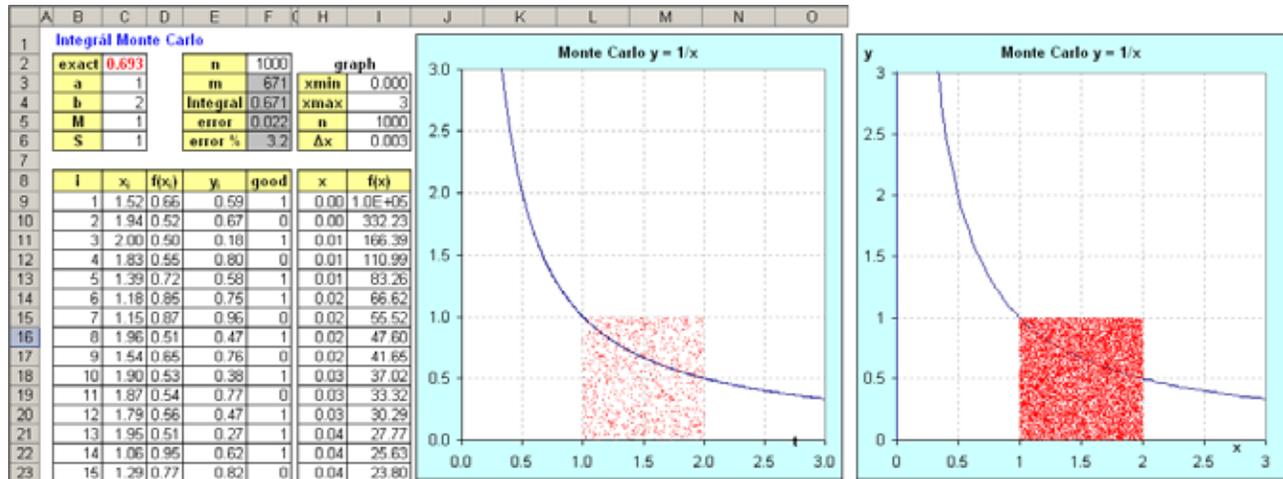

Figure 6. Calculating area by Monte Carlo method; 1000 points (a), 10000 points (b)

THE SURVEY

Applications identical or similar to the presented once were developed with four groups of gymnasium students, 34 altogether. They were familiar with writing formulas, relative and absolute addressing and making bar and pie graphs. They had never graphed a function, heard of Goal Seek and Solver, and used Active X or Form components. A questionnaire survey was conducted with them to find out if they found the lessons interesting, understood the mathematics and learned new skills.

Group NZ: Applications identical to those in Fig. 1 were developed as an introduction to graphing functions in Delphi with eight students of age 17 – 19 at Gymnazium in Nove Zamky in a 90 minute lesson within Computer Modelling Club that the first author runs at the school. It was emphasized at the end that "Now, you are able to graph any function given by a formula", however, no real background was given to the functions graphed, e.g., what problem they origin from, etc. Then, the students were asked to answer the following three most subjective questions: A) The lessons were (1:very; 2:quite; 3: little; 4:not) interesting; B) I understood (1:all; 2:majority; 3:minority; 4:nothing) of the mathematics; C) I learned (1:very much; 2:quite much; 3: little; 4:no) new in Excel. The average answers are in Tab. 1 in row NZ.

Group 2A: Applications similar to that in Fig. 2 were developed with ten students of class 2A (age 16 – 17) of Gymnazium Parovska in Nitra in two 45 minute lessons (20 min break). They simulated free fall and projectile motion in a vacuum. The theory was presented, which was new to the students. Despite it was emphasized that the nearest place in which the theory holds is the Moon due to the vacuum, the students were much engaged – putting the ball in motion was clearly a hit. The students were asked the same questions as Group NZ just the word "mathematics" was replaced with "physics" in question B. The answers are in Tab. 1 in row 2A.

Group 2B: Application similar to those in Figs. 3 and 4 were developed by nine students of class 2B of Gymnazium Parovska in Nitra in two 45 minute lessons (10 min break). The first one was introduced as follows: "You are the owner of a small factory that produces pins. You pack the pins in boxes that you make from square sheets of 100 cm sides that the paper factory delivers to you. The method is shown in the figure. The bigger is the volume of the box, the more money you save on the costs. Find the x at which the volume of the box is maximum". To make the solution closer to everyday life, side a was inputted in centimetres and the volume was calculated and graphed in litres. It was found that x can only go from 0 to $a/2$. The maximum $V_{\max} = 74.1 \ell$ at $x = 16.7 \text{ cm}$ was found by Solver. Then, the problem was solved of finding the x at which the volume is 50ℓ , first by Solver and then by Goal Seek. After showing finding the first root ($x = 6.65 \text{ cm}$), the students quickly found the second one ($x = 29.4 \text{ cm}$). The second application was introduced as follows: "Imagine a battle going on the Moon. Cannon shell was fired by the enemy. We can monitor its motion by radar. Three positions are given by points A, B and C in cells L6:M8. In a vacuum, the trajectory of a projectile is a parabola. Find the points from which the shell was fired and in which it will hit the ground. Find the maximum altitude reached". The application can be solved without creating the system in range L12:O14. Then, y' is computed in cells N6:N8 by formulas referring to cells C5:C7, and Solver constrains refer to cells M6:M8 and N6:N8. Showing the points with negative y coordinate has no sense. At the end of the second lesson, the students were asked the same questions as Group NZ. The answers are in Tab. 1 in row 2B.

Group 2C: Applications similar to those in Figs. 5 and 6 were developed with seven students of class 2C of Gymnazium Parovska in Nitra in two 45 minute lessons (10 min break). It was emphasized at the end that "Now, you are able to calculate any area bounded by the x axis and the graph of a given function", however, no real background was given to the tasks. The students were asked the same questions as Group NZ. The answers are in Tab. 1 in row 2C.

Group	Number	Topic	A	B	C
NZ	8	Graphing functions	1.6	1.3	1.9
2A	10	Free fall and projectile motion	1.1	1.5	1.5
2B	9	Finding extremes and roots, interpolating	1.1	1.8	1.6
2C	7	Calculating area	2.0	2.0	1.9
Altogether	34	Weighted average	1.3	1.6	1.7

Table 1. Average answers to the questions

The most important answer to the authors was that to the first question. It can be seen in Tab. 1 that even if there was no real background to the task, the students found the lessons quite interesting (groups NZ and 2C); if there was a more or less real background, they found the lessons very interesting (groups 2A and 2B). The relative frequencies of the answers for each group are graphed in % in Fig. 7. There were no

answers of 3 or 4. The relative frequencies of the answers for all students, which are the main outcomes of the questionnaire, are graphed in Fig. 8.

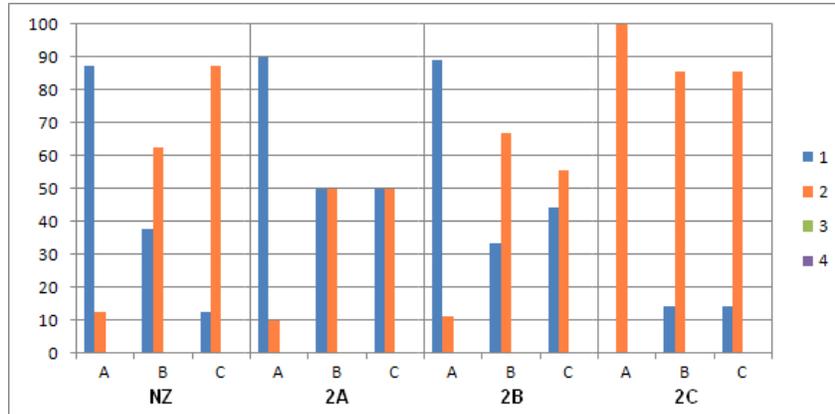

Figure 7. Relative frequency of the answers for each group in %

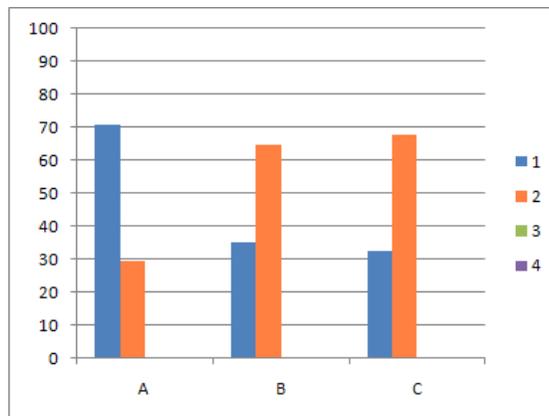

Figure 8. Relative frequency of the answers for all students in %

It holds that: (A) 100% of the students found the lesson interesting (71% very, 29% quite); (B) 35% understood everything and 65% understood the majority of the mathematics; (C) 100% of the students learned much new in Excel (32% very, 68% quite). There is the question if the samples were representative enough. While the students in group NZ are supposed to have positive attitude to maths and sciences, the students in groups 2A, 2B and 2C were chosen randomly. In Slovakia, classes in gymnasium comprise 30 students at most. In the school that the experiment was carried out in, the number of the computers in the computer rooms is 10 so the classes are divided to thirds following the alphabetical list of the students. Thus, each group was a third of the class. The lessons were regular once according to the timetable.

Remark: Actually, four questions were given to the students in Group 2A. The fourth one was if they would like to model fall and projectile motion in the air, which are more realistic but much more complicated than those in a vacuum. They all answered "yes". The question is whether they really wanted to make the model or just kill another lesson. However, when the first author was finishing the lessons with group 2B next day, two of the 2A group students came to him and said that they would come even after the school to develop the models in the air. That was a hit!

CONCLUSIONS

The paper brought a few tips to using spreadsheets for teaching and learning functions and calculus at gymnasium in a constructionist way when the learner develops the application by himself. A questionnaire survey was conducted with 34 gymnasium students to find out whether they found the lessons interesting, understood the mathematics and learned new skills in Excel. The outcome is that 100% of the students found the lesson interesting (71% very, 29% quite), 35% understood all and 65% understood the majority of the mathematics and 100% learned much new in Excel (32% very, 68% quite). Relying on these facts it can be concluded that:

- 1) The combination of the topics and "learning by doing" with spreadsheets resulted in successful lessons.
- 2) Despite being rather unknown, mathematical modelling with spreadsheet is of great interest to students and has a big potential in promoting mathematics and sciences to them.
- 3) The capability for developing, without programming, applications that enable prompt verifying ideas and concepts and promote exploration and discovery through giving immediate feedback to changing data and formulas make Excel a convenient modelling tool at upper secondary level.

ACKNOWLEDGEMENT

The authors are members of the team of Comenius project 510028-LLP-1-2010-1-IT-CO: DynaMat. The authors thank Mr. Milan Holota and Dr. Juraj Opačítý, the headmasters of Gymnázium in Nové Zámky and Gymnázium Párovská in Nitra, for their kind permission to carry out the survey, and Mgr. Alexander Meleg and Dr. Jozef Piroško, informatics, mathematics and physics teachers and heads of School Committee for Teaching Informatics at Gymnázium in Nové Zámky and Gymnázium Párovská in Nitra, for their helpfulness.

MATHEMATICAL MODELLING IN TEACHER EDUCATION COURSES: STYLE OF THOUGHT IN THE INTERNATIONAL COMMUNITY - ICTMA

Maria Salett Biembengut & Emília Melo Vieira

Pontificia Universidade Católica do Rio Grande do Sul – PUC-RS,

Centro Universitário Leonardo da Vinci – UNIASSELVI

This paper presents the mapping of mathematical modelling (MM) pedagogical practices in teacher education courses from publications available in the books organized by the International Conference on the Teaching of Mathematical Modelling and Applications – ICTMA. Mapping refers to the identification, survey, organization, classification, and data analysis. Forty-two papers published in the ICTMA books were identified about teacher education and the data were analysed through the lenses of style of thought in MM, according to the theory of Ludwik Fleck (1979). This study aimed at understanding how knowledge was built by society and became common part of the group, and not at analysing the quality of knowledge departing from immutable criteria. The analysed productions revealed that these researchers constitute a collective of thought indicating the concern with and the support to the official documents and to the issues related to teacher education. The collective of thought about modelling in initial and continuous teacher education courses follows institutionalized standards.

Key-words: Mathematical Modelling, ICTMA, Style of Thought, Mapping.

INTRODUCTION

Mathematical modelling (MM) refers to the process toward the elaboration or the creation of a mathematical model about a problem-situation of some knowledge area, by making use of mathematical theories not only for the solution of a particular situation, but as support to other areas. This process, applied in all sciences, has contributed extraordinarily to the evolution of human knowledge. In modelling, the procedures are basically the same employed in scientific research: problem delimitation; familiarization; hypothesis; model formulation; problem resolution; interpretation; and model validation. According to Biembengut (2003), such procedures require from the modeller: mathematical knowledge and problem-situation knowledge, skills to read, describe and refine the data obtained from the phenomenon under the light of math, and creative and critical senses in the formation, the resolution and the evaluation of the model elaborated. Modelling is rooted in the human creative process and it encompasses scientific research.

In the last four decades in several countries, the defence for this process or method is increasing in the teaching and learning of math, in all levels of schooling. The main justification relies in offering students the opportunity to make use of math in order to comprehend a problem-situation of other knowledge area and know how to solve it. It means that teachers are able to provide students with opportunities to integrate math to other knowledge area, in particular, an area that students display interest in knowing more about. Osawa (2007) claims that the studied problem-situations give rise to knowledge learnt from experience, to comprehension reached through mathematical proofs, judgment, thought and foundation. According to Herget (2007), MM still facilitates students' comprehension of what is abstract (symbolic), by changing their perceptions in relation to the entities that surround them and in different ways, by stimulating their interests and, as a consequence, their learning.

MM for Education has emerged in the 1970s, impelled by the dissatisfaction and criticisms professors and businessmen interwoven in relation to the education of undergraduate students. The situation instigated many professors to find ways to justify math in the schools' curricular program. Among them, David Burghes in 1978, while working with high school teachers, in Cranfield University, produced papers and books about modelling, offered teachers workshops, and organized the first two International Conferences on the Teaching of Mathematical Modelling and Applications – ICTMA, in Exeter University, the United Kingdom, in 1983 and 1985. Since then, every two years, there is an expressive conference with a great number of participants and representatives worldwide (Biembengut, 2003).

This interest in the ICTMA international conferences gave rise to an organized community that, besides promoting the conferences, is part of the International Congress on Mathematical Education – ICME. In the period 1983-2011, there were 15 conferences, and also, the Study Group 14 Conference of the ICME on modelling and applications (M&A). The studies presented in these conferences are published in printed books. There are 15 books published until 2011; 443 papers on M&A with different focuses and from these, 42 were identified by being pertinent to pedagogical practices in MM in teacher education courses. In this corpus, there are applied and theoretical studies. From the applied ones, the focus is on the different schooling phases: from the early years of Elementary School to the end of graduation, and on the initial and continued education of teachers. According to Blum, Niss and Galbraith (2007), in the period 1965-1975, research suggests that M&A promoted arguments in favour of the inclusion of Mathematical Education; in the period 1975-1990, studies are characterized by the development of curricula and instructional materials to encompass the components of M&A; and from 1990 on, empirical studies on the teaching and learning of M&A have been added to the theoretical emphasis of research of the previous phases.

MM for Education has been stimulated and sustained by the gradual establishment of math teachers' communities, as well as the study groups and research groups that followed the proposals for the teaching of math. Worries about what, how, how

much, and to whom teach math have contributed to the strengthening of the studies in MM for Education. These studies lead to research whose results imply proposals for teaching and learning that, in a cyclical process, promote new studies. The studies presented in conferences bring a style of thought that when shared, make ideas circulate and produce a collective of thought.

According to Ludwik Fleck¹ theory (Compared Epistemology), style of thought “consists of a determined attitude and a type of accomplishment that completes it”. And it is characterized by “common problem features that interest the collective of thought, by the judgments the collective thought considers evident and by the methods employed as means to know” (Fleck, 1979, p.145). Consistent with this theory, each study expresses the researcher’s style of thought from the type of accomplishment and/or the collective of people that have a similar style of thought constituted by knowledge and/or shared practices.

Fleck proposed a theory about knowledge focused on heuristics. His theory allows for a historical and epistemological analysis to distinct areas of knowledge. It is centred in the analysis of academic productions, oriented by socio-historical studies to comprehend the interaction between the scientific practice and the contexts in which they occur. It is an “interactive model of the knowledge process, connected to the social, historical, anthropological and cultural presuppositions and conditionings, that as is processed, transforms reality” (Delizoicov et al., 2002, p.56).

Following Salles (2007, p.32), “throughout time, the action of researchers and the social factors that interfere with the constitution of science constructs a specific trajectory, with no determined beginning or end”. It means that the most diverse historical, social and epistemological factors and entities interfere in the generation of scientific knowledge, that in turn requires reflection upon the facts and entities involved, careful and accurate historical analysis so that the common traces in the process of constitution of scientific concepts are identified.

The educational effort to provide better teaching of math culminated with the development of research on MM for education worldwide. As this defence for M&A in the ICTMAs has been on for about three decades, it is considered that styles of thought about MM for education are formed due to the idea circulation from a collective of thought and, this way, understandings change or vary permeating discussions about teacher education in several countries. It is feasible to inquire: *what are the styles of thought about mathematical modelling in courses of initial and continued teacher education in the international scene?*

In the ICTMAs there is circulation of ideas from styles of thought. Each person comes from a social and historical context (active connections) and each person perceives the reality in such a subjective way that nurtures his /her research (passive connections). Therefore, people’s interactions allow for the establishment of styles,

¹ Ludwik Fleck (1896-1961), who was a Polish doctor, published, among other works, *Genesis and development of a scientific fact*, in 1935 by an editor in Switzerland, and in 1979, in English, with the foreword written by Thomas Kuhn.

and by recurrence, collectives of thought about M&A for Mathematical Education. This study aimed at analysing the productions published in the ICTMA's books about pedagogical practices on MM in teacher education courses. These productions, as shared by the scientific community, as ICTMA's, consolidate scientific knowledge.

METHODOLOGICAL PROCEDURES

This study is bibliographical since the data base consists of 42 papers about the pedagogical practices in MM in teacher education courses. From these, 35 were published in nine ICTMAs conferences (1995 to 2011) and 7 were published in the Study Group² 14 book (2007). Although the ICTMAs began in 1983, research focused in teacher education began to be presented from 1993 conferences on, whose publications were released from 1995 on. For this reason, the sources come from the period 1995-2011. This kind of scientific production brings a set of studies conducted by M&A researchers. These studies generated knowledge accepted by the scientific community. According to Biembengut (2008), studies based on bibliographical documents may offer a map about the theme of the problem or hypotheses to conduct the verification by other means.

Thus, the papers, written by whom participated in one or more ICTMAs, constitute a natural source that reveal different contexts (institutions and countries) and enable different interpretations and analyses. In this research phase, the focus resides in identifying the style of thought about modelling the authors of these papers display. We expect in the following phase, interview these authors to better understand their MM practices. This study was developed in two stages, named identification map and recognition map, as follows. These stages did not occur separately.

2.1 *Identification map*

This phase consisted of identifying the field in which the object is inserted in. The 42 papers analysed belong to 32 “first authors”³ of 12 countries of five continents. Following, we identified the countries, the number of papers and the number of same authors(s) and different authors (d): Australia (4: 2s, 2d), Brazil (6: 2s, 3s, 1d), Canada (2d), China (1), Denmark (1), Germany (5: 2s, 3d), Mexico (2d), Portugal (1), South Africa (2s), Sweden (5s), United Kingdom (1), USA (12: 2s, 10d).

In the first moment, we opted to assemble the papers into three groups, published between the years 1995-2011: the first (1995, 1997 & 1999), the second (2001, 2003 & 2005) and the third (2007, 2009, 2010 & 2011). We hypothesized there would be some changes throughout the years. But, departing from a careful study of all papers, we could not identify significant differences. In each paper, the researchers identified

²MM was the 14th theme for the study of the International Commission on Mathematical Instruction (ICMI), initiated in 2002 and published in 2007.

³We use the expression “first authors” due to the fact that we counted ‘one’ for the papers that have more than one author.

and classified the questions, sources and methods upon which the data were obtained. A summary of each paper was done and common topics were highlighted. As all the papers present: (1) justification, (2) process, (3) possibilities and (4) difficulties in making use of modelling for Education, we considered these topics as categories of analysis. These data allowed us to have a system for recognition. Due to space limits, the summaries of the papers and the resulting maps will not be presented in this article.

2.2 Recognition map

We sought to get acquainted with Fleck's Comparative Epistemology (1979) to have a better glimpse of the styles of thought about the pedagogical practices in MM in teacher education courses worldwide. According to him, a style of thought is understood as shared practice and knowledge. For him, when this style is shared, the group displays a collective of thought read the papers attentively and identified similarities among them and could delineate styles of thought in MM. We identified possible traces that were recognized and valued by the community. In addition to that, we sought to comprehend the studies departing from confluent and/or indicative places that suggest styles of thought in a community of modelling for Mathematical Education. In the following section of this work, we sought to make the data explicit such that an illustrative image of the studies and the results could be produced, based on Fleck's epistemological theory.

This study did not aim at analysing the quality of knowledge produced departing from immutable criteria. Instead, it aimed at comprehending how knowledge was constructed by the community and how it was integrated in the common pile of the group in the period 1995-2011. We admit the coexistence of different knowledge models and educational development so that we are able to recognize the similar points among these studies and the possible factors conditioned by the scientific communities. We assume that these processes do not express people's neutrality. We understand that scientific knowledge does not emerge in the methodological order of observation/experimentation in a distinct perspective from the empiricist conception. It is not neutral from the conception of who studies, of who prescribes results.

RESULTS & DISCUSSION

The analysed 42 papers on pedagogical practices in MM in teacher education courses bring the historical, social and educational context in which they were produced. All of them present applied research. They describe the process of modelling and use a group of students, research collaborators, future teachers or teachers in continued education as participants to collect data. These studies depart from specific experiences lived in the classroom and contribute to understand the different issues involved. The authors defend the primacy of MM in the development of Basic Education teachers. According to Sales (2007), these activities contribute in such a

way that the researcher learns to identify stable elements in the research object and, establish facts tacitly accepted by the collective of thought that permeates the international community.

Although curricular programs are similar in the 12 countries from the 5 continents that the authors of the studies analysed belong to, it is not possible to deny that the studies occurred under the cultural reference and own meaning that these curricular contents have to the respective population; ways that guide us to derive the styles of thought. Meanwhile, when organizing the text statements into categories, it was possible to identify that some occurrences and reflections are common in the publications, even considering the elapsed time between one conference and the other and the participants of different countries. These similar reflections suggest the circulation of ideas, allowing for a collective of thought.

According to item 2.1, the established categories were: (1) justification, (2) process, (3) possibilities and (4) difficulties in making use of modelling for Education. In what follows, we turn to the reflections upon each category, considering the styles of thought present in the productions and that commune with the collective of thought.

(1) The authors' *justification* is based on the understanding that MM for Education allows the student in each schooling phase: (a) to learn the mathematical concepts better; (b) to interpret the meanings of the mathematical concepts; (c) to use technological resources to solve problems; and (d) to make students aware of social and environmental issues. This justification, in the 42 papers, is endorsed by the criticism to the style of teaching still in vigour in almost all the countries. The justification of the majority of authors - departing from the criticism to the current teaching and departing from the defence for modelling - suggests a style of thought in this community. This style shows that *MM for Education allows teachers and future teachers to become aware of the various issues of society and of the results the current schooling structure produces*. This consciousness can display another style of thought about the way to teach; guiding them to commit themselves to make use of pedagogical practices that promote better formation of students in Basic Education. This understanding requires knowing how and when to approach curricular contents, but also knowing how to make the students from Basic Education, in particular, draw on this knowledge in moments beyond the school limits. It is a style of thought legitimized by the community of thought that works with modelling for Education.

(2) The *process* of MM defended by the authors is that the teacher should: (a) depart from a subject or problem-situation of any area of knowledge that is interesting to the group of students; (b) ask the group to look for data that give rise to issues and then, seek for the problem solution; (c) orient the students to formulate these data making use of any mathematical structures (concepts, definitions, properties); and (d) guide them to solve the issue and evaluate the results. This style of thought about how to do modelling in sciences is maintained in the process of school teaching; it is how students are prepared for searching. It is characterized by the common traces of the problem-situations that the majority of papers bring as examples. The proposed

problem-situations conduct students to a collective of thought about MM as a process or method that enables knowing and developing competence to deal with issues of their surrounding environment.

The main argument is that modelling provides students with opportunities to make connections between the language present in their surroundings and the mathematical language. During this process, students improve their conceptual structures, their understandings of the mathematical concepts, and more, their critical and creative senses are improved in the formulation of data and in the evaluation of results. This argument indicates a style of thought that considers *MM for Education a way to surpass the linear process of teaching that is decontextualized from students' experience*. It is considered that each student has his/her own cultural spectrum that is revealed in his/her doings, outside the school context. When s/he experiences the modelling process in a triad: research-school-reality, the student can perceive his/her talent, his/her interests and even the importance of the school in this process of literacy to scientific and professional issues or issues related to companionship.

(3) About *possibilities*, the authors argue for MM as a means so that students may (a) construct their knowledge by understanding the concepts involved; (b) choose significant problems to the context; (c) become capable of explaining their reasoning with the correct use of mathematical language; (d) have better performance in mathematical modelling activities; and (e) know how to use it in their pedagogical practices, since these students are future math teachers. This defence, present in all papers, suggests that when doing, people get to know and when people get to know, they do. It is a cyclical process. Going from the simplest to the most complex issues and continuously revising can make modelling a more effective process to deal with the various issues that involve the living context. *MM for Education is a dynamic process: it can be modified whenever necessary so that students' knowledge can be improved*. This instance reveals another style of thought.

(4) The *difficulties* in the implementation of MM reside in the current educational structure: available timings and schedules, curricular programs divided into various subjects. Difficulties emerge for future teachers and in-service teachers. For future teachers the difficulties reside in knowing how to use the mathematical language to describe the problem-situations and, thus, resist to changes. And for in-service teachers, difficulties reside in the available time they have to get acquainted with the themes chose by the students to orient them.

The curricular model in teacher education courses is similar in the various countries. It consists of several disciplines, each one under the responsibility of a teacher and with a restricted number of class hours. Math, although present in all schooling years of Basic Education, follows, in general, the same process of teaching, without connection to the other disciplines of the curricular structure. This model contributes to the fact that the students from these teacher education courses, who experienced a 'traditional' way of teaching for more than 12 years, have difficulty in interpreting

the context and data from a subject of any knowledge area; in recognizing the math required to interpret data; in formulating mathematically and in analysing it.

This difficulty, a consequence of the experienced education by these teachers, emerges when these students or even teachers become aware of MM. They learn about it in a single subject in an initial or continued teacher education course, with a limited number of hours if compared to the time experienced in ‘traditional teaching’. As a result, obtaining effective results depends on the interest the participants involved have in following the modelling pathway; that advances gradually departing from practical and conscious activities about the importance of learning.

The current educational structure in various countries does not lead to the integration among math and the other disciplines of the course, neither the diverse areas of knowledge. As a consequence, *there are difficulties students and also teachers have in making use of modelling in the classroom practices, particularly in the initial and continued education, due to the time spent in this educational structure.* Paraphrasing Salles (2007), MM will only reach a status of legitimized knowledge if it resists to the tests imposed by the group that ‘maintains’ the traditional process in the teaching of math. The incorporation of MM for education can establish a dynamic relation between the ‘traditional’ and the ‘innovations’. Allowing for a change in the conception of math teaching departs from reactive interactions among the teachers in the group. This kind of argument present in many these 42 papers suggests another style of thought.

Departing from the categories: *justification, process, possibilities and difficulties*, it may be claimed that the styles of thought displayed by these 42 paper, of the 32 ‘first authors’ converge in the understanding that modelling can contribute not only to improve mathematical teaching and learning, but also to provoke reaction and interaction between the body of teachers and the body of students involved in the on-going and necessary production of knowledge. It is a mutual share of acquired experiences. These authors, participants of the ICTMAs, make explicit their knowledge gained in the interactions among the theories of MM for Education and their practices of modelling in classrooms. As Wenger (1998, p.45) points out, “this collective learning results in practices that reflect both the pursuit of our enterprises and the attendant social relations”. These interactions conduct to a style of thought.

According to Fleck (1979), so that a style of thought can be constituted, it passes through the phases of instauration, extension and transformation that occur by means of interactions of distinct groups in the circulation of ideas intercollectively and intracollectively. This circulation of intracollective ideas occurs among experts and the circulation of intercollective ideas among non-experts. This process implies seeking for knowledge that brings increment to the existing data and yet, creates a collective a thought. It is worth highlighting that these styles of thought, that come since the teachers-researchers of the first phase (1965-1975) in the classification proposed by Blum, Niss and Galbraith (2007), are present in the community, independently of the country, the geographical distance, the educational system.

These styles may be considered the scientific knowledge of the ICTMA. This knowledge was consolidated by facts, theories and interpretations shared by the community of practice. Perceiving that the process involved in MM for education is even more relevant when dealing with issues that allow having a particular set of data that can be better studied using specific methods and as consequence, become charmed with the solution and the validity of this solution.

FINAL REMARKS

The papers analysed reveal that these researchers who circulate in the conferences organized by ICTMA constitute a collective of thought, indicating the concern and support to the official documents and to the issues related to teacher education. The collective of thought about modelling in math teacher education courses follows institutionalized standards. It means that the events in the modelling process in courses for teachers or future teachers enunciate necessary changes in the educational structure, based on values, goals and other inspiring stimuli that come from the different people within the system.

To Fleck (1979), the researcher's style of thought designates the formal aspects of his/her research that comprises all ways of expressing the units associated in the process and in the results. The style comes from shared practices and shared knowledge. When a certain style is shared by a group of people, a collective of thought is established. It may be claimed that in the ICTMA conferences we encounter groups that share the same style of thought that is composed by collectives of thought. This sharing occurs when the researcher identifies in his/her research object traces that are recognized and valued by the community, that are present in other studies about similar themes. There are hues of this style of thought that arrange facts and fit in the MM theory for education dominant in the discussions of mathematical education. These various elements coalesce around different conceptions of knowledge production, but when confronted, as pointed out by Salles (2007), constitute an extension of the established style of thought.

This fact indicates that the style of thought about MM for Education that circulates in the ICTMAs is established in the knowledge of different groups of researchers. And according to Fleck's theory (1979), the changes in this area will become noticeable as a collective process, in which the transformations will be construed by the community of thought, when the ideas circulate in the ICTMA conferences. The importance of analysing scientific productions throughout time in MM in the international scene is justified by the panorama that this type of research results, providing a map of the contributions, needs and challenges related to MM. According to Witter (1996), it is by means of this type of research that a basis of scientific data may be formed. This basis consolidates certain knowledge and thus, allows for scientific advancement.

Investigating how each style of thought a group adopts or how it is incorporated by the style of the community of thought, how styles are established and transmitted is the beginning of another study. Diverse presuppositions may be formulated. Some may direct the researcher's steps to the origins of M&A in the teaching practices of the school system. It is relatively simple to identify how the ideas and proposals are disseminated. These proposals and ideas, written or verbalized, carry styles of thought, express attitudes or ideals that deal with experiences, beliefs, values and casual sequences, whose order is diverse.

THE USE OF THEORY IN TEACHERS' MODELLING PROJECTS – EXPERIENCES FROM AN IN-SERVICE COURSE

Morten Blomhøj and Tinne Hoff Kjeldsen

IMFUFA, Department of Science, Systems and Models, Roskilde University

We discuss how to support teachers' use of theory on modelling and on learning mathematical concepts in an in-service course on project work and modelling for upper secondary teachers. The course is centred on the teachers' experiments with modelling projects in their own classes. The paper is a case study on how to facilitate the interplay between theory and development of teaching practice. Our analyses focus on modelling as a means for learning mathematics, and on theories on the learning of mathematical concepts. The theories have potentials for improving the teachers' practice, but they need concretisation and re-contextualisation in the teachers' projects in order to be helpful for the teachers.

INTERPLAY BETWEEN THEORY AND PRACTICE IN MODELLING

The research question is: *How to integrate theories on modelling and on the learning of mathematics in an in-service course on modelling for teachers at upper secondary level so as to be helpful for the teachers' development of their own practice?*

During the last three decades, theories in the area of teaching and learning mathematical modelling have developed in close connection with the inclusion of modelling in secondary mathematics curricula, and through interplay with the development of practices of teaching in this area. These theories rest upon the definitions of key concepts related to modelling such as the notion of a mathematical model, the cyclic modelling process and modelling competency. The theories include justifications of mathematical modelling as part of mathematics curricula in general education and suggestions for design of teaching in different contexts. In more recent research, specific learning potentials and difficulties related to modelling and ways of enhancing students' learning of mathematical concepts through modelling have been researched (Zbiek and Conner, 2006), (Blomhøj and Kjeldsen 2006, 2010b). This development opens for a closer interplay with theories on mathematical learning in general. However, also in this area there is a scarcity of studies investigating concretely how theories can be of use for teachers in developing their practice.

Research in mathematics education tends to focus more on the development of theories than on how these theories can function in practice in processes of improving teaching and learning. Hereby, the process of doing research is separated from the process of applying theory in developing practices of mathematics teaching. It is a challenge to find ways to bring theory into play in the practice of teaching. Action research seems to be a fruitful approach to teachers' professional development in that respect (Krainer, 1999). Boaler (2008, p 103) found that the teachers' involvement in

experimenting with their teaching seems to be an important factor in successful use of theory in practice. The development of our in-service course and our related research can be seen as a form of developmental research practice with exactly this aim (Blomhøj and Kjeldsen, 2006).

THE STRUCTURE, ORGANISATION AND PURPOSE OF THE COURSE

The course is designed and taught by the authors in collaboration. It is advertised on an open market for professional development courses. 12 to 20 mathematics teachers participate in each course. The participating teachers come from different schools. The course runs from 5 to 8 months within a school year. In this period, the teachers are involved in experimenting with their teaching. They develop and implement their own modelling projects. The course begins with a seminar over three full days. During the seminar, the teachers work in groups of two or three developing a problem oriented modelling project of the group's own choice. After the seminar they implement their modelling project in their own classes, covering 10 lessons and two written homework assignments for the students. There is a one-day midterm seminar, and the course finishes with a two-day seminar. The teachers write a report that documents their experiments with their modelling projects. The reports are published and disseminated on an internet portal for school teachers in Denmark.

At the first seminar, the participants are introduced to mathematical modelling and problem oriented project work, as well as to theories on the learning of mathematics as presented in the next section. In the first phase of the development of their projects, the groups are asked to emphasize the following four issues: (1) Intentions for their own development. What is it in particular that they want to experiment with as a teacher in their project organised modelling course? (2) What are the main intentions for the students' learning in the course? (3) How to set the scene for the students' problem oriented project work? (4) How to evaluate the students' learning through observations and/or product evaluations? The groups' first proposals are presented and discussed in the first seminar, and then further developed afterwards. Two weeks after the first seminar, the preliminary descriptions and student materials for the modelling projects are distributed to all participants. Within a period of two months the groups finish the detailed planning and each teacher try out his or her modelling project in at least one class. In some cases, it is possible for two teachers working at the same school to observe parts of the course in the colleague's class. This has proven to be supportive for the teachers' reflections and for their further cooperation with improvements of the projects. We therefore encourage participation in pairs of teachers from the same school. The one-day midterm seminar is held after the period with experimental teaching, with the aim of supporting the teachers in reporting their projects and their related reflections in a form that could be helpful for colleagues wanting to do similar modelling projects. A first version of the reports is distributed to all participants a month later. These are discussed at the final two-day seminar after which the groups receive written feedback and suggestions for improvements

before publication of the reports. This organisation allows detailed discussion of the teachers' projects and their relation to the introduced theories.

THE USE OF THEORIES IN THE COURSE

At the first seminar, the teachers are introduced to theories in three different domains: (1) Theory on problem oriented project work (Blomhøj and Kjeldsen, 2010a). Here the emphasis is placed on the importance of formulating a problem, which can guide the students' modelling process, and enable them to take control of the process supported by milestones and supervision. The way in which the scene is set for the project in the class, and the explicit demands for the students' project reports should be the main didactical instruments for guiding the students' project work. (2) Theory on mathematical modelling, e.g. justifications for modelling, modelling competency and the modelling cycle (Niss et al., 2007), (Blomhøj and Kjeldsen, 2010a). The emphasis is on illustrating and discussing the modelling process, reflections in relation to concrete examples, and on the teachers' ideas for modelling problems for their projects. (3) Theory on the learning of mathematical concepts. This element relates to modelling as a vehicle for supporting students' learning of mathematics (Blomhøj and Kjeldsen, 2010b). Here we present and discuss theoretical ideas related to: The important role of representations for the learning of mathematical concepts (Steinbring, 1987); the process-object duality in concept formation (Sfard, 1991); concept images (Vinner and Dreyfus, 1989); and the RME-idea concerning the change of role of a model from "a model of some particular object/situation" to "a model for the learning of a mathematical concept" described by Gravemeijer (1994). In parallel with diSessa and Cobb (2004), we argue that such theories have a lot to offer for improving teaching experiments.

However, the theories need to be concretised and re-contextualised in relation to the teachers' particular modelling projects, in order to be helpful for the teachers. That is the main reason for the design of our in-service course. In the course, the participating teachers are developing their own modelling projects, and through our interplay with the teachers in this process, it is possible to bring the theories into play in relation to the teachers' modelling projects. Until now we have developed three different forms of intermediate representations for presenting and discussing with the teachers, the potentials of the various theoretical ideas for the development of their practice of teaching modelling. These are: (1) Detailed and concrete descriptions of the modelling process behind the models in the teachers' projects. Such unfolded modelling processes enable the teachers to become aware of and discuss the potentials for supporting the development of the students' modelling competency in the planned activity and to help students in case of difficulties, without spoiling the essential modelling challenge; (2) Schemes spanning all the different representations of particular mathematical concepts and their interpretations in a given modelling context. Such schemes can help capture the potentials for supporting the students' mathematical learning and they can be a tool for analysing the students' modelling activities in relation to their mathematical learning potential. Figure 2 represents such

a scheme for the project presented in the next section; (3) Construction of anticipated dialogues between the teacher and a group of students facing some particular modelling challenges or learning difficulties. Discussing such dialogues can help teachers prepare for supporting the students' learning in modelling activities without taking over the students' tasks. In the present paper we focus on the use of (2) as a tool for spanning the mathematical learning potentials in a modelling activity and as a tool for analysing the students' activities in a modelling project.

The methodological approach in our research and development of our course is similar to that of critical mathematics education (Skovsmose & Borba, 2004), where there is a distinction between three types of situations (teaching practices): The current situation (CS) is the practice of the teacher before the course. The imagined situation (IS) is the practice the teacher imagines to establish. The arranged situation (AS) is the practice that emerged in the experiment when the teacher implemented his/hers modelling project in class. Three processes combine the three situations: (1) Experimenting; (2) Analysing; and (3) Pedagogical imaging, see figure 1.

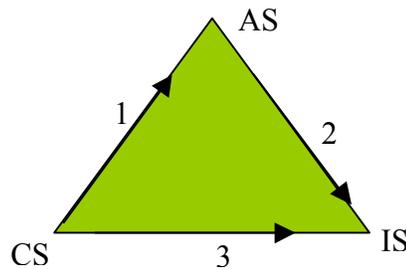

Figure 1: The methodological triangle in critical mathematics education.

In our course, we use theory on mathematical modelling and on the learning of mathematics to establish a shared idea about an imagined situation concerning a concrete modelling project suggested by the teachers (process 3). We help the teachers to use elements of theory as a basis for designing their projects (the arranged situation) (process 1) and for describing their aims for developing their practice of teaching in relation to the imagined situation (process 3). At the final seminar, each project is analysed with respect to the relation between the arranged situation and the teachers' ideas about the imagined situation (process 2), which they have described in their reports. Together with the teachers we reflect upon and develop new ideas about the imagined situation and how to further develop the projects for the next time. In relation to these processes, we focus on developing our interactions with the teachers in order to support their reflections on their projects.

A MODELLING PROJECT ON THE DECAY OF ALCOHOL AND THC

This problem oriented project work in mathematical modelling of the decay of alcohol and THC (tetrahydrocannabinol, the active drug in hash) was developed by four teachers from three different high schools. The project was implemented in three first year classes (age 15-16 years) in ordinary high schools in Denmark.

Before deciding for this theme for their project, the teachers discussed the ethical aspects of the theme. Most Danish young people age 15 and older drink alcohol at parties, and some drink too much! In the current situation hash is illegal to sell and possess but legal to smoke. In average, one or two students in a class of 30 students can be expected to have had some experiences with hash. The teachers found the theme relevant and motivating for the students. They sought it could make the students reflect critically upon their own alcohol habits and possibly prevent them from experimenting with hash. The theme was mathematical relevant since the decay of alcohol and THC is essentially linear and exponential, respectively.

The teachers formulated seven learning goals for the students in the project work:

1. provide the students with a positive experience on using their mathematical skills to answer interesting and relevant questions from their life world
2. support the students' conception of modelling and applications of mathematics
3. teach students to have a critical outlook on mathematical models
4. support the students' learning of linear and exponential functions
5. develop the students' understanding of the parameters in the two models
6. train the students to communicate mathematics
7. support the students' IT competences

These learning intentions were inspired by the theories introduced at the in-service course. They fall into three groups: (I) aspects of developing the students' modelling competency (1-3); (II) aspects of developing the students' concept images and their mathematical understanding of linear and exponential functions (4-5); (III) aspects of developing the students' IT and communication skills (6-7).

The students worked in groups of three to four. They were given a set of four exercises and the following task of writing a kind of newspaper article:

“Write an article for students of your own age about the decay of alcohol and THC in the human body. In the article you should also explain the mathematics you have used to complete the exercises. Your answers to the exercises and your graphs should be integrated into your article.” (Our translation from the teachers' report)

In the first two exercises, the students were presented with a set of realistic, but not authentic data showing the decay with time of some amount of alcohol or THC respectively in a person. The students were asked to draw graphs using T-Inspire or Excel, to describe the graphs in their own words, to determine the time for the amount to decrease to the half two times consecutively (to experience a fundamental mathematical difference between the two cases), to determine the mathematical expression for the functions represented in the graphs, and finally to interpret, in their own words, the significance of the parameters of the functions in the two contexts. The students were encouraged to find data on the web for the decay of alcohol and THC in the human body to compare with the models they had developed from the given data. In exercise three, the students were given data for the amount of alcohol in some popular drinks, and asked to model the decay of the amount of alcohol they

themselves had consumed at their last party. Finally, they were asked to compare the decay of hash and alcohol.

In the following, we focus the discussion on the second group of learning intentions. We analyse the students' reports and the teachers' related reflections with respect to these learning intentions. In the next section, we illustrate how the theories on the learning of mathematics can help span the potentials of the project for supporting the students' learning of the two types of functions. Our analyses rely on discussions that took place at the in-service course, the teachers' reports, their design of the project, the tasks given to the students and the articles written by six of the student groups, two groups from each of the three classes. We round off by discussing the relation between the potentials of the projects and what was fulfilled in the project.

Regarding the first three learning goals, the teachers' evaluations show that aspects of the students' modelling competency were invoked in all three classes. In the articles written by the students, they interpret their linear and exponential graphs for the decay of alcohol and THC, respectively with respect to the modelling context. They translate back and forth between the graphical representation and what it tells us about the amount of alcohol and THC in the body as times go by. Several groups of students reflected upon the validity of the models in the sense that they questioned whether the parameters in a model that was based on data for one particular person are valid for another person. The rate of decay of alcohol is mainly due to the liver and is only slightly depending on the body mass. A constant rate of 8 g/hour is a good estimate for a normal grown up person. For THC one finds a first order decomposition with a half-life period close to three days.

The students came to reflect upon the differences in the way in which the substances decrease in the two situations through the questions about how many hours it takes for the amount of alcohol and THC, respectively to decrease to half of the initial amount. They used the model with their estimation of their intake of alcohol at their last party. Many of the students were surprised to realize how many hours it actually takes, according to the model, before the alcohol in their body has vanished.

With respect to supporting the students' learning of linear and exponential functions and the significance of the parameters it is unclear, whether the students realized the fundamental properties of the two types of functions. As one teacher wrote:

“The idea was that the students should realize that the half time was a constant in the exponential case and not in the linear case. Many students didn't realize that because they used the graphs [to determine when half of the amount had decayed and when half of the half of the amount had decayed] and they reached two different approximations [for the exponential function].”

The students were able to reach an expression for the linear decrease of alcohol and the exponential decay of THC. They were also aware that the parameters in the linear function measure the initial amount of alcohol and the amount of alcohol that disappears per hour – except that in some of the articles, the students were not

accurate in distinguishing between the amount of alcohol and the concentration of alcohol in the body. However, as one of the teachers wrote:

“Surprisingly many of the students had problems de-mathematizing the parameters a ‘ $y=ax+b$ ’ and a ‘ $y=b \cdot e^{ax}$ ’, and interpreting the significance of these parameters for the decay of alcohol and THC, respectively. The main problem was the understanding of a indicating the [absolute] amount of decrease of alcohol per hour and a being a number determining the relative decrease of THC per hour as e^aSo next time I will use different names.”

The article, the students were asked to write, trained the students’ competency in communicating in and with mathematics. In the articles, the students sometimes reasoned with mathematics and other times within the modelling context, e.g.:

“In all these calculations we have seen that hash is in the body for a longer time than alcohol, and therefore it can damage one’s ability to learn if one smokes hash regularly.”

The students performed the calculations on the models constructed with the given sets of data, and for these it took much longer for the body to get rid of the THC than the alcohol. However, the model cannot say anything about learning disabilities!

The teachers’ intentions for the students’ learning were more or less fulfilled. The students used mathematics to model situations from their life world. Nearly all students were able to reflect upon and criticize the models to some extent. The modelling of alcohol and THC created teaching situations, in which the teachers became aware that the students had bigger problems than anticipated with understanding and interpreting the parameters in the linear function and the exponential function both mathematical and in the modelling contexts. In order to remedy this, the project can be further developed by designing and using model eliciting activities as explained by Ärlebäck, Doerr and O’Neil (see this proceeding).

THE USE OF THEORY IN DESIGNING AND ANALYSING THE PROJECT

In our in-service course the teachers were introduced to the model for concept formation in mathematics developed by Anna Sfard (1991) and the basic idea that the access to a mathematical concept goes through the meaning of its representations and their relations (Vinner and Dreyfus 1989), (Steinbring, 1987).

These elements of theory can be combined to form a tool for capturing the potentials for learning mathematics through modelling activities. We view this as a beginning development of a methodology for integrating theory from mathematics education into teachers’ experimentation and development of their own teaching practice. In the scheme in figure 2, we illustrate this idea in relation to the concept of a linear function and the different forms of representations that can come into play in the modelling of the decay of alcohol. In each cell in the scheme there is a representation of the concrete model of the alcohol decay and of the general linear model in the same form of representation. In each form of representation both the process and the object aspect of the concept can be represented. All these representations can be

interpreted and be given meaning in the modelling context. In the representations, the mathematical properties can be pinpointed and related to the properties of the general linear model or to the general exponential model. Hereby, the modelling context can mediate meaning also to the general mathematical model and to the mathematical concepts involved. We believe that the transition from a process to an object understanding of a mathematical concept can be supported in all forms of representations in the scheme. However, this needs to be further researched. The scheme can help span the learning potentials in modelling situations with regard to a particular concept, and hereby be of help for the teachers both in designing projects and in their dialogical interactions with their students.

Figure 2. Shows process and object aspects of representations of the alcohol model.

The teachers were introduced to the learning potentials spanned in the scheme at the first seminar of the in-service course. However, the way the scene was set for the students' modelling work in the project did not systematically challenge the students to work with the different representations. The algebraic and graphic representations are dominant in the students' articles. Moreover, in these two forms of representations, the process aspects are not visible in the students' work.

In the final seminar of the in-service course, the teachers reflected themselves about the unfulfilled learning potentials in the project. Suggestions for how to guide the students to work with the different representations in the scheme the next time were discussed. One way could be to ask the students explain the model in all five representations from both the process and the object perspective in the articles. Also, the learning potentials in comparing the schemes for the linear function and the

alcohol model with that of the exponential function and the THC model need to be addressed explicitly in the requirements for the students' articles. Another way could be to develop model eliciting activities directed towards the different representations (see Ärlebäck, Doerr and O'Neil; Doerr, Ärlebäck and O'Neil, this proceeding)

CLOSING REMARKS ON THE THEORY-PRACTICE RELATION

To support the students' learning of mathematics is an important objective for including mathematical modelling in secondary mathematics. However, in order to meet this objective we need to develop the practice of teaching modelling based on theories on the modelling and on the learning of mathematics. This can be done through theory based experimental work in the context of in-service courses or developmental projects. To facilitate the teachers' use of theory in such contexts it is important that we develop intermediate representations and modes of collaborations, which can mediate powerful theoretical ideas to teachers, so as to be helpful in their development of practice. The representation scheme presented in this paper (see figure 2) is an example hereof, and a beginning for developing a methodology for teachers' use of theory in experimenting with and developing their teaching practice.

BARRIERS AND MOTIVATIONS OF PRIMARY TEACHERS FOR IMPLEMENTING MODELLING IN MATHEMATICS LESSONS

Rita Borromeo Ferri & Werner Blum

University of Kassel, Germany

Mathematical modelling is one central competency within the German education standards in mathematics for primary schools (from grade one to grade four). However, a lot of primary teachers do not know how to deal with modelling in the classroom, what can be often recognized during in-service teacher training or classroom observations. To get more insight into reasons for this reserve, a quantitative study was developed with the aim to investigate central barriers and also motivations of primary teachers for implementing modelling in mathematics lessons. The results show three essential barriers for primary teachers: 1. lack of material; 2. time pressure; 3. Assessment. In the paper we will go deeper into these and further results.

INTRODUCTION AND RESEARCH QUESTION

The national and international research area of mathematical modelling at the secondary and tertiary education levels is rather well established and a lot of modelling problems, materials and practical ideas for teachers are available. Although mathematical modelling in primary schools (grades 1 to 4) is discussed within the international debate as well, there are still rather few research studies. In Germany in particular, there are only very few studies focusing on this topic, and the development of modelling problems for primary classrooms did not really start until the national education standards for mathematics at the primary level (in which modelling is one of five competencies that pupils ought to achieve in grades 1 to 4) became compulsory in 2003. But there is still a big gap between the demand that modelling really starts in primary school and is an essential part of mathematics, on the one hand, and the experiences from everyday school practice, on the other hand, where many teachers do not like to deal with this topic since it seems to be “too complex and too hard for young kids”. Adequate starting points for avoiding this mismatch are, in particular, modelling seminars with practical elements for future primary and secondary teachers at university. We have a lot of experiences with these seminars (see Borromeo Ferri & Blum, 2009) and we are convinced that these teachers will have another view on teaching modelling when they are in school. The biggest problem is to convince those teachers who have taught mathematics for a long time in the traditional way and have heard about modelling, but do not know what it really means and how it can be implemented in their daily mathematics lessons. This special situation with primary teachers in Germany has led us to investigate barriers and motivations for teaching mathematical modelling in primary school more deeply and more systematically.

In the international literature, there are no quantitative findings concerning these aspects for primary school teachers. So our central research question was:

What are the main reasons which hinder or motivate primary school teachers to implement modelling in their mathematics lessons?

THEORETICAL BACKGROUND

A lot of research studies have revealed positive effects of modelling problems in elementary school (Bonotto, 2004) with examples such as shopping in the supermarket or timetables for trains. Also Verschaffel (2002) emphasizes the possibility of modelling activities in primary school, in particular in the context of arithmetic operations (see also Usiskin, 2007). Especially the research of English (2002, 2006) concerning modelling activities of 10- and 11-year-olds are impressive. Young students created, for example, a shopping-guide in the context of a modelling problem (see Mousoulides & English, 2008). Starting with Modelling Eliciting Activities (MEA) already in kindergarten and subsequently in primary school is in Lesh's sense (see e.g. Lesh & Doerr, 2003) the basis for effective modelling in upper grades. A lot of Lesh's case studies show that primary kids are actually able to deal with modelling problems and to get remarkable results, in particular if the teachers themselves like modelling, have knowledge of how to communicate it in the classroom and have stimulated so-called "thought-revealing-activities". We also have used one of Lesh's examples (the "Big Foot" problem) successfully in grade 4. Summarizing existing studies about teaching and learning mathematical modelling, the crucial role of the teacher becomes evident. So modelling can only be learned effectively if there are teachers who have appropriate competencies in this field (Borromeo Ferri & Blum, 2009).

Besides the above-mentioned aspects, our main hypotheses are based on further results of empirical research. Within the LEMA project (**L**earning and **E**ducation in and through **M**odelling and **A**pplications, project director: Katja Maaß) questionnaires, mainly for secondary teachers, were developed concerning beliefs (Maaß & Gurlitt, 2009) and also concerning the question which obstacles and motivations the teachers have for integrating modelling in their mathematics lessons (Schmidt, 2010a). The main results of Schmidt's quantitative study with more than 50 secondary teachers in a pre- and post-test design have revealed three main barriers for teaching modelling: 1. The time needed for working on modelling problems; 2. Lack of materials (no access to suitable modelling problems); 3. Assessment (teachers do not know how to give marks for modelling activities). More generally, the following six categories of obstacles for the implementation of modelling in mathematics classrooms have been identified in the educational debate (compare, e.g., Blum, 1996, 2011; Pollak, 1979; Kaiser-Meßmer, 1986; Maaß, 2004; Burkhardt, 2006; Ikeda, 2007): 1) organisational obstacles (such as the time needed to deal with modelling problems in the classroom); 2) student-related obstacles (lessons become more demanding and less predictable); 3) teacher-related obstacles (non-mathematical competencies and broader beliefs are needed, lessons become more demanding and less predictable, assessment becomes more complex); 4) material-related obstacles (are there enough suitable examples?);

5) systemic obstacles (such as expectations of parents, scientific associations and other pressure groups, or regulations in examinations); 6) research-related obstacles (are there reliable empirical results as a basis for teaching modelling?)

METHODOLOGY AND DESIGN OF THE STUDY

Questionnaire development

The empirical study of Schmidt (2010a, 2010b) was particularly interesting for us because she developed, in the context of the LEMA project, a questionnaire on the basis of findings from those empirical studies in mathematical modelling which have reconstructed relevant obstacles and motivations for teaching modelling (see the end of the previous section). So the construction of her questionnaire can be described as an inductive and deductive procedure. The developed “inductive” items came from theory and the “deductive” items from interviews with experts. This questionnaire was the basis for our own questionnaire development, but we modified items and scales for the purpose of applying it with a sample of primary school teachers. From the original 56 LEMA items, we kept 37 and constructed 6 new ones, based on two extended piloting activities. A central theoretical background for our questionnaire was “The offer-and-use model” (Figure 1) according to Helmke (2006), because the categories of this model (teacher, education, context etc.) were the basis for the structure of our scales (see below).

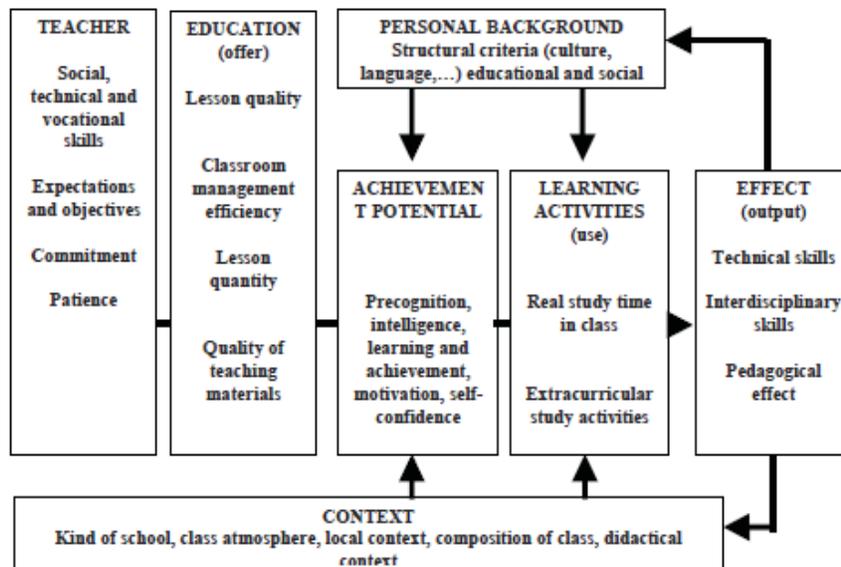

Figure 1: “The offer-and-use-model”, Helmke (2006)

Altogether our questionnaire comprised 14 scales with 43 items and additionally one open item asking for personal comments and experiences with mathematical modelling. Besides demographical questions concerning age, years of teaching, experiences with modelling and subjects studied at university, the scales are labelled as follows:

“*context*” (sample item: The parents of the pupils in my class do not like if I teach modelling problems in mathematics lessons), “*differentiation*” (sample item: modelling problems support stronger and weaker pupils at once), “*time*” (in the sense of lesson time for teaching modelling), “*role of the teacher*”, “*lesson planning*”, “*motivation of the pupils*”, “*material*”, “*creativity*”, “*independence*” (sample item: pupils are able work on their individual solution processes), “*excessive demand*”, “*assessment*”, “*long-term effects in mathematics lessons*”, “*applying mathematics in real life*”, “*long-term effects beyond mathematics lessons*”.

The answer format corresponded to a 3-level Likert scale (Rost 1996) from “strongly agree” to “do not agree” (see Figure 2). The numbers of items per scale differ (from 2 to 6). Of course, only scales with a satisfactory reliability (see below) were used for further analyses. It is important to keep in mind that this questionnaire is focusing on teacher’s personality and so gives only feedback about subjective ideas and attitudes concerning the topic of modelling. The questionnaire was discussed with several primary teachers before using it in the sample.

Hypotheses: On the basis of the theory and of the results of Schmidt’s study within the LEMA-project, in combination with the research on modelling in primary school as well as experiences from teacher education, we assumed the following six scales as examples of *barriers* for modelling: “context”, “time”, “lesson planning”, “material”, “excessive demand” and “assessment”. On the other hand, we supposed the following eight scales as *motivations* for teachers to include modelling: “differentiation”, “role of the teacher”, “motivation of pupils”, “creativity”, “self-dependence”, “long-term effects in mathematics lessons”, “applying mathematics in real life” and “long-term effects beyond mathematics lessons”.

Design of the study and sample

The study was mainly *quantitatively* oriented, because on the basis of experiences in in-service teacher training we knew some of the barriers and motivations, but we still had no empirical knowledge about, for example, a comparison between teachers who studied the subject or not, and so we wanted to get more generalizable results. The data collection started in March 2012 and was completed in April 2012. Our sample comprised 71 primary teachers (female: 64, male: 7) from 8 of the 16 German states and was a convenience sample. Often two or three teachers from the same school got the questionnaire. We were glad about the relatively big sample for this study, having in mind how hard it is to get teachers, particularly teachers who did not study the subject, to spend time for working on such a questionnaire. The schools were in suburban regions respectively in smaller cities. The mean age was 44. The majority of the teachers (43 in total) have studied mathematics as a subject at university. The indicated frequency of integrating modelling was (in total): never: 20; seldom: 37; monthly:

9; weekly: 5. So we can say, as a first result, that for the majority of the teachers, modelling is not an essential part of mathematics lessons.

Data analysis

The underlying theory for the data analysis is the so-called Expectancy Theory or VIE-Theory (Vroom, 1964) which itself is based on the concept of Instrumentality (Peak, 1995) coming from motivation research. Vroom has built his theory on three variables which influence the motivation of a person (see Brandstätter 1999, p. 351ff): Expectancy, Instrumentality, and Valence. In our questionnaire, we left out Expectancy. *Instrumentality* is the belief that a person will receive a reward if the performance expectation is met. *Valence* is the value that the individual places personally on the rewards based on his/her needs, goals, values and sources of motivation. In order for the valence to be positive, the person must prefer attaining the outcome to not attaining it. Expectancy Theory of motivation can, for instance, help managers understand how individuals make decisions regarding various behavioural alternatives. The model below shows the direction of motivation when behaviour is energized: Motivation = Instrumentality x Valence.

The following example of our study shows the procedure:

	Stimme nicht zu			Stimme zu			Hindert mich			irrelevant			Motiviert mich		
	1	2	3	-1	0	1									
<i>scale: lesson planning</i>															
Lesson cannot be planned in detail with modelling problems.															
I cannot plan the lesson in detail.	<input type="radio"/>	<input type="radio"/>	<input checked="" type="radio"/>	<input checked="" type="radio"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	
Pupils do not do what I had in mind while lesson-planning.	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	

Instrumentality

Valence

Figure 2: Example of data analysis (scale: lesson-planning)

The figure shows values from 1 to 3 in the first dimension and from -1 to 1 in the second. For the product of Instrumentality and Valence in this example, we get: $3 \times (-1) = -3$. Overall the motivation values may range from -3 to 3. It should be noted that “motivation” in the usual sense means positive values for motivation here.

In this way, all the data were coded and the software SPSS was used. The reliabilities of 12 of the 14 scales were satisfying, with Cronbach’s α in the range between .65 and .84. Only the two scales “context” and “motivation” had smaller reliabilities; hence these two scales will not be contained in the following diagrams.

EMPIRICAL RESULTS

Relevant aspects from teachers' perspective – an overview

Very briefly we will first show how strong the test persons agreed to the statements in these scales, so we look at *the left part of the rating scale (Instrumentality)* of the questionnaire. The higher the level of agreement, the more relevant is this aspect for the teachers. In the following boxplot, those scales are shown which can be interpreted as *barriers* (see our hypotheses):

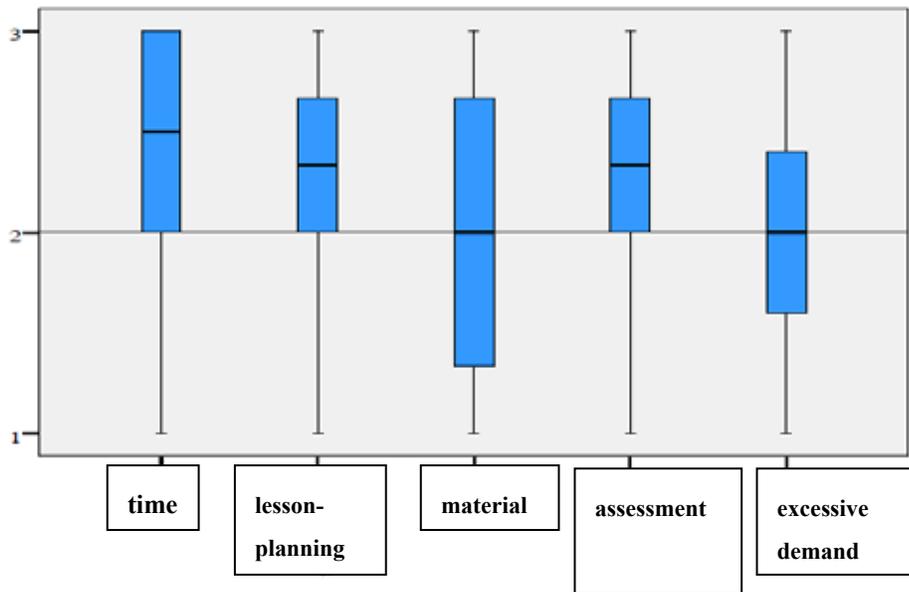

Figure 3: Relevant aspects from teachers' perspective

The values between 1 and 2 show a tendency towards rejection by the teachers, whereas the values between 2 and 3 show a tendency towards agreement concerning the relevance of these aspects. In particular the scales “*time*”, “*lesson planning*” and “*assessment*” have high relevance for the teachers. Regarding “*material*” and “*excessive demand*” different attitudes of teachers become visible. For the scales that can be interpreted as *motivations* from the teachers' perspective, the scale “*independence*” got the highest agreement from nearly all teachers. But also the other aspects (“*long-term effects in mathematics lessons*”, “*applying mathematics in real life*”, “*long-term effects beyond mathematics lessons*”, “*creativity*”, “*role of the teacher*”) show a surprisingly high level of acceptance. Summarizing the first rating scale in more detail, the highest agreement came from the category “*learning activities*”: 87% of the teachers have the opinion that their pupils could be more creative mathematical thinkers when working with modelling problems, and 85% think that the level of self-dependence will be better. The highest value within the category “*effects*” was received by the aspect “*relevance for everyday life*” with 78%. The above-mentioned aspects only show the level of agreement. In the following it is interesting to see

whether this agreement is more a barrier or more a motivation for integrating mathematical modelling.

Barriers and motivations: For investigating the expected barriers or motivations both dimensions in the questionnaire (Instrumentality and Valence) were multiplied and so linked in the sense of the Expectancy Theory. Regarding to our hypotheses we expected barriers concerning all five scales. Analyzing these results in more detail, for 50% of the teachers' "*time*" is seen as a barrier; only 28% are indifferent and for 22% it seems to be motivating. The aspect "*material*" is also a barrier for 42% of the teachers, 41% are indifferent and 17% are motivated. Concerning "*assessment*" the opinions of the teachers were different, and against our expectations, the aspects of "*excessive demand*" and "*lesson-planning*" were not seen as barriers.

Expected reasons of motivation: For seven scales of the questionnaire, answers were expected that tend towards teachers' (positive) motivation to integrate modelling. Especially the aspect of self-dependence was evaluated very positively: 91% of the teachers voted to be influenced positively, 6% were indifferent and only 3% saw a barrier for it. Concerning the "long-term effects beyond mathematics lessons" even 96% of the teachers are motivated, only 6% voted for indifference and for 1% it is a barrier. Only the scale "differentiation" did not show such high positive effects: 69% rated it as positively, 17% were indifferent and 14% regarded it as a barrier. Looking at the other scales, also "*creativity*" and "*applying mathematics in daily life*" had similar positive values.

Differences between teachers who studied mathematics as a subject or not: In Germany not all primary teachers have to study mathematics as a subject; it depends on the particular state. 28 of 71 teachers have not studied mathematics. The analyses show no big discrepancies concerning the aspects of "*time*" and "*lesson-planning*" and the aspect "*material*" seems for both groups of teachers to realize a substantial obstacle. However the aspect "*assessment*" illustrates considerable differences: teachers who did not study mathematics see here a barrier to teach modelling and for the other teachers "*assessment*" is a strong motivator.

Influence of experiences in teaching mathematical modelling concerning barriers and motivations: A small part of the sample (14 teachers) often uses modelling problems in class, 37 persons only seldom and 20 never. This was a good basis for analyzing differences in the attitudes of the teachers with respect to how often they do modelling activities. Already the aspect "*time*" made it clear that there are substantial differences: Experienced teachers do not see a barrier, but for inexperienced teachers time is a strong argument against modelling. Very similar results can be seen for the aspect "*material*". Experienced teachers also show a strong motivation concerning the material. A reason is, of course, that they often use such problems and know where to get these. Regarding the expected reasons of motivation, the scales "*long-term effects in mathematics lessons*", "*applying mathematics in real life*" and "*long-*

term effects beyond mathematics lessons” were a stronger motivator for the inexperienced teachers. We think that experienced teachers recognized the positive effects of these aspects for modelling, too, but for them these aspects were less relevant compared to others.

SUMMARY AND DISCUSSION

Although mathematical modelling is a central competency in the German education standards for mathematics and should thus be a compulsory part of mathematics lessons, a lot of primary teachers still do not have these aspects in their mind and a lot of them are afraid of integrating modelling in their classrooms. For this reason we wanted to investigate barriers and motivations of primary teachers more systematically. The three essential barriers are *material*, *time* and *assessment*. For teachers experienced with modelling, *time* was not such a strong barrier as it was for the inexperienced teachers. One can suppose that the problem of time is rather a prejudice concerning modelling problems and their possible complexity. Probably different teachers set different priorities, because some are willing to invest time for modelling and others do not like to use this kind of tasks. The aspect of *assessment* was a barrier for many teachers. For teachers who did not study mathematics it seemed to be a much stronger barrier than for those who studied the subject. This could be related to their professional education. While teachers who did not study mathematics are fine with tasks which have unique results (right or wrong solution), the specialized teachers are able to assess pupils who work on open problems and so produce multiple solutions. The aspect *material* could not be allocated to a group, but was rated as a barrier for the main part of the sample. Besides the barriers a lot of motivating reasons for modelling could be found, in particular *self-dependence* of the pupils, *creativity*, *long-term effects in mathematics lessons*, *applying mathematics in real life*, *long-term effects beyond mathematics lessons*. Also the *changing role of the teacher* was rated very positively.

The results of the study gave new insight into attitudes and opinions of primary teachers for implementing mathematical modelling in their lessons. All answers of the teachers made clear that they have recognized the benefit of modelling problems and modelling activities in general. All the barriers mentioned before can of course be eliminated or at least reduced by suitable professional development activities. With our results, we have now a better basis for meeting the needs of the teachers in such professional development activities.

PROJECT TEACHING AND MATHEMATICAL MODELLING IN STEM¹ SUBJECTS: A DESIGN BASED RESEARCH STUDY

Wolfgang Bock & Martin Bracke

Department of Mathematics, University of Kaiserslautern

In this paper we introduce our concept of a design based research study on the implementation of a new course STEM. The idea is to create a 3-years course for students of lower secondary level that integrates several STEM subjects, e.g. mathematics, computer science and biology. The subjects are not taught separately but are working on the same overall topic, seeing through the eyes and using the techniques of the respective discipline. After motivation and introduction of our concept we explain the real-world problem for the current round of the study and outline some first results and experiences.

Keywords: Mathematical Modelling, Design Based Research, STEM subjects, Project Teaching, Active Learning

INTRODUCTION

Beginning with the first Pisa study in 2000 (OECD, 2001) there is a worldwide discussion of an appropriate education in the so-called STEM subjects^[1]. One cause was the alarming fact that in many countries the majority of secondary school students fail to reach proficiency in math and science (Kuenzi, 2008). Further studies showed that a lack of substantial subject matter knowledge of teachers is an important reason. Another trigger for the still growing interest in the discussion of education in STEM fields is the demand of industry for highly qualified young people with a degree in one of the STEM fields.

One significant reaction to the above mentioned debate was to strengthen the role of mathematical modelling in teacher training as well as in the curricula. In Germany, this can be seen from the fact that mathematical modelling is mandatory in most of the recently introduced master programs for academic training of mathematics teachers. Moreover, there is a strong increase in the number of publications on mathematical modelling of *real-world*, *realistic* or *authentic problems* over the past decade.

Definition 1: An *authentic problem* is a problem posed by a client, who wants to obtain a solution, which is applicable in the issues of the client. The problem is not filtered or reduced and has the full generality without any manipulations, i.e. it is posed as it is seen. A *real-world or realistic problem*, is an authentic problem, which involves ingredients, which can be accessed by the students in real life.

¹ STEM = Science, Technology, Engineering, Mathematics (in German: MINT)

RESEARCH QUESTIONS

Along working on a real-world problem we want to study the following research questions:

- How can project teaching in STEM subjects be improved?
- How does project learning and modelling in a 3-years real world project affect the sustainability of the techniques and knowledge used throughout working on the problem?
- How can tablet computers be used effectively throughout such a project?
- How do real-world problems affect the intrinsic motivation of the students to learn mathematics/computer science? Here we use standard instruments as QCM, see e.g. (Rheinberg, Vollmeyer & Burns, 2001)
- How do real-world problems affect Self-Efficiency of the students? Here we use standard instruments as in (Jerusalem & Schwarzer, 1999)

Furthermore we want to investigate the usage of tablet computers in STEM and the dependence on the above topics. Here, the application of tablets is twofold:

- **Tool:** Tablets are used for presentation and to create learning portfolios, as a calculator or measuring device (e.g. oscilloscope).
- **Blackbox:** Software is used to provide complex models and techniques which can not be dealt with at the current students' competence level (e.g. Fourier analysis, smartphone programming).

LEARNING BASED ON NEURO BIOLOGY

Very recently it was shown in Neuro Biology, that the chance for a sustainable learning is not only based on the subject itself but also on an emotional learning environment (no cognition without emotion), see e.g. (Beck, 2003), i.e. if the students have an emotional link to the learning group as well as to topic itself. This is based on the dogma of Neuro Science stating that every process of the brain is resulting from integrated processes of single neural cells, i.e. processes which are linked not only to thinking but also to feelings and acting have more sustainability just because they are more integrated and developed in the brain structure. To obtain these links it is important, that children make their own experiences in as many different forms as possible. In (Hüther, G., 2003) there is mentioned how education and learning processes can be blocked.

An optimal learning effect can be achieved, if one looks carefully at the questions a child is posing and to answer them completely and uniquely. (Singer, W. 1999, p.62).

Moreover learning has to be done with examples not by instruction and preaching (Spitzer, 2002). But it is important that the students have a structural impulse. Here

we see parallels to the inductive teaching methods from active learning, see (Beck, 2003, p.5). This is the theoretical fundament of the project presented in this article.

IDEA OF THE JUNIOR ENGINEER ACADEMY “STEM”

Although there seems to be an agreement on the importance of the incorporation of modelling problems into their math lessons on a regular basis teachers face several problems: Often, there is a lack of time since they need to cover the whole curriculum for final examinations. Secondly, many real-world problems are quite complex and do not seem to be suitable for young students (or students at school at all) or as short time projects, respectively. Moreover, many problems cannot be worked on just from a mathematical perspective because they make strong demands on other STEM disciplines – and this is challenging for both students and teachers! Of course, problems can always be simplified, but if this essential step of the mathematical modelling process is taken over by the teacher the students get no training in a very crucial point of the whole process. Later, when working as a STEM professional, nobody will be there to do this first step for them and hence, they will eventually fail to solve their real-world problem.

In summary, it seems to be very difficult to establish a meaningful education in the STEM fields just by modifying the way of teaching for single subjects. We have some experiences from a long-term experiment introducing a significant number of small but realistic modelling projects in regular math lessons (Bracke & Geiger, 2011). But during the study we were facing many of the above-mentioned problems, and this is why we started to make up a new concept for STEM lessons that is currently under evaluation as part of a pilot project between the Felix-Klein-Centre for Mathematics² and the Heinrich-Heine-Gymnasium³ in Kaiserslautern, Germany.

Our concept for STEM lessons

In our pilot we did not just want to develop a new concept for math or physics classes but the idea was to use another organizational structure. Therefore, we chose the Heinrich-Heine-Gymnasium, a high school with a branch for highly gifted students. They already had a compulsory elective lesson called “STEM” which can be chosen by students entering 7th grade. The former concept was to divide the lessons of this 3-years course into three parts: During the first year the students were taught in computer science, during the second year they had additional math lessons and the third year was dedicated to one natural science, i.e. biology, chemistry or physics (in alternating order). Throughout the whole 3-years course the students had three hours of classes per week. It is important to note that the contents of the whole

² The Felix-Klein-Center for Mathematics in Kaiserslautern (<http://felix-klein-zentrum.de>) is a cooperation of the Fraunhofer ITWM and the Dep. of Mathematics, University of Kaiserslautern.

³ <http://www.hhg-kl.de>

course was intended to have no intersection with the standard curriculum of 7th – 10th grades⁴. The main reason to choose this particular school was not the fact that they have a special branch for highly gifted students but the already existing organizational structure. In our opinion it is not a necessary condition to work with highly gifted students: In a similar project conducted by the TheoPrax Centre in Pfinztal, Germany, teachers work with ordinary school classes of grade 8–10 (TheoPrax, n.d.).

Together with the school's administration as well as with teachers of STEM subjects a new course "STEM" was set up: Of course, it is still a compulsory elective course and the time scope is three lessons per week throughout grade 7, 8 and 10. But there is a common topic for every 3-years course and every week there are lessons in mathematics, computer science and one natural science⁵. In the first round starting in 2010 – which is now in its third year – the topic was *Planning Sites of Wind Parks* and besides mathematics and computer science, the students get lessons in physics. The second round beginning in 2011 has the topic *Batteries, Accumulators and Fuel Cells: The Search for the Super-Storage* with chemistry as the natural science. The new topic for the third round is *Bioacoustics – Automatic Recognition of Bird Voices* and as the reader might guess, biology was chosen to be the natural science taught in that course.

Just reading those topics, the whole project sounds quite ambiguous for students of lower secondary level and therefore would be avoided by many teachers at first glance. Our intention was to work on real-world STEM problems that are interesting for the students. The course is not about only learning techniques but about learning concepts and solving problems. The teachers are seen not only as instructors but also as co-workers on the STEM topic. For every course we have a team consisting of regular teachers and "external teachers": The external teachers are graduate students (for computer science lessons in round 1 and 2) and mathematicians for math lessons in round 2 and math/computer science lessons in round 3, respectively⁶. Additionally, each subject has an external consultant, an expert from the University of Kaiserslautern or the Fraunhofer ITWM.

The concept encompasses the regular lessons (three hours of classes per week as mentioned before) and additionally, there are excursions and workshops throughout the whole 3-years course. Examples for excursions are visits of university labs (to conduct own experiments) or other institutes/companies. The regular workshops are

⁴ In the special branch of the school students skip 9th grade by concept, i.e. the lower secondary level consists of grades 7, 8 and 10.

⁵ The natural science is chosen to correspond to the overall topic of the course.

⁶ The second author teaches mathematics in the second round of the project and both authors do a team teaching of mathematics/computer science/physics in the third round.

starting from *Team Building* and *Time/Project Planning* up to *Creativity Techniques* and *Conflict Management*.

An important part of the pilot is financing: For the first round the Felix-Klein-Centre and the Heinrich-Heine-Gymnasium have been awarded with a so-called Junior Engineer Academy by Deutsche Telekom Foundation. This covers the external teachers, excursions, workshops and some materials/devices that are not in the regular budget of the school. Since the first year was very promising both partners immediately decided to extend the pilot to have at least three rounds, i.e. in total a 5-years period.

Example: Bioacoustics – Recognition of bird voices

Since the topics of the first two rounds in our project were related to physics and chemistry, respectively, the obvious idea for the current topic was to find a challenging project involving biology.

While for the other topics we started from a concrete problem (planning sites of wind parks, optimal storage of electrical energy), the starting point for the current round was the external expert⁷, who is a specialist in ornithology and thus has no problem to distinguish between a whole variety of birds just by hearing them singing. For ordinary people, on the other hand, the identification of birds by their voices is a very hard task and most people can only recognize a few very popular species by their sounds. For similar tasks like plant identification where there exist tools – books and smartphone apps – that support amateurs in learning the identification process to a good level.

The recognition tools of birds are mostly books and even smartphone apps⁸ that are based on visual features. But currently there is no application that relies on bird voices as the only (or at least main) feature for the identification: The project WeBIRD⁹ uses a huge database and claims a high accuracy for the recognition process but the corresponding smartphone app has not yet been published. J. Hammarberg (Alexandria Institute (Aarhus, Denmark)) concludes in a blog report (Hammarberg, 2012) that there is some research on the automatic recognition of bird voices¹⁰ but there seems to be no current approach that can be used for an application based on smartphone techniques.

⁷ Hans-Wolfgang Helb was assistant professor for zoology, ecology, behavioral biology and ornithology at the University of Kaiserslautern for 35 years.

⁸ Audubon Birds, BirdsEye and iBird Pro (apps for iOS & Android based systems)

⁹ WeBIRD: The Wisconsin Electronic Bird Identification Resource Database. Project leader is biologist Mark Berres, assistant professor at CALS, Madison, Wisconsin.

¹⁰ C.f. (Jankovic and Köküer, 2011) or (Lopes, Lameiras Koerich, Nascimento Silla & Alves Kaestner, 2011)

Thus we chose the topic *Bioacoustics – Automatic recognition of bird voices* for the current round of our project. The goal for the students is to generate methods and implement software to identify birds not by their visual appearance but by their songs. This is an actual problem in ornithology, where the ultimate goal - a smartphone app that simplifies the identification process - would provide two important contributions for clients from ornithology:

- Support for amateur ornithologists and those who are interested in that field.
- Produce a tool for monitoring biodiversity in ecosystems by non-invasive methods.

From the mathematical point of view the techniques required for this project such as *Fourier analysis* and *Hilbert space theory* are far beyond standard school mathematics. Therefore many mathematics teachers at first glance would maybe refuse to carry out the project. The same problem arises in computer science, where students do not at all know techniques as *machine learning*, *neural networks* and *smartphone programming*.

We started the course with a presentation of the general, complex problem and the expert explained the ornithological background. We also highlighted the ultimate goal of a smartphone app having the features described above as a *nice to have*.

Since this real-world problem is a current research topic, i.e. a client is interested in a solution, we think that the students are more intrinsically motivated to work on this problem and to learn the things they need to know in order to do this (c.f. the section on teaching concepts and design based research). This intrinsic motivation will be one of the authors research topics within this design based research study.

In our opinion the question if such a complex topic can be given to lower secondary level students depends strongly **on the expectations the teachers have**. Moreover, gathering some understanding about the complexity and the exact points which make the problem that difficult would be a big success.

Some comments on introductory lessons and first experiences

In this subsection we describe our idea for and some results from the introductory phase of the course, i.e. the first seven weeks¹¹. In the course we have 19 students, 12 girls and 7 boys, who chose STEM as their elective course for the next three years. Although they are highly gifted, this does not imply that everybody is very good in all of the three subjects – but as mentioned before we do not expect this heterogeneity to be a problem at all. Besides working on the problem itself one important goal of the first weeks was to obtain a deeper insight into the social and

¹¹ Remember that we have three hours of lessons per week (one each in mathematics, computer science and biology).

mathematical or computer science abilities of the class. Vice versa, the students should have a chance to acclimatise in the teaching style of active learning, which was not much used in the years before.

We do not present details on the biology part here since the authors are teaching mathematics/computer science and at least for the introductory phase there is no need for a close ties between the subject. Of course, there is an exchange of information between all teachers on a regular basis. All we want to mention concerning the first biology lessons is that the main goal was to gather some basic knowledge on the anatomy of birds and the way they are able to produce sounds. Later on, it will be very interesting to investigate the role of the singing of the birds and why they are able to sing various and sometimes rather complex songs: Is it a matter of genetic inheritance or of learning from their parents – or maybe a mixture of both?

Concerning the mathematics/computer science part we first have to note that despite having only three subjects in the course we knew that also a lot of physics would be involved right from the beginning.

In fact, in the first lessons the students investigated the physics question: *What is sound?* We therefore decided to replace computer science by physics for the first weeks. Our first lesson started with the four diagrams shown in Figure 1 and the question of their meaning. The diagram was made by the freeware program Audacity.

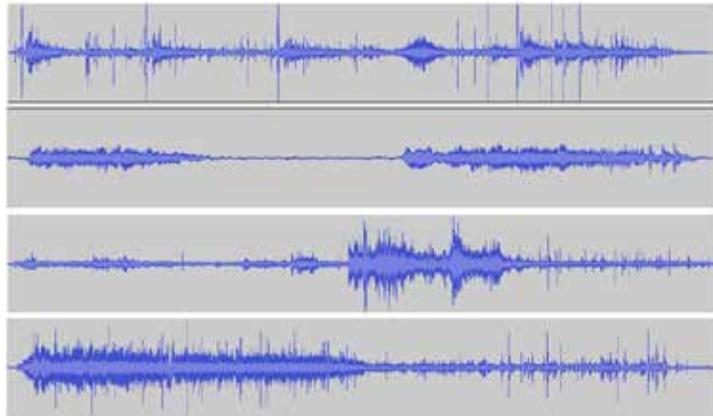

Figure 1: What's that? (Audio tracks visualized with Audacity (Freeware))

The students had an intuitive interpretation and although there are no axis labels they all related these diagrams to sounds. They even gave some qualitative interpretations of the kind of sound they expected behind each graph. This is quite astonishing since of course by labelling and scaling it is possible to assign very different meanings. It would also be interesting if the quasi-symmetry with respect to a horizontal axis (which corresponds to a zero amplitude of the signal in this case) was an implicit factor for the interpretations of the students.

During the first lessons we did a lot of physical experiments to learn more about the nature of sound and the main teaching concept was *learning circles*. A lot of time¹² was spent on working in groups as well as on preparation and presentation of the results. For example, after the first series of experiments the students were asked to prepare a documentary video for each of the experiments. They first had to write their own scripts, then do the corresponding recordings and finally prepare an audio commentary that was mixed together with the video.

The next step was to obtain common definitions for the physical notions of a *tone*, a *complex tonal sound*, a *sound* and a *bang*. To assist the students during this discussion we introduced the oscilloscope as a measuring device¹³ and performed some experiments to get more clarity about the characteristics of the different types of sound.

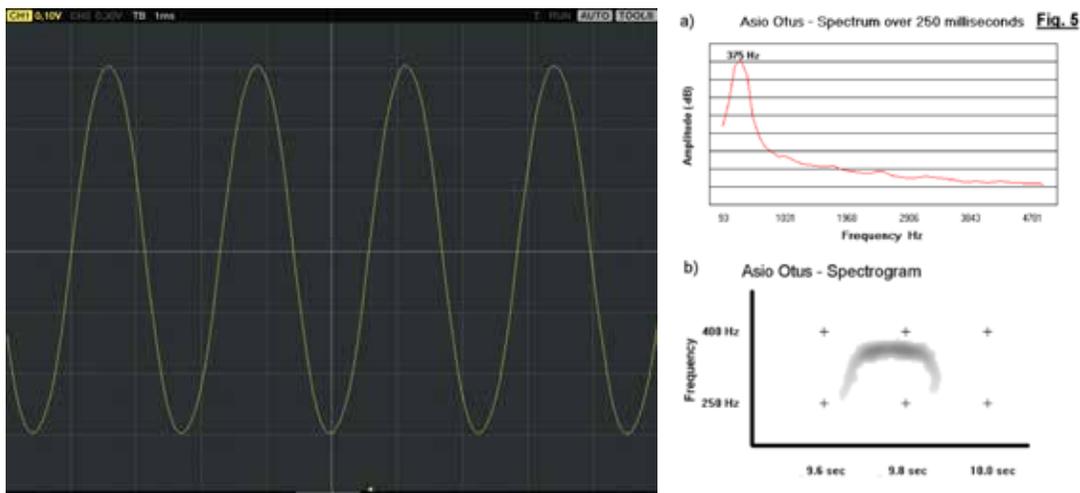

Figure 2: Sounds on the oscilloscope (left) (iPad app *Oscilloscope*), Example for a sonogram, from <http://www.birdsongs.it> (right)

Since during their research the students found the terms of amplitude, frequency and wave length we used screenshots of the oscilloscope (where the iPad app *Oscilloscope* was used) (c.f. Figure 2 (left)) for a tone they have actually heard before and asked them for an analysis, guided by some questions like *Where are the zero-passings/minima/maxima of the graph?* They created value tables for each of the features and plotted the corresponding graphs. Of course, this can be done for different tones and the next goal we agreed about is to derive a mathematical characterization for what seems to be the basis for all the graphs we have seen so far.

¹² In a classical physics course the teacher would probably have spent at most half of the time to achieve the same goals.

¹³ An iPad with the app *Oscilloscope* was used. The feature to connect the tablet to a beamer was extensively used.

In Mathematics the students learned besides the notion of a sine oscillation how to use proportionalities. This was indeed used to obtain the oscillation length. Furthermore the notion of function and graph was introduced. The students learned how to superpose graphs and obtain the graph of a sum of functions. In a next step this techniques are used to investigate the phenomenon of “anti-sonic”, i.e. the fading of a sine signal by superposing it with the same signal at a different phase.

After that, the computer science part starts, since we have to process and analyse data of sound recordings. One main goal for the first year of our course (concerning mathematics/computer science & physics) is the ability to produce and read so called *sonagrams* or *spectograms*, i.e. frequency-time-plots, that display more information than a simple waveform (amplitude-time-plot). An example can be seen in Figure 2 (right).

TEACHING CONCEPTS AND DESIGN BASED RESEARCH

One important point in our teaching concept is to look carefully at the questions the students are posing and trying to answer them completely and uniquely (cf. Singer, 1999). If necessary, we are going to add experiments or mini-lessons to achieve this goal. Educational methods taking this knowledge of learning into account are about 100 years old and go back to Pestalozzi, who already stated that an effective learning is learning with head, heart and hand. By Vygotsky’s theory (Vygotsky 1978), it is crucial to choose the lessons according to the individual zone of proximal development of the students in order to obtain a sustainable knowledge and to improve already existing skills individually. Of course it is not necessary that the teacher poses problems and questions, also the students their selves can ask for problems they are interested in. In our opinion this will even augment the motivation for learning techniques to solve the problems.

Furthermore in our opinion it is important, that at the end of the project we have an end-product. As in a typical order in an industrial company, there should be a product the students have to construct. This is the main goal, which can of course be manipulated during the period. Towards this, the students claim smaller problems to solve, according to their interest and the needs to the final product. With this setting we try to give the structural impulse mentioned above. The main idea of this project is to use the so-called Design-Based Research model, see e.g. (Collective, T. D. - B. R., 2003), to improve the techniques during the process. We plan first to practice the above-mentioned strategy to the group of students to adapt the methods according to their educational success.

NOTES

1. In German, the common analogue for STEM (Science, Technology, Engineering, Mathematics) is MINT which stands for Mathematik (Mathematics), Informatik (Computer Science), Naturwissenschaften (Natural Science), Technologie (Technology). In our opinion the definition of MINT is too restrictive. Thus we include other disciplines

like geo sciences, social sciences and economic sciences. Moreover, STEM explicitly incorporates the engineering disciplines in addition to technology whereas in MINT they are included in the term technology.

THEMES FOR MATHEMATICAL MODELING THAT INTEREST DUTCH STUDENTS IN SECONDARY EDUCATION

Cor Willem Buizert, Jeroen Spandaw, Martin Jacobs & Marc de Vries

Delft University of Technology, Netherlands

In this paper we describe empirical research into the question which possible themes for mathematical modeling interest Dutch high school students. We investigate possible differences between boys' and girls' interests. We also study differences between students in two different streams of the Dutch school system, called havo and vwo. Our study confirms in the mathematical domain the conclusion of international surveys about students' interests in the natural sciences that there are marked differences between boys and girls. However, our study did not find such differences between the havo and vwo streams, although Dutch literature suggested otherwise.

Keywords: Mathematical modeling, high school students, students' interests, empirical study

INTRODUCTION

Modeling is widely seen as an important part of mathematics education. To motivate high school students for mathematical modeling, the modeling context should be appealing to them. Indeed, interest plays a role in determining what people want to learn (Dohn, 2010). Interests that come from the individual itself last longer, whereas interests that are externally induced last for only a short period of time (Carmichael, Callingham, Hay, & Watson, 2010). However, interest is not just a mean. To quote Lavonen, Byman, Uitto, Juuti, and Meisalo (2008, p. 9): “Since Herbart (1841/1965a, 1841/1965b), modern pedagogy has emphasized the value of interest not only as a mean, but as an educational end in itself.” Referring to Hidi, Renninger and Krapp (2004), Lavonen et al (2008) write on p. 9: “...interest-based motivation to learn has positive effects both on the studying processes and on the quantity and quality of learning outcomes.”

This paper focuses on the question which topics for mathematical modeling high school students are interested in. Whether these topics satisfy other suitability criteria for modelling problems for these students is a different matter, which we did not investigate. However, if one wants to design modelling problems for high school students, then it is useful to know which themes do or do not interest these students. In this paper we restrict ourselves to this question.

The research was carried out as part of a Dutch project, called *Havo-Pro*, which aims to help teachers improve their *havo*-education. ‘*Havo*’ is a stream in Dutch secondary education. It is sandwiched between a large pre-vocational stream called ‘*vmbo*’,

which takes about 60 percent of primary school pupils, and a small pre-university stream called ‘*vwo*’, which takes about 20 percent of the pupils. It is meant for students with ‘intermediate cognitive abilities’. From now on we will simply use the Dutch acronyms ‘*havo*’ and ‘*vwo*’ to refer to these streams. For more information about the Dutch school system I refer to eacea.ec.europa.eu/education/eurydice.

The third and fourth grades of *havo* are perceived by many educational professionals (teachers, school leaders, policy makers) as problematic (Vermaas & Van der Linden, 2007). Many students in those classes, usually 15 or 16 years old, seem to lack interest, and to under-achieve (Vermaas and van der Linden, 2007), resulting in stagnation. Lack of motivation is identified as the main problem. With our research into *havo* students’ interests we hope to help alleviate this motivational problem.

Hamer (2010) addresses these issues for science and mathematics education. (In the Netherlands, it is customary to group the natural sciences and mathematics together under the heading ‘*bèta*’.) Whereas at *vwo*, more than 50% of the students choose the science, rather than the humanities track, at *havo* less than 30% of the students do so. *Havo* students tend to think that only especially talented students are qualified to choose the science track (Hamer, 2010). Furthermore, these students tend to underestimate their abilities when it comes to mathematics and science. This holds in particular for girls. Van Langen and Vierke (2008) report that only 39% of the boys and 19% of the girls choose the science stream, even though grades indicate that 65% of the boys and 54% of the girls are sufficiently talented. The lack of *havo* students entering technological tertiary education is thus not a consequence of absence of talented students. Schreiner & Sjøberg (2010) report that lack of interest in science among high school students is a widespread phenomenon in developed, wealthy countries, such as the Netherlands. This confirms the relevance of this phenomenon and shows the importance of investigating students’ interests.

Additional support to study students’ interests about possible modeling themes is given by Ryan & Deci (2000). According to this paper, the main factors contributing to intrinsic motivation are authenticity, competence and relatedness. Modeling tasks usually involve team work, which can contribute to relatedness. Modeling themes that align with students’ (daily life) interests can contribute to authenticity and competence as perceived by the students.

As the title of her report indicates, Hamer (2010) lists 10 points of attention for mathematics and science teachers which may help to improve *havo* students’ motivation, such as ‘working in groups’, ‘activating students’, ‘connecting theory and practice’, and ‘accessibility’. From a constructivist point of view this is hardly surprising. Hamer (2010) claims that these issues are especially important for the *havo* stream. Mathematical modeling problems seem to have the potential to naturally incorporate these recommendations. Other points of attention were concerned with procedural clarity, guidance, and positive feedback. These points are important in the actual design and execution of modeling problems. However, given the motivational problems of *havo* students described above, to design mathematical modeling

problems, one first has to address the crucial question which possible topics for mathematical modeling *havo* students are interested in.

Since almost all schools with a *havo* stream also have a *vwo* stream, we investigated both groups at the same time. There is a second reason for considering both *havo* and *vwo* students. As teacher trainers at Delft University of Technology (except for the first author), we wish to develop a module which we can use to train our pre-service teachers how to design modeling problems for high school students. These pre-service teachers will usually teach at both *havo* and *vwo*. Therefore we are interested in *vwo* students' interests, too. Furthermore, it is interesting to investigate which (if any) differences exist between *havo* students' and *vwo* students' preferences. Since Schreiner & Sjøberg (2010) found remarkable differences between boys' and girls' interests, we will also study these differences.

So we arrive at the following research questions for this paper:

1. Which themes for mathematical modeling are interesting to students in second, third and fourth year (students aged 13 – 16) of *havo* and *vwo* ?
2. What are the differences in interests between *havo* and *vwo* students?
3. What are the differences in interests between boys and girls?

THEORETICAL BACKGROUND

Researchers have recently performed an international study into high school students' interests in the natural sciences and technology. This research project is called ROSE, an acronym for 'Relevance of Science Education' (Schreiner & Sjøberg, 2010). To investigate students' interests, the international research team used a questionnaire. Schreiner and Sjøberg (2010) report that there are remarkable differences between countries, but even more striking differences between boys' and girls' interests. Lavonen, Byman, Uitto, Juuti, and Meisalo (2008) used the questionnaire to investigate interests of Finnish high school students. They also found remarkable differences between boys' and girls' interests.

Other well known large-scale studies such as TIMSS and PISA do not measure the affective dimensions of science education. Indeed, as Schreiner & Sjøberg (2010) write on p. 4: "It is a worrying observation that in many countries where the students are on top of the international TIMSS and PISA score tables, they tend to score very low on interest for science and attitudes to science. These negative attitudes may be long-lasting and in effect rather harmful to how people later in life relate to S&T [science and technology] as citizens."

Constructivism also teaches that educators should not ignore the affective dimensions. Furthermore, one should connect to pre-existing knowledge, and align with real world problems students are familiar with and that appeal to them. Hamer (2010) suggests that this is of key importance especially for *havo*.

Since research into interest is usually done using questionnaires, we decided to use a questionnaire, too. For mathematics education, however, we did not find a suitable questionnaire in the literature, so we had to develop one for ourselves.

METHOD

The validated ROSE questionnaire served as a starting point in the development of our own questionnaire. To generate potential themes of interest related to mathematics education, we looked at the Dutch mathematics curriculum, topics used in national modeling contests *Wiskunde A-lympiade* (Alympiade, 2011), and mathematical games. We also used the results of surveys into trends concerning young people (see Youngmindz, 2011). We used these different sources to minimize the risk of overlooking potential themes of interest. These trends were grouped into gaming, music, technology (gadgets, computers), environmental engagement, money, health, and sports. All our items were related to one of these groups, and we tried to give the different groups equal importance in our questionnaire. Finally, we tried to cover different branches of mathematics, deterministic and probabilistic, discrete and continuous, using computers or not. Exemplary questions can be found in table 3.

The questionnaire consisted of 70 questions, 51 of which dealt with the theme of this paper: students' interests. The first 50 items were of the ROSE type, i.e. questions of the form "Would you like to learn about...?" using a four point Likert scale with extremes marked "no" and "very much". The remaining item was an open question, asking for an interesting topic that was missing in the preceding questions. This question did not reveal new topics, except 'fashion' and unserious answers.

DATA COLLECTION AND ANALYSIS

The questionnaire was answered by 287 students, aged 12 to 18 ($M = 14.46$, $SD = 1.16$) from 7 Dutch secondary schools. Since we will be interested in differences between boys and girls, havo and vwo students, we list their numbers in table 1.

	girls	boys	total
havo	53	80	133
vwo	76	78	154
total	129	158	287

Table 1: questionnaire sample

Due to missing values, the data analysis below may use fewer students.

To verify the structure of the questionnaire, we first ran a principal component analysis (PCA) on the 50 items. The overall Kaiser-Meyer-Olkin measure (KMO) was 0.90 ('superb' according to Field, 2009), and all KMO values for individual items were $>.79$, so the sample size was adequate for factor analysis (Field, 2009). Bartlett's test of sphericity $\chi^2(1225) = 6376$, $p < .001$, showed that correlations

between items were sufficiently large for PCA (Field, 2009). Using a scree plot (see Figure 1), we decided to keep 5 components, which together explained 48,2% of the variance. We discarded the 13 items with absolute loadings $< .4$ (Field, 2009). All Cronbach α 's were $> .78$ and they were not improved by deleting more items, so statistical reliability of the 5 subscales was good.

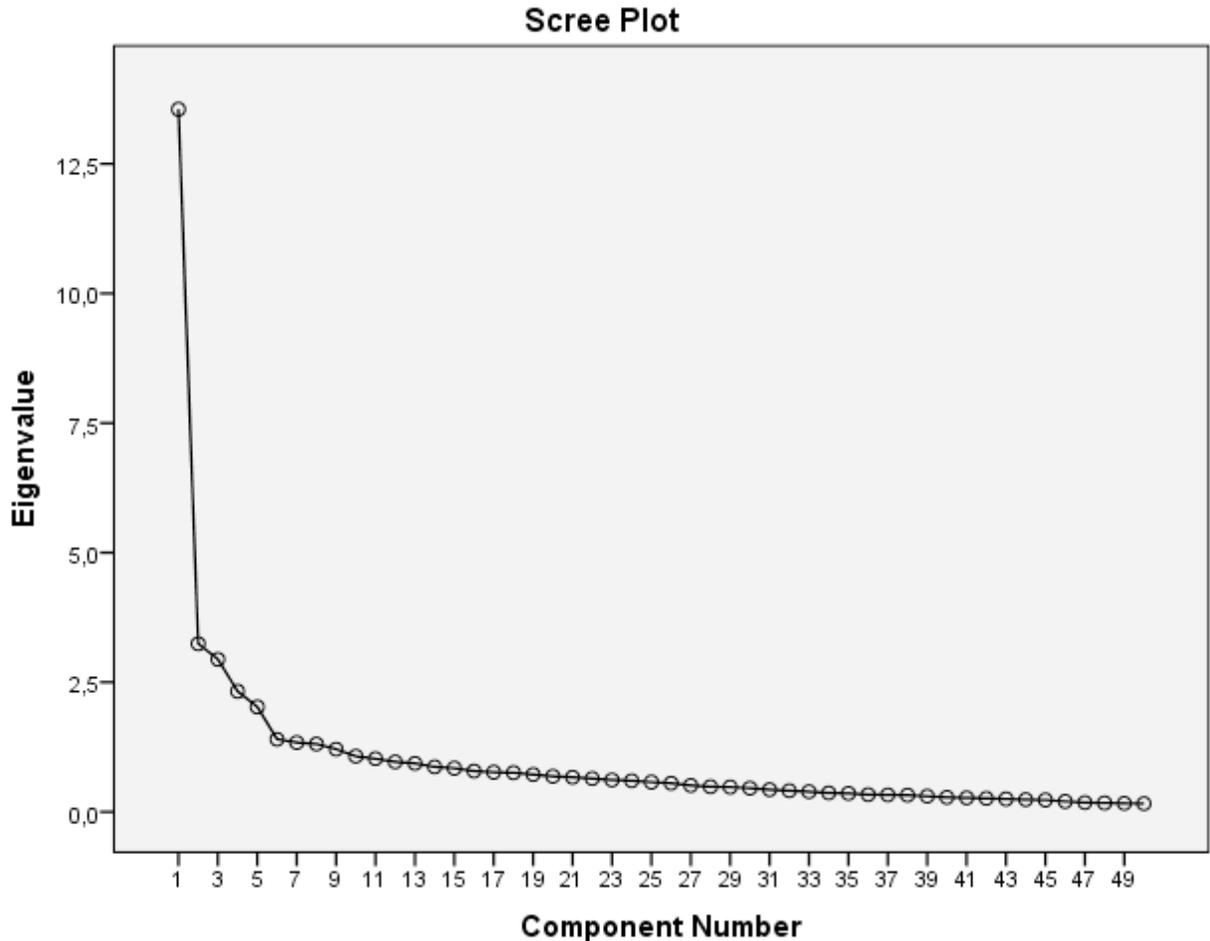

Figure 1: Scree plot of eigenvalues

Looking at the pattern matrix (oblique rotation), the five factors turned out to centre around the themes ‘environment and climate’, ‘sports’, ‘finance and politics’, ‘electronic devices and computer games’, and ‘finance and consumership’. Recall that to set up the questionnaire we used the seven categories ‘gaming’, ‘music’, ‘technology (gadgets, computers)’, ‘environmental engagement’, ‘money’, ‘health’, and ‘sports’. ‘Health’ and ‘music’ have disappeared, ‘gaming’ and ‘technology’ have merged into one factor, whereas ‘money’ has split into a ‘politics’ and a ‘consumership’ version.

The number of items in the pattern matrix for our five factors were 9, 5, 6, 9, and 8, respectively. Interpretation of the first factor was a little problematic, since 4 out of

the 9 items did not fit our description ‘environment and climate’. Similarly, the third factor ‘finance and politics’ contained 2 items dealing with voting systems. Finally, the fifth factor ‘finance and consumership’ contained 2 items about music, one about epidemics and one about lotteries. Fortunately, the dissident items in the third and fifth factor had small loadings, except for the epidemics item in factor 5.

We computed factor scores by averaging the remaining questions for each factor: 5 for factor 1, 5 for factor 2, 4 for factor 3, 9 for factor 4, and 4 for factor 5. In table 2 we give the mean factor scores. Mean scores which are higher than the average 2.5 of the Likert scale are set in boldface. We have performed *t*-tests to compare boys with girls, *havo* students with *vwo* students. For (2-sided) *p*-values < .10 we give the effect score $r = \sqrt{t^2 / (t^2 + df)}$. Effect scores near .1 are small, effect scores near .3 are medium (Field, 2009).

	Mean <i>N</i>	<i>M</i> (girl) <i>N</i>	<i>M</i> (boy) <i>N</i>	<i>p</i> <i>r</i>	<i>M</i> (<i>havo</i>) <i>N</i>	<i>M</i> (<i>vwo</i>) <i>N</i>	<i>p</i> <i>r</i>
F1	1.87 281	1.77 128	1.95 153	.02 .14	1.85 129	1.89 152	.62
F2	2.62 285	2.44 129	2.77 156	.002 .18	2.53 132	2.71 153	.11
F3	2.26 280	2.01 126	2.47 154	< .001 .29	2.30 130	2.23 150	.42
F4	2.69 284	2.49 128	2.85 156	< .001 .23	2.60 132	2.79 152	.08 .11
F5	2.60 283	2.72 127	2.50 156	.02 .14	2.54 132	2.65 151	.23

Table 2: Factors and means

Table 2 shows clearly that differences between boys and girls are quite substantial, whereas differences between *havo* and *vwo* students are negligible. Not a single difference has 2-sided *p*-value < .05. There is only one difference between *havo* and *vwo* with *p* < .10, namely ‘electronic devices and computer games’. The effect is small ($r = .11$), *havo* students being a little less interested than *vwo* students.

Differences between boys and girls were more pronounced. All factors have 2-sided *p*-values < .05, boys being more interested than girls, except for the fifth factor. However, since the sample was quite large, small differences can already be significant. Indeed, the first and fifth factor have small effect size ($r = .14$). The

largest difference with medium effect size ($r = .29$) was found in the factor score belonging to ‘finance and politics’. The remaining two factors ‘sports’ and ‘electronic devices and computer games’ are a little more popular among boys (effect sizes .18 and .23, respectively).

The most popular factor is ‘electronic devices and computer games’ with $M = 2.69$, especially among boys ($M = 2.85$) and *vwo* students ($M = 2.79$). Girls seem to favour the slightly mysterious factor 5, which we dubbed ‘finance and consumership’.

Now we have a rather clear picture on the level of our five factors, we return to the individual items. Which items had the highest mean scores, corresponding to highest level of interest? In table 3 we give the top ten items for boys and girls. We indicate which factor (if any) the items belong to. Since we know that differences between *havo* and *vwo* are small, we do not separate between these two groups.

CONCLUSIONS

We found that the themes which interested our students most were ‘electronic devices and computer games’, ‘finance and consumership’, and ‘sports’. Surprisingly, there were no significant (2-tailed $p < .05$) differences between students in the *havo* and students in the *vwo* stream. At first sight, this seems to be at odds with Hamer (2010), which deals with differences between these two streams. However, that paper deals with *pedagogical* differences between *havo* and *vwo*, not with subject matter. On the other hand, there were significant and sizeable differences between boys and girls. This confirms the findings of Schreiner and Sjøberg (2010), and Lavonen et al. (2008).

Teachers and other developers of teaching materials for secondary schools should be aware of these findings when selecting topics for mathematical modeling assignments. To attune to the needs of *havo* students, they should also take into account the list of ten points of attention by Hamer for *havo* education.

Although we did not investigate this in depth, we expect that the favourite themes mentioned above are suitable for modeling tasks. Indeed, many such modeling tasks have already been designed more or less successfully in the Netherlands and elsewhere. Furthermore, one can use our results to improve existing modeling tasks.

Table 3: Top 10 items for boys and girls.

For example, in order to improve students' motivation we modified a modelling task about traffic jams by adding a financial component about the costs involved.

Of course, the design of modeling problems involves much more than identifying topics of interest. For example, which activities are best suited to develop certain modeling competencies at a certain level? Interesting and important as these questions are, they were not part of the research described in this paper.

STUDENTS' MODELLING OF LINEAR FUNCTIONS: HOW GEOGEBRA STIMULATES A GEOMETRICAL APPROACH

Susana Carreira*, Nélia Amado*, & Fátima Canário**

* Univ. of Algarve & UIDEF, Univ. of Lisbon; ** Escola Secundária de Palmela

The use of technology has crucial influences on mathematical modelling. We present a study with a class of 8th graders solving tasks involving linear models, where students regularly used GeoGebra. Our aim is to examine students' approaches to application and modelling situations in the "technology world" of the modelling activity. The results show that students skipped much of the algebra work, and rather chose a geometrical approach, harnessing the affordances of the tool.

INTRODUCTION

The impact of digital tools in mathematics teaching and learning is, to a great extent, concerned with the changes that the use of technology operates in the forms of understanding and approaching mathematical ideas and processes. In many ways technology challenges the traditional hierarchy and disconnection of mathematical topics and it also reshapes the nature and purpose of mathematical representations in doing mathematics. This has clear implications on a learning context that involves exploring and applying mathematical models given "the way technologies can provide multiple connections in mathematics, supporting a student's holistic development of mathematical understanding" (Pead, Ralph & Muller, 2007, p. 318).

Developing and exploring mathematical models with technological tools reveal new sides that go far beyond the idea of gaining more computational or graphical power in dealing with mathematical models. In fact, as some researchers have been suggesting, the well-known modelling cycle needs to be re-conceptualised to integrate a third world – the technology world (Greefrath, 2011; Greefrath, Siller & Weitendorf, 2011; Siller & Greefrath, 2010). Not only the modelling cycle can be augmented to include a third world where the computer model and the computer results are fundamental parts but, most importantly, the impact of digital tools occurs at all stages of the modelling cycle. The formulation of the mathematical model and the computer model are fused together and the same goes for the application of the mathematical model and the implementation of the computer model.

As Greefrath (2011) points out, one of the consequences of using digital tools is the "algebraicising" of numerical data. In fact, different available software and computer packages can provide algebraic representations of real data inputs, offer a graphical representation of the generated algebra, and additionally allow establishing connections between them dynamically.

In the case of real problem situations involving linear change, the mathematical models involved are typically associated with the concept of linear functions, including its algebraic formulation, together with its tabular and graphical representation. However, when using GeoGebra students may easily get an algebraic

expression of a linear function just by plotting two points of the graph and choosing the tool to create a line through two points; the equation of the line appears as an independent object. Therefore the process of creating and applying a mathematical model may change significantly. The act of building a model is fused together with the computer outputs resulting from entering a table of numerical data and then translating it into other mathematical representations (a graph or an equation).

Given such significant consequences of computer use in students' access to different interconnected representations of linear variation, it is important to investigate how students' approaches to linear models are influenced by the affordances of GeoGebra.

This study focuses on a class of 8th graders developing mathematical and computer models with GeoGebra, and aims to investigate how students' ways of formulating and applying linear models are shaped by the technological tool.

THEORETICAL FRAMEWORK

The emphasis given to particular goals behind mathematical modelling in education has enabled researchers to distinguish among different perspectives (Kaiser & Sriraman, 2006). Accordingly, both a conceptual modelling and a contextual modelling perspective are important roots to situate the theoretical stance of this study. Realistic situations (some of them requiring experimental data collecting) are seen as providing the opportunity to elicit students' broad understanding of linear functions, like constant rate of change and parameters involved in linear graphs. Following that initial basis, contextual problems are seen as opportunities for conceptual development, connecting different aspects of linear models, like relating tables to graphs and to equations in finding answers to particular problem-based questions.

Different theoretical standpoints have been suggesting possible ways of looking at the effects of introducing digital tools in students' understanding of mathematical models. One way of addressing the interplay between modelling and technology focuses primarily on the medium that the modeller is using and stands on the idea of co-action, which acknowledges an interactive influence between the user and the technological tool (Moreno-Armella, Hegedus & Kaput, 2008).

(...) we introduce the idea of co-action to mean, in the first place, that a user can guide and/or simultaneously be guided by a dynamic software environment (Moreno-Armella, Hegedus & Kaput, 2008, p. 102).

The student and the medium re-act to each other and the iteration of this process is what we call co-action between the student and the medium (Moreno-Armella & Hegedus, 2009, p. 510).

From that point of view, the use of technological multi-representational tools frames students' representational choice (Nistal, Van Dooren, Clarebout, Elen, & Verschaffel, 2009) and this is reflected on their modeling approaches when solving modelling tasks.

Studies on the strategies developed by students in problem solving tasks have shown that they tend to avoid the algebraic treatment of the problem and prefer non-algebraic routes as those based on arithmetic reasoning, on trial and error, working backwards, etc., all summing up to a certain compulsion to calculate rather than to do algebra work (Stacey & MacGregor, 2000).

A similar movement of deferring algebraic approaches is reported by Yerushalmy (2000), where students made intensive use of technology in a function approach to school algebra, through modelling tasks. Based on linear break-even situated tasks proposed to pairs of students in three interviews, separated in time, the study shows how students' strategic approaches to the problems evolved: from graphical representations to predominantly numerical methods, to relations between quantities, to graphs of functions and finally to the algebraic expressions.

The learning starts with graphical representations of variations, used later on to analyze patterns of numbers by watching the behaviour of the increments, moves on to analysis and construction of relations between quantities that are defined globally, to accurate graphs, and then to explicit expressions (Yerushalmi, 2000, p. 142).

As already stated the technology world brings in more opportunities for students to decide which representational modes they find the most efficient to formulate and apply mathematical models to real situations. Therefore students' approaches to mathematical modelling are likely to evolve within such versatile contexts and to match different levels of mathematization (from the real world to mathematics or within the mathematical world). In such evolving processes of representational decisions co-action between the student and the tool becomes an important concept in that the tool offers an answer (e.g. the algebraic expression) as a result of an alternative representational act from the user (e.g. plotting a graph).

Our study looks at the ways in which students approach linear models in a multi-representational environment, based on an intentionally designed set of tasks, and especially considering how translations are produced from one representation to another as a result of a co-action process.

RESEARCH METHOD

The teaching experiment supporting this study was developed in a class of 8th graders aged 12-14, the majority being 13 years-old, from a public school located in the metropolitan area of Lisbon. The class is characterised by an overall good level of mathematics achievement. The teaching experiment was designed in line with new Portuguese curricular orientations, according to which understanding in algebra topics is to be supported by modelling real situations. A sequence of 7 tasks was developed over a period of one month and took seven lessons with different durations: 3 lessons of 90 minutes and 4 lessons of 45 minutes. All lessons took place in a computer lab where students were organised in pairs, each pair having one computer to work on. In each task students were to formulate and apply a mathematical model within a problem situation by selecting information, interpreting

the situation, getting ways of representing it mathematically and applying it to find answers to specific questions about the real context. Some of the tasks required that students engaged in real data collection, either from an experiment performed in the class or outside. All the tasks were conceived to activate the use of mathematics, namely the concepts of linear variation and linear function, in connection to contextualised questions. The tasks evolved from problem situations aimed at eliciting linear models' general properties to more focused problems where the context was explored to stimulate the use and application of linear models for obtaining particular solutions.

Students had acquired an early level of knowledge about GeoGebra previous to the teaching experiment; in general, they were familiar with the Graphics View, the Algebra View and the Spreadsheet View of the software but they were not fully aware of the fact that once they created geometric constructions on the Graphics View the equations were displayed in the Algebra View, as a result of the interactive nature of graphics and algebra in GeoGebra. So the teacher decided to allow students to discover for themselves any additional details of the program while performing the tasks. Students were not bound to use the computer but rather they were free to choose how to solve each task. Accordingly, in the same task, some students could work with GeoGebra, others with paper and pencil, and even others could use both.

For this study, different types of data were collected: the work produced by the students (written records, files created in GeoGebra with access to the construction protocol), the daily log of class observation, and information recorded on audio and video of two pairs of students.

A qualitative methodology and a case study design with strong descriptive and interpretative dimensions were adopted. From each of the pairs that were videotaped one student was elected to become the core of a case. Nevertheless, the other member of the pair and whole class discussions were sometimes integrated in the case.

In the following we present a segment of the case of Pedro, one of the students who belonged to a videotaped group, which in a way reveals exemplar instances of the kind of modelling approaches that took place in the class when GeoGebra was used as a multi-representational tool.

DATA DESCRIPTION AND ANALYSIS

A selection of four tasks is presented for the case of Pedro and his partner, Diogo. The selected tasks (1, 4, 6, and 7 of the sequence) are intended to illustrate the development of students' approaches to modelling over time.

Task A: Water filling

In the class students performed a simple experiment of filling beakers with water from a tap and recording the volume of water after successive equal time intervals. The water flow was changed and the experiment repeated two or three times.

1. In filling the beakers with water what are the variables involved and what is the relationship between them?
2. Find an equation to describe each experiment. Describe how the water flow affects the equation.
3. What is the volume of water after 15 seconds, in each case?
4. How long does it take to fill up a volume of 5 liters, in each case?

Pedro and Diogo entered the collected data organised by columns in the Spreadsheet View and plotted the several points (ordered pairs of time and volume) in the graphical area. Then they created several straight lines in the Graphical View until they found the one that they considered the best fit. The students then realised that the equation of each line was automatically shown in the Algebraic View of GeoGebra.

Pedro: Look, it also makes the equation!

To answer the question of finding the volume after 15 seconds, Pedro and his partner decided to enter the equation $x=15$ in the input bar and obtained the correspondent vertical line (equations are immediately displayed in the Algebra View and graphed in the Graphics View).

Teacher: What are you doing then?

Pedro: We are making the intersection between this and the other lines.

Teacher: Oh, very well thought out.

Pedro: And we have discovered the points of intersection (in the Algebraic View).

Their next action was to inspect the intersection points appearing in each of the linear graphs and relating the displayed y -coordinates of those intersection points to the volumes of water after 15 seconds, in each case. Following the same reasoning, the two students entered the equation $y=5000$ (volume in ml) and determined the intersection points between the horizontal line and the linear graphs. By reading the x -coordinates of the intersection points, Pedro answered: Experiment 1 – 435 sec; Experiment 2 – 141 sec; Experiment 3 – 115 sec. Thus they obtained the answer for the time (the x -coordinate) needed to fill the beaker with 5 litres, for each water flow.

Task B: The stack of shopping baskets

On a trip to the supermarket in their extra-school time, students conducted some data collection, measuring a stack of shopping baskets with a variable number of baskets. They measured the height a stack of one basket, two baskets, and so forth. As the number of baskets increased, students recorded the height of the stack on a table.

1. Create a graph that fits the data collected in your table.
2. Find a model to represent the height of a stack of shopping baskets depending on the number of baskets in the stack.
3. What is the height of a stack of 50 baskets? Explain.

In the class, using the information recorded in their tables, they started to create a graph in GeoGebra, showing no difficulties in performing this action. Pedro and his partner began by using the Spreadsheet View and entered the data organised in columns, then marked the points in the Graphics View and obtained a straight line. Instantly, in the Algebra View, they got the expression $y=8x+30$ (figure 1). At this stage they understood that the rate of growth was related to the height of the outer edge of a basket overlaying the previous one in the stack.

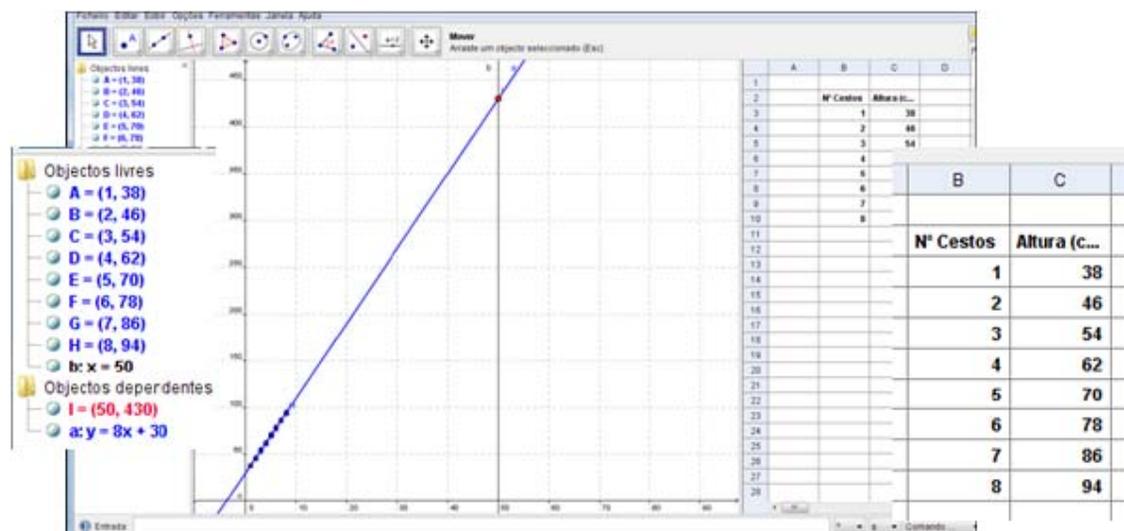

Figure 1: Computer model of the height of the stack (screenshot of students' file)

The question of finding the height of a stack of 50 baskets showed different approaches in the class. Two approaches were used among the several pairs of students. Some took the algebraic expression obtained in GeoGebra and used paper and pencil, assigning the value 50 to x to compute the y . Other pairs chose to work in GeoGebra, entered the equation of the vertical line and by intersecting lines obtained a point and its coordinates. This was the case of Pedro's group who arrived at point $I(50,430)$, as shown in figure 1.

Pedro's explanation on the processes used was given in the following way:

Pedro: But we also found another way to solve the equation.

Teacher: How is that?

Pedro: Well, x was number of baskets, and as the number of baskets had to be 50, we made 8 times 50 plus 30. And we got 430.

Teacher: And besides, how did you do it the other way?

Pedro: It was like this: we draw the line $x=50$ and intersected it with the line already there and it gave the point where y was 430.

Task C: The cost of having your own car

The problem statement provided some data on the monthly cost of owning a car depending on the distance travelled. Students started by using the Spreadsheet View to enter the given data.

The cost of owning a car depends on the number of kilometres travelled per month. Based on the information published by "Time Magazine", the cost changes linearly with distance, and it is 336 € per month for a distance of 300 km and 510 € per month for a distance of 1500 km.

1. Find an equation that expresses cost versus distance.
2. Make an estimate of the monthly cost to a travelled distance of: 1000 km; 2000 km.
3. Find the maximum distance not to exceed a monthly cost of 600 euros. Explain.
4. Find the y-intercept in the graph of cost versus distance. How do you interpret it?

Then they plotted the two points from the table and draw the line through them in the Graphics View. Again GeoGebra allowed students to have the graph of the function and its algebraic expression simultaneously displayed (figure 2).

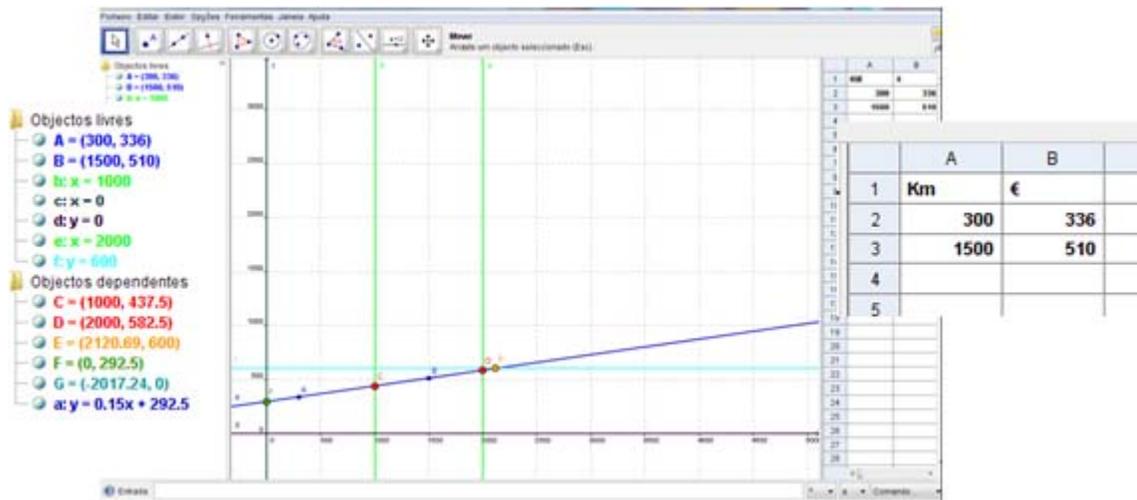

Figure 2: Model of the cost depending on the distance (screenshot of students' file)

To obtain an estimate of the monthly cost in the case of a travelled distance of 1000 km per month, students graphed the vertical line by entering the equation $x=1000$ and then determined the intersection point of the two straight lines. To calculate the cost for a distance of 2000 km, the procedure was similar to the previous one, leading to the coordinates of another point.

Students were also asked to determine the maximum distance not to exceed the monthly cost of 600 €. Soon they decided to plot the horizontal line of equation $y=600$ and, by looking for the intersection of the two lines, as happened in the previous cases, they answered to this question (figure 2).

Finally they interpreted the meaning of the y-intercept of the graph in the context of the problem. They conclude that, even if the car was parked (0 km travelled), the owner had to pay expenses (292.5 €). The students were quite surprised at this result and gave it a contextual meaning as shown in the dialogue:

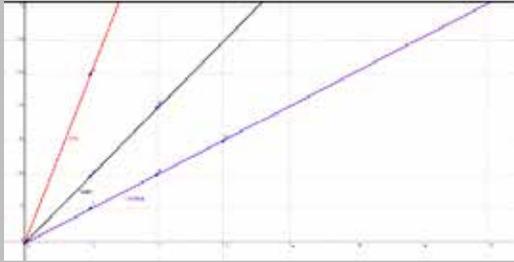

Diogo: It's the taxes, it's for the government!

Pedro: The meaning of this value? It means that I may not drive at all but I still have to pay at least 292.5 euros.

Task D: Speed in typing on a computer

The problem statement on the speed of typing a text on a computer included a graph with three linear functions plotted. To answer the questions, students would have to examine the graphs. They could just use paper and pencil or they could also use GeoGebra to solve the task.

Ana, Beatriz and Carolina are learning to type a text on the computer. Their teacher tested their speeds and measured the time (in minutes) and the number of words written, obtaining the given graphs.

1. What is the fastest student?
2. How many words can each one write per minute?
3. How long does it take each of them to write a text with 520 words?

Pedro chose to plot the given graphs in GeoGebra, thus transposing the situation to the computer where he continued to develop his work. Then he explained:

Pedro: So far I plotted the lines shown in the problem in GeoGebra and then it gave me the equations of the lines. Now I will graph the line $y=520$ and intersect it with the previous lines to know how many words can they... (pause) how many minutes each of them takes to type 520 words.

This way, the student obtained the intersection points and gave the following answer:

Pedro: Ana takes 20.8 minutes, Beatriz takes 52 minutes and Carolina takes 104 minutes.

The teacher questioned the student on the use of GeoGebra in getting the equations for each case and checked if Pedro would be able to do it without the software. Pedro was one of the fastest students in using the software to obtain graphs from tabular data and reading out the algebraic outputs; he was also very alert to the possibility of entering an equation and getting the correspondent graph. So, he moved forth and back from one representation to the other and it was important to see if he was just relying on the tool or if the tool was offering him the chance to see the formal mathematical model embedded in multiple interconnected representations.

Teacher: Now tell me one thing, you chose to use GeoGebra but could you have done it without GeoGebra?

Pedro: If I had not done it with GeoGebra... (pause) then I would have to find the expression.

Teacher: How? For example, in the case of Ana, which is the expression?

Pedro: Well it is a straight line passing through the origin, so the model is $y=kx$.
And as 1 corresponds to 25, we get $y=25x$.

CONCLUSIONS

Along the sequence of tasks, the formulation of mathematical models developed, in most cases, with the use of the computational tool. Mostly, the modelling process started with some numerical information and students used the Spreadsheet View to convert this tabular information into a graphical representation. The results show that students used the graphical representation of the mathematical models as the main source for developing their analysis of the models, which allowed them, among other things to *avoid* the traditional way of solving equations. The action of the students (plotting a graph) was followed by a prompt from the tool (the equation). This in turn generated new actions from the students: entering formulas to get vertical or horizontal lines. The tool then provided points of intersections and their coordinates; the students looked at the values that were displayed to find solutions for the equations and thus applying the model to find their answers. The way in which the computer was used illustrates an iterative process of co-action between the students and the tool. Moreover there is also action and reaction between the computer model, the mathematics world and the real context in providing meaning for the variables and for the algebraic expressions.

The case of Pedro indicates that, in many situations, the students were able to get the solutions algebraically. Therefore it seems that working with algebraic expressions and solving linear equations was not a strong obstacle to most of the students. The option for the geometrical manipulation of linear models is echoing previous research that highlights students' preference for non-algebraic approaches (Stacey & MacGregor, 2000). In our study, this kind of preference can also be explained on grounds that go beyond potential difficulties in algebraic manipulation. The affordances of the computational tool were assimilated by the students and reflected on their use of geometrical objects (lines, intersections, points, coordinates) to come across alternative approaches for exploring the model.

The geometrical representation became their object of reference in the modelling process and moreover it became a means to obtain the algebraic equation in the Algebra View. This seems to be a good example of the "algebracising" mode of the software used (Greefrath, 2011). In fact, at the beginning students were not actually aware of this utility provided by the software but quickly started to appropriate it in their exploration of the models. Similarly they realised that by entering an equation in the input bar ($x=k$, or $y=k$), the geometrical object immediately came up in the Graphics View. Consequently, this automatic translation from geometry to algebra and vice-versa had an influence on students' modelling approaches, namely in their representational choice. Regarding the application of models, the strategies used were essentially geometrical, taking advantage of the possibility of plotting new lines and

relating the objects in the Algebra and Graphics Views. This is the main reason why many of the equations involved in the problems were solved from a geometrical point of view, by intersecting lines and obtaining the coordinates of the intersections.

The data reveal how students were guided by and simultaneously guided the computational tool to explore and understand linear models, showing the co-action between the student and the medium (Moreno-Armella & Hegedus, 2009) in the “technology world” of the modeling activity (Siller & Greefrath, 2010).

TEACHING PRACTICES AND MODELLING CHANGING PHENOMENA

Helen M. Doerr, Jonas B. Ärleback & AnnMarie O’Neil

Syracuse University, Linköping University, Syracuse University

While much research has demonstrated the positive impact of mathematical modelling on student learning, considerably less research has focused on the teaching practices that are needed to support modelling approaches to student learning. In this study, we examined the characteristics of teaching in a classroom setting where the students engaged in a sequence of model development tasks designed to support their abilities to create and interpret models of changing physical phenomena. The results illustrate the demands that modelling tasks place on teachers, ways of responding to those demands, and suggest needed pedagogical shifts in teaching practices.

Over the past three decades, much research has focused on the potential of mathematical modelling to impact student learning throughout K-16 mathematics. But despite the evidence from research on the positive impact on student learning, progress has been slow in the widespread adoption of mathematical modelling as a classroom practice (Blum & Borromeo Ferri, 2009; Maass, 2011). While many factors influence changes in schooling, one crucial factor in any kind of change in classroom practices is the teacher (Godwin & Sutherland, 2004; Ruthven, Deaney & Hennessy, 2009). But the teaching practices associated with mathematical modelling have received somewhat limited attention from researchers (c.f., Blum & Borromeo Ferri, 2009; Doerr, 2006; Lingefjard & Meier, 2010; Maass, 2011; Wake, 2011; and others). As we have argued elsewhere (Doerr, 2007; Doerr & Lesh, 2011), the knowledge needed for teaching mathematics through modelling and applications appears to differ in some significant ways from traditional approaches to teaching mathematics. In this paper, we examine the nature of teaching practices that support student learning through mathematical modelling, and thereby contribute to an understanding of the knowledge needed for teaching mathematics through modelling. To that end, we investigated the characteristics of teaching in a pre-college classroom setting where the students engaged in a sequence of model development tasks to support their abilities to create and interpret models of changing physical phenomena.

THEORETICAL BACKGROUND

Over the last twenty years, researchers have documented the difficulties that students encounter in learning to create and interpret models of changing phenomena (Carlson et al., 2002; Michelsen, 2006; Thompson, 1994). To address these difficulties, we designed a model development sequence (Doerr & English, 2003; Lesh et al., 2003) to support the development of students’ abilities to model changing physical phenomena. This modelling approach to

student learning is what Kaiser and Sriraman (2006) identify as a “contextual modelling” perspective, emphasizing tasks that motivate students to develop the mathematics needed to make sense of meaningful situations. Many researchers have used model eliciting activities (MEAs) developed by Lesh and colleagues (Lesh et al., 2000; Lesh & Zawojewski, 2007) to investigate the development of students’ conceptual systems (or models) in a wide range of settings and contexts. In this study, however, we moved beyond a single model eliciting activity to design a model development sequence whose goal was to produce a conceptual system (or model) that can be used to make sense of a collection of structurally similar physical world contexts.

A model development sequence begins with a model eliciting activity, in this case, designed to confront the student with the need for the construct of average rate of change. This construct is central to students’ abilities to create and interpret models of changing phenomena. The MEA is followed by one or more model exploration activities and model application activities (c.f., Doerr & English, 2003; Lesh et al., 2003). Model exploration activities focus on the underlying structure of the elicited model and on the strengths of various representations and ways of using representations productively. Model application activities engage students in applying their model to new situations, which can result in further adaptations to their model, extending or deepening understandings of representations, and refining language for interpreting and describing the context. In this study, the model development sequence was intended to support the development of the students’ generalized understanding of average rate of change and their abilities to create and interpret models of changing phenomena. Throughout model development sequences, students are engaged in multiple cycles of descriptions, interpretations, conjectures and explanations that are iteratively refined while interacting with other students and participating in teacher-led class discussions.

The diversity and complexity of the multiple cycles of the development of the students’ models places substantial knowledge demands on the teacher, as teaching “becomes more open and less predictable” (Blum & Borromeo Ferri, 2009, p. 47). As Maass (2011) found in her study, responding to the openness of modelling tasks was especially challenging for teachers with a “static” disposition with its strong focus on final examinations and on teacher-centered pedagogies. The openness of modelling tasks, which is in part a consequence of the diversity of student thinking, leaves the teacher with the need to develop strategies to support the students in making progress with the task, but without directly showing the students how to resolve their difficulties (Lingefjord & Meier, 2010). However, as Lingefjord and Meier note, “it is obviously not enough to ask the teacher to avoid giving a solution to their problem” (p. 106). What the teacher needs is a range of strategies to draw on and, just as importantly, a set of rationales that will enable her to interpret the events of the classroom, select tasks to further the development of students’ models, and

engage students in the self-evaluation of their models (Doerr, 2007). Such a range of strategies and rationales would provide the basis for responding to students without doing the task for them, or as Blum and Borromeo Ferri (2009) characterize it, for maintaining the balance between providing sufficient guidance for the students while preserving student independence. Characterizing such strategies and elaborating their underlying rationales by the teacher is the focus of this study. To that end, our study was guided by the following question: what are the characteristics of the teaching practices that support students' abilities to create and interpret models of changing physical phenomena when engaged in a model application activity?

METHODOLOGY

This study used design-based research as an approach to studying teaching and learning in the classroom with the intent of contributing to theories of teaching while producing outcomes that are useful in naturalistic settings (Cobb et al., 2003). This design experiment began with the collaborative framing by the researchers and the teacher (third author) of a model development sequence that was intended to support students in developing their concept of average rate of change and in creating and interpreting models of changing physical phenomena. We first describe the model application activity that occurred near the end of the model development sequence, elaborating the intended learning goals for the students. We then describe the context in which the teaching occurred and the iterative cycles of analysis that occurred to understand the teacher's actions in the classroom and her interpretations of those actions.

In the model application activity examined in this paper, students were asked (1) to create a model of the intensity of light with respect to the distance from the light source, (2) to analyze the average rates of change of the intensity at varying distances from the light source and (3) to describe the change in the average rates of change as the distance from the light source increased. The students were given flashlights, meter sticks and light sensors to use with their graphing calculators to measure and collect data of how the light intensity varied with the distance from the light source. Light intensity changes with the distance from the light source at a non-constant rate and can be modelled by an inverse square function. In earlier model exploration tasks, the students had explored the patterns of change in linear and exponential functions. However, the patterns of change for an inverse square function are not approximated by either of these patterns, and hence students needed to draw on other known functions for this context and provide a rationale for choosing a function. Since all of the students had taken a prior course in physics, it is nearly certain that they had studied the inverse square law that applies in this situation. However, we did not assume that the students had investigated or understood or would recall that the reason for the inverse square law in this context is related to the geometry of the sphere. Thus, having students make sense of the relationship to the surface area of the

sphere and ways of representing that relationship was part of this model application activity. In addition, students needed to apply their model of average rate of change in a context where the independent variable was not time, but was distance. Finally, students had to interpret negative average rates of change in terms of the light intensity and distance. Overall, this model application task required the students to apply and extend their concept of average rate of change to a new context of changing physical phenomena.

CONTEXT AND PARTICIPANTS

The sequence of model development tasks formed the basis for a six-week course for students who were preparing to enter their university studies. The teacher had four years of experience teaching secondary and college students; this was her third year teaching the summer course. There were 35 students in two sections of the course, all of whom had volunteered to participate in the study. Eleven of the students were female and 24 were male. All students had completed one year of physics and four years of study of high school mathematics; 21 students had studied calculus in high school and 14 had not studied any calculus. Pairs of students completed the model application activity over the course of three lessons. Throughout their work on the task, the teacher led several whole-class discussions that involved students in discussing their emerging models of light intensity and representations of how that intensity changes. The teacher also engaged in conversations with pairs of students as they created their model of light intensity and considered how the intensity changes with respect to distance.

DATA SOURCES AND ANALYSIS

The data sources included videotapes of all class sessions, written field notes and memos, class materials such as worksheets and a record of board work, the teacher's lesson plans and annotations made by the teacher during the lesson. Following each lesson, there was an audio taped debriefing session with the teacher, which captured the teacher's reflections on the lesson and any changes to the plans for subsequent lessons. The model application activity took place over three lessons; each lesson lasted one hour and 50 minutes. Our analytic approach was a collaborative examination of the teacher's actions in and interpretations of classroom events. The analysis of the data took place in two phases. Consistent with the iterative approach of design-based research, the first phase of analysis took place during the six weeks of teaching. In this phase, the research team met with the teacher and regularly engaged in discussion about the model development sequence, the progress of the class as a whole, and our observations about students' thinking about average rate of change and their use of mathematical representations for expressing their ideas. Analytic memos were written by members of the research team to document their emerging

understandings of the teaching practices and observations about student learning.

In the second phase of the analysis, members of the research team viewed the videotapes and wrote a detailed script of each lesson, identifying the nature of the teacher's activity and the teaching dilemmas that occurred in each lesson. Following the principles of grounded theory (Strauss & Corbin, 1998), codes were developed to categorize the teaching practices. As we analyzed the practices, we sought confirming and disconfirming evidence in the teacher's lesson plans and annotations during the lesson, and with the teacher's perspective on the lesson from the de-briefing interviews. We present two of the results of our analysis of the teaching practices that supported the students as they created their models: (1) revealing and revising student ideas; and (2) developing and refining representations. We also discuss the difficulties encountered by the teacher in balancing the tension between guiding students and maintaining their independence.

RESULTS

Revealing and revising student ideas

Throughout the model application activity, the teacher engaged the students in revealing and revising their ideas about how the light intensity changed as the distance from the light source increased. This episode occurred at the beginning of the activity. The teacher asked the students about their intuitive ideas on the changes in light intensity, based on their everyday experiences with light. She posed the following question: "Imagine the tail lights of a car moving at a constant speed away from you. Is the light intensity (1) fading at a constant rate, (2) fading slowly at first and then quickly, (3) fading quickly at first and then slowly, and (4) unsure." The students responded to this question using a student response system (also known as voting systems or "clickers"), with the results shown in Table 1. The teacher routinely used the option of "unsure" to discourage students from guessing and to encourage students who see difficulties or ambiguities in a question to continue thinking, without being forced to choose a particular response.

<i>Responses</i>	<i>Number and Percent Response</i>
Fading at a constant rate	8 57%
Fading slowly then quickly	4 29%
Fading quickly then slowly	1 7%
Unsure	1 7%

Table 1: Student responses to the rate at which light intensity changes

The teacher engaged the students in a discussion about their reasoning and found that students had several different perspectives on this context. One

student argued: “no matter how big the light is, you can see it at different distances”; this argument suggests that the light intensity does not change with respect to distance. Several students offered an argument in support of fading at a constant rate by reasoning that “the speed of the car is constant.” Others focused on the constant speed of light and reasoned that even though the constant speed of light is different from the constant speed of the car “it’s like running in a train” where one can simply add the speeds. However, some students were sceptical about the relationship of the constancy of the speed of the car and of the speed of light to the intensity of the light. One student posed the question: “the car moves constantly, but how do you see the light?” and another asked: “we’re talking about intensity. How does that relate to the speed of light?” This discussion was entirely an argument among the students, and revealed their reasoning about how the intensity of light changes at different distances from the light source.

At this juncture, the teacher stepped in, leaving their arguments unresolved, and gave them a task that would enable them to evaluate and potentially revise their ideas. The teacher signalled this as she said: “We are going to sort this out.” She gave them data collection equipment that they could use to measure light intensity at different distances from a point source of light. The teacher deliberately did not discuss their ideas further because, as she later commented, she did “not want to give it all away.” Rather, she intended for the students to engage in collecting and analyzing data that would enable them to answer this question for themselves. By collecting and graphing data, the students evaluated the alternatives and came to the resolution that the intensity of light decreased at a non-constant rate as the distance from the light source increased.

Developing and refining representations

In keeping with the methodology of design-based research, this model application activity was developed through several iterations. In previous versions, we found that students encountered difficulties in developing meaningful representations of the change in light intensity with respect to distance from the light source. Hence, as we began this modelling task with the students, we explicitly focused on students’ images of light intensity. In the lesson following the data collection, the teacher posed a question, analogous to that in the previous episode, but intended to further develop students’ representations of light intensity. The students were asked to interpret a “dot” representation of intensity at various distances from a flash bulb and to find the intensity at two unknown distances (see left side in Figure 1). The students initially had difficulty understanding and using this representation. The teacher then introduced the table representation shown on the right in Figure 1. The students recognized that an equation fitting this data would be useful, as one student commented that we “need an equation, but we don’t know what it would be.”

At this juncture, the teacher polled the students to find out which parent graph they thought would best correspond to the table of data, thus revealing (as in the previous episode) students' ideas about a possible symbolic representation. Most of the students focused on two of the answers, with 57% ($n=8$) choosing an exponential function, 29% ($n=4$) choosing $y=1/\sqrt{x}$, and with 7% ($n=1$) each choosing $y=1/x$ and $y=1/x^2$. As before, the teacher asked the students to resolve the question of finding an appropriate equation to fit the data. Using their graphing calculators and working with partners, the students rejected $y=1/\sqrt{x}$ as a parent graph. Two pairs of students came up with two distinct functions: $y=1400(1/x^2)$ and $y=715(0.58)^x + 12$, both of which fit the given data reasonably well. However, this response from the students had not been anticipated by the teacher in her planning and left her uncertain, in the moment of teaching, as to how to proceed.

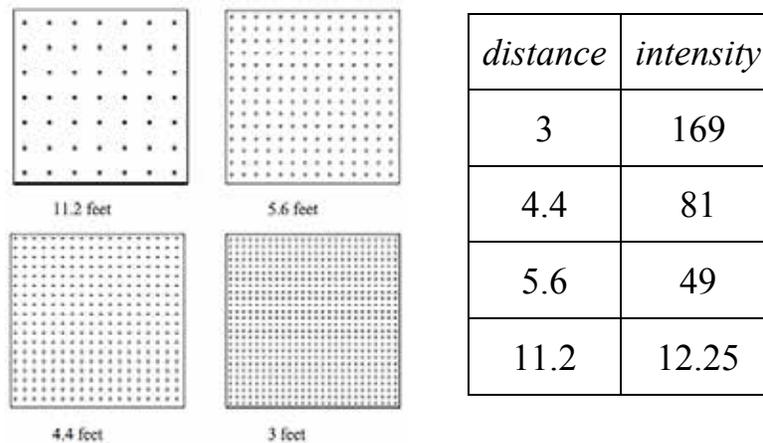

Figure 1: A dot and table representation of light intensity

Unlike the previous episode, where the teacher knew that collecting and graphing data would enable the students to evaluate and revise their ideas about the changing intensity of light, it was less clear how to engage the students in a critique of these two functions, especially since both functions were a reasonably good fit of the data. The teacher juxtaposed the projection of the graph of each function and the data, and turned the question over to the students, asking “which [function] makes more sense?” Several students saw the exponential function as “more accurate” and one student argued that the graph of $y=1400(1/x^2)$ would show up in the second quadrant and hence “wouldn’t be accurate to the data.” Still uncertain as to how to engage the students in a critique of these functions, the teacher re-polled the students as to which parent function would best model the data. This time, 86% ($n=12$) of the students chose an exponential function and 14% ($n=2$) chose $y=1/x^2$. Re-polling the students gave the teacher some additional time to think about how to proceed; during this time she quickly conferred with a member of the research team who suggested focusing the students’ attention on the long term behaviour of both functions. The teacher linked the long term behaviour of the function to the students’ intuitions that the intensity of light should get “closer and closer to zero as we

get out further and further.” This led them to reject the exponential decay function, which did not approach zero.

For the teacher, this somewhat partial resolution was critically important, since the inverse squared behaviour needed to be understood as a meaningful and explanatory representation of the change in light intensity with respect to distance, not simply as a “good fit.” However, the issue we wish to raise is that knowing how to further the students’ own thinking, in the moment of teaching, was neither obvious nor easy from the perspective of the teacher. In this episode, as the teacher ended the lesson, she focused the students’ attention on the critical question of *why* an inverse squared representation was reasonable. She said that the “thing I want you to think about is ‘why’? Why does this inverse square function make sense in this situation?” To answer this question, the students would need to further develop their ideas about representing how light intensity changes in terms of the distance from the light source.

In the next lesson, the teacher again focused the students’ attention on making sense of how light intensity is changing with respect to distance. She began by asking the students about “why it [an inverse square function] would make sense?” and “How do you think about light coming out of a light source?” Several students responded with ideas about light going in “all directions equally,” “travels evenly,” and “in all directions.” The teacher pursued these ideas and asked: “what image do you think of when you think of all directions equally?” One student offered an image of rays: “near the point source, they are really close. But then they go apart. ... As they [the rays] get farther from the point source, they get farther from each other. ... And that’s why the intensity is less.” Several other students offered an image of “spheres” moving out from the light source.

The discussion continued as the teacher built on these images, with student generated representations of enlarging spheres and re-visiting the dot-based representation of intensity; this discussion eventually led to the formula for the surface area of the sphere. The students had moved from the dots representation, to a table representation (both shown in Figure 1), to a symbolic representation, to images of rays and spheres, and to the formula for the surface area of a sphere. At this juncture, the teacher was again faced with deciding what to do next. Rather than guide the students through bringing these ideas together, the teacher turned these elements of representing their model of changing light intensity back to students, asking them to think “about all these ideas and put some of this together ... One of the questions is why do you think light behaves this way [as an inverse square]?” She encouraged them to use the representations that had been discussed as “ways to reason about that” and thus develop and refine their representations of changing light intensity.

DISCUSSION AND CONCLUSIONS

This study began with the design of a model development sequence intended to develop students' abilities to create and interpret models of changing phenomena. The design of that sequence provided multiple opportunities for students to generate and revise ideas, to interpret and give meaning to various representations, and to reason about changing phenomena. When students are engaged in such modelling activities, teachers are likely to encounter substantial diversity in student thinking, including student approaches that can not be fully anticipated. This places substantial new demands on teachers to respond with strategies that support students in making progress with the modelling task, but without overly directing students in resolving their difficulties. The results of this study highlight two teaching practices in response to those demands. First, explicitly revealing the diversity of student intuitions about changing phenomena provided an opportunity for the teacher to engage students in revising their ideas. Second, supporting students in developing and refining their representations of changing phenomena enabled the teacher to make visible representations that could be useful in providing explanatory descriptions about the behaviour of changing phenomena. In engaging in these practices, the teacher encountered moments that caused tension in knowing how to productively proceed in the lesson without simply directing the students toward some known solution. In both cases, the teacher made an important pedagogical shift from a practice of teacher evaluation of student thinking to engaging students in the self-evaluation of their ideas. Such a practice is well aligned with preserving student independence (Blum & Borromeo Ferri, 2009).

DEVELOPING A CRITERION FOR OPTIMAL IN MATHEMATICAL MODELLING

Ole Eley

University of Bremen, Germany

***Abstract:** Optimisation of real-world phenomena with the help of mathematics constitutes one direction of mathematical modelling. Thus, actions carried out while working on optimisation tasks will be located in the modelling cycle. Aspects of the concept of optimal are discussed on a meta-level. In order to identify processes of optimisation, some transcripts of students working on an optimisation task are analysed. Successively changing the perspective on the problem to be solved, starting from an individual and broadening to a collective (or economic) perspective, seems to be a successful approach which leads to an extraction of a suitable criterion for “optimal” in certain cases.*

***Key words:** mathematical modelling, optimising, conception of optimal*

INTRODUCTION

The term “optimal” plays an essential role in everyday life, whether it is advertisement that praises a product’s optimal features or practices in life that have to be improved or optimised. So, optimising is daily routine, although often on a subconscious level. Because one is confronted with the word, it is important to be able to reflect on its meaning. This reflection contains asking in what sense something is optimal and – maybe more crucial – for whom it is optimal. Furthermore, it is necessary to know different aspects of the concept of optimal to be capable of optimising professionally or scientifically. Finding optimal solutions for real world problems with the help of mathematics is part of mathematical modelling. When Maaß (2010) lists “objectives linked to the implementation of modelling”, especially two items seem to be relevant in the context of a conception of optimal:

- “The students should be able to apply mathematics in their everyday life and their professional life.
- Mathematics is supposed to help students in understanding their world and in critically viewing mathematical information in the sense of active citizenship.” (Maaß, 2010, p. 289)

The Duden (2007), a dictionary of German language, describes the word “optimal” as *best possible under given restrictions, with regard to a goal to be achieved* (Duden, 2007, p. 1238; *my translation*). These are also main aspects of the notion of optimal in mathematics. The challenge lies in capturing restrictions as well as the goal and in translating it into mathematics. Modelling tasks which encourage an examination of the word “optimal” should contain questions where neither the restriction nor the goal is obvious a priori. Restrictions, on the one hand, can often be determined by

applying assumptions and collecting additional data. On the other hand, the goal to a high degree depends on subjective and intuitive assessment of the situation and on the perspective from which the situation is considered. Therefore, the goal has to be negotiated with participants. For some goals this might be more complicated than for others. For example, cost minimisation can be considered as a clear goal where a consensus is found soon (except from sources of costs). In contrast, striving for maximum fairness can be expressed in many different ways which requires reasonable compromises.

This paper argues that certain modelling tasks can foster the development of a conception of optimal. An analysis of students working on optimisation tasks suggests that there are ways of elaborating a criterion for “optimal” that seem to be more successful than others.

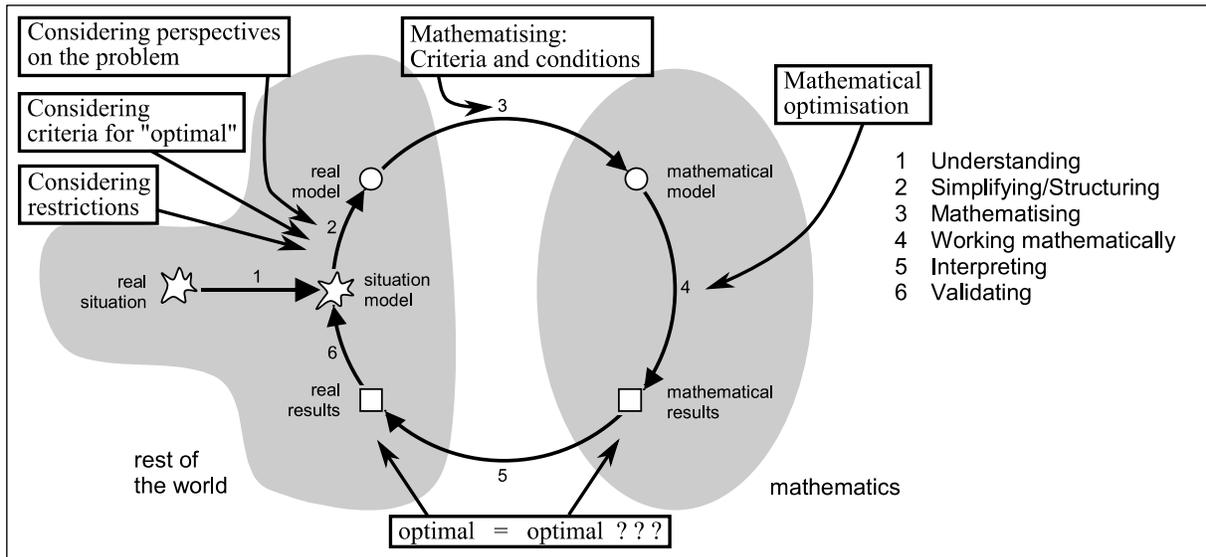

THEORETICAL BACKGROUND

Schreiber (1979) describes *optimality* as a fundamental idea in the Bruner sense. In this context optimality is seen as *property of forms, variables, numbers etc. satisfying a given condition best possibly* (Schreiber, 1979, p. 167; *my translation*). While this highlights the relevance of an attributing (static) meaning of optimisation for mathematics education, Schupp (1992) identifies *optimising* as fundamental and focuses on the procedural (dynamic) meaning. In formulating levels of optimising he emphasises the last level called “meta-optimisation”, in which a reflection on optimising with students takes place. This includes besides others the reflection on solving processes, strategies as well as on intra- and extra-mathematical meaning of optimising (Schupp, 1992, p. 114). In the context of the reflection on the best solution method it is hinted that a decision concerning this matter depends on the situation, the criterion, the question what is to be understood as “better” (or best), and on the individual preferences (Schupp, 1992, p. 159). In this sense this perspective on optimisation includes uncertainty and a need for critical considerations of decisions and results which is characteristic for mathematical modelling in general.

Understanding optimising related to real-world phenomena as one direction of mathematical modelling, the actions of optimising can be located in the modelling cycle (see figure 1). Relevant conditions and restrictions have to be identified and structured. These conditions and restrictions can be expressed in a *real model*. But a real model requires even more: Finding a suitable perspective on the problem or weighing up different perspectives as well as choosing a criterion for optimal can be considered as *simplifying and structuring* and takes place in the *rest of the world*. Is there a certain perspective extracted and an objective criterion for optimal is expressed, a *real model* was created. Objective criteria are considered as those, where anybody else would decide on the fulfilment of the criteria in the same way. The translation of the criterion and the conditions into mathematics leads to a *mathematical model*. In the case of linear optimisation, for example, this could be expressed as an objective function and side conditions. Working mathematically – i.e.

mathematical optimisation – provides *mathematical results* which have to be interpreted to get *real results*. Validating concerns the correspondence between real results and the situation (Borromeo Ferri, 2006). This contains the question whether “optimal” in the mathematical sense can be accepted as “optimal” in the real-world sense. The answer to this question may lead to acceptance or refusal of the solution.

Figure 1: Main aspects of optimising as part of the Modelling Cycle by Blum and Leiß

(2006, p. 1626).

In a single optimisation task there are several ways to deal with different perspectives. While above it is described that one perspective has to be extracted, it is also possible to keep all perspectives in order to mathematise them separately. This allows a comparison of the perspectives concerning the results they lead to. Some perspectives may lead to the same result, so that an extraction of one perspective is not necessary.

Especially in steps 1 to 3 and in steps 5 to 6 of the modelling cycle meta-knowledge on optimisation is needed, in the first steps in order to realise the need of finding different perspectives and in the last steps in order to be able to critically question an “optimal” solution in a mathematical sense. Furthermore, results from validating may provoke a shift in perspective which leads to a revised real model.

METHOD

The analysis is based on data which was gained by Busse (2009). In the context of his PhD-thesis four pairs of 16-17 year old German students were videotaped while working on modelling-tasks outside lesson hours. Afterwards each student watched the video record that was showing him or her. In doing so the students were asked to verbalise thoughts concerning the real-world context which emerged while working on the tasks. Both the student and the researcher could interrupt the video record to initiate this verbalisation. This so called stimulated recall was recorded likewise. The

transcripts concerning one of the modelling-tasks (see Fig. 2) are analysed here. Although the task does not mention optimisation, it constitutes an optimisation task as the question on the “best position” of the common house is implied.

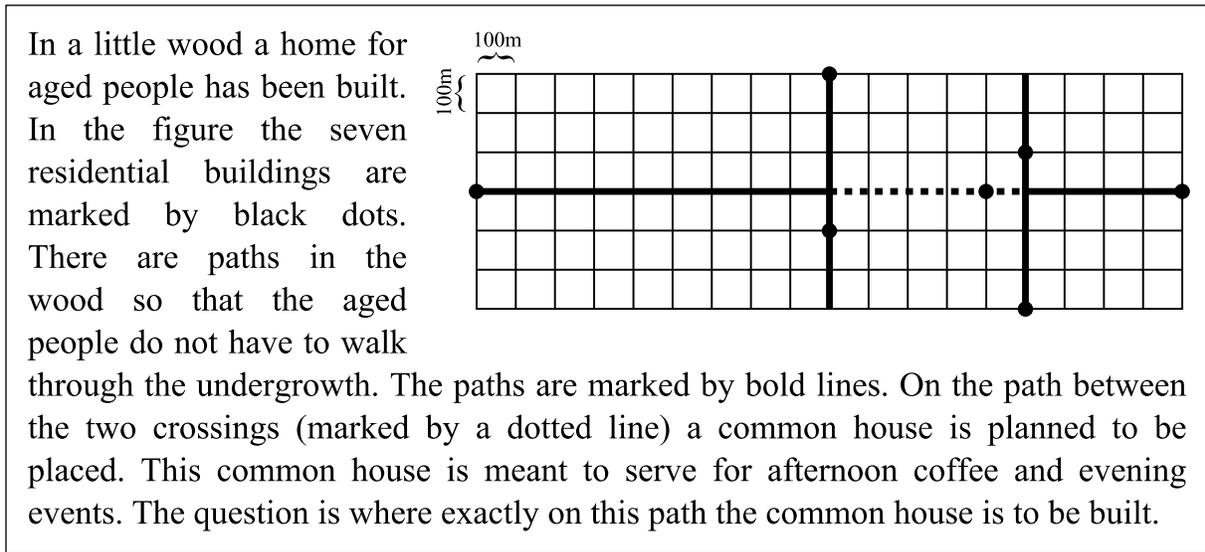

Figure 2: Modelling-task “Home for Aged People” (Busse 2011, p. 40).

The analysis includes three steps:

- Text segments concerning a *certain perspective on the task*, a *criterion for optimal*, a *restriction* or a *solution* are extracted. These aspects can be on an explicit or implicit level.
- The working process is traced by considering the aspects mentioned in the first item.
- An abstraction from the working process is made.

PRELIMINARY RESULTS

As a first approach towards a solution, three pairs of students state that the common house *can be placed anywhere*. The remaining pair expresses negative knowledge by considering that the common house *should not be placed at the right crossing*. Whereas in the first case no criteria for a “good” place for the common house seem to be available, there are hints for such criteria in the second case, although implicit and vague. For example, one criterion could be a low maximum range from the residential buildings to the common house. These different utterances do not permit judging on the student’s work but they rather constitute an approach to the task which concludes that there is a lack of information.

In further examination of the problem the four pairs proceed in a very different way. One pair is first irritated by the lack of information and needs hints from the researcher. Then these students intuitively mention a criterion and a solution which they accept without or with an unconscious and intuitive validation in the sense described by Borromeo Ferri (2006). It takes them less than five minutes to finish the

task so that the full potential of the task is not tapped. The chosen criterion and the matching solution seem coincidental.

The question is what is necessary to accept the working process as suitable, in which way criteria can develop and how these criteria can influence a solution. This is described in the following by having a closer look on another pair's working process. Its members Heinrich and Ingo reflect on different perspectives and matching criteria intensively.

After reading the instruction Heinrich spontaneously states a criterion [1]:

51 H: Oh. So that everybody has the lowest possible distance.

This focuses on the distance between the residential buildings and the common house and expresses a possible need of every single aged person. In this way the problem is regarded from an *individual perspective*. The fact that a shorter distance for one person could mean a longer distance for another person constitutes a conflict caused by this criterion which is not seen consciously at that time. Heinrich repeating this statement in variation (line 100) a goal comes to the fore soon:

139 H: But I'm assuming that as little as possible uh- so, that all have [...] a distance that is fair.

So *fairness*, which in the stimulated recall turned out to be seen as equality, dominates the working process from now on. In the stimulated recall Heinrich verbalises his thoughts:

154 H: [...] that if possible all people will have the same distance- or better, so that, that it is not unfair [...] that not most of the people have a short distance and one person has a very long distance.

This highlights the relevance of the residential house at the left end which will be furthest away from the common house. In order to reduce the longest distance between the residential buildings and the common house Heinrich votes for the common house to be at the left crossing (line 741). Referring to this position for the common house he concludes:

769 H: Actually this is fairest. Because then the longest distance is nine hundred [pointing at the house at the left end].

This perspective can be called a *group-related perspective* because certain groups – here groups that are disadvantaged – are considered. It constitutes a shift from the individual perspective towards a more abstract one.

Whereas Heinrich is the more active in the promotion of this solution Ingo brings into account a new perspective. The new perspective could be described as a *collective or economic* one. He states:

915 I: We can also do it so- uh that you uh- test it for all and then you take the sum of the distances to all houses [...] and where the sum is lowest.

927 I: [...] Look. You sum-up all distances from every house. [...] Distances to the house in the middle. You sum it up. Then you have a sum. And

you make this for every possible position of the [common] house.
That means six all in all.

944 I: [...] Then you compare the sums and where the total distance is lowest-

948 H There it is best. In fact that's true.

951 I: But the problem is that this is not fair.

981 H: No, that's not fair.

This point of view can be described as a *collective or economic perspective* because individual needs remain unconsidered. Instead, it is argued in a more unemotional and economic way. A time-consuming calculation that is carried out by the students results in the best position for the common house being at the same position as the house on the dotted line. A long discussion on whether the one or the other solution is the most suitable leads to the acceptance of the first one. So, the group-related perspective with the matching criterion is chosen as appropriate in this case. In the stimulated recall it is argued (line 955) as indicated in the transcript above that the second solution might be good in other contexts, but in the context of aged people where long distances are covered laboriously it is refused.

Reference back to aspects of the concept of optimal

In the case of Heinrich and Ingo the solving process includes main aspects of the concept of optimal. On the one hand, that means an intensive discussion on the aim of an optimal solution by considering different perspectives, here called individual, group-related and collective perspective. On the other hand, the conditions and restrictions were taken into account thoroughly.

Abstraction of the case: From individual to collective perspective – choosing the “right” one

A natural behaviour in determining which solution works best is to wonder which solution would work best for oneself, assuming oneself being one of the persons affected by the decision to be made. Concerning the *Home for Aged People* task one consequence of this perspective could be:

Everybody wants to have the shortest (or longest – if noise is expected) possible distance between his residential building and the common house.

A conflict occurs when *better* for one person means *worse* for another person. This can be the case in many situations when several people are involved. Therefore, a new perspective is necessary. From the perspective of involved people that are disadvantaged, a group-related criterion is generated which diminishes disadvantages. This criterion can be expressed as:

The longest distance should be lowest possible.

Changing to a more collective and economic perspective may lead to the following statement:

The sum of distances of all aged people should be lowest possible.

Successively the perspective changed from individual criteria via criteria of certain groups to a rather collective and economic criterion where individual needs remain unconsidered.

Solely applying the collective and economic criterion brings a wide difference in distances. One person would have to walk much longer than another. Under the condition of fairness – which is seen as equality – this criterion seems unsustainable for the students so that the group-related perspective is considered as the “right” one.

It should be mentioned, that not one perspective is of higher quality than another per se – it is worth considering the needs of every single person (individual perspective) – but considering many perspectives as a whole constitutes a great level of understanding of the situation and the concept of optimal.

CONCLUSION

Mathematical modelling is challenging for students. Managing the lack of information is one obstacle. Optimising provides further difficulties, for example, the choice for a suitable perspective and the matching criterion for optimal is not clear a priori. The transformation of the perspective from which the pair described looks at the problem suggests that this approach fosters successful optimising and therefore can be used as strategy in the rest-of-the-world-part of the modelling cycle. The transformation of the perspective can be characterised as changing successively from individual to collective needs with respect to existing restrictions.

Working on optimisation tasks like the one described here can foster student’s understanding for the need to consider many perspectives on an optimisation problem. This plays a main role in terms of the conception of optimal. And this is what enables students to question models and “optima” declared by others critically.

However, there might be other determining factors and strategies that provide good results. In further studies it should be explored, whether the strategy presented here turns out to be sustainable in other optimising tasks as well and whether other determining factors and strategies can be identified. The impact of student’s meta-knowledge about optimising is a question that has to be explored likewise.

Furthermore, sources for the shift of perspectives should be explored. That contains the question on what causes a change of perspective.

NOTES

1. The statements of Heinrich and Ingo are part of the transcripts produced by Busse (2009). They partly have been translated from German into English by the author. For the reason of better readability, pauses and accentuations are not displayed. Names have been changed.

MATHEMATICAL MODELLING DISCUSSED BY MATHEMATICAL MODELLERS

Peter Frejd

Department of Mathematics, Linköping University

This paper examines and discusses how two mathematical modellers work and what aspects of mathematical modelling they emphasise. Based on interviews it was found that they operate differently in terms of work organisation and work tasks. They also emphasised different aspect of modelling, one stressing mathematical aspects and the other focusing on other aspects, like how models are being used in the society.

Introduction

The relevance of using mathematics in and for out-of-school activities, in particular in and for waged labour, is one main argument for teaching mathematics in education (Romberg, 1992). However, the synergy between mathematics used in different workplaces and mathematics taught and learned at school is not always straight forward, but one *major issue* described as an interface between mathematics and a workplace is mathematical modelling (Sträßer, Damlamian & Rodrigues, 2012). Mathematical modelling is described both in curricula and research literature as a link between education and workplace settings.

The Swedish curriculum for upper secondary school emphasizes, in the section of the aim of the subject mathematics, the use of mathematics in relation to workplace situations and to use investigating activities in an environment close to practice (Skolverket, 2011). One investigation activity is mathematical modelling, which is described as one of the seven teaching goals, i.e. to develop students' ability to "interpret a realistic situation and design a mathematical model and to use and validate a model's properties and limitations" (ibid, p. 91, my translation). The descriptions from the Swedish curriculum above indicate the use of realistic modelling activities in the mathematics classroom with a relation to workplaces, at least if the modelling problem is chosen adequately.

One example of educational research literature addressing the issue of modelling and workplace mathematics is the proceedings from the EIMI-study (Educational Interfaces between Mathematics and Industry) conference (Araújo, Fernandes, Azevedo, & Rodrigues, 2010). It includes several papers often related to engineering and modelling. Other examples of research literature that include modelling at a workplace are focusing on what Skovsmose (2006) would call *operators*, like bankers (Noss & Hoyles, 1996), telecom technicians (Triantafillou & Potari, 2010) and operators in a chemical plant (William & Wake, 2007). *Operators* are employees that make their working decisions based on apparatus, technology, with input and output of numerical values, in contrast to *constructors* who develop the technology, and *consumers* who evaluate models used for decisions based on information

gathered from reading, watching, and/or listening to statements (Skovsmose, 2006). A common finding related to *operators*' use of mathematics is illustrated by Noss and Hoyles (1996), who investigated bankers' use and understanding of models and modelling. They found that the bankers mainly used computer aided tools with input and output values and the bankers did not consider the underlying mathematical structure of the models they used. The understanding of the mathematical models was preserved to the *rocket scientist*, as the bankers called the *constructor(s)* of the models. However, Noss and Hoyles (1996) did not interview or discuss the situation with the *rocket scientist* themselves, at least not in that paper, which could have been one way to create a communication link between the *constructor* and the *operators*. Overall there seem not to be much attention in research literature focusing on those that are *constructors* in the field and who call themselves mathematical modellers. How do they work? What aspects of modelling do they emphasise? What mathematics do they use? What are their views about modelling? What challenges do they meet in their work? How do they communicate with *operators/ consumers*?

The questions stated above are explored in an ongoing research project, where this pilot-study is a part. The research project will contribute to the ongoing research in mathematics education about modelling and to the understanding and conceptualization of workplace mathematics in that answers may develop new insights into pedagogy and curricula, links between school and workplace, and how mathematical meanings are created in and out of school contexts. This paper will focus on the first two questions above, with aim to examine and discuss how two modellers work and what aspects of mathematical modelling they express as central during their work.

WORKPLACE MATHEMATICS

The goals within the research area of workplace mathematics are several, such as to explore what and how mathematics is used in specific professions (Noss & Hoyles, 1996), to identify discrepancies and similarities between what mathematics is taught in school and what mathematics is needed in the workplace (Triantafillou & Potari, 2010), to analyse communication between *operators* and *consumers* (William & Wake, 2007), and to find strategies that will improve a general curricula that better prepare students for future work (Wake, 2012). What seems to be accepted by educational researchers is that workplace mathematics is not identical to school mathematics. Workplace mathematics is situated dependent and more complex, including specific technologies, social, political and cultural dimensions that are not found in any educational settings (e.g. Noss & Hoyles, 1996; Wedege, 2010). For example the linguistic conventions of representing mathematical models (formula, graph, table) (Triantafillou & Potari, 2010; William & Wake, 2007) are different in mathematics education and in some vocations. Even though the models in a workplace are specific, they offer a potential together with metaphors and gestures to facilitate communication of mathematics between *operators* to *consumers* (William & Wake, 2007). To allow communication about development and validation of mathematical

models are also described as “principals for strategic curriculum design” that support workplace mathematics (Wake, 2012, p. 1686). Other principals given by Wake (2012) are: to take mathematics in practice into account; facilitate activities that pay attention to technology; and, to let students criticise mathematics used by others.

METHODOLOGY

According to Wedege (2010) a researcher investigating mathematics at workplaces should consider two closely linked approaches, a *subjective approach* and a *general approach*. A *subjective approach* focuses on the workers’ abilities and their (subjective) needs in their specific workplace, whereas a *general approach* focuses on (general) demands from the labour market and the society for “formal” (school) mathematical competencies needed in a workplace. A heuristic theoretical model by Salling Olesen (2008), addressing both these approaches, is suggested as a helpful research tool for investigating the dynamics of workplace learning and especially for workplace learning in mathematics (Wedege, 2010). Workplace learning is described “as the process in which individual workers learn by participating in work as a specific activity” (Salling Olesen, 2008, p. 115). An investigation of workplace learning at a specific occasion could be seen as a snapshot of what skills, emotions, knowledge and commitments the worker(s) have developed up to that point in time.

The model is described by Salling Olesen (2008) with the use of a triangle, where each corner is the centre of a small circle (see the figure on p. 119), to illustrate a relation between the three components *the societal work process* (division of labour, type of tasks and work organisation), *the knowledge available* (discipline, craft, methods and skills used in a workplace), and *the subjective working experiences* (individual/collective life history and their subjectivities like values, norms, emotions, etc that appear to be profession specific). Inside the triangle the words experiences, practices, identification and defensive responses are written to illustrate “that learning in the workplace occurs in a specific interplay of experiences and practices, identification and defensive responses” (p. 118). For example, a mathematics teacher may say “this modelling task is useful as a class activity (learned by experience), but it doesn’t fit into our school made tests (learned through practice)” and “to calculate the half-life of Caesium we do in mathematics (learned through identification), but to set up models for radioactivity belongs to physics (learned through a defensive response)”. The suggested theoretical model is helpful for this paper, since “the model pays particular attention to the cultural nature of the knowledge and skills with which a worker approaches a work task, whether they come from a scientific discipline, a craft, or just as the established knowledge in the field” (p. 118) and “we can also see general subjects and skill such as literacy and mathematical modelling in this perspective” (p. 124). Modelling used in a vocation may be seen as the craft and the discipline will refer to mathematics. In addition the three components (*the societal work process, the knowledge available and the*

subjective working experiences) may indicate the origin of the given reasons why the modellers emphasise some aspects of modelling more than others.

One appropriate method to capture the complexity of workplace mathematics is to use observations in a workplace together with interviews (Wedegge, 2010). For this paper, I have used and developed semi-structured interview questions that pay attention to Salling Olesen's (2008) model and the research aim. The main source used in the construction of the interview questions is the set of critical questions developed by Jablonka (1996) for analysing mathematical models. According to Jablonka, the key aspect when someone is working with mathematical modelling is to judge the quality of the mathematical model. The interview questions are stated in the appendix together with a description of their purpose (to describe **how they [the modellers] work** and examine the modelling **aspects emphasised**) and their relation to Salling Olesen's (2008) three components (*societal*, *subjectivity*, and *knowledge*).

This is a pilot study and both the participants Adam and Ben (fictitious names) were previously known to me. The interviews were conducted and audio taped in June 2012 and lasted about 40 minutes (Adam) and 90 minutes (Ben) and later transcribed, summarized and analysed based on the categories **how they work** and **aspects emphasised** together with the three components of Salling Olesen (2008).

RESULTS AND ANALYSIS

Case Adam

Adam got his PhD in numerical analysis working with solutions to partial differential equations. He held a post doc position for a year and a half and after that he has worked with climate modelling and aerodynamic problems. Recently, part of his position is situated at a university working to develop new methods to solve differential equations. Mathematical modelling is very central to him, he said. He gets his working problems, with an aim to describe/simulate a reality, from meteorological institute and aircraft manufacturers. Briefly, the problems consist of a set of differential equations, developed by some physicist, which Adam solves by constructing computer programs. The programs consider initial values and constraints and they are used to simulate and compare to real data. The division of labour at his company is constructed after individuals' different abilities (i.e. numerical analyst, meteorologist, geophysicist and computer scientist). They work collaboratively, often in pairs, to understand what the best way is to solve something, but the collaboration is also about everyday problems like how something is going to be delivered. The main tool used for communication is mathematics, "you cannot formulate anything without it [mathematics]", said Adam. Artefacts used are whiteboards, computers or anything that can illustrate and/or simplify the problem to find a solution. He expressed that "mathematical modelling means to translate physics to mathematics" and gave an example about the movement of a pendulum that can be modelled by a differential equation. In addition he expressed that he is not involved in all steps of the modelling work: his competence consists of "translating mathematics to a computer model that

will emulate the ‘real’ mathematical model”. Adam mentioned that there are several difficulties while solving the equations like how to represent the move from the continuous model to a discrete model, to make simulations that are both accurate and stable and produce a result that someone can trust. The programming languages used are Fortran, C or C++, but he also uses other ICT tools like Mat-lab and statistical toolboxes in the modelling work. He expressed that most of the programming he has learned in his vocation. Doing climate simulations one needs to know input values, such as how the climate is now, where on the earth you are, how the vegetation is, how fast the earth turns. In order to minimize problematic data they use many different measure series made by satellites, which measure thousands of things. However, measurement errors and techniques are not his field of expertise, Adam said. You can verify and control a model, because you know some expected values, but it is difficult in practice with computer codes to actually get these values. This part he expressed as a very central part of his vocation and a bit frustrating, because the computer programs he writes do not always do what they supposed to do. The results the modelling team produce are predictions, therefore it is not possible to know which solution is correct. The validity of the results is based on historical data and climate trends. Nevertheless, a critical point brought up is that these models are just predictions that the *operators/consumers* need to consider, and there is one unit at the workplace dealing with communication between *constructors* and *operators/consumers*.

The mathematical modelling (the craft) in Adam’s work situation seems to be originating from pure mathematics (discipline), in particular the solving of differential equations, and may be considered as intra-mathematical modelling. He has to reformulate the given task in the mathematical domain, select relevant data, translate the mathematical model to a computer model, solve the computer model and interpret and evaluate the result, and finally evaluate the validity of the computer model. Adam’s interpretation of modelling work and what aspects he emphasised may be influenced from all three components from Salling Olesen’s (2008) model. Maybe most important for his reasons to emphasise the mathematical aspects of modelling is the work task (*societal*) described as differential equations. Other reasons that he expressed were the work organisation (*societal*) with predefined division of labour (numerical analyst, meteorologist etc) and his experience of teaching mathematical modelling courses at the university focusing on differential equations (*societal*). There are things that he has learned through work, i.e. programming and other methods related to ICT, which he expressed as a central part of modelling (*knowledge*). More reasons for his emphasis on the mathematical aspects may be the way they communicate with the use of mathematics (*societal*) mediated by artefacts (whiteboards, computers etc) as a part of their work practice (*subjectivity*). In addition, according to Adam, his description of modelling was similar to those of his colleagues, which may have evolved through their practice (*subjectivity*).

Case Ben

Ben has a PhD in mathematics with a thesis on probability theory. His working experience, where he explicitly worked with mathematical modelling, is wide. He has experienced modelling from a variety of practices, such as a municipality, the military defence, consulting companies and he has worked at different universities. Some examples of work tasks are: constructing water conservation plans (constructing a reality), simulating the interplay between humans and their recourses (simulating/creating reality), and to develop measurement instruments for identification and estimation problems (constructing tools). His modelling knowledge has not come from general education, he has learned through his vocation, especially programming (Fortran). He argued that one of the strengths of mathematics is that you have a notation that makes it possible to present research and findings in a compact way and to identify cause and effect. Ben described modelling by describing how he worked with modelling. The modelling tasks, he said, are given to him by supervisors or companies. When companies ask for help they have often thought through the problems and want to get help with the mathematical parts. However, he stressed, “as a mathematical modeller one must first make the complete problem clear to oneself, it is not enough with the last part /.../ this process to identifying the problem and formulate the problem is a very long and slow process”. He continued to express that he does not necessarily always end up with the same problem as the one given to him. To identify what processes, what variables, and what quantities are needed is important, but most important is to know what type of data exist or can be developed. Also, the consumer’s (the company’s) purpose must be taken into consideration; otherwise it may be problems to put the paper product into action. Validating is also expressed as an essential part of the modelling work and described as difficult. Ben is a bit concerned that people often draw too far conclusions from their models, especially when models are built only on simulated data, because reality is something else and more complex, “the only positive one can get out of a simulation is if it doesn’t work, than it won’t work in real life either, but you cannot be sure of that either”. However, if the problem is about economy or efficiency of something than it is possible to put the result back into practice and confirm whether it was a saving or not. A result is often one among other results (a maximum can be flat and several values may give almost identical results) and then the consumer has to consider the outcome. Ben expressed that the consumer often wants to have a yes or a no and he needs to explain that the world is not dichotomous. For communication it is useful if the consumers understand the mathematical model, but sometimes they do not understand the model, which may be problematic, especially if they like the result and can use the model. Other times the consumers do understand the model, but they are not interested to control the underlying reasons and assumptions, which may also cause problems. The “misuse” of mathematical models is frequent according to Ben and he gives an example, which he has read recently in a statistical journal and refers to the ad hoc and quasi methodology used in PISA. Ben expressed that he works

individually quite often, but that there are regular meetings with the consumers to make reconciliations. A problem with these meetings is that the consumers have to build up a certain body of knowledge for the meetings to be constructive, which may be too much to ask for, he said. Ben also said, that he has become a bit skeptical towards mathematical models used in the society, “one doesn’t solve society problems with the use of mathematical models – they may be used in negotiations by one or the other part”. The best negotiator often wins and the best option is not always picked, but that is democracy. ”You cannot talk about any un-political neutral mathematical models”, he added.

In contrast to Adam’s description of modeling, with an emphasis mainly on the mathematical domain, Ben’s description is wider and including aspects related to non-mathematical issues. Ben stressed the following aspects: to identify and formulate the problem; to identify relevant processes, variables, quantities and existing or none existing data; and validating the model. He also expressed a concern how models are being developed and used in the society and in companies as well as emphasized that communication between *constructors, operators and consumers* about mathematical models is a factor for a healthy democracy. Much of his reasons can be analyzed from different components of Salling Olesen’s model (2008). The design of the working task (*societal*) seems to effect Ben’s expressions. His working tasks are quite general and he needs to clarify and formulate a problem for himself to be able to identify possible variables, and processes, which may be why he expressed these aspects as central. The division of labour (*societal*) plays a part. Ben often works individually (*subjectivity*), which means that he has learned through his practical experiences (working with these tasks), and through communication with consumers and employers, what aspects are valued as important in his community of practice. In line with Adam, Ben expressed that he had learned programming (*knowledge*) and that this was useful for his occupation and a part of the modelling work. The concern about how models are used in society and about the political commitment of modelling in society may stem from an individual (*subjectivity*) conviction based on experience from being a *constructor* (developing models used in the society), *operator* (used and tested colleagues’ models for society) and *consumer* (reading and listening to explanations of models, such as PISA).

DISCUSSION AND IMPLICATIONS

Both Adam and Ben call themselves mathematical modellers but their descriptions of how they work with modelling at their respective workplace are quite different. Adam works in a modelling group where the members have different specific roles and Adam’s role is to solve well-defined problems (solve differential equations). The division of labour may be one *societal* reason why Adam mainly emphasises mathematical aspects of the modelling and he does not put too much attention to other aspects because it is not a part of his position. Ben on the other hand has a wide experience of working individually (*subjectivity*) with more open problems, which

may be a reason for stressing aspects related to non-mathematical issues. An aspect he brought forward is his critical approach to how models are being developed and used in society where the best models according to the modeller is not always the model chosen in practice, since there are more stakeholders that come into play in society (i.e. politicians, companies, negotiators, etc) with their own purposes. Similar and other social aspects of modelling that one ought to consider in mathematics education are elaborated and reflected about by Jablonka (2010). However, there are also similarities identified, for example that both modellers have learned programming at the workplace which was seen as a typical *knowledge* for their vocation, both expressed the importance of qualitative data and validation, and both described communication about mathematical models between *constructor*, *operator* and *consumer* as an essential part of the mathematical modelling. This last similarity identified, i.e. that communication between different practitioners with use of mathematical models is important for mathematics education, is discussed by Wake (2012) and William & Wake (2007). As was discussed above, modelling can function as a link between school mathematics and workplace mathematics. Ben's expressions and the statements about modelling in the Swedish curriculum (see the introduction) highlight the importance of interpreting a realistic situation and to evaluate a model's properties and limitations in modelling work, which means that these aspects also should be emphasised in mathematics education. However, both modellers expressed that validation is difficult in their work, and according to Jablonka (2010) validation mostly is a missing part in classroom practice, because the result is almost never put back into action in out of school settings. Still and maybe more problematic for modelling to be the ideal interface between industry and mathematics education, is the difference in objectives. In industry mathematical modelling is "the gateway into the use of mathematics" (Sträßer et al., 2012, p. 7872) whereas in education modelling is a mathematical classroom activity either as an aim in itself (to develop modelling competencies) or as an aim to develop a broader mathematical ability (didactical tool to learn mathematics) (see e.g. Blum & Niss, 1991). To develop a modelling competence, will be difficult to pursue based on this study since the two modellers presented such different descriptions. However, only few students will end up as mathematical modellers and thus the other aim, to use modelling as didactical tool to develop a broader understanding of mathematics, might be more useful for students. Modelling as a didactical tool could be used in teaching about mathematics hidden in technology, which is one aspect of modelling emphasised both in research literature (e.g. Jablonka, 2010; Noss & Hoyles, 1996; Wake, 2012) and in this study as important. One example of activities is to critical analyse mathematical models developed from technology and are used in the society. Not just to develop students' mathematical understanding of technology and to gain knowledge about the importance of communication between *constructors* and *operators/consumers*, but also to develop a critical view of how mathematical models are used in the society, which is an important ability of a critical citizen in a democracy (Skovsmose, 2006).

Appendix

Interview questions	<i>The main aim of the interview question is to find:</i>
1. What is your academic background?	Individual life history (<i>subjectivity</i>)
2. What are your working life experiences before you got here?	Individual life history (<i>subjectivity</i>)
3. What is your vocation and what role does mathematical modelling play in your vocation?	Individual life history (<i>subjectivity</i>) and the institution with its culture (<i>societal</i>)
4. What does mathematical modelling mean to you? Make a general description how you work with a modelling problem (from start to end).	Individual/ Institution's view of modelling, both how they work and aspects emphasised (<i>subjectivity, societal and knowledge</i>)
5. Have your view on modelling changed during the years? (If yes) How?	Individual life history, change in aspects emphasised and why (<i>subjectivity and societal</i>)
6. Who gives you the problems to work with? What are the aims with the problems you get?	Work tasks (<i>societal</i>), aspects emphasised .
7. How do you work with mathematical modelling in your vocation (by yourself, in groups) If it is group work how/what communication take place? What types of artefacts are used?	Work organisation and communication (<i>societal</i>) as well as methods used (knowledge), how they work .
8. What type of problems do you work with?	Work tasks (<i>societal</i>), aspects emphasised .
9. What kind of models do you develop (static/dynamic, deterministic/stochastic, discrete/continuous, analytic/simulations)?	What mathematics/ methods are used (<i>knowledge</i>), aspects emphasised
10. What are the connections between input and output?	Methods used (<i>knowledge</i>), aspects emphasised
11. How was the necessary measurement data obtained? Is there a way to control the quality and the origin of the data? Can you give example of values and quantity of the data?	Methods used (<i>knowledge</i>), how they work and aspects emphasised
12. What factors may have affected the investigated phenomena (measuring instrument or its use)?	Methods used (<i>knowledge</i>), aspects emphasised
13. Is it possible to control the result? What types of assumptions have been made according to the context? Who decide what assumptions are being important? What is the accuracy of the result?	Methods used (<i>knowledge</i>), individual/ institution's view on assumptions (<i>subjectivity and societal</i>), aspects emphasised
14. How does the solution contribute to understanding and action?	individual/ institution's view on the result (<i>subjectivity and societal</i>), aspects emphasised
15. What is an acceptable solution? Who set the goal for the mathematical activity? Who defines the criteria? Are there other solutions?	Methods used (<i>knowledge</i>), individual/ institution's view on criteria used/defined (<i>subjectivity and societal</i>), aspects emphasised and how they work
16. Are there any risk to use the result? If so, how is that considered? Is ethical issues discussed?	Methods used (<i>knowledge</i>), individual/ institution's view on ethical issues (<i>subjectivity and societal</i>), aspects emphasised and how they work
17. Is mathematical modelling something that was a part of your education in school or something you learned in your vocation?	Individual work life experience (<i>subjectivity, societal and knowledge</i>)

INVESTIGATING STUDENTS' MODELING COMPETENCY THROUGH GRADE, GENDER, AND LOCATION

Abolfazl Rafiepour Gatabi & Kazem Abdolahpour

Faculty of Mathematics and Computer & Mahani Mathematical Research Centre
Shahid Bahonar University of Kerman, Iran

Master of Mathematics Education, Teacher of Mathematics, Kerman, Iran.

Abstract

Main purpose of this study was determining the levels of competency of modelling in grade 9th and 10th Iranian students. In this regard we investigate the role of grade, gender and living location in the modelling competency and barrier level. In this study 779 students are participate (366 students from rural location and 413 students from urban places). Students asked to solve a real world problem. Data source was students worksheet and field notes. For analysing of the data, SPSS was used. Especially Mann-Whitney U test was employed. Finding of this study show there isn't a gender difference in mathematical modelling competency. There is no difference between rural and urban students performance, but grade 10 students have better performance than grade 9 students.

INTRODUCTION

Iranian educational system is centralised. Mathematics education goals are set at the national level and the Ministry of Education develops the syllabi and textbooks (Kiamanesh 2005). Mathematics textbooks distribute in all over the country in each school year. All students have same mathematics textbooks. Mathematics teachers asked for using these textbooks in their teaching as a main material. Upon TIMSS advanced mathematics teachers questionnaire, about 95 percent of mathematics teachers in grade 12 use official mathematics textbooks as a main material in their teaching (TIMSS official website).

Recently, a new reform of school mathematics curricula was started in Iran. In the third edition of national curriculum, there are some part about modelling and application. Mathematics textbooks in the grade 9, 10, and 11 started to change from 2008. These new versions of mathematics textbooks were based on the previous version and have similar chapters, although their order is changed. One of

the goals of this new version of math textbook was modelling and application. So, writers of textbooks modified new textbooks upon real world application approach.

There is common myth (Rafiepour, Stacey and Gooya, 2012) about application of mathematics between scholars in Iran. If learners have good background in mathematics then they can apply their mathematical knowledge in solving real world problems. Although this myth rejected by several researchers in mathematical modelling community such as De Lange (2003) and Niss, Blum & Galbraith (2007). So we need to do a large scale study for showing that students haven't good results in solving real world problems.

The aim of this paper is studying Iranian students' mathematical modelling competency. Indeed below research questions leading our study:

- Is there any gender difference in mathematical modelling competency?
- What is the role of grade in mathematical modelling competency?
- Are there any differences between students performance on the rural and urban places?

LITERATURE REVIEW

Many countries consider modelling and application in their teaching and learning approaches in last two decade (Niss, Blum, Galbraith, 2007). In Iran educational system, and especially in new version of math curricula, noticed to modelling and application. Although researches upon content analysis of new Iranian math textbooks show that modelling problems are scarce in the textbooks but there are some standard application problems in the textbooks (Rafiepour, Stacey, and Gooya, 20012; Rafiepour, 2012).

When we call modelling approach, we mean a process that started with a problem situated in the extra-mathematical world (EMW) – perhaps a real world everyday problem or a problem from another discipline such as physics or biology. The modelling process continues with formulating the EMW problem in mathematical terms. This is called vertical mathematization by Freudenthal (1991). When this process is complete, the mathematical problem can be solved by the application of mathematical concepts and solution processes. Finally the mathematical solution must be interpreted to provide an answer to the EMW problem, and checked for its adequacy in answering the original question. A new cycle of formulation to improve the model may then begin. In the formulation stage, the problem solver faces a problem situated in a real context or science context, and then gradually trims away aspects of reality, recognizing underlying mathematical relations, organising according to mathematical concepts, and describing the stripped down problem in mathematical terms. In the interpretation stage, the problem solver

considers the mathematical result(s), and uncovers their meaning in terms of the real context. In figure 1 a simple diagram of modelling cycle presented.

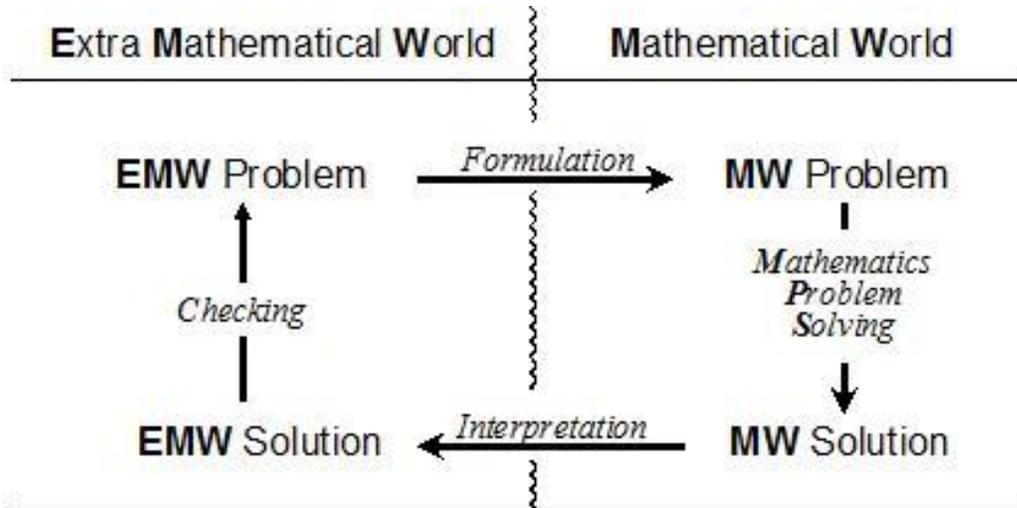

Figure 1: A model of the modelling cycle (adapted from OECD, 2006)

There are several definitions for modelling competency. For example Blum and Kaiser (1997, cited in Maab, 2006) define it by several sub-competencies. Other researchers such as Ikeda and Stephens (1998) address it as an assessment schema. Blomhøj and Jensen (2003) define modelling Competency as someone's insightful readiness to carry through all parts of a mathematical modelling process in a given situation.

However in this study we use Maab (2006, p. 117) definition: "Modelling competencies include skills and abilities to perform modelling processes appropriately and goal-oriented as well as the willingness to put these into action".

For assessing modelling competency, there are several theoretical frameworks. Such as Jensen (2007), that introduced a multidimensional competence-based assessment for Assessing Mathematical Modelling Competency. His model contains 3 dimensions: *Degree of coverage*, *Radius of action*, and *Technical level* (Blomhoj & Jensen, 2007). This model isn't as much as easy to use for assessing students' mathematical competency in large scale study. So we didn't use this model as our theoretical framework for mathematical modeling competency assessment.

In this study we use the framework that provide by Ludwig and Xu (2010, p. 80) with six different consecutively levels (Figure 2). Indeed, we need a framework to use it easily for lots of students' worksheet.

- Level 0: The student has not understood the situation and is not able to sketch or write anything concrete about the problem.
- Level 1: The student only understands the given real situation, but is not able to structure and simplify the situation or cannot find connections to any mathematical ideas.
- Level 2: After investigating the given real situation, the student finds a real model through structuring and simplifying, but does not know how to transfer this into a mathematical problem (the student creates a kind of word problem about the real situation).
- Level 3: The student is able to find not only a real model, but also translates it into a proper mathematical problem, but cannot work with it clearly in the mathematical world.
- Level 4: The student is able to pick up a mathematical problem from the real situation, work with this mathematical problem in the mathematical world, and have mathematical results.
- Level 5: The student is able to experience the mathematical modelling process and validate the solution of a mathematical problem in relation to the given situation.

Figure 2: six level for assessing mathematical modelling competency

METHOD

Participants

In this study we use two step cluster sampling. At first stage we identify all districts of Kerman (one of the south provinces in Iran). Then we determine urban and rural district via official document produced by educational Administration. Finally in each district we determine one school and collect data from selected classes in grade 9 and 10. In sum 779 students from 33 classrooms were participated in this study. 413 students were female and 366 students were male. 366 students were from rural places (17 classrooms) and 413 students were from urban places (16 classrooms). All of these students were in grade 9 and 10 (15 and 16 years old) in Kerman. Details of participants show in table 1. These students

haven't any special teaching toward mathematical modelling before the test. They just familiar with some standard application through the new version of Iranian mathematics textbooks in grade 9 and 10.

	Gender	Grade 9	Grade 10
Rural	Boy	121	59
	Girl	120	66
Urban	Boy	120	67
	Girl	83	143

Table 1: participants of this study

Data Collection Instrument

For data collection, we use a real world problem that involve to peeling a pineapple. This problem get from Ludwig and Xu (2010, p. 80). We use only one problem for data collection because of time limitation. Peeling a pineapple problem choose for our study because our pilot study shows that this problem was interesting for most of students.

In the data collection session, we go to the classroom and show a picture about peeling the pineapple as below and ask students to explain that Why does the salesman peel the pineapple in this way? Is there any mathematical way for describing salesman manner?

Figure 3: method of salesman for peeling a pineapple

All of the Students activities were videotaped then transcribed. Students' worksheets and field notes of researchers were considered as a data set in this study.

Data Analysis

For analysis of the data two mathematics teachers code all students worksheet separately upon figure 1 schema. In this process, coders use film of the students' activities and filed notes. Degree of agreement between coders was reported more than 85%. Indeed each coder read every student (779) response and decides about level of competency for each student upon table 2. There are only a few

disagreements (about 80 cases) between two coders to allocating level of competency for each student's response. For responding to the research questions we apply Mann-Whitney U test for two independent groups.

RESULTS¹

The level of students modelling competency in rural and urban places in grade 9 and 10 reported in table 2 and 3.

Level of competency	Grade 9		Grade 10	
	N	%	N	%
Level 0	94	39	21	16.8
Level 1	89	36.9	37	29.6
Level 2	44	18.3	53	42.4
Level 3	12	5	7	5.6
Level 4	2	0.8	7	5.6
Level 5	0	0	0	0

Table 2: The level of students modelling competency in rural places

Level of competency	Grade 9		Grade 10	
	N	%	N	%
Level 0	66	32.5	53	25.2
Level 1	80	39.4	76	36.2
Level 2	56	27.6	67	31.9
Level 3	0	0	2	1
Level 4	0	0	3	1.4
Level 5	1	0.5	9	4.3

Table 3: The level of students modelling competency in urban places

CONCLUSION AND DISCUSSION

Gender difference is one of the components in equity issue. In the pilot study we confronted with different performance in the case of boys and girls in solving real world problem. So we concentrate on gender issue as a first research question. In the first research question we investigate the role of gender in the mathematical

¹ -Output of SPSS omitted because of the space limit.

modelling competency. Upon output of SPSS, at the 0.05 significance level we couldn't find gender difference between students, thus our hypothesis about gender difference was rejected. Although we saw there are some sort of gender difference in solving real world problem, but for discovering this differences we need more in-depth qualitative research.

In the second research question we search for finding a role for grade of students in modelling competency. Indeed we would like to address the impact of grade in modelling competency. Upon output of SPSS, at the 0.05 significance level we find, students in grade 10 was better performance than students in grade 9. As we seen, students in grade 10 have better performance in real world problem solving than grade 9 students. This result is in the line with Ludwig and Xu (2010) results.

In the previous pilot study, we observed that students who living in rural places have better conception about real world problems, therefore we decide to examine this hypothesis. In the third research question we investigate the role of place of living (rural/urban) on mathematical modelling competency. There is no statistical significant difference between rural and urban places in mathematical modelling competency. Indeed rural and urban students have similar performance on solving real world mathematics problem.

Upon new reform in mathematics curricula and mathematics textbooks in grade 9, 10 and 11 in Iran, and considering mathematical modelling and application in new series of textbooks, it seems to be necessary to investigate Iranian students' performance in mathematical modelling competency. Current study examines Iranian students' performance in solving a real world problem and determines their level of mathematical modelling competency. This finding could be use as a base for doing further research in Iran and comparative study with other countries. Descriptive results show weak ability of Iranian students' modelling competency; although there are a few students that can achieve level 5 of mathematical modelling competency. These students are able to experience the mathematical modelling cycle completely and validate the solution of a mathematical problem in relation to the real world situation. This is a good point. Indeed we are in the start point of a long way; there are lot of things to do.

SOLUTION AIDS FOR MODELLING PROBLEMS

Gilbert Greefrath & Michael Riess

University of Münster, Germany

One option to help students to process modelling problems is the use of solution plans. Some of these solution plans will be introduced. As part of a qualitative study a solution plan in connection with a modelling problem was used in Grade 6. The students were observed and interviewed during it. The assessment strongly shows differing work processes but comparable written solutions from the students dependent on the solution plan.

MODELLING AS COMPETENCY

Mathematical modelling is one of the six mathematical competencies that are accounted for in the German educational standards for mathematics. Students should acquire the skills, based on diverse mathematical content, to translate between reality and mathematics in both directions. Due to the high significance of this competency for classes, solution aids for students when working on modelling problems in math class will be discussed in this article. That is why the competency of modelling will be briefly introduced in the following.

The core of mathematical modelling was already described by Pollak (1977) as interplay between mathematics and the “rest of the world“ (see Fig. 1).

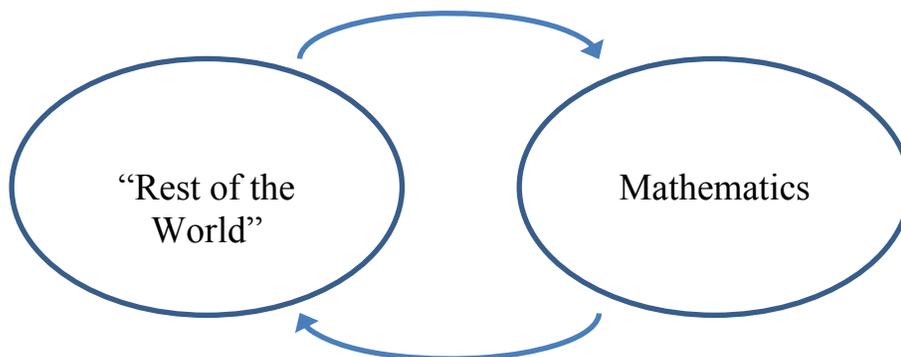

Fig. 1: Mathematics and the “rest of the world“ (cf. Pollak 1977)

Modelling competency is described more precisely in Blum et al. (2007) as the ability to perform the respective required process steps while switching back and forth between reality and mathematics adequately in regard to the problem as well as to analyse given models or comparatively assess them. Modelling cycles (similar to that in Fig. 1) describe the different sub-processes of modelling activities in different detail and with different perspectives (Kaiser & Sriraman, 2006). A selection of these so-called partial competencies is listed in Table 1.

Partial competency	Indicator
Understanding	The student constructs her/his own mental model of a given problem situation and thereby understands the question.
Simplifying	The student separates essential and un-essential information of a real situation.
Using mathematics	The student translates appropriate simplified real situations in mathematical models (i.e. term, equation, figure, diagram, function).
Interpreting	The student relates the results obtained in the model to the real situation.
Validating	The student checks the results obtained in the model based on the real situation.

Table 1: Partial competencies of modelling (a selection)

The conscious division of modelling into partial processes is a possible way to reduce the complexity for those teaching and those learning and to set up suitable problems. Such a view of modelling especially makes it possible to train individual partial competencies in a targeted way and thus to construct extensive modelling competency. Also the view of the partial processes of modelling can be used to create solution plans for students and to thereby make solution aids for processing modelling problems available. Sjuts (2003) describes activities of planning, monitoring and checking, that are also initiated by solution plans, as *procedural meta-cognition*.

SOLUTION AIDS

Solution plans can aid the processing of modelling problems. These plans are used in the context of strategic aids and not in the sense of programmed learning. Blum (2006), for example, developed a solution plan for students as part of the DISUM Project that is based on a simplified model building cycle (see Fig. 2).

This solution plan contains four steps called *understanding the problem*, *creating a model*, *using mathematics* and *explaining results*. Every step is explained to the student with a question and some clarifying points.

Blum's solution plan belongs to the so-called indirect general strategic aids because although he does refer to general specialised modelling methods he does not give any concrete assistance that is based on the tasks in steps 2 and 3 of this solution plan and the commonality of the strategic aid is abandoned in favour of content-oriented pointers. Because of the pointers to equations and the Pythagorean Theorem it is a matter of a content-oriented strategic aid. This solution plan can be prepared for students. Its usage can also be practiced with the help of example problems.

1 Understanding the problem	What is given, what is sought?	Read the text precisely Imagine the situation exactly Make a sketch
2 Creating models	Which mathematical relationships can I establish?	Fill in missing entries, if required, i.e. set up equations or plot triangle
3 Use mathematics	How can I solve the problem mathematically?	I.e. work out the equation or use Pythagorean Theorem, write down the mathematical result
4 Explain the result	What is my end result? Is it logical?	Round off the result and relate it to the problem – possibly back to 1, write down answer

Fig. 2: Solution plan for modelling problems (Blum, 2006)

In a study by Schukajlow et al. (2010) as part of the DISUM project, significant differences in student achievement in modelling was verified using this solution plan in regard to the Pythagorean Theorem area of content. The class with the solution plan proved to be the more effective form of teaching and learning. In addition, the students in the solution plan group were also more aware of using cognitive strategies, in other words the solution plan.

A shorter solution plan is used by Zöttl & Reiss (2010) in the content area of geometry. This is reduced to three phases, namely

- Understanding the task,
- Calculating,
- Explaining results.

As part of the KOMMA Project, completed solution examples were used in addition to the solution plan above from Zöttl & Reiss (2008) that consisted of a problem and the description of the solution steps. In the area of mathematical justification and verification positive effects could already be ascertained when such solution examples were used (Reiss & Renkl 2002).

An alternative solution plan can be found in Greefrath & Leuders (2013). In the set up of this solution plan the problem solving steps of Polya were taken more strongly into consideration than in the plans cited above. In his book *How to solve It* Polya developed a catalogue of heuristical questions that are supposed to help process problem solving tasks. Here the problem solving process is divided into the following sections (Polya, 1973): Understanding the problem, devising a plan, implementing the plan, review. Schoenfeld (1985) follows up on it and describes certain steps in more detail. At the end of the problem solving process he differentiates between

verification and transition. The proposed solution plan for learners at the start of secondary school therefore contains five steps and can be used for modelling as well as for problem solving tasks:

- Understanding the problem: Formulate it in your own words.
- Choose the approach: Describe assumptions and plan the calculation method.
- Performing: Perform the calculation.
- Explain the result.
- Checking: The result, calculation and approach.

The solution plan is similar to problem solving activities in order to use it more frequently than a solution plan specifically for modelling problems. Because every modelling problem is also a problem, the strategies suitable for problem solving are also helpful for modelling.

Certain authors also use a simplified modelling cycle as solution aids for the students. As part of a qualitative study in Grades 7 and 8, Maass (2004) studied the modelling competence of students and by the end of the study could reconstruct proportionate meta-cognitive competencies in a large percentage of the students. A result she also describes is that the students sensed the knowledge of the modelling process and the depiction of the cycle as an orientation aid.

But disadvantages to such solution plans have also been named. Meyer and Voigt (2010) lead the way saying that a solution plan dependent on a modelling cycle with a structured formula for processing practical calculation problems from the 1960's and 1970's can be compared, where they were offered to students as alleged solution aids and turned out to be additional learning material.

Another option for a solution aid for processing modelling problems that does not address solely the modelling process but can also be used for general problem solving situations is asking and answering indicative questions or simpler questions (Greefrath & Leuders, 2013). Here the students learn to ask and answer questions about the modelling problems. Two goals can be achieved hereby. Firstly, it is easier to recognise which information the text in the problem really supplies – possibly even information necessary to solve the problem – and which must be procured in a different way. Secondly, the modelling problem to be processed is disassembled into partial steps that can initially be processed individually reducing cognitive load (Sweller, 1988) before the partial results are then put together to solve the problem. Later the students can ask themselves such questions and decide whether they can be answered with help from the text.

STUDY DESIGN

As part of a qualitative study up to now three pairs of students from 6th Grade of a secondary school were observed while working with the solution plan from Greefrath

& Leuders (2013) and subsequently questioned. A qualitative study was chosen to get information about the processes while working with the solution plan. Of course the generalizability of such a qualitative Study is low, but the goal was to get information about the processes in detail. Up to now there are no empirical results on students working with this specific solution plan.

The students' activities while working on the task and the subsequent interviews were filmed. Until now three such interviews were evaluated. The students worked on two problems one after the other. The first problem served to understand the solution plan and to put the given steps into the right order. The second problem consisted of using the solution plan. For this the above solution plan from Greefrath & Leuders (2013) was presented together with the following problem:

Work out the following problem according to this solution plan: What amount of liquid do I drink every week?

The videos of the observations and interviews were completely transcribed and evaluated following Grounded Theory (Strauss & Corbin, 1990). Here the transcripts were worked through line-by-line and the individual lines of text openly coded. In this way categories were developed which were then used to evaluate the results. The coding was done by two independent persons in order to achieve highest possible interrater reliability. (Hilmer, 2012)

RESULTS

After viewing the openly coded lines of text the following categories were developed that were then used to code the interviews:

- Orientation on the plan and example
- Fulfilling the requirements of the plan
- Difficulties in implementing the plan and example
- Incorrect or incomplete conversion

The fulfilment of the requirements of the plan will be observed in more detail in the following. Also the individual five steps of the plan were individually coded as part of this category and used for the following analysis. These are the first empirical results for this special solution plan.

Interview 1:

This tandem is strongly oriented on the given solution plan but they especially considered the concrete example of the first problem. The students mixed up the phases *Choose approach* and *Perform* and the test persons oriented themselves alternately on the question, example and plan. Although the plan did encourage meta-cognitive processes, it did not supply optimisation of problem processing. Figure 3 depicts the phases of processing of this pair of students.

PHASE	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Understand the problem	x					x									
Choose approach			x		x			x		x			x		
Perform		x		x					x			x			
Explain result											x			x	
Check							x								x

Fig. 3: Solution phases in Interview 1

The mix-up of the second and third steps of the solution plan becomes clear in figure 3. Even though the observation shows that both students could not orient themselves strongly on the given plan, they still answered the question as to whether the plan had helped them:

“I thought it was good that I could always look there. If I had to do it by heart I think it would be more difficult. This way I had a kind of comparison“

Interview 2:

This pair of students oriented themselves clearly on the given solution plan. Difficulties only came up partially in the description of the corresponding phases. A content error occurred in the last processing step. Here the necessary plausibility observation does not succeed. Figure 4 shows the phases passed by this pair of students and shows a definite difference to Interview 1:

PHASE	1	2	3	4	5	6	7	8
Understand the problem	x							
Choose approach		x		x				
Perform			x		x		x	
Explain result						x		
Check								x

Fig. 4: Solution phases in Interview 2

This pair of students shows the sequence that should be given by the solution plan much clearer. Interestingly, one of the two students pointed out in the subsequent interview that he sees a connection with the known solution aid for written problems: Question, calculation, answer. Altogether the use of such a solution plan was seen as being very positive by the students. The written solutions of the pair of students clarified the clear sequence and the maintained structure of the solution plan.

Understand the problem: How much do you drink in one week?

Choose approach: I drink ca. 2 litres a day. I would calculate 2×7 .

Perform: $2 \text{ l} \times 7 = 14 \text{ l}$

Explain result: I drink ca. 14 l a week and ca. 2 l a day.

Check: That would be $9 \times 1,5$ litre bottles and one 0,5 litre bottle.

Interview 3:

This tandem oriented themselves on the phases of the solution plan. All the phases are listed except for the last phase. But they oriented themselves more on the example given in the first problem than on the plan itself. This led to problems in some places with the abstraction of the example. The phases *Choose approach* and *Perform* were processed separately and successfully. The following two phases however were mixed up and shortened. The overview shows the sequence of the phases:

PHASE	1	2	3	4	5	6	7	8	9
Understand the problem	x					x			
Choose approach			x						
Perform		x		x			x		
Explain result					x			x	
Check									x

Fig. 5: Solution phases in Interview 3

This pair of students was very positive about the solution plan and finds the added explanations to be important:

Interviewer: Did the plan help you?

Student 1: I would say that if it wasn't there, the explanations, only understanding the problem, choosing the approach, I wouldn't have gotten it. Here it says to formulate in your own words, describe assumptions and plan the calculation method. That helped.

Interviewer: And if you had done the question without the plan? Would you have done it the same way?

Student 2: It would have been more difficult and would probably have taken a bit longer.

This group of students also noted down the written solutions according to the given plan structure. (Hilmer, 2012)

DISCUSSION

Of course this qualitative study with only three pairs of students is limited, but the three interviews assessed show that the student solutions were influenced by the given solution plan. Especially the written solutions receive a structure clearly adapted to the solution plan. Here it becomes clear that the choice of solution plan can have a great influence on the written solutions of the students.

However the actual solution path of the student pairs do not always follow according to the given plan. Even if the written, fixed solutions of the students all have the same structure the solution process of the tree pairs differs clearly. This reminds one of the individual modelling routes that were described by Borromeo Ferri (2007). The decisive question in judging the effectiveness of these plans as solution aids is whether the solution process plays a role in the modelling process or only influences the result. Apparently there are students that have greater difficulties dealing with such a plan and others who only need a short introduction to work with the plan.

Regardless of whether the solution plan sustainably influenced the solution process, the six students interviewed made positive comments about the solution plan and felt supported by it. This highlights in a certain way the results of Schukajlow et al. (2010). Also the use of finished solution examples, like in our study in the first problem, seems to appeal to some students.

In the near future this study will be continued with additional cases and the observation of diverse solution plans. A detailed study of the solution processes seems indispensable since the difference were visible in the solution processes; however the written solutions of the students only exhibited few differences.

MERGING EDUCATIONAL AND APPLIED MATHEMATICS: THE EXAMPLE OF LOCATING BUS STOPS

Horst W. Hamacher, Jana Kreußler

Department of Mathematics, University of Kaiserslautern, Germany

{hamacher,kreussler}@mathematik.uni-kl.de

Abstract: *The reduction of complex mathematical models for solving real-world problems to a level applicable in secondary education is considered to be a very important goal to increase motivation and understanding. This is, for instance, witnessed by its inclusion in mathematics curricula of many countries and the OECD study PISA (OECD, 1999). The actual implementation of this goal of merging educational and applied mathematics (MEAM) is, however, still in its infancy and rather difficult. In this paper we present a case study in which we discuss our experiences with a two-day modelling project for German high-school students in the age group of 15-19 years. As real-world problem we introduce the problem of locating new bus-stops in public transportation systems. The mathematical optimization tools to tackle this problem reduce to questions solvable by basic geometry. The paper also includes an evaluation of this case study with regard to the motivation of students and our conclusion for the mathematics curricula of schools.*

Keywords: Applied mathematics, modelling, motivation, empirical research.

INTRODUCTION

The optimization problem of locating new bus stops in an urban area is just one of many mathematical real-world problems found in industry and society which are also suitable to be taught in schools. Research on how to merge educational and applied mathematics (MEAM) and how to insert it to the curricula of secondary education is still in the early stages. Integrating real-world problems to everyday school life is an aim we want to achieve to prepare and advance students for their academic studies and later employment, as well as motivating students of all capability levels for the subject mathematics (Blum et al., 2002). It is important that students learn and know the connection between mathematics and problems found in industry and everyday life as this can improve their understanding of mathematical issues as well as their motivation and enjoyment. The OECD study PISA (Programme for International Student Assessment) also emphasizes on bonding real-world and mathematical problems (OECD, 1999) which shows how important it is to integrate management mathematics to regular school lessons.

As applied mathematics and modelling real-world problems play a decisive role in industry and science the goal we pursue is to regularly integrate this to lessons in school, i.e. to merge educational and applied mathematics. The merging does not only have to take place by means of modelling problems, but can also mean to

integrate these topics to school lessons in a more classical way. By emphasising specific curricular mathematical content, challenging applied mathematical topics can be used to repeat, combine or develop new and old mathematical subjects.

Since the 1990s handling modelling problems in regular school lessons or during extra-curricular projects of 2 to 5 days is a successful activity started by a group of industrial and management mathematicians at the University of Kaiserslautern (Bracke et al., 2011). Embedding real-world modelling into regular school lessons was discussed and evaluated by Bracke et al., combining the knowledge from selected topics of a whole school year using a modelling cycle as described in Figure 2 by Blum et al. (2005). This study came to the conclusion that real-world modelling tasks can be integrated into regular school lessons of a whole school year and that the attitude of students towards this method was very positive. Kaiser et al. (2006; 2010) studied authentic modelling problems with students during modelling weeks and describe problems which are mainly suitable for students of an upper secondary level in school. Their study also showed that most of the students taking place in the evaluation would appreciate if such authentic problems were included in school mathematics more often, since they liked the opportunity to apply mathematics in real life. Maaß et al. (2007; 2011) emphasise the insertion of modelling problems into regular school lessons on a lower secondary school level. Precise modelling tasks were developed and evaluated during the project STRATUM with the successful aim to improve modelling competencies of lower achieving students. Methods to teach authentic problems concerning combinatorial optimization were discussed by Lutz-Westphal (2006). The focus does not lie on modelling problems but the integration of combinatorial optimization problems to regular school lessons. A feedback questionnaire was given to participating students to evaluate what they liked or disliked about the topics. The feedback was on the average very positive. We can hence say that applied mathematical problems as well as modelling problems in general seem to enhance the joy and understanding for mathematical applications.

Management mathematical problems seem to be particularly suited for modelling activities, since these problems are often very close to the everyday-life experience of the students (Bunke et al., 2007; Kreußler et al., 2012). Operations research, including the area of mathematical optimization, is a field of study which implies a vast number of applications from industry and everyday life. Geometrical methods can often be used to solve optimization problems which provide an excellent opportunity to integrate management mathematics to lessons in schools while staying within the framework of given curricula at the same time. Several examples of this type have been developed in the research project MaMaEuSch: Management Mathematics in European Schools (Hamacher, 2001-05) or can be found in the book Hamacher et al. (2004).

In the subsequent sections we consider the optimization of bus stop locations and its integration to secondary mathematical education in schools. At first, we present the mathematical background and a solution strategy in order to highlight the advanced

mathematics behind this topic. Afterwards, we discuss the difficulty of reducing the presented mathematics to a level suitable for schools and present a modelling project studying the motivation of students concerning management mathematical topics.

PLANNING BUS STOPS – A GUARANTEE OF ACCESSIBILITY

Due to the increasing growth of population in urban areas the optimal location of bus stops becomes a more and more important task to maximize acceptance and convenience of public transportation systems and to minimize pollution, noise and congestion. To achieve these goals the public transportation network of a city should be an efficient and worthwhile alternative to travelling by car. This includes better prices, small travelling times and short distances to the nearest bus stops. We should also take into account that construction costs and travel times both increase with each additional bus stop. Therefore, we need to find a compromise between short travel times and enough bus stops within reach for all customers. The distance a customer is willing to go to the nearest bus stop is called the *covering radius*. Research by Murray (2001) showed that approximately 92% of the already existing bus stops in Brisbane, Australia, were redundant, assuming a covering radius of 400m for bus stops. The reduction of bus stops could hence lead to an enormous gain in time and, as a result, to an increasing number of customers.

We now want to specify the exact problem statement. We are given an already existing public transportation network, i.e. the roads of a city, represented by a planar undirected graph $G = (V, E)$. The edges $e = (v_i, v_j) \in E$ represent possible bus routes between the nodes v_i and $v_j \in V$, whereas the set V consists of important breakpoints and junctions of the given transportation network. There is given a finite number of customer locations $P = \{p_i \in \mathbb{R}^2, i = 1, \dots, m\}$ and a covering radius $r > 0$. The *Continuous Stop Location Problem (CSLP)* now wants to find a minimal number of bus stops that cover a given number of customers within the covering radius r while all points on graph G are possible locations for new bus stops (Schöbel et al., 2009). The set of all points on the edges of graph G can be defined as $T := \bigcup_{e \in E} e = \{x \in \mathbb{R}^2: x \in e, e \in E\} \subseteq \mathbb{R}^2$. Given a covering radius $r > 0$, a customer location $p \in P$ is *covered* by a point $s \in T$, if $d^p(p, s) \leq r$. Furthermore, we define the *unit ball* B_p of a customer location $p \in P$ as all points $x \in \mathbb{R}^2$ whose distance to p is less than or equal to 1. $B_p^r := p + rB_p = \{x \in \mathbb{R}^2: d^p(x, p) \leq r\}$ then defines all points $x \in \mathbb{R}^2$ whose distance from $p \in P$ is less than or equal to the covering radius r . To solve *CSLP* we use the ideas of Schöbel et al. (2009) who present a suitable algorithm for our problem. In the first step we need to check whether *CSLP* is solvable at all. This can easily be done, since *CSLP* is solvable as soon as each customer location $p \in P$ is covered by at least one point $s \in T$, i.e. if $B_p^r \cap T \neq \emptyset$, $\forall p \in P$. Since we are given a continuous set T of possible bus stop locations at the start, our goal is to reduce this to a finite dominating set $S_{cand} \subseteq T$ for which we know that it must contain at least one solution S^* . *CSLP* can then be stated as a well-known *Set Covering Problem* and hence be solved by any algorithm known to solve

this, for example the greedy algorithm suggested by Chvatal (1979). The algorithm to solve *CSLP* can be summarized as follows. We are drawing circles $B_{p_i}^r \forall p_i \in P, i = 1, \dots, m$ with a given covering radius r around all customer locations. The intersection points of these circles with the given road network as well as given junctions and breakpoints form the candidate set S_{cand} of possible bus stops. Assuming the same construction costs for all bus stops we can set the costs $c_j = 1 \forall j$ without loss of generality. We then sort these candidates in decreasing order of the number of customer locations covered by them. Using the greedy method of Chvatal (1979) we start choosing bus stop locations beginning with the candidate that covers the maximum number of customers, continuing by always choosing the candidate of highest coverage left. As soon as all customer locations are covered the optimal candidate set S^* is found.

A BUS STOP MODELLING PROBLEM

Since the optimal planning of bus stops in a city forms an important up-to-date subject it is a good example to demonstrate students the application and usefulness of mathematics outside school. To find out whether working on exercises dealing with management mathematics can foster the interest and pleasure of students for the subject mathematics a number of schools in Germany, more specific the State of Rheinland-Pfalz, were visited by mathematical staff of the University of Kaiserslautern. Two-day modelling projects were given to groups of three to five students currently attending 10th to 13th form in school, i.e. students at the age of 15-19 years. A variety of different projects were presented at the start such that students were able to choose a project matching their interests. One of the projects was called “Where should bus stops be positioned?” where the Continuous Stop Location Problem discussed above was a possible modelling tool. This project was presented and dealt with in two of the participating schools. The students were free to choose a project of their interest. In each school one or two groups of students worked on the bus stop modelling problem which came to a total of 14 students.

The students were given an exercise sheet explaining the significance and importance of optimal bus stops with respect to time and money. The data included a specific road network with information about the position and number of customers at the start (see Figure 1) together with the task to find a minimal number of bus stops for the given road network such that as many customers as possible are able to reach a bus stop within a covering radius of 400m. The discussion of the students with regard to the specific radius is a very interesting example of the extended modelling cycle, but is beyond the scope of this paper. The students were then confronted to tackle the given task by running through a modelling cycle which is well-known in tackling real-world problems and has, for instance, been described in Blum & Leiß (2005) for educational mathematics (see Figure 2). The concept of a modelling cycle was explained to and discussed with all students at the beginning of the two-day modelling period in order to prepare them for the task lying ahead. While the students were working on the projects, teachers and university staff acted according to the

“principle of minimal help” (Aebli, 1978): Students had the freedom to independently discuss and develop ideas; the modelling staff only interfered in small doses to avoid dead-end streets in the modelling process.

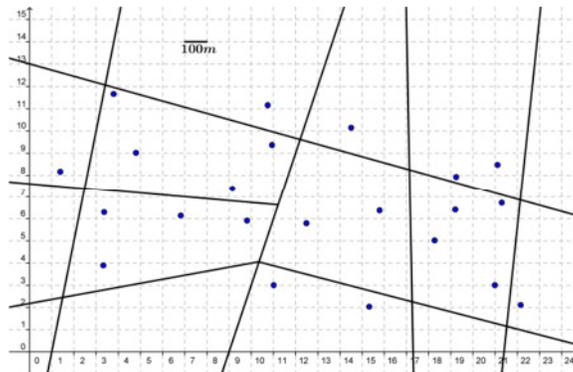

Figure 1: Road network given to students during modelling project (lines indicate streets, points the position of buildings, e.g. hospitals, schools, supermarkets, etc.)

One of the goals of the two-day modelling projects was to improve and strengthen the general mathematical competences (e.g. arguing mathematically, mathematical modelling, communicating) required by the curricula of the German school system (MBWJK, 2007). Additionally, management mathematical topics like locating bus stops were used to motivate students with projects concerning relevant real-world problems as well as improving their understanding of the application of mathematics outside school. Finally, as the previous example shows, these subjects automatically combine and repeat many individual basic contents of school mathematics.

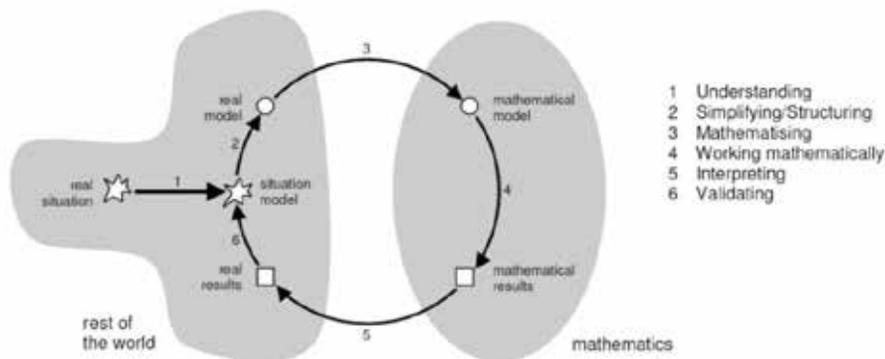

Figure 2: Modelling cycle according to Blum & Leiß (2005)

After having developed a strategy to tackle the problem, the students were asked to generalize their approach such that it could be applied to any other city. In addition, the students examined the city centre of their own city and were able to present optimal bus stops often matching the in reality existing stops, confirming the efficiency of their strategy just developed.

Student Results

The outcome of the two-day modelling project was, in general, very impressive. On their own account the students developed strategies very similar to the algorithm

solving *CSLP* that we have presented above. This can, for example, be seen in the following student solutions (Figure 3). Since most of the students assumed an Euclidean distance measure, circles with the given radius of 400m were drawn around each of the marked customer locations. Afterwards, the students sought for those areas where as many circles as possible intersected and which were then marked red (see left picture of Figure 3). The points where those areas intersected with the transportation network were then defined to be possible places for new bus stops. Choosing points from the highest to a lower number of intersections the number of required bus stops was minimized, exactly as done in the greedy algorithm discussed earlier.

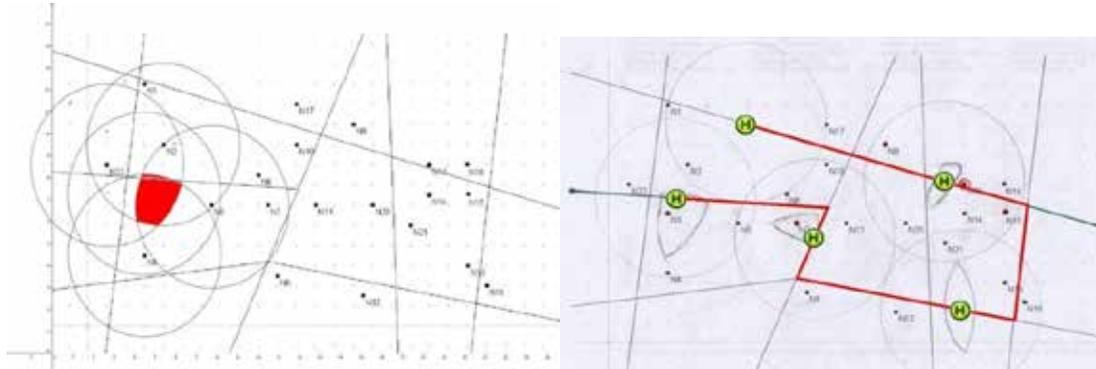

Figure 3: One solution by students of 11th form

Another group of students of 11th form improved this method even more by including the weights, i.e. the number of people at a customer location. The size of the radii drawn around each location was then adapted with respect to the importance of the place considered. The more customers likely to travel from a certain location, the more important it became and, hence, had a smaller radius drawn around its location. The maximum radius allowed remained to be 400m. Other students not only presented solutions for an optimal route but also thought about a most customer-friendly or economic solution, ensuring that a certain percentage of customers was being covered. Some students observing the city centre of their own town developed a grid of triangles placed over the map such that each pedestrian would be able to use a bus stop within reach of 400m. The corner points were then adjusted to the streets as well as taking important places of the city into account. As no distance measure was given beforehand, the students were able to develop alternative ideas to Euclidean distances integrating the nature of street networks into their models.

Evaluation of Survey

At the end of each modelling project the students were asked to fill in an evaluation sheet asking multiple-choice as well as free-answer questions. They were, for example, asked about their overall impression, how they liked the choice of their topic and if they could identify and understand the connection between mathematics and business as well as its usefulness outside school. This empirical survey was used as a preliminary stage for further research planned in this area. It gives a first impression of the usefulness and effect that the integration of management

mathematical topics can have on students in school and justifies its embedding into everyday lessons. Altogether, the feedback was very positive. The multiple-choice questions could be answered on a scale from 1 to 6, where 1 means “very good/much”, decreasing to 6 standing for “very bad/little”. The following table lists some questions with their corresponding average and median student answer, demonstrating the results of the 14 students working on the project “Where should bus stops be positioned?”

Question	Average	Median
Overall impression	1,9	2
Choice of topic	2,3	2
Were you able to identify the connection between maths and business?	2,0	2
Did you learn what mathematics is useful for outside school?	1,9	2
Did you enjoy working on the project?	1,8	2

These answers show that the students enjoyed the MEAM approach and found the topics of management mathematics on the average “good”. This was also confirmed by the free-answers. For instance, the question “What did you like most?” was answered with statements like “Using classic school mathematics to solve real-world problems.”, “Getting to know applications of mathematics in practice.” or “The material to work on.” In addition to this, observing the students was also very meaningful. It was obvious that the students were working very enthusiastically and enjoyed the teamwork with their schoolmates. Often, students continued working on their projects in the evenings at home, presenting further ideas and solutions the following day. Even students who, at first, seemed a little uninterested or usually displayed a low competence level in mathematics were inspired by the topics and worked very hard and enthusiastic in the end. Since all the students who were tested were very motivated to work on topics concerning management mathematics we draw the conclusion that the inclusion of applied mathematics to the curricula of schools will increase the motivation and understanding of the subject mathematics in schools.

EMBEDDING INTO THE CURRICULA OF SCHOOLS

Optimizing bus stops in a city is a topic covering a lot of different subject-matters specified in the curricula of secondary schools. By didactically reducing and adapting the contents to the abilities of the students in question this topic could also be discussed with students in lower grades. Especially the required geometrical competences to solve the problem can already be achieved in 5th and 6th grade. The curriculum for 5th and 6th grade of the German school system in the State of Rheinland-Pfalz (MBWJK, 2007) lists general mathematical competences like “arguing mathematically”, “mathematical modelling” or “communicating”, as well as content-related competences that should be learned by students of this age. These

topics include drawing circles and identifying center point, radius and diameter, getting to know the difference between a straight line and a line segment, using the Euclidean distance to describe the shortest distance between points and learning how to use dynamic geometry software. These subject-matters already form a good background to study the Continuous Stop Location Problem on a visual, geometrical basis. The curriculum for 7th and 8th grade introduces the absolute value, while the theoretical calculation of intersection points as well as solving systems of linear equations using matrices is not covered until 11th or even 13th grade (MBWJK, 1998). The difficulty in reducing the topic of optimizing bus stops to the competence level of a group of students lies with the different backgrounds and knowledge the students might have gained so far. It might be necessary to introduce the theory of graphs in one class while another group of students might have already studied and used these in other subjects, e.g. computer science. Management mathematical topics are, hence, also very suitable for interdisciplinary education and can show students the important connections of their subjects in school.

There is a variety of possibilities how to insert the topic of optimizing bus stops into everyday lessons at school. This could, of course, be done by means of a modelling problem as shown above, usually taking at least 3 to 4 lessons of 45min each. In doing so, the teacher should not be expecting a specific solution but remain open for all kind of solutions presented by the students. Most of the teachers may find this very hard as they are used to pose questions to the class where they know the exact answer beforehand. For this reason, continuing education training courses for interested teachers with the aim to learn how to organize and teach modelling projects in school are regularly offered at the University of Kaiserslautern and find great acceptance among teachers. On top of that, the teachers should of course be familiar with the mathematical content concerning the modelling task. As we have pointed out, modelling projects dealing with subjects of management mathematics are very attractive to all students tested and are a great possibility to not only combine different topics learned in school but to also improve the capability of working in a team, discussing mathematical matter as well as improving modelling competences, which are all part of the mathematical competences required to be learned according to the German curricula for secondary schools. Another method would be to include this topic into the standard lessons, either using it as a motivating example or to strengthen already learned tools. This could, for example, be done at the beginning of the topic “Linear Algebra & Analytical Geometry” in 11th – 13th grade (MBWJK, 1998) driving towards the exact calculations of geometric intersection points. Motivated by this interesting example and its usefulness, students could at first develop geometric ideas guided by their teacher, learning afterwards how to implement these ideas theoretically.

SUMMARY AND CONCLUSIONS

The optimal planning of bus stops in urban areas is a management mathematical topic suitable to be taught in schools. Dealing with up-to-date mathematical problems can

lead to greater motivation and understanding of the subject mathematics and its application outside school. This was tested in a preliminary survey during two-day modelling projects with students of various schools in Germany and showed how enthusiastic and interested students of all competence levels can be when dealing with management mathematical topics. Integrating real-world problems to lessons in school can not only increase motivation but also prepare students for further studies and their working life after school. This can, for example, be done by introducing modelling problems. Their solution procedure combines different topics learned in school and also enhances mathematical competences like “mathematical modelling” and “communicating”. Management mathematical topics are also a good opportunity to be included into the curricula of secondary schools while being compatible with the guidelines given therein. Examples like the optimal planning of bus stops can be used to motivate at the beginning of a new topic as well as strengthen already learned facts. Hence, we conclude that management mathematics should be included in the lessons in schools more often as this increases motivation, understanding and pleasure for the subject mathematics.

ABOUT MATHEMATICAL MODELING IN THE REALITY OF THE CYBERNETIC WORLD

Marcus Vinicius Maltempi and Rodrigo Dalla Vecchia [1]

UNESP - Univ Estadual Paulista and Universidade Luterana do Brasil, Brazil

In this article, we explore the relation between mathematical modeling (MM) and the cybernetic world, understood as any environment produced with digital technologies. We seek to provide evidence that the MM practiced in the reality of the cybernetic world has singular characteristics that interfere in the process of constructing models. Toward this end, we discuss reality from a theoretical perspective, in order to understand the reality of the cybernetic world. This understanding is related to data collected while working with university-level mathematics students as they develop electronic games using the Scratch programming environment. We conclude that the reality of the cybernetic world is one dimension of reality with specific characteristics related to space, time, and plasticity, which opens up new possibilities for using MM in mathematics education.

INTRODUCTION

Research and teaching practices that link mathematical modeling (MM) and digital technologies, pointing to a synergy between the two, are increasingly common (Campbell 2010; Siller & Greefrath 2010; Greefrath 2011; Borba & Soares 2012). According to Kaiser (2011) and Dalla Vecchia & Maltempi (2012), despite the existence of different conceptions of MM, the issue of reality is always present, leading us to assume that there is an intrinsic relation between MM and reality. The nature of reality is a delicate question, however, which is further complicated in the context of digital technologies, generating descriptors such as: reality of the cybernetic world, augmented reality, hyper-reality, virtual reality, mundane reality, physical reality, etc. Thus, we question whether the reality to which MM refers encompasses the reality of the cybernetic world, and seek to identify the specific characteristics of MM in the context of this reality.

Seeking answers to these questions, we present a theoretical discussion regarding reality followed by results of a study conducted with university-level mathematics students, aiming to understand mathematical modeling as it is practiced in the cybernetic world.

REALITY AND REALITY IN THE CYBERNETIC WORLD

In this article, we assume the perspective of reality proposed by Bicudo (1999, p. 31, our translation), understood as:

a dynamic, temporal, historical whole, perceived in the man-world encounter, not separate from the perceiver, who speaks of it and interprets it, building a web of

meanings in the intersubjectivity upon sharing experiences and communicating interpretations.

Thus, reality can be understood as lived reality that occurs in specific times and spaces, constituted in the natural field where all thoughts, actions, and perceptions of the different subjects who live in it originate. We ask, however: Can the cybernetic reality be understood as a dimension included in this reality?

Research by Bicudo & Rosa (2010) suggests that it can. However, considering the cybernetic world as reality requires conceiving of it from a perspective that differs from that of modern science, which speaks of physical, objective reality by referring to the place and time where measurable entities, which can be physically manipulated, are located or placed. As Bicudo and Rosa point out, from this perspective, the cybernetic world cannot be considered real, given that the “whereabouts” of this world presents itself in a different manner. In philosophy, however, we find that the real, and consequently, reality, can have distinct ways of showing themselves, involving, among other aspects, the actual and the virtual (Granger 1994).

The actual can be considered that situation or entity which shows itself to the observer who contemplates the here and now, i.e. that which appears in mundane reality. Actualization is the process by which something moves from a situation of potentiality to the actual state, in which potentiality signifies “characteristic of what is potent, of that which has the force to be, which carries within itself the potential to become” (Bicudo & Rosa 2010, p. 24, our translation). According to these authors, the opposite of actual is the non-actual, i.e. that which was not actualized and is in a state of potentiality, including the virtual, which “refers to the way, in general, that it could become actualized through actions that are together with the available materials and the techniques, in particular applications, explanations of the empirical, etc.” (p.27, our translation). In other words, the essence of the virtual lies within itself, and is not necessarily linked to the actual, although it may contain situations that may become actualized. For this actualization to occur, the act and the material must occur at the same time, rendering it dependent on them, in such a way that the nature of the material conditions the manner in which the actualization takes place. In addition, according to Granger (1994), the reference is responsible for the relation between the actual fact and the virtual fact, and in the reality of the cybernetic world, this reference is based on the scientific and technological device being used, which supports the actualizations that occur in it (Bicudo & Rosa 2010).

Thus, the virtual is real but not actual, because it has not yet happened through acts and the material at hand. According to Granger (1994), the sciences (mathematics in particular) do not deal directly with facts presented to the observer in mundane reality, i.e., actual facts; rather, they deal with virtual facts. In this way, we could say that mathematics is virtual, but has the potential to branch out into actual facts. Physics and chemistry, for example, avail themselves of mathematics, but they use it

as a tool in their theoretical constructions, which are not exact like mathematical theory, since no matter how theoretical they are, they operate with mathematical apparatuses (mathematical knowledge, formulas, ways of operating, etc.) and the empirical dimension in which our acts take place. According to Bicudo & Rosa (2010), computer science also operates with mathematics (which, as we said, is virtual) and, unlike physics and chemistry, deals with another dimension of available “material and form”, namely: communication, information, and the creation of programs within a landscape pre-established by mathematical knowledge. And upon actualizing the virtual (the potentiality present in the mathematical apparatus) through form and the available material and effectuated acts (decisions), reality is being constituted which, therefore, also encompasses that which is addressed in the cybernetic world.

Thus, actualizations in the sphere of the cybernetic world emerge from the relation of the human being with the scientific apparatus, through commands, languages, and actions that occur in the encounter between human and computer as well as in the communication between humans and others subjects that is made possible by the system of technological reference. In this broad dimension of reality, which opens up to the experience of the subject, space and time are of a different nature, being more branched out and fluid, such that actions may not actualize in the same manner as they do in everyday lived reality without digital technologies. Thus, we see the reality of the cybernetic world as assuming a plasticity that enables the construction of environments in which the physical relations established in the mundane can either be experienced or totally ignored.

Understanding the cybernetic world as a dimension of reality, as a modality of lived reality, implies the emergence of a set of possibilities that can be investigated, in the philosophical as well as educational fields. Based on the above, it is our understanding that the essential aspects of the reality of the cybernetic world are associated with singular time, space, and plasticity, constituting a basis for investigation of the mathematical modeling process when the situations involved address this broad dimension of reality. Thus, in a broad sense we assume MM to be a dynamic and pedagogical process of building models grounded in mathematics ideas that refer to and aim to address problems of any dimension encompassed in reality.

MATHEMATICAL MODELING IN THE CONSTRUCTION OF ELECTRONIC GAMES

The cybernetic world is a singular space where the actions taken may not be actualized in the same manner as they are in everyday lived reality without digital technologies. Aiming to investigate MM in the reality of the cybernetic world guided by qualitative research methodology, we ministered a course entitled “Construction of Electronic Games”. We believe that the construction of electronic games paves the way for the locus of the happenings that are related to the situations of the game to be

the reality of the cybernetic world. This enables investigation of MM in which the “where” of the happenings is a space that differs from the classical physical notion, thus making possible advancements in understanding of the nature of MM practiced in the reality of this world.

Eight university-level mathematics students participated in the course, which took place in eight 4-hour periods from May to July, 2009. The set of information composed of their words and gestures and their interactions with each other and with the software and other media constituted a fundamental part of the data analyzed. Data was collected using written notes, cameras and mainly by means of the Camtasia software, which makes it possible to capture simultaneously the image of the computer screen and images and audio of the students as they interact with them. Parts of the video and audio recordings were transcribed, categorized and analyzed according to our theoretical referential.

The main software program used was Scratch, a free software, developed at the Massachusetts Institute of Technology (MIT), which was conceived based on many ideas from Logo. It is a visual programming language that allows users to construct, interactively, their own stories, animations, games, simulators, songs, and art. The commands are composed of blocks that are dragged to a specific area and connected, creating a program that can be executed. Some excerpts from a program made with Scratch are presented in Figure 1.

Within the perspective of MM adopted, we consider a program, or part of a program, made with Scratch to be a model, as we assume that it is the result of an association of situations from reality (actual facts) with concepts related to mathematics (virtual facts), by means of a reference. In this case, Scratch assumes the role of reference which apprehends the situation being investigated, enabling the manipulation of concepts and symbols according to logical formal rules (propositional calculus). The set of commands that can be actualized in the cybernetic world is limited, but they can be interwoven to configure more complex commands. This reference makes it possible to work with a set of pieces of knowledge associated with science and that branch out and become interwoven as users/authors interact with the situations they wish to represent using the Scratch language.

RESULTS AND ANALYSIS

In this section, we analyze data collected with one pair of students in interaction with the second author of this paper and his assistant, who ministered the course. These students decided to create a game in which a car, controlled by the player, would navigate around obstacles that appeared on a road. At first the students created a model (part of a program) responsible for the movement of the car that allowed its vertical movement over the entire window (area used to execute the program). However, the car’s movement extrapolated the region occupied by the road in the

image, giving the impression that the object was floating. Laura, one of the students, then posed the question: *And how do we get it to stop floating?*

The effort to re-create a movement similar to an automobile in mundane reality was what guided the consequent steps to solve this problem, as can be observed in Laura's description of her objective: *I want to... like, if it reaches this height here, this (x,y), it stops. It moves zero steps. Otherwise it will go there, up above. I don't want it to go beyond this height; in this case, I can't go above or below the road. I want it to go only on the road.* Thus, it can be observed that the student's reference is clearly a fact that actualizes in the mundane world, which is the movement of the car in this dimension of reality.

On the other hand, the thing that generated all this questioning was not a specific situation that occurred with an automobile and experienced by the student in mundane reality, but rather actions that involved the manipulation of Scratch while creating a game, and which were actualized on the computer screen. The situation, in this case, only revealed itself to be problematic to the student within the reality of the cybernetic world, since it allowed the structure that was built to become actualized in a different way compared to everyday experience. Thus, there was a sort of tension created between what was imagined by the pair of students and what was actualized in cyberspace, creating a problematic field that led to various actions by the students.

With this, one can see how the cybernetic world opens the way for "realities that are possible, projected, and invented" (Bicudo & Rosa 2010, p. 20), and that this creative process can configure itself in the tension generated between aspects that refer to situations inspired by mundane reality and the potentiality provided by the plasticity of the cybernetic world which, through actualization, makes it possible for occurrences experienced in this space to extrapolate the physical situations of the everyday.

The model for the movement of a car, created by this pair of students using Scratch, ceases to be something imagined or thought and becomes a fact that is subject to manipulations of the language itself. This manipulation of the language involves a web of concepts, notably supported by mathematics, which allows the situation being investigated/modeled, when apprehended by language, to be altered or modified, enabling actualizations in the cybernetic world that are distinct from those that occur in mundane reality (a floating car, for example).

To achieve their objective, the pair of students made changes in the model associated with the movement of the car throughout the construction process. In the first model, presented in Figure 1a, there are in fact no limits to the movement of the car. In Figure 1b, however, the model includes conditioners that allow movement only within stipulated limits. Thus, although the player decides how to move the object, all the actions are previously established by the model. Unlike mundane reality, the fact actualized by the model in the reality of the cybernetic world is completely

determined by the model itself, which is also characteristic of this dimension of reality in the face of the model constructed.

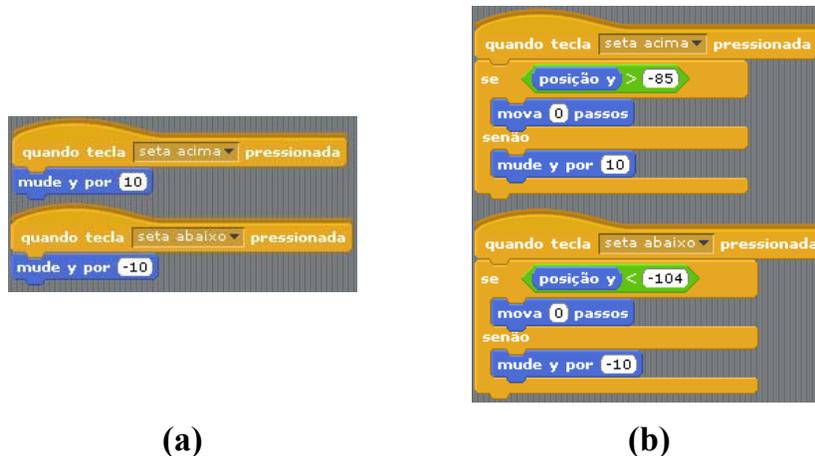

Figure 1: Initial model (a) and final model (b) made using Scratch

In this sense, we understand Bicudo & Rosa (2010, p. 28) when they state that “[...] reality in cyberspace is virtual because it is based on the sciences, notably mathematics”, i.e. it is a dimension of reality, but it lends itself to virtual adjectification because it is totally supported by the scientific apparatus. This common base enables a complete determination of the operations, which are actualized in the reality of the cybernetic world.

According to Bicudo & Rosa (2010), this determination is compensated by the multiplicity of ways in which these actualizations can take place. In the specific case of MM, which involves a process of construction, this multiplicity does not reveal itself only in the possibilities that the (ready-made) model offers, but also in the very construction of the model itself, allowing a multiplicity of possible paths which influence the final structure, depending on the way they are actualized in the reality of the cybernetic world, and the objective of those involved. This aspect can be observed at two different moments during the interaction between the Laura and the researcher:

Laura: And how do we get it to stop floating?

Researcher: You need to put some conditioners, right? It’s going to stay stopped there, right? [Referring to the horizontal movement].

Laura: It stops.

Researcher: Does it stop or... does it “move” zero steps?

Researcher: Or... stop moving. So you can put, change X to Y, you can put an “if”. An “if-else”...

Laura: Put an “if-else”, then, in the middle of this here [of the commands]?

Researcher: Right. “if-else” or “if”, I’m not sure. You would have to test it there to see what works.

The researcher's last suggestion indicates that one of the ways to find a solution is to test the different possible paths, indicating that the idea of multiplicity is present not only in the actualization of the game by the player, but also in the process of constructing the game itself. The following excerpt indicates a new multiplicity of paths to be followed:

Laura: When the y mouse is equal to, in this case, to this point y here [pointing again with the mouse to the position of the car and observing that it is located at $y = -65$]

Assistant: Equal or less. I'm not exactly sure what the objective is there.

Laura: OK, so I'm going to experiment.

In this excerpt, the research assistant expresses doubt regarding the path to be taken, indicating two paths ("equal or less"). These distinct possibilities are taken up by Laura, and her subsequent actions show that the use of the word "experiment" was associated with the use of all three symbols that the command could assume, thus presenting a multiplicity of paths.

In this way, we affirm that the MM activity presented involved a problem that resulted from the tension created between what was imagined by the students and its actualization in the cybernetic world, which revealed aspects that differ from the actualization of an automobile in mundane reality. This difference, in the analysis presented, occurred by means of the apprehension of the phenomenon by the reference, which is given by the Scratch language. Because it has the same structure as the cybernetic world, the constructions of the model and of space itself are interwoven, showing that, in the reality of the cybernetic world, the model (which is the apprehension of the phenomenon by the reference) completely determines the possibilities of the player's action. In addition, the follow-up actions related to the problem of the car were associated with the change and adaptation of the model to the situation desired by Laura, which consisted of keeping it within the limits of the road. This process involved experimentation with various different commands. When the car failed to behave as desired, changes were made. These changes in the model continued until the model was adapted to the desired situation.

This is consonant with some views of MM that see the effort to adapt the model to the situation as an important stage in the modeling process, as in research carried out by Bassanezi (2004), Biembengut & Hein (2007), Borromeu Ferri & Blum (2010), and Kaiser, Schwarz & Tiedemann (2010). According to these authors, the adaptation of the model, or of the solution the model provides for the situation to which it refers, is denoted by validation, and can be consolidated through comparison of the data obtained using the model to the empirical data. If the comparison is unsatisfactory, the model is re-formulated to find a better solution.

When another pair of students in the course was analyzed, however, we observed that they did not proceed to reorganize their model when faced with a situation that failed

to behave as they wanted. Rather, they sought to re-organize the entire visual environment in which the model was referenced and would become actualized. These students decided to create a game in which the objective was to navigate on a map of a fictitious city by changing two variables, denoted “meters” and “degrees”. The map was initially created based on an image the students obtained from the Internet (Figure 2).

Figure 2: Map in the Scratch programming environment

When the MM addresses a problematic situation from the cybernetic world, it can be influenced by mundane reality, as discussed above. Nevertheless, it is still possible to see aspects related specifically to the context of the cybernetic world. The experience of this second pair of students is an example of this, in which the “where” characteristic of reality in cyberspace shows itself decisively in the way they develop their work, broadening the mundane possibilities. It is precisely based on this potentiality of creation and re-creation of spaces that we believe the MM process can manifest itself differently compared to cases where the reference derives from the everyday, since it is supported by a reality that can be constructed, imagined, thought and re-thought, showing an environment that is plastic and transforms itself.

Some of the problems faced by this pair of students involved the relation between the scenario (map) and the object that moved in it. The object was supposed to return to the stipulated starting point upon touching the edge of the streets, but this was not happening. The following excerpt shows the researcher attempting to help the students and illustrates one of the singular aspects of the cybernetic world, plasticity:

Researcher: So I think the best thing would be to put a stronger border here. [Referring to the edge of the streets in the image represented on the map]

Fernanda: Do it with Paint, maybe. [Referring to the software Paint, which can be used to edit images. This idea was later abandoned in favor of using the software Excel].

The researcher shows that one possible solution to the problem presented by the model created by the students would not involve changing it, but rather changing the

background scenario that limited the action of the object. The researcher's suggestion reveals a plastic view of the cybernetic world that was immediately corroborated by the student. This agreement led the students to change the scenario. Initially, they aimed to totally deconstruct the model, i.e., to build a completely new one. However, the use of the Excel software allowed them to re-build it based on the original map. It was at this moment that the student, Fernanda, again showed that she considered the space where the model was being constructed to be malleable, revealing an aspect that is very distant from a reference to the physical, mundane reality which is already actualized. This aspect can be observed mainly when the students say: *We can make it thin, like this, and afterwards we can augment it, OK?*

Our interpretation is that there was a concern regarding the borders and the thickness of the streets, perhaps influenced by the researcher when he suggested making the border "stronger". However, when the student says, "We can make it thin, like this", we believe the student was, at first, attributing importance to the outline of the streets in the construction of the map; but the rest of her comment, "and afterwards we can augment it", revealed that the malleability of the construction of the environment was already incorporated. In other words, the student was not initially concerned about all the details that constituted the map and could influence the commands used, since the environment constructed could be modified to fit the desired format.

This observation strengthens the idea of the plasticity of the reality of the cybernetic world and reveals a singular aspect when we perceive the problematic situations of this construction from the perspective of mathematical modeling. In fact, when the reference is mundane reality, the model is normally "refuted"; however, in the reality of the cybernetic world, it is possible to refute the "reference", and maintain the main idea. With this, one observes the existence of a potential space where it is possible to consider naturally situations in which a model was invented by the students. The plasticity of the cybernetic world, allows, at least potentially, the creation of a space in which imaginative aspects can be actualized, thus representing a differential for the practice of mathematical modeling itself.

NOTES

1. We would like to thank the members of the GPIMEM-Technology, other Media and Mathematics Education Research Group and Anne Kepple for their careful reading of earlier versions of the text and suggestions, and Maria Viggiani Bicudo for helping us to understand some philosophical questions regarding reality. This research was supported by the Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP).

PARENTAL ENGAGEMENT IN MODELING-BASED LEARNING IN MATHEMATICS: AN INVESTIGATION OF TEACHERS' AND PARENTS' BELIEFS

Nicholas G. Mousoulides

University of Nicosia, Cyprus

As part of a larger project aimed at promoting mathematical modeling as an inquiry based approach to mathematics and science, this study aimed to: (a) describe teachers' and parents' beliefs about inquiry-based mathematical modeling and parental engagement, and (b) explore the impact of a modeling-based learning environment on enhancing parental engagement. The research involved three sixth-grade teachers and 32 parents from one elementary school. Teachers reported positive beliefs on parental engagement and parents' potential positive role in implementing innovative problem solving activities. Parents expressed strong beliefs on their engagement and welcomed the modeling approach. Implications for parental engagement in mathematics learning and further research are discussed.

Keywords: Parental engagement, teacher beliefs, modeling, interdisciplinary problems, model eliciting activities.

INTRODUCTION

This study argues for an inquiry-based approach in the teaching and learning (IBL) of mathematics, one that is based on a models and modeling perspective (Lesh & Doerr, 2003). A modeling based IBL approach can serve as an appropriate means for bridging complex real world problem solving with schools mathematics (English & Mousoulides, 2011). This bridging is necessary, as complexity gradually appears in all forms of the society and the education, and new forms of mathematical thinking are needed (English & Sriraman, 2010). With this into account, researchers and educational policy makers highlight the need to promote an IBL approach in mathematics that enhances students' abilities in designing experiments, predicting complex systems, manipulating variables, working in teams, and effectively communicating with others (Lesh & Zawojewski, 2007).

Integrating such an innovative approach in mathematics is not a straightforward process. It conflicts with various factors, including national curriculum requirements, the need for more time and resources, teachers' beliefs and practices, and parents' beliefs and attitudes towards such innovations. The significance of parents' role in mathematics education has been documented in a number of studies (see Epstein et al., 2009), and parental engagement has been documented as a positive influence on children's achievement, attitudes, and behaviour. However, to achieve appropriate parental engagement teachers have to find appropriate methods to involve parents,

especially when it comes to use innovative methods, like mathematical modeling (Deslandes & Bertrand, 2005).

There is a lack of studies that focused their research agenda on the parents' role during the implementation of innovations, such as mathematical modeling. To this end, the present study focuses on designing a teaching experiment on mathematical modeling, one that also involves parents, in an attempt to create an environment for engaging parents and creating a relationship between teachers and parents. The study further explores teachers' and parents' beliefs as a means to further improve parental engagement and communication between parents and school.

THEORETICAL FRAMEWORK

The theoretical framework review focuses on two strands: (a) instructional interventions to promote mathematical inquiry through a modeling perspective, and (b) parental engagement in the mathematics classrooms with an emphasis on teachers' and parents' beliefs.

A Modeling Perspective in Inquiry Based Learning in Mathematics and Science

In successfully working with complex systems in elementary school, students need to develop new abilities for conceptualization, collaboration, and communication (Kaiser & Sriraman, 2006; English & Sriraman, 2010). In achieving these abilities, a number of researchers propose the use of an inquiry-based approach in the teaching of mathematics, one that builds on interdisciplinary problem-solving experiences that mirror the modeling principles (Haines, Galbraith, Blum, & Khan, 2007; Lesh & Doerr, 2003). Specifically, the present study proposes introducing Engineering Model-Eliciting Activities (EngMEAs) within the mathematics and science curriculum; realistic, client-driven problems based on the theoretical framework of models and modeling (English & Mousoulides, 2011).

Engineering Model Eliciting Activities (EngMEAs) have been in the focus of our work for the last few years (see Mousoulides, et al., 2008; English & Mousoulides, 2011). EngMEAs provides an enriched modeling approach by offering students opportunities to repeatedly express, test, and refine their current ways of thinking as they endeavour to create a structurally significant product for solving a complex problem. The development of the models necessary to solve the EngMEAs has been described by Lesh and Zawojewski (2007) in terms of four key, iterative activities: (a) Understanding the context of the problem / system to be modelled, (b) expressing / testing / revising a working model, (c) evaluating the model under conditions of its intended application, and (d) documenting the model throughout the development process. The cyclic process is repeated until the model meets the constraints specified by the problem.

Parental Engagement

Parental engagement has been documented as a positive influence on children's achievement in mathematics, regardless of cultural background, ethnicity, and

socioeconomic status (Epstein et al., 2009). A significant body of research provides solid support for building parental engagement, by reporting a constant correlation between increase in parental engagement and increase in student achievement and students' success, socially and emotionally (Cutler, 2000; Epstein et al., 2009).

Active parental engagement, however, is quite difficult to be maintained. Therefore, programs of parental engagement should be carefully designed and implemented, taking into account all related variables and barriers (Musti-Rao & Cartledge, 2004). Musti-Rao and Cartledge (2004) argue that schools should be less concerned about parental engagement in schools, and more concerned about determining what role parents can play so that parents productively involve themselves in their children's education. They suggest inviting parents' experiences in science, technology, and engineering into discussion, and including parental engagement strategies in teacher professional development courses. They also propose a number of strategies for engaging parents, such as mathematics and science fairs, community involvement utilizing science and engineering experts, and the establishment of a clear communication between teachers and parents, in an attempt to bridge teachers' and parents' beliefs and expectations (Musti-Rao & Cartledge, 2004).

Epstein and Van Voorhis (2001) identify teacher beliefs as an important barrier to creating effective relationships between home and school. They report that teacher beliefs could impact the relationship between parents and teachers. Teachers enter the teaching profession with personal (positive and negative) beliefs about parental engagement that may not be addressed until they interact with students' families and that might result in not involving parents and other community members in the classroom. Teachers who believe that parental engagement could contribute to positive student learning outcomes are more likely to be involved in parental engagement practices than teachers with negative views.

Parents' beliefs on mathematics teaching and learning and the significance of their engagement might also impact parental engagement. Often, the beliefs and expectations between families and educators are not shared collectively, and in many cases parents might have negative beliefs that can lead to stereotypes regarding the relationship between them and teachers. In order for parents' beliefs to change into positive ones, parents should be open to invitations to be engaged in school mathematics, while more parental engagement training on how to work with parents and communities is needed for teachers (Cutler, 2000; Epstein, et al., 2009).

THE PRESENT STUDY

The Purpose of the Study

This study investigated teachers' and parents' beliefs on parental engagement during the implementation of a modeling activity, and examined the impact of Twitter[®], a contemporary technological tool, as a means to facilitate: (a) parental engagement and (b) the interactions between the students, the teacher, and the parents.

Participants and Procedures

The research presented in this study was part of *PRIMAS*, a larger research design that includes: (a) inquiry-based mathematics and science instruction, (b) integration of engineering model-eliciting activities as a part of the mathematics and science instruction, and (c) examination of various forms of parental engagement, including workshop participation, participation in classroom activities, and communication with teachers. During their participation in *PRIMAS*, a longitudinal four-year project on Inquiry and Modeling Based Learning in Mathematics and Science, 62 elementary and secondary school teachers in Cyprus participated in workshops on inquiry- and modeling-based teaching and learning in mathematics and science. During workshops teachers were provided with appropriate student and teacher materials for integrating modeling in their day-to-day practices.

This study followed three teachers who implemented modeling activities in their classrooms. The teachers were from one public K-6 elementary school in the urban area of Nicosia, the capital of Cyprus. One teacher used to teach both mathematics and science in one class, while the other two teachers used to teach mathematics and science respectively in a second class in the same school. The two classes (22 and 19 eleven-year old students), their parents and the three teachers worked on the *Water Shortage* activity, during the second year of the *PRIMAS* project.

Prior implementing modeling activities in their classrooms, the three teachers attended three five-hour workshops on afternoon or Saturday sessions. An additional workshop on the use of Twitter[®] and on parental engagement good practices, also took place. In one of the first three workshops and in the additional workshop, one parent from each student family was also invited to participate. Twenty-eight out of the 41 parents accepted the invitation and participated in the two workshops, which were conducted by *PRIMAS* personnel.

The three workshops provided teachers with some insights on IBL, mathematical modeling, and on parental engagement in mathematics. An introduction to the *Water Shortage* activity took place in the last workshop. During the second part of the workshop teachers and parents were introduced to Twitter[®] and on the possibilities it could provide for the mathematics classroom, as an online technological tool which can break down the rigid classroom schedule barriers and allow teachers, students, and parents to collaborate. Teachers were actively engaged during the workshops, as they shared questions, suggestions, and examples from their own practices and beliefs.

The Implementation of the Water Shortage activity

The *Water Shortage* model eliciting activity entailed: (a) a warm-up task comprising a mathematically rich newspaper article, designed to familiarize the students with the context of the modeling activity, (b) “readiness” questions to be answered about the article, and (c) the problem to be solved, including tables of data (see Table 1). The

activity asked students to assist the local authorities in finding the best possible country that could supply Cyprus with water.

The problem was implemented by the teachers and the author. Working in groups of three to four, the students spent five 40-minute sessions on the activity. During the first two sessions the students worked on the newspaper article and the readiness questions and familiarized themselves with Google Earth and spreadsheet software. During group discussions students identified the significance of the problem and submitted a relevant tweet (one Twitter[®] account was created for each group of students). Twelve parents commented on students' tweets, by emphasizing that water shortage was among the country's most important problems. Some parents further provided additional sources of information. During the second session students reviewed their parents' comments and suggestions that were provided through Twitter[®].

Country	Water Supply per week (m ³)	Water Price (m ³)	Tanker Capacity (m ³)	Tanker Oil cost per 100 km	Port Facilities for Tankers
Egypt	3 000 000	€ 4.00	30 000	€ 20 000	Average
Greece	4 000 000	€ 2.00	50 000	€ 25 000	Very Good
Lebanon	2 000 000	€ 5.20	30 000	€ 20 000	Average
Syria	3 000 000	€ 5.00	30 000	€ 20 000	Good

Table 1: The provided data for the four countries

In the next two sessions students worked on solving the problem. They developed a number of appropriate models for solving the problem, and shared these models with their teachers and parents. During model development students were prompted by teachers to share their ideas with their parents. To facilitate model sharing, a public Wiki was created, in which students could easily upload their files. Student then shared the links to their models with their parents, using appropriate tweets. Twenty-six out of the 28 parents that participated in the implementation of the activity followed their children's tweets and provided feedback and suggestions to their models. In total, during model development parents and teachers sent more than eighty tweets. However, a significant number of these tweets just encouraged students to continue the good work, while only a few tweets actually provided constructive feedback and identified weaknesses in students' models. During the last session students wrote letters to local authorities (as required by the activity), explaining and documenting their models/solutions. Finally, a class discussion focused on the key mathematical ideas and relationships that students had generated.

Interviews

All three teachers (two females and one male) and six parents (three females and three males), randomly selected out of the 28 parents that were involved in the study, participated in individual semi-structured interviews. Three areas of interest were investigated: (a) participant's (teacher or parent) beliefs on mathematical modeling and the implementation of the EngMEA, (b) parental engagement, and (c) their experiences during the EngMEA implementation with regard to collaboration and communication. The interviews were conducted right after school or in the early evening. Each interview lasted between 45 to 60 minutes and all interviews were audio recorded and later transcribed. Data from the semi-structured interviews were summarized through sequential analysis. A grounded theory approach was adopted. Themes were identified and clustered through axial coding, which was conducted in AtlasTI software.

RESULTS

Results are based on the qualitative analysis of interviews. The results are presented in terms of the themes that arose from the sequential analysis of teachers' beliefs and practices and parents' beliefs, with regard to mathematical modeling and parental engagement.

Teachers' beliefs

Teachers' responses could be summarized in three broad categories: (a) student cognitive goals and teaching effectiveness, (b) student affective goals, and (c) constrains of using a modeling based approach. Teachers had positive beliefs on the impact of IBL modeling-based approaches in students' cognitive gains. "This open approach get the children to think critically, set their own questions to reach the solution, and become independent in solving quite complex problems", a teacher commented. A second teacher added: "I really enjoy teaching [in a setting like this]. This is the only way to teach higher order thinking skills and problem solving skills." Teachers were also emphatic in commenting on the affective goals of using a modeling approach. They claimed that such approaches could help students develop "a love for mathematics and science". A teacher reported: "Some students rarely participate in more traditional lessons. Now, they repeatedly said that they like those activities [Primas modeling activities] very much". Teachers were also concerned with the constrains that are related to mathematical modeling, and especially with time: "There is so little time for extra curricular activities ... modeling activities require a lot of time and efforts; how can you complete, even a part of it [activity], in 45 minutes?" Another dimension of teachers' comments was the use of Twitter[®]: "At the beginning I was sceptical ... but then I was impressed by parents' involvement and how it [involvement] benefited students' work ... I will continue using it [Twitter[®]] in my lessons, when possible. Well, this is obvious from the number of my tweets!" Another teacher added: "I love it! It is great when students and parents are

involved. I had the impression that the lesson was on going; 24 hours a day. This is teaching!”

Teachers explicitly underlined the importance of active parental engagement. One commented: “Parents have good ideas to discuss with their children ... there was a fruitful interaction between parents and children at home ... we had discussions [in class] almost everyday ... based on the interactions with their parents at home”. Another teacher added: “Workshops helped parents to be involved and to realise that everyone was valued and that their role was crucial to the success of the activity. But of course that was not easy; only half of parents participated, right? And I am not sure how many of them spent much time finding resources at home and provided accurate feedback to students’ solutions”. Another teacher shared the same belief, that for fruitful parental engagement careful planning and organization were needed.

Another theme that arose during teachers’ interviews was the impact of parental engagement in students’ growth and involvement. Teachers reported that the activity could not be the same without parental engagement, which was clearly positive and constructive. Teachers also proposed that: “This approach was a good example and we clearly need more good examples in engaging parents in mathematics, which, I believe, is beneficial for students’ achievement”. Another teacher pointed: “Is there a better way to engage parents both at school and home? I do not think so. And I am confident that such appropriate engagement will help children improving their grades and attitudes towards mathematics and science”.

Parents’ beliefs

Parents were enthusiast and welcomed the modeling activity. They found the activity interesting and challenging not only for their children, but also for them. A parent, who was actively involved throughout the activity, commented: “I have been always good in maths ... but the activity opened new horizons for me ... I frequently visited the Wiki and commented on students’ tweets. It was great!” Another parent said: “Such activities could help our children to develop important skills, needed beyond school ... I am very happy that we use such approaches in our school”. Although interesting, the activity was also found to be difficult. A parent mentioned: “Well, I could not know for sure that the solution was correct, and that was somehow annoying. Perhaps more guidance could help”.

All six parents explicitly commented on the partnership climate that was generated. “I had the feeling that we [parents and teachers] were equal partners”, one parent commented. She said: “It was far better than sitting at the back [in the classroom] to watch a lesson. We were actively involved and we had constant communication with our children and the teacher. It was really good”. Another parent added: “I was following teacher’s comments and suggestions and I tried to build on these, by discussing the problem at home with my child ... Yes, it helped our communication”.

To improve parental engagement in schools, parents seemed to unanimously agree that good communication and active engagement was the key. Parents suggested that

a variety of engagement strategies could assist all parents to be engaged. One parent noted: “Attending lessons is not bad, but it cannot be the only way of engagement. I enjoyed the two workshops very much, although I had to leave work early. We should have workshops more often”. Another parent mentioned a strategy currently employed in the school: “Last year children had to work on two projects. Those projects were not focused on maths, but required some maths and science. I would like to see more projects like these, in which I can work with my child at home”.

Although quite satisfied with the situation, parents explicitly mentioned that they expected from school and teachers to do more, in order to enhance their (parental) engagement. It was revealed that school’s climate had a significant impact on the overall effectiveness of parental engagement. From parents’ responses a number of factors were uncovered, showing what schools should do in order to encourage and enhance parental engagement. A parent mentioned that schools should promote parental engagement using various methods, and not only by expecting from parents to be engaged. She said: “Schools and teachers must actively seek and promote the parental engagement. Not all parents are engaged by default”. The importance to implement initiatives that engage students was also mentioned by two parents. One of them mentioned: “Such activities are one of the best ways to engage parents, because their children are also engaged. When children are excited and discuss their mathematics work at home, parents are more inclined to be engaged in mathematics”.

DISCUSSION

The purpose of this study was to examine teachers’ and parents’ beliefs on parental engagement in mathematics teaching and learning, with a focus on modeling as a problem based approach. The results supported the expectation that such an approach was likely to positively affect teachers-parents’ partnership and possibly student outcomes (Epstein et al., 2009). The environment generated, provided opportunities for parents and teachers to establish appropriate communication and collaboration venues, which resulted in improved students’ models (English & Mousoulides, 2011). The modeling activity implementation as a means to engage parents in school mathematics could be considered successful; teachers were increasingly refocusing their teaching to incorporate and respond to students’ ideas and needs, and parents were responding positively to their new roles as engaging partners in their children learning. With regard to Twitter[®], results revealed that Twitter[®] assisted in generating a safe, shared knowledge space in which teachers and parents gained insights into students’ learning, helped students to develop better solutions, and provided more opportunities for reflection and discussion.

During interviews, teachers expressed positive beliefs towards modeling, although they identified challenges and demands in their knowledge and other institutional constrains (Epstein et al., 2009). Using a modeling perspective in mathematics teaching, teachers had opportunities to adopt a more interdisciplinary, real world based approach, in which students’ role was central and parents’ impact had the potential to be very positive. Clearly, teachers’ beliefs were important in determining

parental engagement in their classroom. Positive teachers' beliefs and attitudes were needed to maintain the best possible parental engagement and to build mutual understandings and collaboration for the improvement of mathematics teaching (Cutler, 2000).

Interviews with parents revealed that they hold positive beliefs and attitudes towards innovations in the mathematics classroom, like a models and modeling perspective. Parents also reported significant positive beliefs towards their engagement in schools, indicated at the same time the necessity for the school and teachers to take actions. Parents identified that a clear and constant bidirectional communication venue was urgently needed and they stressed that the modeling environment could be a successful method to achieve this goal. Parents also commented that many schools might focus their partnership activities on forms of engagement, like classrooms observations and formal meetings with teachers, although these were not perceived to be the most effective form of engagement activities.

The findings from this study suggest a need for researchers to expand their definitions of parental engagement, beyond traditional ideas of school and classroom norms, to include a dimension related to active parental engagement and technology rich modeling environments. Despite its limitations, this study provides new insights into the importance of modeling related parental engagement practices in mathematics teaching and learning. It suggests that teachers and schools that have positive beliefs towards parental engagement and facilitate the use of inquiry- modeling-based approaches are more likely to have positive active parental engagement and probably better students' learning results. Unquestionably, students need high-quality instruction to improve mathematics learning. However, if schools, teachers, and parents work together in creating appropriate, collaborative environments, they are more likely to see higher students' learning outcomes.

STUDENTS' DISCUSSIONS ON A WORKPLACE RELATED TASK

Trude Sundtjønn

University of Agder

This study is situated in a mathematics course in the vocational education programmes in Norway. The students worked in small groups to make a budget for a hair salon. The real world connection made the students puzzled by the big numbers they calculated, and offered the students opportunities to discuss and evaluate their answers. They did not trust their own calculations without checking with others and, unsolicited, the students started comparing answers and discussing with other groups. The students were in the first stage of an inquiry process, but rarely moved on to ask their own questions or question their own estimates.

Key words: vocational education, real world, inquiry, task design, discussion

BACKGROUND

In Norway most of the adolescents (over 90%) continue with education after the 10 years of compulsory schooling (Statistics Norway, 2012). About half of them attend vocational education programmes to get a trade certification. These vocational education programmes are mostly structured as two years of school based courses followed by two years apprenticeship. In the vocational education programmes less than half of the students finish on time (The Norwegian Directorate for Education and Training, 2011), and one of the reasons for this is that they fail in mathematics (Norwegian Ministry of Education and Research, 2010).

During the first year all vocational students attend a mathematics course consisting of 84 hours course work. It is a goal stated by the government that this mathematics course should be oriented towards their vocation (The Norwegian Directorate for Education and Training, 2010a), though the content of the curriculum is the same for all nine vocational education programmes. The course consists mostly of topics the students have met before, numbers and algebra, proportionality, percentages, and geometrical shapes. Some new topics include price indices and accounting. From observations of lessons and conversations with teachers my impression is that students have forgotten, are confused about or never have understood parts of the mathematics they met earlier. The mathematics teachers are usually unfamiliar with the mathematics of the students' future jobs.

In a collaborative project with mathematics teachers from different vocational schools in the county, we, didacticians [1] and teachers have started to build a community for improving the teaching and learning in the mathematics course in the vocational programmes (MTPL research group, 2011). This paper is about how a task connected to their future employment encouraged students in a vocational education programme to discuss and use inquiry in mathematics. The research is

based on findings from the pilot study of my doctoral research. The research question discussed in this article is: How and in which situations do students show an inquiry approach on a work place related task?

THEORETICAL PERSPECTIVES AND RELATED RESEARCH

The project is based on the key ideas from the LCM/ICTML and TBM-LBM projects (Carlsen & Fuglestad, 2010; Jaworski et al., 2007) about creating learning communities of teachers and didacticians. This learning community is supported by workshops, discussions between didacticians and teachers and school visits. Inquiry is an important concept in the community (Jaworski, 2005), both as inquiry into mathematics teaching and learning, and as a goal for student activity. Wells (1999) describes inquiry as ‘‘a willingness to wonder, to ask questions, and to seek to understand by collaborating with others in the attempt to make answers to them (Wells, 1999, p. 121)’’. The tasks are provided for the students to experience an inquiry approach to mathematical activities. This inquiry approach can be visible when the students investigate, experiment, ask their own questions and try to find their own answers.

Skovsmose (2001) writes about different milieus of learning, and make distinctions between the tradition of exercises and landscapes of investigations. In both educational paradigms there is the possibility for division into mathematics, semi-reality and real-life references. Inspired by this model and the inquiry goal, the teacher and I aimed to design a task that would be in the landscape of investigations and connected to real-life. The task should be possible to develop in different directions, encouraging the students’ inquiry during the problem solving activity.

To make the students aware of the use of mathematics in their future workplace, the task was connected to the students’ future vocation by use of artefacts like receipts and authentic rental fees. Williams and Wake (2007) note that teachers, students and workers find it difficult to identify mathematics in the workplace. Furthermore research has revealed students’ difficulties with word problems based on real-world situations (Greer, Verschaffel, & Mukhopadhyay, 2007; Verschaffel, De Corte, & Lasure, 1994). The students often disregard the context and give answers that do not make sense in the real world, for instance that one needs 31 remainder 12 buses to transport soldiers (Silver, Shapiro, & Deutsch, 1993). This signalled there was a challenge to make the students aware of and to use the real world connection when they solved the task. The given task was intended to encourage the students to use realistic assumptions and give them the possibility to evaluate their answers.

METHODOLOGY AND RESEARCH SETTING

I first met the teacher in workshops at the university, and he volunteered his class for the pilot study. Information about the research project was given to all participants.

One student declined to participate in the research, and therefore worked apart from the class during the research period. My case is situated in a class of 15 female students aged 16 and 17 who study in the vocational education programme ‘Design and Crafts’. This programme aims at education for jobs like jewellers, dressmakers, hairdressers and florists. According to the teacher, the students’ performance ranges across all attainment levels and there are some low achievers in his class, which is typical for the vocational mathematics courses. There are episodes in the collected data where this is evident, for example one of the students sang the multiplication song to calculate nine times five after saying she is not good at the nine times table.

The class was about to start working on an economics unit, where the competence objective was that the students should be able to “make budgets and do accounting using different tools” and “calculate taxes” (The Norwegian Directorate for Education and Training, 2010b). Together the teacher and I prepared a vocational oriented task about a budget for a hair salon. The task was revised several times before it was used in the classroom, mostly to make the level appropriate and the text clear. Many of the students planned to become hairdressers, related vocations like skin care workers, or other occupations where they would work in a small business. In addition the students, regardless of their future vocation, had experiences being customers at a hair salon. The students spent about two hours (three lessons) working on the budget. The teacher suggested, and I agreed, that I should present the task since I had formulated it, and take the leading role in the classroom with the teacher as observer and assistant. The students worked in small groups of three or four. Both the teacher and I circulated in the classroom to help the students.

The first task was supposed to help the students reflect on their own experiences as a customer at a hair salon. They were asked to write down “what is a usual price for a lady’s hair cut?”, “what is the highest price you could have paid to get your hair cut?” and “what is the lowest price YOU could have cut someone’s hair for? (Remember that you do not get paid the whole price yourself)”. After a class discussion about this the students continued with the second task. This task was to “write down the most important expenses a hair salon has in a month” and “write down the most important income a hair salon has in a month”. Then they were given a sample budget on paper and information on rental fees (per square meter), sample prices on haircuts, electricity, phone prices and so on, and the third task asked them to “use the information you are given. If some important expenses or income is lacking you need to discuss to get realistic numbers”. They were also to calculate the loss or profit. This third task took most of the allotted time for the students.

To do these tasks the students needed to decide prices, how many and what types of haircuts they could manage in a day, which and how big expenses the salon had and so on. This is in line with the inquiry idea where the students should investigate and ask their own questions. From a mathematical point of view there are possibilities for

the students to learn about budgeting, estimation, modelling how many customers they can expect per day, calculating sales tax and area to determine rental fees. Much of this information is connected to rate of change, like haircuts per day, area needed per worker and rent per month. These rates of change are also connected with each other so that if one has many hair colourings per day one need to have more employees or fewer regular haircuts. The students mostly needed ‘elementary’ mathematics like addition and multiplication to start on the budget, but they had to decide and estimate the important information. When the students finished a paper version of the budget, they started to use a spreadsheet. But they used it only to record their data, and did not apply formulas to be able to alter their input. It could have been possible to make a dynamical budget model on a spreadsheet for the students to encourage them to try out different scenarios. The task opened up the possibility for the students to collaboratively inquire into the mathematics of budgeting, and together decide what a good and realistic budget is. There was no definitive correct answer to the task, and the students were challenged to explain and defend their choices, both by the teacher and when the groups talked to each other.

In order to document the activities the lessons were video recorded with one camera. When the task was introduced the video camera had a view of the students and the projector screen. During the students’ work with the task the camera was focused on one group with three students, and their discussions with the group next to them. The students were instructed to work as normal as possible and try not to be disturbed by the presence of the camera. After the lesson, the students’ notes were collected, and I discussed the students’ work with the teacher. This session was audio recorded. The recordings both from classroom activity and my conversations with the teacher were transcribed. I translated the Norwegian transcript into English aiming at the closest fit of words and meanings. No students were interviewed about the tasks.

From the transcripts it appeared that the size of the numbers often puzzled students. This made me curious, and I identified all episodes where the students discussed their answers. The episodes presented below are selected from this set of episodes and are representative of the work done by the students on this task. To observe if the students began to inquire into the mathematics I looked for engagement, if the students expressed puzzlement, what they were puzzled about and if something in the task or their work triggered their curiosity. In addition I noted how and with whom the students sought to discuss and evaluate their answers, and if they asked the teacher, the other students or did something else.

SOME FINDINGS DEDUCED FROM THE DATA

In this paper I focus on the episodes where the students discussed their answers. These episodes were analysed looking for how and in which situations the students showed an inquiry approach in their work. This analysis showed that:

1. The students were often surprised by and wondered about their results.
2. The students compared and validated their results by discussing with other groups or the teacher/didactician.
3. The students evaluated their results, and sometimes reconsidered their initial assumptions.

These observations are possible to link to the notion of inquiry. It can be observed that the students sought to understand their answers, started asking questions and discussed with each other. The following excerpts are from the work of small groups A and B, which were located next to each other. The groups worked separately, but did sometimes interact. In the transcriptions behaviour are written in italics.

The students were often surprised by their results

The students in both group A and B were often surprised and disbelieving of their results. This can be observed in the following episode at the beginning of the first lesson. Group A decided that their classroom was about the right size for their salon, and made an estimate of the size of the room to be about 50 square meters. The rental fee was given as 1200 NOK per square meter, about 160 euro.

Student A1: We'll say 50 then. 50 times 1200. *They take up cell phone calculators.*

Student A2: First to calculate it. Damn. *Pressed something wrong on the calculator.*

Student A1: 60 000.

Student A2: *Laughter.* Okay.

Student A1: Sick. Gosh.

Student A2: In a month?

Student A1: Yes. If we have about this [size of room].

Student A2: Wow. *All three students focusing on their notes and looking surprised.*

This was also evident in the other groups. In group B student B1 claimed loudly that one cannot pay 42 000 in rent to which student A1 replied "we have 60 000 monthly", while the other members of group A giggled. Student B1 showed her surprise by exclaiming "yes, wow!" This surprise can be connected to the real world setting of the task, and that the students had a sense of how much money this is. For the students 60 000 is about equal to three or four months' salary when they start their apprenticeship. This puzzlement made group A and B compare and discuss informally their answers with each other.

The students validated their results by discussion

To confirm their estimates and numbers the students approached both the teacher and didactician and each other. Often the students first asked the teacher/didactician, and then compared with the other groups. It therefore looked like validating with their

peers was at least equally important as feedback from the teacher. Here group A and B were still wondering about the rent, and asked me about it. I explained that “well, but it is actual real numbers”. The students giggled and exclaimed “goddamn. Oh my god”. I then tried to point the students to that “... You earn some [money] also. You do not earn 450 kroner one day in a month, in a way, on a lady’s haircut. You earn some more” to which student B1 contradicted with “not 42 000 NOK”. But student A1 then said “yes, yes, you do [earn] that. Oh my God.” and giggled again.

The students did not appear to be satisfied with my answers, and were still hesitant about the big numbers. I did not provide a “right” solution, but tried to encourage the students to reflect on if there may be an explanation for their seemingly big numbers. They continued to work in separate groups after this exchange, but did not change their answers even though they appeared unsure. The students might also have thought that since I did not say that it was wrong, their solution had to be fine.

The lesson ran out of time, and we continued the next mathematics lesson, four days later. The students worked on deciding income from different items, like ladies’ haircuts, product sales and hair colourings. After doing this the students added up to get their total income and group B again asked me about the validity of their results, and started discussing with group A.

Student B1: But we have only 4 haircutters, and we earn [income of salon] almost a million a month. Is it very unlikely to earn that much in a month? *Addresses Trude.*

Student A1: We have hundred and fourteen [114 000].

Student B1: Hundred and fourteen. What?!

Trude: Then you can evaluate why you have that much difference.

Student B1: Oh my god, we have a million a month.

Student A1: What?

Student B1: *Yes. Smiles and giggles.*

Student A1: Yes, but this [114 000] is a week.

Student B1: Oh, you have calculated a week. Well then.

I tried to ask the students to evaluate why they had different answers, but the comparison between weekly and monthly income appeared to end the progress of the discussion. The students were still interested in the numbers, and when a student from another group came by two minutes later they again discussed their income.

Student A1: Yes, we earn this much a week. Hundred and fourteen thousand.

Student C1: Week?

Student A1: *Giggles.* Yes.

Trude: Weekly?

Student A1: Yes, we calculated a week.

Student C1: We earn, about, eeh, around 75 000 a month.

Student A1: What? *Asks with a sharp voice.*

Student C1: A month. That is lots.

Student A1: That is little. They have a million. *Points to group B.*

The students then continued working without changing their answers. Here I observe that the students compared the answers with each other, and they did not agree about what is too much income. When the group with a million in income was drawn into the comparison everything else appeared small, even though there is a big difference between the other groups. The students' continuation of the work could indicate that the strangeness of the big numbers was reduced with the comparison with the other groups. There may also be a misunderstanding between the students about earnings, income and profit. Both the students and I used the words interchangeably, and this may have caused some of the puzzlement over the amount of money generated.

Evaluating the results and reconsidering assumptions

There were episodes where the discussion between students led to changes in their estimates for the budget. This can be seen by the following episode where group A started to make the budget in Excel after finishing the paper version. Their own notes did not show their estimates, so the group reversed the operations to figure out their earlier estimates. For instance they took 240 000 in earnings from hair colourings, and divided by the colouring price and got 240 persons. The students had assumed that they could colour four persons per employee every day, so four colourings times three employee times twenty days a month. When making the budget for a week they did not reflect on this, but now they started questioning their estimate.

Student A1: Then it is 240 we colour a month. We can't colour 240 persons a month!

Student A2: I believe we can colour about 100 persons, no, not even that.

Student A1: Not even that. Maybe 50, 70 something. Then this is wrong again. How many should we say that we can colour, 50 or 70?

They decided on 70, and continued working. There are also situations where the students compared their results with other groups, and identified the factors that made the differences between the budgets. When group B had finished their budget and calculated the profit they approached group A to compare the results.

Student B1: How much did you have in profit?

Student A1: Wait a minute. First we had three hundred [300 000], now we have two hundred and eighty four [284 000].

Student B1: *Shows her notes with the profit 122 160 kroner.*

Student A1: But you have more employees, we have a bigger salon [in square metres].
You pay 42 000 in a month, we pay 60 000 [in rent].

Student B1: We have four employees.

Student A1: We have three.

Student B1: Yes.

Student A1: Then it is a bit ...

Student B1: We earn actually more [than you].

Here the students realised that one of the important variables in the budget is the number of employees and therefore the ability to generate high earnings. It seemed important to have the best salon, and they gave the impression of being satisfied with having the salon with the highest profit. These competitions between the groups are also evident in other episodes, and the students discussed what is included in the prices in their different salons, like free coffee, the work space and so on.

DISCUSSION

The students looked like they engaged in the task, but this could be an effect of the video recording, and the novelty of a different teacher/researcher. The students were interested in the camera, and there are instances of them singing and dancing in front of it. I will still argue that the students did not act for the camera while working. When they fooled around they did not do mathematics, until they remembered their task. When they started working again they gave the impression of being focused on the task and not the camera. I therefore believe that what they said during their mathematical activity is what they would normally express in the classroom.

The task of making a budget for a small business, like a hair salon, is something many of the students will encounter in their working life. This may have given the making of the budget some authenticity even though it was clearly a task in the school setting. It could be that the real world setting made the students willing to question their answers and discuss them with members of the other groups. This questioning may be an indication that the students were engaging in an inquiry process and started to seek understanding with the others. The puzzlement with the answers, and thereafter discussions seemed to contradict the research on word problems where the students mostly ignored the real world setting.

At the start of the lesson the students and I spent some time discussing different prices at hairdressers, and this gave me the impression that students associated this with their own experiences. This starting activity was helpful when the students made estimates and worked out the budget. The students may have been more aware of the connection to the real world, and therefore more critical of the realism of their

answers. When they are making a budget in their work life they will need to estimate the customer base, and how much income the small business can generate. The task presented in this study could help them to understand how different expenses and incomes are connected to each other.

The task planned to be consistent with Skovsmose's landscapes of investigations with connections to real life references. My findings show that the students displayed a willingness to wonder. They were often surprised by their results, and could be on the way toward an inquiry stance in mathematics. They were seeking confirmations from the teacher and didactician and the other groups to validate their results, and while solving the task the students discussed and evaluated their answers with the others. It looked like they were more likely to trust their calculations when they realised that the other groups had gotten answers that had similarly big numbers. After working with the task for a while they did not seem so puzzled by the big numbers. The students reconsidered and revised their answers when they discussed if they really could colour the hair of 240 persons a month. I sometimes tried to encourage the students to ask questions and stimulate them to discuss what made the differences in their answers, and therefore what would make the most impact on the budget and profit. This was not an easy process to start, and even though the students discussed their answers it rarely went further than comparisons between the groups.

To summarise, the findings suggest that the students showed an inquiry approach in the work place related task when they got puzzling answers. The students tried to correct or validate their solution through asking questions to the didactician or the teacher, and by comparing or discussing with the other students. They sometimes revised their answers, but did not start asking their own questions. This questioning could have been further encouraged if one had more comparisons in the whole class, and challenged the students to defend their choices. This could have been done by comparing the different groups' budgets on a spreadsheet managed by the teacher, and thereby opening up possibilities for discussion and explanations.

To further develop the research and the real world connections the task could be expanded with the students investigating how hair salons make their budget, and what income and expenses they have. They could gather information on a typical daily income of a hair salon, and then revise their budgets. This real data might prompt more discussion and evaluations of their budgets, and possibly be the start of more inquiry processes for the students. To find out why the students did not change their answers it would be informative to interview some students. I will continue the research with other vocationally oriented tasks and other students.

NOTES

1. As in the LCM project I use the term didacticians for the researchers/educators from the university since both teachers and university researchers can engage in the research (Jaworski, 2005).

TEACHER BEHAVIOUR IN MODELLING CLASSES

Katrin Vorhölter, Susanne Grünewald,
Nadine Krosanke, Maria Beutel, Natalie Meyer

University of Hamburg

The paper deals with the question of teacher behaviour in modelling classes and focuses on teacher interventions. Different aspects of interventions are considered, such as triggers of interventions and teachers' purposes as well as effects and consequences of interventions. The presented results indicate that interventions which are based on the demand of explaining the state of work and invasive interventions that are triggered by a lack of students' progress of work can foster students' independent solving processes.

Keywords: Teacher interventions, mathematical modelling, empirical research

INTRODUCTION

Mathematical modelling has been one of the main research areas at the Working Group of Didactics of Mathematics at the University of Hamburg already for a long time. During this time various aspects of mathematical modelling have been investigated. In recent years, the focus has been on fostering students modelling competencies most effectively. At the moment, two different PhD theses are carried out. One of them compares the effectiveness of a holistic versus an atomistic approach (for detailed information see Grünewald, 2012). The other one focuses on the effect of different kinds of teacher interventions (for detailed information see Stender, 2012). Within recent research the question of teacher behaviour in modelling classes and the effects of teacher interventions were analysed. In this paper we will introduce selected results of these current research studies based on two master theses.

THEORY

Mathematical Modelling in the classroom

As mathematical modelling is the topic of this working group, we do not want to outline mathematical modelling in general. But as mathematical modelling in the classroom deals with different aims (see Kaiser & Sriraman, 2006 for an overview), we want to stress those points which are important for our understanding of modelling, which is reflected by the modelling tasks chosen for the studies. Departing from the realistic or applied perspective on modelling described by Kaiser & Sriraman (2006) the modelling tasks dealt with need to be complex in order to foster the pragmatic aims required by the realistic perspective on modelling. This means that the modelling process starts with a question to answer and some background information. Then students therefore have to find out the information they need to work on the task. Sometimes this information can be calculated by given

photos, sometimes the students have to read them up and sometimes they have to make assumptions on the basis of their own experience. The grade of complexity depends on the students' experience with modelling tasks as well as on the time they have to work on the problem. Another characteristic is that the task is not implemented in a special content, so the students are completely unsure which mathematical techniques are useful for solving the given problem. Furthermore, we try to choose authentic tasks, i.e. tasks which are relevant at least for a special group of people, at the best for the students themselves.

Scaffolding in mathematical modelling classes

Teaching is a complex process. In order to support students effectively, teachers not only have to have strong knowledge about different contents, but also about different types of teaching methods and adequate assistance. One theoretical approach that deals with tailored and temporary support that teachers can offer students is scaffolding. Because scaffolding has been studied extensively in the last couple of decades, slightly different approaches exist [1]. However, the central goal of all scaffolding approaches is to enable students to solve problems on their own. For this purpose, students are supported in a very practical way when they are not able to solve given problems or when they get stuck. The support takes place on both the cognitive level (required strategies and concepts) and the meta-cognitive level (instructing self-regulated learning). The main principle is a consequent orientation of the students' individual learning process, which Van de Pol et al. (2010) calls *contingency*. A condition, therefore, is the willingness and the competency of teachers to be responsible for the demands of thinking and understanding of students. So the teacher should have content and diagnostic knowledge. In particular, when students work on complex modelling tasks and can choose mathematical techniques on their own, the teacher must be able to decide in a short period of time, if the students approach is expedient or not. Depending on how self-regulated students are in their working process, the teacher reduces the support, which is called *fading* in the sense of Van den Pol et al. (2010), because the teachers are *transferring the responsibility* to their students.

Within the framework of scaffolding, Hammond and Gibbons (2005) developed a model, which differentiates between scaffolding on a macro- and on a micro-level: on the one hand, teachers can provide or foster different didactical settings (e.g. group work) and consider different students' characteristics (e.g. thinking styles, beliefs). This kind of assistance on a macro-level is called *designed-in-scaffolding*. This can be planned before attending class and has to be based on pedagogical content knowledge as well as on didactical knowledge about the modelling process. On the other hand, teachers can intervene at special times while students are solving mathematical problems. This kind of assistance focuses on a micro-level and Hammond and Gibbons call these interventions *interactional scaffolding*. Interactional scaffolding cannot be planned in detail. The single interventions have

to be based on pedagogical content knowledge as well as on didactical knowledge about the modelling process. Whether these interventions are adequate or not depends on the circumstances in which they occur. Consequently, adequate intervention must be a consequence of a teachers' diagnosis of a students' difficulties while solving mathematical problems.

When talking about different kinds of interventions, one has to distinguish between the trigger, the level, and the effect of interventions. Concerning triggers, Leiß distinguishes between invasive and responsive interventions: every time teachers intervene on their own initiative, the intervention is called invasive. If students ask for help, the intervention is called responsive (Leiß, 2007: 105f.).

The most well-known distinction between different levels of interventions is the taxonomy of assistance according to Zech (2002). He differentiates motivational, feedback, strategic, content-oriented strategic and content-oriented assistance. The intensity of the intervention decreases gradually from motivational assistance to the content-oriented assistance. This classification has been used several times to describe possible assistance in modelling processes (see Leiß, 2007; Maaß, 2007). Based on this categorisation, Leiß created a descriptive analysis of adaptive teacher intervention in the modelling process. The analysed interventions were classified by their trigger, level, and intention (see Leiß, 2007). The main results of Leiß' study were, among others, that strategic interventions are included in the intervention-repertoire of the observed teachers only very marginally and that the teachers often choose indirect advice where students have to find only one step by themselves in order to get over their difficulty. Further studies like Link (2011) cannot confirm these results. This is significant because in these studies it was found that, in particular, strategic interventions lead to metacognitive activities of learners (see Link, 2011). The mentioned studies have one recommendation in common: Maria Montessories' principle "Help me to do it by myself".

Besides different triggers and levels of intervention and the knowledge of the modelling cycle, teachers should also be aware of the role of metacognition within mathematical modelling for a basis of possible interventions. In recent research on metacognition, a distinction between declarative metacognitive knowledge (i.e. learning strategies, person and task characteristics) and procedural metacognitive skills (i.e. controlling, monitoring and self-regulation) is made (Schneider & Artelt, 2010). Stillman, Galbraith, Brown & Edwards (2007) developed a theoretical framework for studying students' procedural metacognition. Galbraith & Stillman (2006) point out that reflections should be related to mathematical content and the processing decisions for fostering the students' modelling competencies. Only in this way can students become better modellers and not just solvers of separate problems.

To sum up, in order to foster students modelling competencies teachers should see themselves as *moderators or facilitators of knowledge* rather than as *disseminators of information* (see Herget & Torres-Skoumal, 2007).

PROJECT SETTING AND SAMPLE

The research results we want to present in the following were achieved within different frameworks. For this reason the conditions of data collection and, of course, the research questions were different in detail, although both projects were focused on teacher behaviour in modelling classes. In the following, we will briefly describe these different conditions as well as the samples and methods used to collect and analyse the data. An overview of the different project settings and samples of the two studies is given in table 1. Beutel and Krosanke (2012) as well as Meyer (2012) analysed teacher behaviour in modelling activities of grade 9 students, but Beutel and Krosanke collected data during modelling days, while Meyer collected data from two of six modelling activities in double lessons that were integrated in normal math classes. The modelling days [2] are carried out once a year for all grade 9 students in one secondary school (Gymnasium). Over three days they are asked to work on one complex modelling task, which they can choose between four different tasks. The students work in small groups and are supervised by two university students who were prepared for this within a master seminar at university. So one can say that these students are experts concerning the special tasks and novices concerning teaching in general. In 2012, 160 students attended the modelling days and were looked after by 32 university students, so each small group contained about 10 students. All groups that had chosen one special task (“traffic lights or roundabout”) were videotaped. During the other modelling project (ERMO, Grünwald 2012) different forms of arrangements (holistic and atomistic approach) were tested against each other in order to evaluate, which is more effective in fostering students’ modelling competencies [3]. For this purpose, around 20 classes of the 9th grade of six secondary and district schools were divided into two groups: group A tackled modelling problems according to the holistic approach and group B tackled modelling problems according to the atomistic approach. The intervention period started in February 2012 with a teacher training. During the intervention period the classes performed six modelling activities. Before the first and after the fifth modelling activity the students wrote a modelling test. In addition to these tests, they filled in a learning questionnaire at the end of each modelling activity and the teachers filled in short questionnaires about the run of the modelling activity. During the modelling activities the students in the holistic group dealt with complete modelling problems with an increasing complexity of tasks. The students of the atomistic group dealt with sub-processes of mathematical modelling separately. The modelling activities of both groups were designed with an autonomously-orientated learning environment – such as small group work, the principle of minimal help and a demand for reflection.

Table 1: Framework of the studies

	Beutel & Krosanke	Meyer
Students	One group of four students in grade 9, secondary school	Two classes in grade 9, divided into small groups, secondary and district schools
Teachers	University students, experts in modelling, novices in teaching	Experienced teachers, novices in modelling
Length of analysed solving process	2 days, each lasting 5 hours	2 lessons, each lasting 1.5 hours
Modelling tasks	One complex modelling task, students chose on their own	Two modelling tasks, all students working on the same task given by the teacher
Data collection	Videotaping of the whole solving process	Audiotaping of the solving processes, interviews with the teachers after each lesson
Data analysis	Qualitative content analysis	
Research aim	Analysis of teacher interventions and the effects and consequences on students behaviour	

Beutel and Krosanke chose one of the videotaped groups of students who worked on the task “traffic lights or roundabout” and analysed the interventions given by the university students. The reasons for the selection of this group were the quality of video and tone, the level of performance and – most importantly – the level of communication (in this particular group every aspect and every assumption were discussed, calculations were read aloud). This special group only consisted of four students who had very low experiences with modelling tasks and were looked after by one female and one male student. The videotaped students worked for ten hours on the question whether traffic lights or a roundabout is more effective for crossroads. Meyer watched the behaviour of two different teachers who were willing to be observed and interviewed from the holistic group during the first and the third modelling activity. Moreover, the two teachers were recorded, so Meyer was able to analyse the teachers’ verbal interaction with the students in detail. After each lesson she did an interview with both teachers.

Beutel and Krosanke, as well as Meyer, analysed their data using qualitative content analysis by Mayring (2010). Beutel and Krosanke reconstructed learners’ problems as well as the teachers’ behaviour, both in relation to the different steps of the modelling process. This proceeding allowed a more sophisticated look at the

potential and the effects of teacher interventions during the modelling process. In contrast to other studies, Beutel and Krosanke analysed the effects of interventions in the context of the complete modelling process by short-term and long-term considerations connected with the solution process of the students. In addition, a more differentiated view was sought on the success of the teacher interventions. So the main aim of the study was to describe the effects of intervention at various levels and to analyse them according to their appropriateness. Meyer encoded all interventions following Leiß (2007), with regard to the three main categories: trigger, level, and intention. The main aim was to investigate teachers' behaviour in modelling lessons, divided into introduction, group work and presentation phase. Furthermore, Meyer tried to relate the teachers' behaviour to the concepts of the role of a teacher as a *disseminator of information* respectively a *moderator or facilitator of knowledge* (see Herget & Torres-Skoumal, 2007).

RESULTS

Beutel and Krosanke, as well as Meyer, analysed teachers' behaviour in different kinds of modelling classes. In the following, we will outline the results of both studies referring to two aspects: different types of triggers of interventions and teachers' purpose of the intervention as well as effects and consequences of interventions.

Types of triggers and teachers' purpose of the intervention

The interventions identified by Beutel and Krosanke were mostly invasive. A detailed view reveals that these interventions were given after a period in which students were not working on the task. So Beutel and Krosanke conclude that teachers intervened not to guide students to solve the modelling task but obviously their aim was to help the students because they had recognized problems. The strategic intervention which occurred most often was the request to present their state of work. As well as strategic interventions, feedback and content-related interventions occurred.

Meyer encoded the interventions of both teachers as mostly invasive, but while the interventions of teacher A mainly referred to organisational aspects of the modelling activities teacher B provided much more content-related help. The analysis of the observed math lessons shows clear differences in the teachers' intervention behaviour and suggests the typing of teacher A as *moderator or facilitator of knowledge* and teacher B as *disseminator of information*. Teacher A as *moderator or facilitator of knowledge* acted in a restrained manner during the different phases of the modelling classes. This, for example, can be seen in the fact that he did not immediately correct students' mistakes such as inadequate assumptions in the solving processes. Teacher B as *disseminator of information* intervened much stronger and more often during the modelling classes than teacher A. Teacher B, for example, corrected students' mistakes immediately and controlled the solving

processes by setting the steps of solutions that he considered adequate. Instead of providing content-oriented assistance, teacher A's interventions were mostly motivational and strategic, for example the students were asked for the problem formulation and encouraged to make appropriate assumptions, as well as to use their own context knowledge.

Effects and consequences of interventions

Concerning the effects and consequences of interventions, Beutel and Krosanke reconstructed that the strategic intervention *presentation of state of work* had potential both for students and teachers. One consequence of this particular kind of intervention is the reflection and the structuring of present results and present action. As a result, Beutel and Krosanke could reconstruct students' ability to solve a partial problem after an intervention was given; the realization of the importance of obtained results and thus their incorporation into the solution process and the verbalization of previously remained intuitive insights. Another consequence, as mentioned before, was that Beutel and Krosanke were able to confirm this special kind of intervention as a diagnostic tool for teachers.

Looking at the effect of interventions, Beutel and Krosanke differentiate between short-term and long-term effects. However, a definition of effects was impossible because of the complexity of effects. But in trying to define effects, Beutel and Krosanke inevitably had to look at interventions which led to metacognitive processes. They were able to reconstruct effects on the declarative level as well as on the procedural level of metacognition. In most cases, strategic interventions are the trigger of such processes, but content-related interventions and feedback can also lead to metacognitive processes. Every time Beutel and Krosanke analysed feedback as a trigger of metacognitive processes, feedback was given in combination with a content-related intervention. They also point out, that metacognitive processes that were triggered by teacher interventions do not always lead to progress in the solution progress; sometimes the interventions did not influence the solving process at all.

As a result of the behaviour of teacher A as a *facilitator of knowledge*, Meyer observed the students as being encouraged to think and work for themselves. Due to the many teacher interventions of teacher B as *disseminator of information* during the solving processes the students were hardly able to work for themselves. Through numerous hints the students were directed to appropriate solutions.

While teacher B mainly focussed on the mathematics and the correctness of the real solutions, teacher A aimed at organizing and supporting the students' individual learning processes. Meyer assumed that the behaviour of the *moderator or facilitator of knowledge* can especially help students work independently on modelling tasks and promote the development of students' mathematical modelling competencies.

CONCLUSION

Both studies dealt with the question of teacher behaviour in modelling classes. In both studies the effects of teacher interventions were one analysed aspect. While the study by Beutel and Krosanke aimed at describing the effects of an intervention at various levels and analysing them according to their appropriateness, the study by Meyer focussed on describing the role of the two teachers as *moderator or facilitator of knowledge* respectively as *disseminator of information*.

Both studies describe the observed teacher interventions as mainly invasive, while different types of interventions could be reconstructed, for example motivational, strategic and content-oriented assistance. However, differences between the preferred types of intervention among the teachers could be identified. The study by Meyer shows exemplarily two different types of teacher behaviour in modelling classes, teacher A as moderator or *facilitator of knowledge* and teacher B as *disseminator of information*. While teacher A mainly used motivational and strategic assistance, teacher B provides more often content-oriented support. The study by Beutel and Krosanke describes the role of the teachers as moderator or facilitator of knowledge i.e. the teachers did not aim at guiding the students to solve the modelling task in a prescribed way. Concerning the effects and consequences of interventions, both studies reconstructed mainly strategic interventions.

The different results of these studies point out that invasive interventions are not to be rated as more appropriate than responsive interventions or the other way around: invasive interventions, which are of a organisational nature or which are carried out because teachers diagnosed a lack of progress or students' helplessness, seem to be valuable for the students' solving process.

A second point is that teacher B often expressed his own uncertainty in how to intervene in a strategic way. The university students who were acting as teachers in the other project were trained for this work over several weeks. According to this one can conclude that the usage of strategic interventions can be promoted by specific training activities within teacher education and that they are also accessible for young students.

A third point is that for all of the researchers it was difficult to find out which interventions were effective and have consequences. This is due to different aspects: the effectiveness of an intervention does not only depend on the intervention itself but also on the student to whom it is given. Thereby, one cannot generalize the effectiveness of special types of interventions. Another reason is the definition of effectiveness: can you classify an intervention as effective, if it enables the students to continue their work for only for a few minutes? What about long-term-effects? Meyer could classify the teachers she had observed as *moderator or facilitator of knowledge* (teacher A) and as *disseminator of information* (teacher B) and reconstruct that the behaviour of teacher A promotes students' independent solving

processes much more than those of teacher B. If the results of this case study can be generalized, it would help us to answer the question of which interventions are adequate.

NOTES

1. An overview on different approaches of scaffolding is given by Van de Pol et al. (2010).
2. The modelling days are one important part of Peter Stenders PhD project (Stender, 2012) and are based on the idea of modelling weeks, which are carried out since several years at different universities (Kaiser & Schwarz 2010).
3. A definition of modelling competencies is for example given by Maaß (2006).

STUDYING THE TEACHING/LEARNING OF ALGORITHMS AT UPPER SECONDARY LEVEL: FIRST STEPS

Dominique Laval

L.D.A.R. – University Diderot – Paris 7

KEYWORDS

Algorithm, Algorithm Workspaces, Modelling competencies, Programming, Simulation.

SUMMARY OF ONGOING RESEARCH WORK

The new French curriculum for upper secondary mathematics introduces building algorithms as a task for every topic. The underlying assumption is that an algorithmic approach can help students access to mathematical notions. The design and construction of algorithms by students is located within a more general framework of modelling approaches in mathematics. The first steps in this work include: **1.** Initial questions **2.** A specification of the knowledge at stake **3.** The elaboration of a theoretical framework taking into account general frameworks in math education and in computer science education, as well as frameworks related to modelling **4.** The preparation of a didactical engineering **5.** A projected study of students' modelling competencies.

Initial questions

According to the new French upper secondary curriculum in mathematics, teaching algorithmic should help to give sense to a number of studied concepts. The questions are: **1.** How teaching can go beyond this objective so that algorithmic becomes a learning object? **2.** How working on algorithm can be considered as a modelling task?

The knowledge at stake

1. The conception and execution of algorithm. **2.** The concept of algorithm: as a “tool”, as an “object”. **3.** The “Algorithmic Workspaces”. **4.** The modelling competencies.

Theoretical frameworks

Our theoretical framework is based on dialectic “tool-object” (Douady, 1984), a transposition of “Geometrical Workspaces (GW)” (Houdement and Kuzniak, 2003, 2006) to “Algorithmic Workspaces” (AW). Further, we will use the description of the levels of modelling competencies (Henning and Keune, 2007). In this approach, an algorithm will be seen as a model of a real world situation. This transposition GW to AW makes possible to start by thinking the interactions between objects, artifacts and paradigms when analysing tasks, and helps to analyse the respective positions of students and teachers, under influence of curricula. We propose to structure the AW into a network of components: **1.** sets of objects; **2.** artifacts “programmable”; **3.** a set of theoretical ideas that help to create and justify algorithms on the objects for execution by the artifacts. The paradigms algorithmic allow to interpret the contents of the components and to define their functions on three levels to algorithms:

Level I: an intuitive approach of algorithms of real life situations. At this level, for instance, the algorithm's effectiveness follows naturally from its description.

Level II: a “natural” axiomatic of algorithms. Effectiveness of the algorithm used, its efficiency and complexity are questioned. The algorithm can become an object.

Level III: formal treatment of algorithms (e.g. Turing machines).

At all three levels, just like in geometry, representations of algorithms involve specific registers (Duval, 2006) with conversions and treatments.

Preparation of a didactical engineering

The method is based on the idea of a didactical engineering (Artigue, 1992). In a framework of modelling approach in mathematics, a random process' simulation tasks is analysed. We consider a random phenomenon based on number of births within a family that stop either: – after the birth of the first son – after the family has four children. We expect from the students that they can implement and understand simulation with diverse instrumental choices and representations of randomness. It is implemented with three 11th/12th grade classes.

Projected study of students' modelling competencies when building algorithms.

In a modelling approach, the student is confronted with the following challenges:

- describe the various steps between the observation of reality and the construction of the mathematical model developed;
- move to the simulation, and then write, in natural language, one (or more) algorithm (s) the model obtained, and the simulation defined;
- encode the algorithm(s) obtained for use in machine language;
- do relevant interpretation of the results obtained.

THE ROLE OF MODELING ON EFFECTS OF IRANIAN STUDENTS

Abolfazl Rafiepour Gatabi & Fereshteh Esmaili

*Faculty of Mathematics and Computer & Mahani Mathematical Research Centre
Shahid Bahonar University of Kerman*

Master of Mathematics Education, Teacher of Mathematics, Tehran, Iran.

Abstract

In this study, twelve problem (4 modeling problems, 4 word problems and 4 pure math problems) used a pre-test and post-test for 92 grade 10 Iranian students to examining their effects (enjoyment, value, interest and self-efficacy) about different type of problems. There are three session teaching units between pre and post test as an intervention. Results of this study show that effects of students were improved.

Keywords: Modeling Activities- Effect- Enjoyment- Self efficacy.

In this study, 92 Iranian students (39 girls and 53 boys) in grade 10 participated. The main purpose of this study was investigating impact of modelling activities on effects (enjoyment, value, interest and self-efficacy) of students about different type of mathematical problems (Modelling problems, Word problems, and Pure Math problems). This study was in the line of German educators' research (Schukajlow, et al, 2011).

For data collection, we use questioner contain 14 problems- 4 problems were modelling, 4 of them were word problems and last 4 were pure mathematics problems. These problems come from research literature about modelling in the case of modelling problems, and from Iranian textbooks in the case of word and pure problems. This questioner was used in pre-test and post-test for assessing the effect of students. Between these two tests, there is an intervention. This intervention was containing 3 modelling activities (different with pre- & post- test) that teach to students in 3 ordinary classrooms session-about 75 minutes for each session.

In pre-test and post-test, students asked for self-reporting about 12 problems without solving these problems. This self-report tool comes from Schukajlow, et al (2011), and contains 4 statements for each 12 questions as below:

- I would enjoy after solving this problem....
- I think it is important to be able to solve this problem....

- It would be interesting to work on this problem...
- I am confident I can solve this problem...

Students asked to answer these statements with 5 point Likert scales contain strongly disagree; disagree; neither agree nor disagree; agree; strongly agree. These data used for SPSS. For data analysis, ANOVA, T-test and Pearson correlation was used. Other sources of data collection were classroom observation and semi-instructed interview with students.

Results of this study show that the effect of Iranian students about modelling problems was lower than other problems. While in Schukajlow, et al (2011) study, students have same effect about different type of problems. Iranian students have more enjoyment about word problems and pure math problems than modelling problems. They also have less self-efficacy about modelling problems than other two types of problems. These finding was different with Schukajlow, et al (2011) study. We think this different result is rooted in stronger background of German students in modelling activities in both research and practice.

Another interesting finding of our study was about Iranian students' opinion about modelling problems. They think these types of problems did not belong to mathematics. This finding is in the line with Rafiepour and Gooya (2010) research. Rafiepour and Gooya (2010) discuss about Iranian teachers' opinion about real world problems. In some cases, Iranian math teachers didn't believe to real world problem. Indeed, these Iranian mathematics teachers thought real world problems didn't belong to mathematics but belong to other field of knowledge like economy, biology and so on.

All students in their interview said they had enjoyed with modelling activities and they would like to have such activities in the official curriculum and textbooks.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG7: MATHEMATICAL POTENTIAL, CREATIVITY AND TALENT

Roza Leikin, University of Haifa, Israel

Alexander Karp, Teachers College, Columbia University, NY

Jarmila Novotna, Charles University, CZ

Florence Mihaela Singer, University of Ploiesti, Romania

This was the second meeting of the *WG Mathematical Potential, Creativity and Talent* that was established at CERME 7 in 2011. The goal of the WG is to draw the attention of the mathematics education community to the field of mathematical creativity, mathematical potential and mathematical giftedness. The WG was formed to encourage discussion among researchers in the field of mathematics education and research mathematicians, and to promote empirical research that will contribute to the development of our understanding in the field. Following the debate at WG7 at CERME-7, we carried on an international exchange of ideas related to research on the didactics of teaching highly able students as well as on the promotion of creativity in all students.

The papers accepted for presentation in the WG served as a starting point for the group discussion. Participants were not expected to give a formal presentation of the papers. At each session a keynote speaker was assigned. Keynote presentations were allotted 15 minutes followed by 5 minutes of questions from the audience. All other participants were given 5 minutes for presentation of the main ideas excerpted from their papers with another 5 minutes of questions from the audience. We varied the forms of the discussions (e.g., whole group discussion, small group discussion) on different topics assigned by the group leaders

Four central topics were assigned for discussion by the group participants: (1) mathematical reasoning, creativity and giftedness, (2) mathematical problems for the gifted and mathematical problems for the development of creativity, (3) teachers and the teaching of mathematically gifted students, along with teaching all students with and for creativity, and (4) research methodologies in research on creativity and giftedness.

MATHEMATICAL REASONING, CREATIVITY AND GIFTEDNESS

The following questions led the discussion on the topic of mathematical reasoning, creativity and giftedness: How can gifted children and twice-exceptional children be helped to develop their potential and capabilities? How does mathematical creativity express itself at the preschool level and how is it observable? What kinds of reasoning (and to what degree of creativity) do talented students use when solving a non-routine problem? What contextual

variables, personal characteristics and math-specific abilities combine to allow high potential in math?

Marianne Nolte told about the city of Hamburg's inclusion policy and how it has led to joint school education of disabled and non-disabled children. The goal of the Center for Gifted Students at the University of Hamburg is to develop the potentials of all children to the fullest possible extent. The center pays special attention to gifted and twice-exceptional children who are at particular risk of talent loss. In this work the problem of non-recognition is demonstrated based on four case studies on special talents combined with developmental impairments. Melanie Münz argued that in research on mathematical creativity early childhood is seldom taken into count. She illustrated instances of two children, four and five years of age, coping with a mathematical task while mathematically creative ideas emerged spontaneously from the interactions between the children. Elisabeth Merlot shared her observation that some successful participants of mathematical Olympiads are under-achievers in school mathematics and argues that more attention should be devoted to high ability students in school.

MATHEMATICAL PROBLEMS FOR THE GIFTED

At this session Alexander Karp shared with the participants his analysis of the problem sets found in textbooks for the mathematically gifted. Oleg Ivanov and Konstantin Stolbov presented their conception of typologies of mathematical problems, and Romualdas Kasuba discussed the importance of learning mathematics with pleasure. Karp suggested that in order to advance our understanding of the role of mathematical problems in realisation of high mathematical potential, the sets of problems for the mathematically gifted were compared with the sets in the ordinary textbooks. He argued that this analysis leads to the conclusion that gifted students are assumed by the textbooks' authors to learn some algorithms more easily and better and to apply new ideas to other domains more easily and quickly than ordinary students. This analysis leads to raising two concerns: First, practitioners and theoreticians seem to arrive at the same ideas independently, while collaboration between them could be especially productive. Second, the role of these more challenging problems in the development of the gift is not quite clear; specifically, whether it would be beneficial for “ordinary children” to be taught using problems similar to those given to the “gifted”.

The participants stressed that there are many approaches to and classifications of problems. Ivanov and his colleagues suggested a two-dimensional model for classification of problems. Dimension 1 corresponds to the schemes of mathematical reasoning (i.e., algebraic, analytic, combinatory-algorithmic, or what is called by the authors 'syllogistic'); while Dimension 2 describes the kinds of activities and approaches typically used by students for solving a

problem. Kinds of activities may include codifying, interpreting, restructuring, transforming and transferring, etc., etc. This classification can be of help in demonstrating the similarity of activities and approaches across the subject domain boundaries and in this way demonstrate the unity of the mathematics. This approach can help educators in developing new problems and activities, and in identifying the need to develop additional tasks in different domains.

Discussion of the paper by Kasuba led to the suggestion that in order to make problem solving pleasurable many conditions need to be fulfilled. A problem can and even should be challenging while still being “solvable” and age- and development-appropriate. A problem should be attractive, meaning, for example, that it should have an interesting formulation and representation. A problem should have an effective solution, first of all meaning that by “doing very little” we “obtain a lot”.

Participants agreed that it is not an isolated problem, but rather the interconnected set of problems that helps to develop mathematical creativity. It was stated that, except for very artificial and overloaded tasks, almost any problem can be made useful in the process of education if it is included in a meaningful environment. This mathematical environment should demonstrate to students the openness of the study and the reasons and the rationale for the study. It was emphasized that problem solving sessions are particularly useful if and when pedagogical values are combined with mathematical values. The concept of “problem solving space” was coined and used to describe the entire problem solving process in the class, which includes the supportive and organizational role of the teachers and developing an especially conducive atmosphere of creativity.

TEACHING AND TEACHERS OF MATHEMATICALLY GIFTED STUDENTS ALONG WITH TEACHING ALL STUDENTS WITH AND FOR CREATIVITY

Florence Mihaela Singer, Jarmila Novotná, and Els De Geest presented didactical ideas directed towards the development of mathematical creativity in all students. They focused their attention on teachers' role in teaching with and for creativity. Mihaela Singer presented a case-study of a professional who teaches in a mixed ability class, and analyzed mismatches between the teacher's self-efficacy beliefs and his specialized content knowledge. Jarmila Navotna focused on the effects of didactical heterogeneisation on students' creativity, namely students' ability to come up with new solutions to problems that are novel to them. Els De Geest discussed pedagogical approaches of experiential learning and the use of pedagogical constructs in an undergraduate distance-learning mathematics education course and whether these can lead to creativity regarded as ‘possibility thinking’.

Participants were involved in an experiment in which they were asked to imagine that they are school principals and have to interview a new teacher for 'teaching for creativity'. A set of qualities that should be examined were formulated, such as excellent and broad mathematical subject knowledge and competence in observing and interpreting occurrences in the classroom including learning processes, children's original ideas and unexpected initiatives. The list of teachers' qualities also included willingness to change practice, interest in further professional development, creativity in interpreting the curriculum, variability in teaching and risk-taking.

With respect to teacher preparation for teaching the gifted along with development of teachers' beliefs, mastery in pedagogy, robust and deep content knowledge at the university level and school level, the participants stressed the importance of knowledge of extracurricular mathematics and of elementary mathematics from an advanced standpoint. These teacher education programs have to be enhanced by intensive problem solving, observation of practice and mentoring by a personal adviser who is an expert in the education of the mathematically gifted.

RESEARCH METHODOLOGIES IN RESEARCH ON CREATIVITY AND GIFTEDNESS

Discussion of methodologies in research on mathematical creativity and giftedness was based on multidimensional examination of mathematical giftedness performed by Roza Leikin in collaboration with her colleagues from the University of Haifa, Israel (Ilana Waisman, Miriam Lev, Nurit Paz-Baruch, Shelley Shaul and Mark Leikin). Since mathematical giftedness is an extremely complex and ill-defined construct, this study searches for deep insights into its nature and attempts to define it. It connects two fields of educational psychology – mathematics education and gifted education. The connection between theories of mathematics education and theories of giftedness is reflected in the sampling procedure and research tools specifically designed for our study. The study has a multidimensional character as it examines and compares the mental activity of participants with different levels of mathematical exceptionality in three dimensions: cognition, neuro-cognition and mathematical creativity. The study suggests that mathematical giftedness can be defined as a combination of general giftedness and excellence in mathematics. This combination leads to the manifestation of cognitive, neuro-cognitive and creative properties at an upper edge of a continuum (revealed on a number of tasks). At the same time, several tasks led to the observation that mathematical giftedness can be characterized by qualitatively different phenomena in students.

SUMMARY

The Working Group entitled *Mathematical Potential, Creativity and Talent* encourages discourse between research mathematicians, mathematics educators and educational researchers. This discourse is reflected in papers included in the proceedings of the WG.

Based on the discussion that took place in the WG, we argue that further development of clear definitions of concepts related to creativity and giftedness should be encouraged. Characteristics of mathematically gifted students should be identified through careful systematic research and through the design of identification tools. Mathematics education researchers should pay more attention to mathematical creativity and its advancement among both students and teachers. Teachers' characteristics should be better described and teacher education programs directed towards developing creativity and advancing mathematically talented students should be carefully designed.

MEMORY AND SPEED OF PROCESSING IN GENERALLY GIFTED AND EXCELLING IN MATHEMATICS STUDENTS

Nurit Baruch-Paz, Mark Leikin, Roza Leikin

University of Haifa

The present study examined the memory and speed of processing abilities associated with general giftedness (G) and excellence in mathematics (EM). The research involved four groups of 16-18 years old participants varying in levels of G and EM. A total of 160 participants were tested on a battery of three memory tests and five speed of processing tests. Working-memory was found to be related both to G and EM factors. The results reveal that G factor is related to high-level short term memory and that E factor is associated with high-level visual-spatial memory. Gifted students who excel in mathematics (G-EM group) outperformed the other three groups in all speed of processing tasks. The results can contribute to the theoretical knowledge regarding the similarities and differences in memory and speed of processing abilities in G and EM groups.

Key words: general giftedness, excellence in mathematics, memory abilities, speed of processing

INTRODUCTION

Despite increasing interest in gifted students and their education, little empirical data is available concerning the cognitive skills of gifted individuals who excel in mathematics. To date, much of the research on the relationship between different cognitive abilities and mathematical competencies has been conducted on low achieving mathematics students (e.g., Swanson & Jerman, 2006). Few studies have examined highly mathematically gifted adolescents (e.g. Dark & Benbow, 1991; Swanson, 2006). Previous studies on mathematical ability and memory were undertaken mostly on children in elementary school (e.g., Hoard, Geary, Byrd-Craven & Nugent, 2008 ; Bull & Johnson, 1997; Smedt et al., 2009) while very few examined high school students (e.g. Dark & Benbow, 1991). The contribution of speed of processing to mathematical excellence was also examined in several studies (Fry & Hale, 1996; Hoard et al., 2008;) but no study has yet examined the associations between general giftedness (G) and excellence in mathematics (EM), with regard to memory and speed of processing abilities.

BACKGROUND

General Giftedness, Memory and Speed of Processing

Earlier studies identified a connection between measures of intelligence and Working Memory (WM) or Short Term Memory (STM). For example, Ackerman, Beier and Boyle (2005) conducted a meta-analysis of the literature from 1972 to 2002 that examined the relationship between WM or immediate memory (i.e., STM) and intelligence. The study revealed a correlation between measures of STM and general

ability and observed a link between simple span memory and intelligence. Similar results were obtained by Carroll (1993) who demonstrated an average correlation between immediate memory factors (i.e. tasks requiring storage and retrieval of information) and general ability.

In addition, a number of research studies have focused on the hypothesis that speed of processing is part of one's intelligence. The faster the speed of processing the higher the IQ score (Deary, 1993; Deary, 2000; Finkle & Pederson, 2000). Vernon (1983) investigated the relationship between several measures of speed of cognitive information-processing and WISC (Wechsler Adult Intelligence Scale) and Raven Advanced Progression Matrices scores in tests on intelligence. The results suggested that the speed factor accounts for 65.5% of the variance in intelligence scores. The conclusion was that individual differences in intelligence can be attributed, to a moderate extent, to variance in the speed or efficiency with which these operations are performed.

A considerable amount of recent evidence suggests that elemental speed of processing abilities (e.g., encoding speed, efficiency of short-term memory storage and processing, and simple and choice reaction time) may be related to intellectual giftedness (Dark & Benbow, 1991; Kranzler, Whang & Jensen, 1994; Vernon, 1983). As to the relationship between giftedness and memory ability, some studies have demonstrated that gifted children display a higher rate of memory capacity compared to their non-gifted peers (Gaultney, Bjorklund, & Goldstein, 1996; Harnishfeger & Bjorklund, 1990). For example, Calero, García-Martín, Jiménez, Kazén & Araque (2007) compared WM capacity between children with high and average IQ aged 6 to 11 years and found that high IQ children had significantly higher scores on WM than their average-intelligence coevals.

Excelling in Mathematics, Memory and Speed of Processing

Memory abilities are thought to be critical to many aspects of mathematical learning (e.g., Meyer et al., 2009). In particular, WM storage is regarded as being essential for solving complex (multi-step) arithmetical problems (Hoard et al., 2008). Children who excel in early mathematics learning tend to have a high WM capacity (Hoard et al., 2008; Meyer et al., 2009; Passolunghi, Mammarella & Altoe, 2007). Dark and Benbow (1991) showed that individual differences in WM span were associated with intellectual giftedness in mathematics. Testing intellectually gifted 13 and 14 year-olds, they found that mathematics achievement was related to enhanced performance on a WM span task with digits and other tasks involving the detection of stimuli, whereas verbal precocity was related to enhanced performance on tasks involving verbal stimuli. Additionally, Hoard et al. (2008) found that intellectually gifted individuals had an advantage in visual-spatial memory (VSM).

Speed of processing seems to be important as a predictor of variations in arithmetic performance (Durand, Holme Larkin & Snowling, 2005; Fry & Hale, 1996; Hoard et al., 2008). Bull and Johnston (1997) found that processing speed, as measured by

visual matching, crossing-out tasks, and perceptual motor speed, was a unique predictor of arithmetic skills, independent of reading ability, for 7 year-old children. Taub, Floyd, Keith & McGrew (2008) showed that processing speed was significantly related to quantitative knowledge for children of ages 9 to 13.

Some studies examined the contribution that speed of processing and short-term memory make to arithmetic calculation (Berg, 2008; Johnson, Im-Bolter & Pascual-Leone, 2003; Geary & Brown, 1991). Case et al. (1982) found a linear relationship between speed of processing and storage capacity of the working memory. In a study of 6 to 11 year olds, they reported that faster counting speed predicted higher counting spans. The explanation for these results is that the faster a child processes relevant information, the more information the child can retain over a short period of time.

Accordingly, this study examined the memory and speed of processing abilities associated with factors of general giftedness and excelling in mathematics. The aims of the present study were as follows:

1. To examine which memory abilities are associated with G and EM factors
2. To examine the differences in speed of processing among students, according to G and EM factors.

METHOD

Participants

We report herein our findings on 160 10th -12th grade students (16-18 years old) right-handed male and female students who were recruited for the study (see Table 1). The participants were subdivided in four experimental groups, determining the research population by a combination of G and EM factors:

- G-EM group: students who are identified as generally gifted and excelling in mathematics;
- G-NEM group: students who are identified as generally gifted but do not excel in mathematics;
- NG-EM group: students excelling in mathematics who are not identified as generally gifted;
- NG-NEM group: students who are identified as being neither generally gifted nor excelling in mathematics.

Table 1: Description of study groups

	Generally Gifted (G) Raven ≥ 27	Non-Gifted (NG) Raven ≤ 26	Total
Excelling in mathematics (EM) SAT-M ≥ 26 or HL in mathematics with math score ≥ 90	$n=34$	$n=44$	$n=78$
Non-excelling in mathematics (NEM) SAT-M ≤ 22 and RL in mathematics with math score ≥ 90 or HL in mathematics with math score ≤ 80 .	$n=36$	$n=46$	$n=82$
Total	$n=70$	$n=90$	$n=160$

Tasks and Materials

Memory abilities tests

1. Short-Term Memory - Digit Span test (WISC III; Wechsler, 1997)

The test involves two parts: during the first phase the participant is asked to listen to random digits read out loud and then to repeat the digits in the same order. If the participant recalls the digits correctly, another trial is administered. Successive trials are administered using random digits increased by one digit and so forth until the participant fails two attempts. The maximum possible span is nine digits.

During the second phase the participant is asked to listen to a random set of digits read out loud and then to repeat the digits backwards. If the participant recalls the digits correctly, another trial is administered. Successive trials are administered using random digits increased by one digit and so forth until the participant fails two attempts. The maximum possible span is eight digits. The measure of both test parts constitutes a standard score based on Israel's norm scale scores (from Hebrew version of WISC III).

2. Working Memory for Digits and Letters test (WISC III; Wechsler, 1997)

The participant is asked to listen to a mixed series of letters and digits and then to rearrange them by first repeating the digits in the correct order, and then the letters in the correct order. If the participant recalls the digits and letters correctly, another trial is administered. Successive trials are administered using random letters and digits increased by one letter or digit and so forth until the participant fails two attempts. The maximum possible span is eight letters and digits. The measure of the test constitutes a standard score based on Israel's norm scale scores (from Hebrew version of WISC III).

3. Visio-Spatial Working Memory test (Corsi, 1972)

This block-recall task consists of ten blocks arranged randomly on a wooden board. The test involves two parts: during the first part the researcher points at a sequence of blocks at a rate of one per second. After the researcher completes the sequence, the participant is asked to replicate the sequence. If the participant recalls the sequence of blocks correctly, another trial is administered. Successive trials are administered adding one more block each time and so forth until the participant fails two successive attempts. The maximum possible span is ten blocks.

During the second part, the researcher points at a sequence of blocks at a rate of one per second. After the researcher completes the sequence, the participant is asked to replicate the sequence backwards. If the participant recalls the sequence of blocks correctly, another trial is administered. Successive trials are administered adding one more block each time and so forth until the participant fails two successive attempts. The maximum possible span is ten blocks. The measure of both test parts constitutes a standard score according to the accepted Israeli scale (from Hebrew version of Visio-Spatial Working Memory test).

Speed of processing tests:

1. Visual- matching test (Woodcock-Johnson Tests of Cognitive Ability, 2001)

The test consists of rows that include one target symbol and 19 additional symbols. The participant has to circle all the symbols that are identical to the target symbol. The time limit for the assignment is 120 seconds.

2. Cross-out of numbers test (Woodcock-Johnson Tests of Cognitive Ability, 2001)

The test consists of 60 rows, each with six numbers. The participant has to circle two identical numbers in each row. The time limit for the assignment is 120 seconds.

3. Digit-symbol test (WISC III, 1997)

The test consists of a code table displaying pairs of digits and symbols, and rows of double boxes with a digit on the top box and nothing on the bottom box. The participant has to use the code table to determine the symbol associated with each digit (the test consists 133 digits), and to write as many symbols as possible in the empty boxes below each digit. The time limit for the assignment is 120 seconds.

4. Symbol-search (WISC III, 1997)

The test consists of rows marked by one target symbol and five additional symbols. The participant has to decide if the target symbols appear in the row of symbols and to mark YES or NO accordingly. The test consists of 60 items and the participant has to mark as many items as possible within 120 seconds.

5. Simple arithmetic exercises (Openhaim-Bitton, 2003)

The participant has to solve as many simple arithmetic exercises as possible within two minutes. The accuracy and number of correct answers will be examined.

The dependent variables in each test were: accuracy (in %) of correct answers.

Data Analysis

To investigate the questions addressed in this study, multivariate analysis of variance tests (MANOVA) were used to compare the scores of participants in each test. The between-subject factors were: G and EM factors and the within-subject factors were the scores on all memory and speed of processing tests.

RESULTS

Memory tests

MANOVA revealed two significant effects. First, a main effect of the G factor ($F(3,150)=4.32, p<.05$) was obtained. In this case, univariate ANOVA tests showed that the source of differences between the groups was the STM test ($F(1,152)=12.20, p<.01$) on which G students achieved higher ($M=12.6, SD=2.7$) STM scores as compared to NG students ($M=10.7, SD=2.4$). Results of performance on the memory tasks (means and standard deviations) are presented in Table 2.

Table 2: Performance of participants on three memory tests: standard scores for correct answers in each memory test

Memory tasks		EM	NEM
		<i>M (SD)</i>	<i>M (SD)</i>
STM	G	12.8 (2.7)	12.4 (2.8)
	NG	10.9 (2.3)	10.5 (2.5)
WM	G	10.6 (2.2)	10.8 (2.7)
	NG	10.8(2.7)	9.7 (2.2)
VSM	G	12.5 (2.1)	11.8 (1.5)
	NG	12.0 (2.5)	11.3(2.2)

Note: G=Gifted; NG=Non-Gifted; EM=Excelling; NEM= Non-Excelling STM=Short-Term Memory; VSM= Visual-Spatial Memory; WM= Working Memory

Additionally, a main effect of the EM factor was found to be marginally significant on the VSM score ($F(1,152)=3.65, p<.06$). In this case, EM students scored higher ($M=12.2, SD=2.3$) than NEM students ($M=11.5, SD=1.9$).

An interaction of $G \times EM$ factors was found with regard to the WM total score ($F(3,152)=3.22, p<.05$). The WM scores of EM students were similar in G ($M=10.6, SD=2.2$) and NG students ($M=10.8, SD=2.7$). However, the WM scores of NE students were significantly higher for G ($M=11.7, SD=2.4$) than for NG students ($M=9.7, SD=2.2$).

Speed of Processing tests

MANOVA revealed an overall significant main effect for the G factor ($F(5,149)=2.50, p <.05$) and the EM factor ($F(5,149) = 4.35, p<.01$). In this case, univariate ANOVA tests showed the source of differences between the groups was the Cross-out of numbers and Simple arithmetic exercises tests. In this case, G students outperformed NG students and EM students were more accurate than NEM students in both tests (see also Table 3).

Additionally, univariate ANOVA tests showed an interaction between $G \times EM$ factors with regard to the Symbol-search test ($F(1,153)=4.11, p<.05$) and the Digit-symbol tests ($F(1,153)=5.88, p<.05$). The accuracy of NG students in both tests was similar in EM and NEM students. However, the accuracy of G students in both tests was significantly higher for EM than for NEM students (see also Table 3).

Table 3: Performance of participants (in %) on five speed of processing tests

SIP tasks		EM	NEM
		<i>M (SD)</i>	<i>M (SD)</i>
Visual matching	G	68.3 (12.3)	61.1 (14.8)
	NG	61.1 (11.2)	62.4 (11.6)
Cross-out of numbers	G	75.2 (6.2)	71.1 (5.6)
	NG	70.2 (8.4)	68.4 (10.0)
Digit-symbol	G	67.0 (11.4)	61.7 (10.0)
	NG	63.7 (7.6)	65.1 (9.3)
Symbol-search	G	76.0 (12.4)	69.7 (12.0)
	NG	70.9 (9.1)	71.9 (11.2)
Simple arithmetic exercises	G	97.0 (5.0)	89.8 (10.8)
	NG	92.3 (9.8)	83.6 (14.6)

CONCLUSIONS

The aim of the present study was to examine the memory and speed of processing abilities associated with general giftedness (G) and excelling in mathematics (EM). Results showed that there are different memory abilities associated with G and EM factors.

The findings revealed that G is related to high STM ability and the EM factor was found to be linked with high VSM. In addition, the results demonstrated that the WM scores of students excelling in mathematics were comparable in G and NG individuals. However, the WM scores of NEM students were significantly higher for G students as compared to NG students.

The results regarding speed of processing tasks show that the gifted students who excel in mathematics (G-EM) outperformed the other three participant groups in these tasks. The findings, however, discerned discrepancies between tests: in some tests a difference in performance was associated with both G and EM factors while in other tests, only the G factor was associated with the differences between the groups.

The findings obtained in the study partly support previous observations and suggest that memory and speed of processing abilities seem to be important factors in explaining mathematical giftedness. The findings add to the theoretical knowledge pertaining to the cognitive processing of G-EM and G-NEM students and can enlighten educators and instructional designers, thus enabling them to better plan effective educational programs tailored to the unique educational needs of gifted students excelling in mathematics. With this in mind, educational programs for G-EM students should address the observation that these students possess high abilities in visual-spatial memory and in information processing and should therefore implement the use of visual aids in teaching mathematics in gifted classes.

STUDENTS' PICTURE OF AND COMPARATIVE ATTITUDE TOWARDS MATHEMATICS IN DIFFERENT SETTINGS OF FOSTERING

Matthias Brandl

Chair for the Didactics of Mathematics, University of Passau, Germany

The fostering of promising students in mathematics can be done in different ways. By the results of a survey in different settings we try to give advices for a suitable way of selecting and fostering potentially mathematically gifted students. Therefore we look at the students' picture of and comparative attitude towards mathematics.

Keywords: mathematical giftedness, fostering, selection, beliefs, attitudes.

INTRODUCTION

There are different ways of selecting promising students for reasons of fostering (in mathematics) consequently leading to different settings:

One way is to offer additional courses or materials for volunteers, which means that the *interest* of the students is the main motivational force. The general importance of this aspect was already identified by Kruteskii (1976), for example, who lists a “general synthetic component”, a “mathematical cast of mind”, i.e. the necessity of an aptitude and interest for mathematics in order to be successful within this subject. He states “It is expressed in a selectively positive attitude toward mathematics, the presence of deep and valid interests in the appropriate area, a striving and a need to study it, and an ardent enthusiasm for it” (Kruteskii, 1976, p. 345). The mathematician Kurt Devlin appears to have the same opinion when he declares that “whatever it is that causes the interest, it is that interest in mathematics that constitutes the main difference between those who can do mathematics and those who claim to find it impossible” (Devlin, 2000, p. 275).

Another way to identify promising students is to rely on teachers' choices, so it is not only the students' interest driving them to the courses but also a *qualitative* external selection process. Linke & Steinhöfel (1986, 1987), amongst others, discussed this process.

And a third way would be a *quantitative* procedure of testing the students (see Nolte, 2012, Kontoyianni et al., 2011, Hagborg & Wachman, 1992, Bittker, 1991, Löser, 1985, amongst many others) or simply choosing those with the best marks in mathematics (see, to some degree, BSHA in the next section, for example).

In practice, selection processes often are designed as multilevel mixtures of these three ways (see Wagner & Zimmermann, 1986, for example). From a psychological perspective, these selection methods represent different aspects of the causality between a giftedness potential on the one side and performance or assessment,

respectively, on the other side. We already discussed these aspects in Brandl (2011) and Brandl & Barthel (2012) and gave some initial results concerning theoretical insights and corresponding practical consequences there.

In this paper we want to look at different settings of fostering again in order to compare the students' perceptions of and comparative attitudes towards mathematics. This was already done for just one setting in Brandl & Barthel (2012), where we concluded that there are strong hints that mathematically gifted students should be fostered separately from their (old) classmates. The reason was/is just their absolutely different attitude towards mathematics and therefore the absolutely different learning atmosphere they deserve or create, respectively, for and/or by doing mathematics.

THE DIFFERENT SETTINGS

We did our empirical survey in three different settings. The first is a German boarding school for high attaining students, where successful candidates are chosen by very stringent assessments, representing the third selection method sketched in the introduction (“*quantitative* selection”); the second setting, the fostering courses at our university, represent a mixture of mostly the first (“*interest*”) and a little of the second (“*qualitative* selection”) selection method. As a contrast to these two settings we added a “normal” class from a regular higher secondary school.

Boarding school for high attaining students (BSHA)

In order to be selected for this German boarding school for high attaining students, applicants have to fulfill several requirements: in the main subjects – German, Mathematics, a foreign language and natural sciences – students need to achieve at least the mark “good”; an average mark “good” in the last two school reports; a general IQ score of approximately 130 points in the intelligence structure test I-S-T 2000 R (Liepmann et al., 2010) and a successful participation in a two-day assessment center concerning social skills. The sample group consists of 8 classes with 113 students from 11th and 12th grade (which represent almost all students within these grades). Their age ranges from 14 to 18 with an average age of 16; the number of boys and girls is balanced. On a scale from 0 (fail) to 15 (excellent) the median of their marks in the subject mathematics in the last school report is 12.

Fostering courses at university (FCU)

Offering of special fostering courses in mathematics at schools or at universities is quite common and has a long tradition. However, there are different kinds of selection processes for these courses, including identification by a teacher, special tests for mathematical giftedness, students' interest (self-selection) or a combination of those; see Nolte, M. (2012) amongst many others, for example. At the University of Passau, these kinds of courses have been offered for several years. The participants are split into at least two groups consisting of 13-to-14-year-olds and 15-

to-16-year-olds. There are no tests for IQ or mathematical giftedness; mostly the students are attending the courses because of their own interest in the subject. Unfortunately, the numbers of participants (and so the samples) are rather small: 9 “younger” and 6 “older” ones. Typically, the participants of the “higher” course are former participants of the “lower” course.

Regular higher secondary school (RHSS)

In order to compare the results from the data collected at the BSHA and the FCU with a “normal” school, identical questionnaires were given¹ to 23 students of a class in a 11th grade at a regular higher secondary school (“Gymnasium”). The average age is the same as at the BSHA and the sample consists of 9 female and 14 male participants. As might be expected, their average mark in mathematics is much lower than that of the BSHA sample.

METHODOLOGICAL REMARK

One of the methodological issues of this study is that the number of participating students in the survey is different for the three settings (BSHA, FCU and RHSS). So, the conclusions drawn from the evaluation of the three groups cannot be interpreted in a general way based on representative quantitative empirical data. However, as *all* students from 11th and 12th grade of BSHA and *all* students from the courses of FCU were chosen, the results may still be representative for the different settings in a *qualitative* way; and as *all* students from one whole class from the 11th grade at RHSS were chosen, the RHSS sample can serve as a representative *qualitative* counterpart. The more or less qualitative results of this survey can so be seen as a starting point or a pre-study, respectively, for a deeper and representative quantitative research.

PICTURE OF MATHEMATICS

The questionnaire given to the students was identical² for all three settings. One of the foci of this questionnaire is students’ notion of mathematics; answers could be given on a bipolar 5-point Likert-type scale. The categories on the horizontal axis in the following figures are:

- 1: Calculations, rote learning, algorithms
- 2: Problem solving, proofs, riddles
- 3: Creative process of building a theory
- 4: Tinkering³ with beautiful things
- 5: Competence to get a safe and well-paid job
- 6: Modelling, language of nature
- 7: Symbols, numbers, patterns, formulas, abstract structures

8: Texts, theorems, laws

9: Something for freaks

Boarding school for high attaining students (BSHA)

For the BSHA we got the following profile:

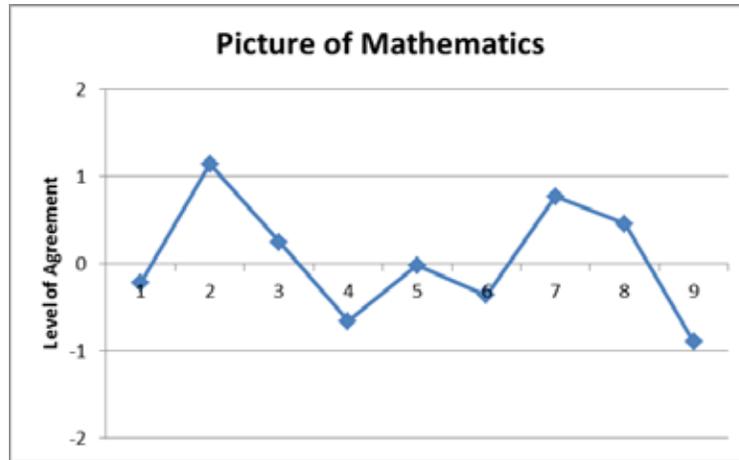

Figure 1: Picture of Mathematics (of 11th and 12th grade altogether) at the BSHA.

The diagram shows an ambivalent picture of mathematics: though the students of the BSHA do not believe that mathematics is something for freaks (9) but is rather problem solving and proofs (2), patterns (7) and theorems (8) instead of rote learning (1), however, they rather don't see it as a tinkering around with beautiful things (4) or the language of nature (6). This might be caused by the fact that the lessons at the BSHA are bound to the general curriculum necessary for the central-posed A-level exams.

Fostering courses at university (FCU)

Participants in the FCU answered like this:

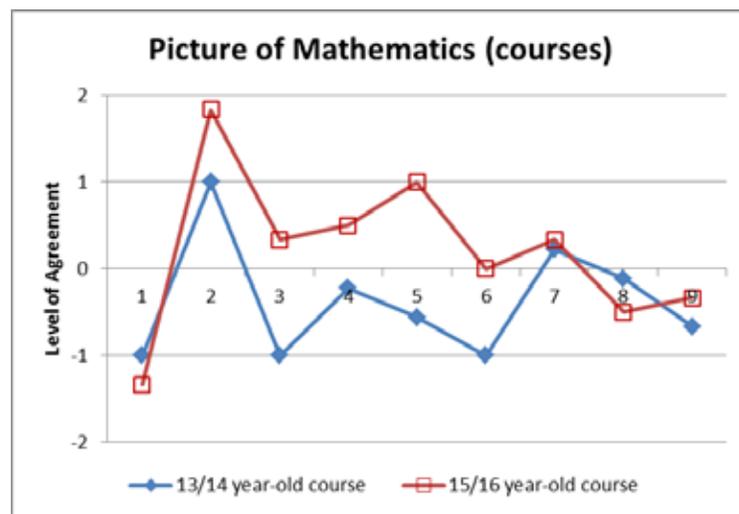

Figure 2: Picture of Mathematics of the 13-to-14-year-old and 15-to-16-year-old ones at the FCU.

Whereas the curve for the younger students is quite similar (despite being a little bit more negative) to the one at the BSHA, the older students (fitting better to the group at the BSHA and the RHSS) show a generally more positive picture except for the numbers 1 (rote learning) and 8 (theorems). The main difference from the BSHA diagram can be seen in the far more positive values concerning problem solving (2) and tinkering around with beautiful things (4). We attribute these differences to the freely chosen mathematical contents of the lessons and the way of dealing with mathematics within these courses.

Regular higher secondary school (RHSS)

The 11th grade at the RHSS delivered the following picture:

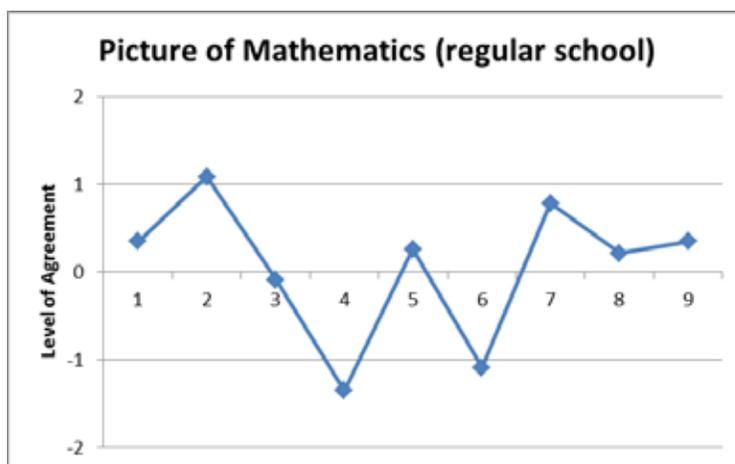

Figure 3: Picture of Mathematics of an 11th grade at the RHSS⁴.

First, the line in figure 3 is completely different from the line of the older ones in the FCU, illustrating the diverging perspectives of mathematics of interested students and those who are not. Second, although being (surprisingly) similar in most points to the diagram in figure 1 for the BSHA (items 2 to 8), there is a tendency to see mathematics as some kind of rote learning process (1) and something for freaks (9).

COMPARATIVE ATTITUDE TOWARDS MATHEMATICS

The data for the different attitudes towards mathematics came from answers on a 7-point Likert-scale. The students had to rate their own attitude towards mathematics as well as estimate the one of their classmates at the current school (or the university courses, respectively), their classmates at their – for BSHA: old – school (dispensed for RHSS) and society as a whole. The categories on the horizontal axis in the following figures are:

1: ugly, terrible	-----	aesthetical, beautiful
2: hard	-----	easy
3: boring	-----	interesting, exciting
4: incomprehensible	-----	logical

Boarding school for high attaining students (BSHA)

The results are shown in figure 4:

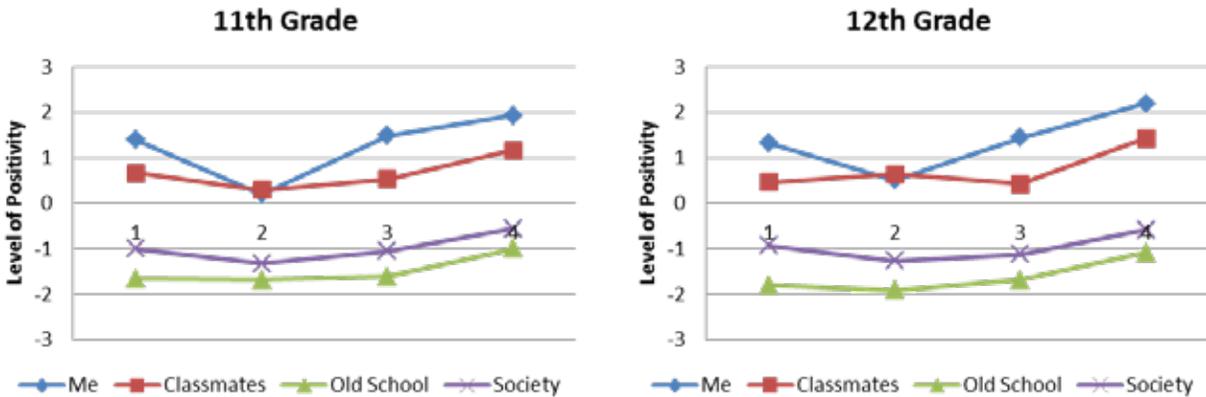

Figure 4: Attitude towards Mathematics, separately for grades 11 and 12, at the BSHA⁵.

All students rated themselves more positively than the rest (classmates, old school, society). This might suggest a sort of “I’m sure that the others don’t find math as interesting and nice as me”-thinking. Furthermore, there is a remarkable gap between the estimated attitudes of the current classmates compared to the old ones. Of course, all members of the sample were selected because of their very good marks in mathematics. Nevertheless, the difference of the two lines shown in figure 4 indicates that they must have felt like strangers in their old classes. Additionally, the attitude towards mathematics in society is always rated quite low, but higher than that in their old class (see also Brandl & Barthel, 2012).

Fostering courses at university (FCU)

The attitudes of participants of the FCU are shown below:

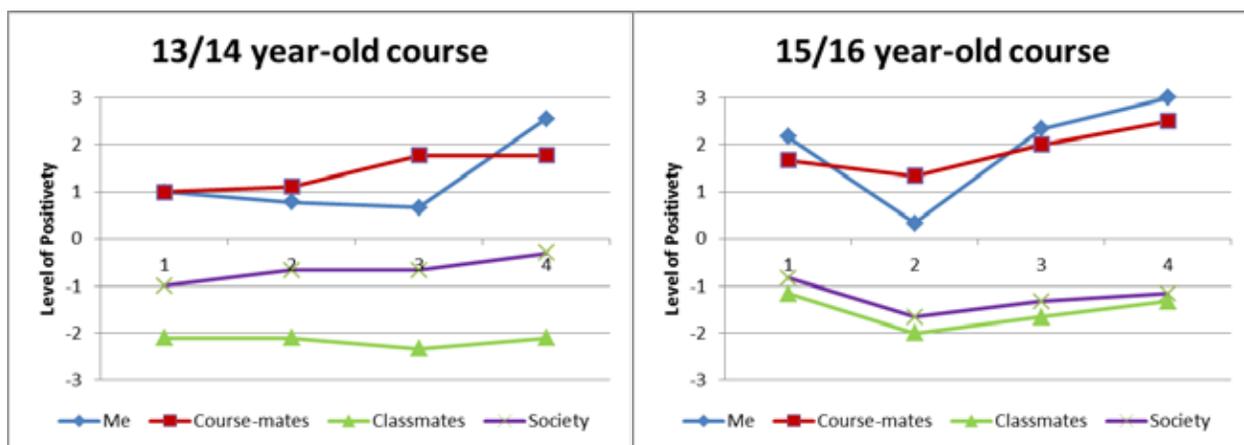

Figure 5: Attitude towards Mathematics, separately for the 13-to-14-year-old and 15-to-16-year-old ones, at the FCA.

First of all, just like for the BSHA students, the students themselves and their course-mates show a positive attitude towards mathematics in contrast to the estimated

negative one of their “normal” classmates and society. The gap between the current course-mates and the “normal” classmates is quite huge compared to the analogical gap (between “classmates” and “old school”) in figure 4. Furthermore, the students’ rating of society’s attitude as more positive than that of their “normal” classmates is similar to that of BSHA students.

Regular higher secondary school (RHSS)

In contrast, at the RHSS the following rating was given:

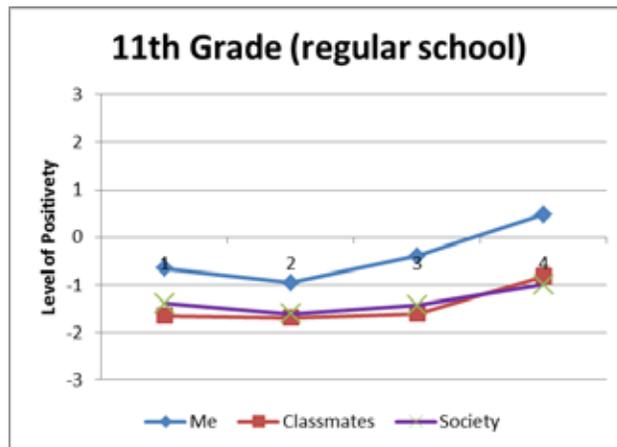

Figure 6: Attitude towards Mathematics at the RHSS⁶.

Clearly, there is only one slightly positive rating for the individual logical sight (“Me”, 4). All of the other ratings are, on average, negative, which is a marked difference from BSHA and FCU students. Of course, this results from the fact that now not only the highest attaining or interested ones are asked. Surprisingly, the levels for the estimated attitudes of classmates and society are at almost the same height as it is for BSHA and FCU. So this seems to be very stable across students from different attainment levels. Another stable characteristic, one that held across attainment levels, was the gap between “Me” and all the others, although in this instance the classmate group are current classmates instead of former classmates. One distinctive feature in the RHSS survey responses is the nearly identical curves for classmates and society; these curves were separated to a greater degree in the BSHA and FCU survey responses.

HYPOTHESES / QUALITATIVE CONCLUSIONS

Based on these observations in the diagrams from figures 1 to 6, we draw the following qualitative conclusions that may serve as hypotheses for a larger and deeper quantitative study:

- The picture / perspective of mathematics of somebody who is interested in mathematics differs essentially from one averaged over an “ordinary” class; it seems⁷ also to be more positive than that one averaged over a “high-attaining” class.

- In general, the beauty of mathematics and the possibility of thinking of mathematics as just a tinkering around are only stated by students who were “chosen” for special courses because of their interest in mathematics. So, on the one hand, this stays in line with the findings in Kruteskii (1976) and Brandl & Barthel (2012) that the strong motivational force *interest* and the ability for *aesthetical sensation with mathematics* are correlated in some way. On the other hand, it seems as if an institution depending on an official curriculum (instead of a free choice of contents) is not able to establish any kind of playful aesthetical enjoyment by doing mathematics in class for a (often large) group of highly different interested and motivated students.
- There is a gap between the (more positive) attitude towards mathematics of *students themselves* and the estimated attitudes of their *current classmates* at BSHA and RHSS. We interpret this as a sort of “I’m sure that the others don’t find math as interesting and nice as me”-thinking in all math classes. This psychological fact may be used by the teacher, as the awareness of the students’ individual understanding of their potential in and their attitude towards mathematics can help to establish a more comfortable atmosphere in order to foster the students according to their individual needs.
- The levels for the estimated attitudes of their old (BSHA) / “normal” (FCU) / current (RHSS) classmates and society in all three settings always are at almost the same (negative) height; so this seems to be quite stable. This could reflect the “negative image” of mathematics in society, which perhaps is projected onto or adapted by the classmates. Furthermore, this may be a signal that the “mathematical climate” in ordinary math classes at regular (secondary) schools may be not supportive for establishing successful learning processes in mathematics. This is underlined by the fact that in the case of BSHA and FCU the estimated attitude of the old / ”normal” classmates is rated even lower than that one of society.
- In the context of actual fostering by separation of the particular students there is also a significant gap between the (more positive) attitude towards mathematics of *students themselves* and the estimated attitudes of their *old* (BSHA) and “*normal*” (FCU) classmates, respectively. It is biggest when looking at the interested ones (FCU).

Probably the environment of an ordinary math class (like at RHSS) is not suitable and supportive for promoting mathematics as something beautiful, challenging and joy-bringing. Students from BSHA / FCU may have felt / feel some kind of alienated in their old / “normal” classes. Based on these preliminary results, separating them from their old / “normal” classmates seems to be a promising way to give them an appropriate surrounding for performing and learning mathematics.

However, in individual problem-centered interviews with all the (eight) mathematics teachers at BSHA almost all teachers confessed that the main problem when it comes to the students' performance (especially in mathematics) seems not to be their more or less existing giftedness potential, but the psychological hindrance of a *narcissistic wound / shock* that comes from being confronted with just best-of-students in class and the eventual loss of this status for oneself. So, apart from aspects more or less related to (mathematical) beliefs and attitudes discussed in the previous paragraphs, pedagogical and psychological issues strongly connected with performance and assessment (And not the giftedness potential in the first place!) have to be considered seriously and may even be seen as decisive if a separation/selection is considered.

Hence, additional non-performance orientated courses (as realized in FCU, for example) seem to be suitable settings.

We hope that these preliminary and qualitative results can serve as guiding hypotheses in order to be confirmed in a deeper quantitative research.

NOTES

1. This survey was done in the context of the exam thesis of Christian Barthel, which was supervised by the author of this paper. So the results described within this paper concerning the RHSS are based to some part on Barthel, C. (2011).
2. The questions related to the estimation of the comparative attitudes of the students themselves in relation to other groups were modified slightly to fit the context of BSHA, FCU and RHSS (example: 'classmates' for BSHA was changed to 'course-mates' for FCU).
3. This is motivated from the description/definition of mathematical giftedness in Ruelle (2007).
4. Figure 3 is related to figure 20 in Barthel (2011, p. 53).
5. Figure 4 is partly taken from figure 2 in Brandl & Barthel (2012) and appeared first in Brandl (2011c).
6. Figure 6 is based on figure 26 in Barthel (2011, p. 64).
7. Probably the sample size of FCU is too small to come to a stronger conclusion.

POSSIBILITY THINKING WITH UNDERGRADUATE DISTANCE LEARNING MATHEMATICS EDUCATION STUDENTS: HOW IT IS EXPERIENCED

Els De Geest

The Open University, United Kingdom

This paper reports on the Creative Thinking in Mathematics Education Enquiry (CTMEE) at The Open University. The study investigates whether the pedagogical approaches of experiential learning and the use of pedagogical constructs in an undergraduate distance learning mathematics education course can lead to creativity seen as ‘possibility thinking’ (PT) (Grainger, Craft and Burnard, 2007). Data consist of 23 quantitative and qualitative responses from students to an on-line questionnaire. It is the analysis of the latter that are discussed in this paper. Findings suggest that such pedagogical approaches can indeed contribute to developing possibility thinking. This paper offers a descriptive categorization of how the features of the PT framework are manifested with undergraduate distance learning mathematics education students.

Keywords: possibility thinking, creativity, experiential learning, e-learning

INTRODUCTION AND BACKGROUND

Possibility thinking (PT) is, in essence, thinking about possibilities. PT has been described as being the process of thinking that leads to creative development (Aristeidou, 2011). It is thus seen as at the core of and driving force for creative thinking (Craft, 2000, 2001; Craft and Jeffrey, 2003; Grainger et al., 2007; Craft, Cremin, Burnard, Dragovic and Chappell, 2012; Craft, McConnon and Paige-Smith, 2012). PT is about ‘everyday creativity’, also referred to as ‘little *c* creativity’ or ‘what if’ thinking. It is about trying out different possibilities, identifying problems and solving these (Craft, 2002); it is about ‘thinking in novel and valuable ways about the world using imagination as close to the notion of creativity’ (Craft, 2000, p.9).

Grainger et al. (2007) developed a framework for identifying and analysing possibility thinking of teaching and learning. The framework was originally developed within the context of primary school children. The features of this framework for identifying an analysing PT involve:

PT feature	What this could involve...
Play	As a result of time for immersion, ideas incubate and questions emerge through playful encounters

	[with others or the tasks/concepts]. Extending of boundaries. Engagement, interest and motivation.
Immersion	Opportunities and time for extended periods to immerse in particular activities which are frequently revisited.
Question posing	‘What if’ scenarios. Questioning, generating ideas. Questions of students treated with deep respect and interest. Making predictions, compensation, improvisation, testing.
Self determination	Ownership. To exercise agency (one is the agent in the change/activity) and autonomy (self chosen action; self directed acted; self initiated activities). Expected to take risks.
Risk taking	Challenges with no clear-cut solutions. Developing courage to take risks. Contributions are valued.
Being imaginative	‘As if’ thinking. Being imaginative and imagining. Consider what might be, alternative world frames. Can position oneself differently and postulate reasons for this.
Making connections	Connections between ideas and activities and between one’s own and others’ lives.

Table 1: Features of PT and what these could involve. Amalgamated and adapted from Grainger et al. (2007).

The Centre for Mathematics Education in the Open University (OU) offers distance learning courses in mathematics education at undergraduate and postgraduate level. The pedagogical approach taken in all these courses is one of experiential learning (Kolb, 1984; Dewey, 1938) where students are asked to undertake mathematical tasks for themselves, reflect on this experience, try the tasks out with learners, and reflect on both experiences. The courses also use *constructs* which act as labels for experiences, such as *do-talk-record*, *generalising and specialising*, *conjecturing & convincing*, *imagining & expressing* (Pólya, 1962; Mason, Burton and Stacey, 1982). These pedagogical underpinnings of experiential learning and constructs are made explicit in the course materials and are referred to in research publications (Mason & De Geest, 2010).

The CTMEE project intended to address the following research aims:

1. To find out whether, and if so, how, the features of the PT framework resonate with adult learners in a distance learning setting?

2. To find out whether experiential learning and the use of constructs in the teaching of mathematics contribute to developing possibility thinking
3. To find out whether there are any there any other pedagogical approaches within the courses that nurture possibility thinking

This paper reports on the findings to the first research aim. Findings to the second and third research aim have been reported in De Geest (2012).

RESEARCH DESIGN

Data was collected via an on-line questionnaire of students on the course ‘Developing Algebraic Thinking’ (course code ME625; Mason, Graham and Johnston-Wilder, 2005). This is a third level undergraduate distance learning course that can count towards Graduate Diploma in Mathematics Education and/or a BSc(Honours) Mathematics and its Learning . The course is open to everyone, though it is intended particularly for students working or aspiring to work in mathematics education. It integrates development of the core ideas of algebra with relevant pedagogical constructs and principles and aims to extend awareness of how people learn and use algebra. Examples of mathematical tasks in the course are:

It was reported that during 1992 in a certain county, although black students were only 10% of the school population, 40% of school exclusions were black. This means, it said in the report, that black students are 6 times as likely to be excluded as white. Justify, comment and construct a general method for making similar calculations from other similar data.

(Task 9.3.4, Mason et al. 2005, p189)

And

Write down two numbers

Write down two numbers which total 36

Write down two numbers with a difference of 8

Write down two numbers with a total of 36 and a difference of 8

(Quickie 10.1, Mason et al. 2005, page 199)

The questionnaire was developed based on the model of possibility thinking of Grainger et al. (2007). It consisted of statements which respondents were asked how these fitted with their experiences first within the context of experiential learning (part 1), then in the context of the use of constructs (part 2), with response options ‘happens often/sometimes/a few times/not at all’. For example, to find out whether the students had experienced the feature of the PT framework of risk taking as a result of experiential learning in the course, the statement read:

Trying out tasks for myself, reflecting and trying the tasks with others in ME625...
prompt me to take risks in my thinking and my practice

This was followed by response options of ‘happens often/sometimes/a few times/not at all’. To obtain exemplification of their experiences, respondents were invited to describe a particular incident of how/when this happened. It is the analysis of these qualitative responses that are discussed in this paper.

All 120 students registered on the course were invited to take part in the study shortly after the due date of the final assessment but before they received their results. Twenty-seven responses were received, of which twenty-three were useable (four did not go past the consent part of the questionnaire). All had completed the questions relating to experiential learning (part 1), and 17 completed both sections. Twelve respondents provided 39 exemplifications of their experiences. Responses varied in length from short statements to more elaborate responses. Several responses mentioned specific tasks, or specific constructs.

The qualitative responses were analysed using a grounded theory approach such as constant comparison and were informed by the PT framework (Grainger et al., 2007). The analysis questions used were ‘what are the students experiencing in terms of the PT features?’ and ‘what triggers/influences this experience?’.

RESULTS AND ANALYSIS

The analysis provided exemplification of how features of PT, as described earlier in this paper, were manifested with the students:

Play/playfulness

Playfulness seems to take the form of exploring and experimenting. Such activities are no longer considered a waste of time. Assessment tasks were mentioned as leading to extensive exploring. Important also was mentioned that having the toolkit on how to explore from using constructs. Knowing how to get unstuck seems important so students can work through being stuck when exploring and experimenting as illustrated by the responses:

“I now keep a notebook with me so I can explore 'What if...' whenever this may occur to me.”

“Manipulation and drawing is no longer a waste of time.”

“On tasks for TMAs [assignments for assessment] I often ended up exploring so much that I had far too much information to answer the questions!”

“The constructs have made it possible for me to explore the inner aspects of tasks. I was able to work through being stuck most of the time by using the course constructs. “

“Previously I would have stopped as soon as the going gets tuff and would therefore have missed out on the inner aspects.”

Immersion

There were no explicit responses indicating the students had experienced opportunities and time for extended periods to immerse in particular activities which are frequently revisited. Perhaps it might be implied from the course design and the students responses about playfulness which seems to suggest students were engaging with tasks for some time.

Question posing

Students reported asking ‘what if’ questions by being required to extend and adapt tasks. They had learned ways to extend such tasks by using constructs such as *Dimensions of Possible Variation* (DoPV). They had become aware of these DoPV from being presented with tasks which had many-right-answers and/or many-right-ways to solve the tasks as illustrated by the responses:

“Being asked to extend tasks prompted this [posing questions] at first but then it started to become more natural.”

“If I understand an idea then I can still further my understanding by asking question like 'what if...'. “

Self determination (autonomy and agency)

Self determination, directed action and self chosen action in the forms of autonomy and agency seems to be very present with the students. Many responses mentioned experiencing ownership of ideas, of learning and of feeling valued. Experiential learning and reflection stimulated students to develop their own conjectures about theories of learning and of mathematics learning based on new and old experiences. This is aided by the tasks with their focus on many-right-answers and many-right-ways to solve the problem: they seem to validate and respect own ways of thinking and at same time offer new ideas and approaches. The requirement for adapting and extending task, the stimulus to create own examples and been given a toolbox of constructs and frameworks to do so, means students are in charge of their own learning. They report feeling interested, focussed and motivated as a result and as illustrated by the responses:

“Being told something is 'correct' or 'incorrect' is not always helpful. In fact, for me, it is usually rarely helpful. More helpful and important is the reasoning, which make something valid or invalid. Experiential learning has the advantage that it does not force a view. On the contrary, one discovers through experience the dimensions of variation of a problem and its associated range of permissible change. This means that there is an element of real ownership associated with ideas.”

“Lots of ideas which I was able to construct my own tasks from.”

“That I can decide what is the best way for me and that by doing this I can encourage my learners to find the best way for them.”

“I could see that the tasks I encountered and took on were very much up to me; how did I extend them? What resources worked for me?”

“If you create your own examples or expand one that is given you are taking charge of learning and that makes you more interested and focused.”

Risk taking

Students report feeling comfortable with taking risks, indeed one response read ‘no fear of failure’. Taking risks meant a change in teaching practice by moving from using textbooks to investigative mathematics, using an approach of experiential learning in the classroom. Taking risks also happens within the students’ own learning of mathematics by moving out of their comfort zone and challenging themselves by doing mathematics tasks which they consider beyond ‘their level’. Important seems to be the ability to know how to get unstuck which can be achieved by using course constructs and frameworks. It was also mentioned that the impact the tasks had on the student’s own motivation, encouraged to take more risks in classroom. It is not clear what that motivation is. The course and task design’s emphasis on many-right-answers/many-right-ways contributes to the students feeling that their thinking and ideas are valid and valued. This could give a sense of feeling safe. The requirements of the assessment tasks push the student out of their comfort zone as illustrated by the responses::

“I have been encouraged and required to think and work in new ways, without fear of failure.”

“Seeing the impact of the tasks on my own motivation encouraged me to "take more risks" in the classroom.”

“When I was stuck I used different constructs to get unstuck.”

“Using techniques from constructs and frameworks to get you out of stuck situations.”

“Having constructs at hand I feel capable of dealing with problematic situations.”

Being imaginative

Students reported feeling imaginative as having new and different experiences of and approaches to learning mathematics. The ‘low entry high ceiling tasks, the many-right-answers/many-right-ways design and the requirement for developing own examples and adapting tasks all seem to stimulate being imaginative. Experiential learning and reflection makes students become aware of their own learning and on working on developing a (new) structure of thinking. Making connections between mathematical ideas as a result of the task design leads to solving problems in more than one way as illustrated by the responses:

“Experiencing the connection between different concepts allowed me to solve a problem in various ways and also to prompt learners to seek alternative ways of solving a problem.”

“The experiential approach to learning actually allows for all sorts of approaches to be tried. This is because the approach requires you to start with what you perceive to be important and, through a collection of smaller tasks, assess the appropriateness of your choice. From the experience of the process and the actual results obtained you can make further, more informed, choices.”

Making connections

Students made connections with other areas of mathematics, other mathematical approaches, and with becoming aware of own learning. Working on imagery seems to offer a way to connect abstract ideas. The emphasis in the course and task design of that there is not one right way or right answer, but many, seems lead students to being able to empathize with differing ways of learning of other people. Reflection lets students become aware of their own learning, of their assumptions about learning and the role of their own past experiences and make connections between these. These are then challenged as a result of having to do the tasks themselves, and having to adapt and then try out the tasks with learners. Several respondents reported a change in their teaching as a result, and in particular a change in their questioning. Another aspect of development concerns being able to express and talk about learning and pedagogies by using constructs and frameworks as vocabulary as illustrated by the responses:

“I was looking at it with fresh eyes. I could see how other might approach it. I could develop the question, adapt for different learners.”

“By learning mathematics in new ways I have become more aware of what works for my learners.”

“Throughout the book our preconceived ideas are challenged.”

“Returning regularly to the construct showed me how the way I learn relied on what I previously knew and the way I had previously tackled similar problems. Also showed me why less experienced learners may struggle to make these connects.”

DISCUSSION AND CONCLUSION

This is a small case study specific to one course in mathematics education of the Open University and is thus limited in scope and range. It involves self-reporting and this may not be entirely reliable. It is also likely that respondents willing to spend about 20 minutes answering a questionnaire might be biased to be positive about their experiences as a student on the course and would have a positive story to tell. It is also not clear what the implications are of the timing of the research, that is the students were invited to take part in the study shortly after the due date of the final assessment but before they received the results.

The intentions of the study as reported in this paper were to find out whether the features of PT (Grainger et al., 2007) which was developed in a classroom setting with primary aged school children would resonate with the experiences of adult learners, in a distance learning setting, in the context of mathematics education learning. It seems that these students experienced the features of PT, although there was not sufficient data to get insights into what the feature of immersion would entail in this setting.

TYOLOGIES OF MATHEMATICAL PROBLEMS: FROM CLASSROOM EXPERIENCE TO PEDAGOGICAL CONCEPTIONS

Oleg A. Ivanov, Tatiana Yu. Ivanova, and Konstantin M. Stolbov

St. Petersburg State University, Lyceum For Physics and Mathematics # 30, Lyceum “Physical-Technical High School”, St. Petersburg, Russia

In this paper we propose a new classification of mathematical problems. Usually one speaks about low-level and high-level problems, exercises and authentic mathematical tasks. We aim to classify problems in terms of the activities and schemes of solutions needed to solve them. Moreover, we intend to introduce a two-dimensional model of classification. Finally, we suggest an approach aimed at developing an inductively-associative form of thinking.

Keywords: classification of problems, schemes of solutions, kinds of mathematical activities, associative thinking

INTRODUCTION

Students’ different styles, approaches and problem solving strategies have been a matter of interest of many mathematics educators during the last decades (Schoenfeld, 1980 and 1992, Selden & Selden, 2005, etc). By learning problem-solving, “pupils should acquire ways of thinking, habits of persistence and curiosity, and confidence in unfamiliar situations” (NCTM, 2000). One of the main problems of teaching mathematics is selecting the tasks which best ‘promote and develop mathematical talent’ (Chamberlin, 2010). V. G. Dorofeev (1983) suggested using tasks in, as he put it “rich problem neighbourhood”. This means that for a given problem other problems exist which are connected to it by mathematical content, schemes of reasoning, and/or a circle of mathematical notions used in the solutions. The idea of a recent study by R. Leikin (Leikin, 2007) was to teach students to find diverse solutions of a given problem, which form what the author calls the ‘solution space of a mathematical problem’. These papers include similar ideas since in both works pupils are accustomed to looking at the interrelations between problems, methods, notions, etc. A. P. Karp (1997) has suggested discriminating different types of combinations of problems, such as “prompting” (when the first question prompts the answer to the second one) or “control” (when one question helps to verify the answer to the previous one).

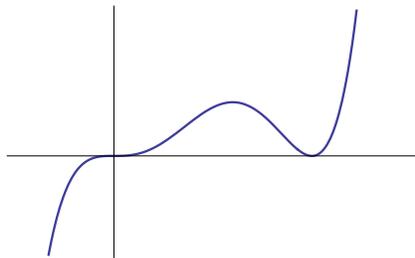

In this paper, pedagogical characteristics of separate problems are explored and discussed regardless of the problems’ level of difficulty, though, we are mainly interested in pupils with advanced academic capabilities. When talking about teaching problem-solving, it is not enough to distinguish between *low-level* and *high-level* tasks. Chamberlin says that “HOT (*high-order thinking* – author’s comment) tasks are those in which the problem solver needs to engage in cognition to successfully solve the problem” (Chamberlin, 2010, p.66). But what if a pupil is able

to solve one HOT task but is unable to solve another? Can the cognition processes in these cases differ from each other?

THE STARTING POINT: ANALYZING PRACTICE

The highest priority of any educational process must be mathematical (intellectual) development. When studying mathematics, pupils solve many problems all the time. However, problem solving means more than just a straightforward execution of standard procedures. “Advanced ways of thinking, such as analyzing, conjecturing, defining, proving, generalizing ... can and should be developed from elementary school onward” (Selden & Selden, 2005). Based on our intuition and experience, we have selected the following problems by means of which it may be possible to, so to speak, “enter the child’s mind”.

1. Find the range of the expression $a^2 - 2a + b$ for $a \in [-2, 3]$ and $b \in [-2, 1]$.
2. The numerator of a given fraction is increased by 1 and the denominator is increased by 2. Compare the fraction obtained with the given fraction.
3. Check whether or not 100903027 is a prime number.
4. Suppose x^{199} and x^{213} are both rational numbers. Is it true, then, that the number x is also rational?
5. Give a formula for a function whose graph looks like the curve in the following figure.

6. Does there exist a line tangent to the parabola $y = x^2 - x + 5$ and parallel to the line $y = 2011x$?
7. Find the largest value of the fraction $\frac{n^2}{2^n}$ where n is a positive integer.

Here are the solutions of these problems (given by the authors). Pupils’ solutions (and mistakes) will be discussed later on.

Problem 1. The key point of the solution consists in rewriting the given expression in the form of $(a + 1)^2 - b - 1$. Now, since $-1 \leq a + 1 \leq 4$, the interval $[0, 16]$ is the range of the expression $(a + 1)^2$. Since $-2 \leq b \leq 1$, the interval $[-2, 1]$ is the range of the expression $-b - 1$. Consequently, since “the letters a and b vary independently”, the interval $[-2, 17]$ is the range of the given expression.

Problem 2. First of all, let us formulate the problem in the algebraic form. Let k be the numerator of the given fraction and let n be its denominator. After increasing the

numerator by 1 and increasing the denominator by 2 we obtain the fraction $\frac{k+1}{n+2}$. In order to understand which fraction is greater, consider their difference. Thus we obtain $\frac{k}{n} - \frac{k+1}{n+2} = \frac{2k-n}{n(n+2)}$. Consequently, the initial number is greater if and only if the inequality $2k > n$ holds. The obtained inequality is equivalent to the inequality $\frac{k}{n} > \frac{1}{2}$. Thus, if the given number is greater than 0.5, we obtain a number which is less than the given one. And if the given number is less than 0.5, then the obtained number is greater than the given number. Finally, if $\frac{k}{n} = \frac{1}{2}$, then $n = 2k$, therefore $\frac{k+1}{n+2} = \frac{k+1}{2k+2} = \frac{1}{2}$, which means that the obtained number equals the initial one.

Problem 3. Certainly, it is possible “to guess” the desired factorization. However, a natural way to answer the question consists of using the notion of decimal representation of integers. For example, the number 103 is “one hundred and three”, or “one hundred plus three”. Since the given number can be rewritten in the form of $100900000+3027 = 1009 \cdot 100000 + 3 \cdot 1009 = 1009 \cdot (100000 + 3) = 1009 \cdot 100003$, it is a composite number.

Problem 4. Certainly, the rationality of some power of a given number does not imply the rationality of this number. It is well-known that the number x such that $x^2 = 2$ isn't rational. On the other hand, if the numbers x^2 and x^3 are both rational then their quotient $x = \frac{x^3}{x^2}$ is rational, too. This observation is the key to solving this problem. Since the numbers x^{213} and x^{199} are rational, their quotient $\frac{x^{213}}{x^{199}} = x^{213-199} = x^{14}$ is rational as well. Similarly, the quotient of the number x^{199} and the fourteenth power of the number x^{14} is rational, so the number $x^{199-14 \cdot 14} = x^3$ is rational. Moreover, the number $\frac{x^{14}}{x^{12}} = x^2$ is rational; consequently, the given number $x = \frac{x^3}{x^2}$ is also rational.

Problem 5. Certainly, there exists a rather routine method of “graphing functions”. However, here we have the converse task. Let us try to find a polynomial $p(x)$ whose graph looks like the given curve. First of all, one has to describe properties of a function defined by its graph. Obviously, number $x = 0$ must be its root with multiplicity of three or more and the number $x = 2$ must be a root with multiplicity of two or more. Let's consider functions $y = x^3$ and $y = (x - 2)^2$. Their product is a function with the described properties of its roots. Therefore, let $p(x) = x^3(x - 2)^2$. We have to check that the behaviour of the function is similar to a function with a given graph and, in particular, that the function $p(x)$ has three intervals of monotonicity. For that purpose let us calculate its derivative,

$$p'(x) = 3x^2(x - 2)^2 + 2x^3(x - 2) = x^2(x - 2)(5x - 6).$$

Therefore the function $p(x)$ increases on the intervals $(-\infty, 6/5]$ and $[2, +\infty)$ and decreases on the interval $[6/5, 2]$.

Problem 6. It is well-known that two lines in a plane are parallel if their slopes are equal. The slope of the line tangent to parabola $y = x^2 - x + 5$ at point (x_0, y_0) equals $2x_0 - 1$. The slope line $y = 2011x$ equals 2011. Thus, these lines are parallel to each other if and only if $2x_0 - 1 = 2011$, consequently, if $x_0 = 1006$. Therefore, the answer is positive; there exists a line tangent to the given parabola which is parallel to the given line.

Perhaps, it would be more natural to use the condition of tangency of a line to a parabola in terms of multiplicity of roots of an equation. Indeed, line $y = 2011x + b$ is tangent to graph $y = x^2 - x + 5$ if and only if the equation $x^2 - x + 5 = 2011x + b$ has a unique solution, that is, if the discriminant of the quadratic equation $x^2 - 2012x - (b + 5)$ equals zero. Obviously, the equation $2012^2 + 4b + 20 = 0$ has a solution; thus, the desired tangent line exists.

Problem 7. For an “expert” mathematician, it is obvious that the given sequence decreases starting with a number represented by k . In order to find this number, one has to solve the inequality $\frac{n^2}{2^n} > \frac{(n+1)^2}{2^{n+1}}$. By multiplying both sides by the common denominator we obtain the inequality $2n^2 > n^2 + 2n + 1$, $n^2 > 2n + 1$, and $(n - 1)^2 > 2$, which is valid for all $n \geq 3$. Consequently, the fraction attains its largest value for $n = 3$. Thus, the answer is $9/8$.

For a novice learner, it would be reasonable to use the following “heuristic strategy” (Schoenfeld, 1980, p.794): “Given a problem with an integer parameter n , calculate special cases for small n and look for a pattern.” The following table contains the result of the calculation of the initial terms of the given sequence $x_n = \frac{n^2}{2^n}$.

n	1	2	3	4	5	6
x_n	0.5	1	1.125	1	$\frac{25}{32} \approx 0.781$	$\frac{9}{16} \approx 0.563$

Now the behaviour of the given sequence becomes completely clear. One only has to prove that this sequence decreases starting with its third term.

These problems appeared to be extremely hard for pupils from ordinary classes. The usual situation in a classroom is the following one: pupils look at the statements of the problems, sit still, and do not know what to do. In their attempts to give solutions to some problems they wrote that “Since the denominator of the fraction increased by a bigger number than its numerator, the value of the fraction decreased” (Problem 2) or “Since the power of an irrational number may be a rational number, the rationality of x^{199} and x^{213} does not imply the number x is rational” (Problem 4) without giving any justification for their assertions. Unfortunately, the majority of Russian pupils are still used to solving problems only by means of prescribed rules. Usually, when asked

to solve a problem, they are only expected to recognize one suitable method. As a result of such teaching and learning, they get stumped if, for example, more than one method is needed to solve a problem (as is the case in the solution of Problem 6). The results found among pupils from classes with an advanced mathematical education were different, though even they were not completely successful. Certainly, while the facts that should be proved in Problems 1-7 appear to be rather unexpected, their solutions do not require “complicated mathematics”, no one needs to know or use “sophisticated techniques” to solve them, as all necessary notions and methods are familiar to all the pupils. So, what makes them so difficult?

Let us examine the solutions presented above. The notion of the range of a function (expression) is used in the solution of Problem 1, whereas the solutions of Problems 2 and 3 are purely algebraic. In the first case we suggest speaking about *the analytical scheme of reasoning*, in the second one – about *the algebraic scheme of reasoning*. Certainly, since in Problem 5 one deals with properties of functions, the scheme of reasoning in the solution of this problem is analytical. Despite the fact that the solution of Problem 7 is based on solving a rather routine inequality, the scheme of reasoning is analytical since the main idea consists of studying *the behaviour* of the given sequence. The solution of Problem 4 is different since its key point is the construction of an algorithm. The corresponding scheme could be called *a combinatory-algorithmic scheme of reasoning*.

Now, let us examine the starting points of all these solutions. In Problem 7, the calculation of the terms of the given sequence for small n made clear the behaviour of this sequence. In other words, we carried out *a mathematical experiment* which resulted in *setting a hypothesis*.

The solution of Problem 1 consists of three steps. First of all, we have *to codify* the statement of the problem in order to write it in a symbolic form, namely, the fraction $\frac{k}{n}$ is given and the fraction $\frac{k+1}{n+2}$ is obtained. In this situation, G. Pólya (1973) used the word *translation*; he wrote that “to set up equations means to express in mathematical symbols a condition that is stated in words; it is translation from ordinary language into the language of mathematical formulas”. We prefer to use the word “codifying” to describe a more general situation. For example, one may codify a subset of a finite set by means of a sequence of 0s and 1s.

In the second step we rewrote the inequality $a > b$ in the form of $a - b > 0$ and transformed the difference of fractions. Finally, we have *to interpret* correctly the obtained condition on the numbers k and n . Indeed, by rewriting the inequality $2k > n$ in the form of $\frac{k}{n} > \frac{1}{2}$, we obtain the condition on the value of the given fraction.

We propose to distinguish problems by the kinds of activities used to solve them. We have already identified such kinds as: *a mathematical experiment*, *setting a hypothesis*, *codifying*, and *interpreting*. Certainly, there also exists such a kind as

using a standard method. For example, two standard methods were used in the first solution of Problem 5.

It is noteworthy that the mathematical experiment that can be carried out in the solution of Problem 1 shows that the obtained fraction may be more or less than the given one. Indeed, $\frac{1}{3} < \frac{2}{5}$, though $\frac{3}{2} > 1 = \frac{4}{4}$. Although we are not able to set the correct hypothesis after this experiment, it can protect us from reaching the wrong conclusion. However, the mathematical experiment in Problem 3 is sure to fail since the smallest divisor (larger than 1) of the given number equals 1009, which is the 169th prime number.

The activity employed in searching for the solution of Problems 1 and 3 may be called *restructuring*. One is engaged in the same kind of activity when performing substitutions in order to reduce a transcendental equation to an algebraic one, or, more generally, when representing some given function as composite of other simpler functions.

In the second solution of Problem 6, a problem from calculus was transformed to a problem concerning multiple roots of polynomials. The same kind of transformation occurred in the solution of Problem 5. Thus, ideas and methods from some themes of mathematics were used to solve problems initially stated in terms of another theme. Such kinds of activities may be called *transforming and transferring*.

To conclude this section, let us consider one more problem (Koichu, 2010, pp.258-259).

Problem 8. N players take part in an individual tennis competition. What is the overall number of games, if a player who loses a game leaves the competition?

B. Koichu observed that in solving this problem “the most frequently used start was considering the problem for small values of N ”. However, later on he says that this approach “led the solvers away from the immediate solution”. When one sees that the number of games for $N = 2, 3, 4$, and 5 players equals, correspondingly, 1, 2, 3 and 4, he or she will, obviously, generalize a hypothesis in which the number of games equals $N - 1$. Thus, the mathematical experiment leads to a correct hypothesis. To prove it, one has only to observe that any game excludes one player; therefore, after $N - 1$ games there will be only one player left – the winner of the competition. Thus, to solve this problem it is reasonable to use such kinds of activities as *carrying out a mathematical experiment* and *setting a hypothesis*. On the other hand, the proof of the hypothesis is purely logical. Certainly, any solution is an example of logical reasoning; we suggest calling such schemes of reasoning *sylogistic* (in particular, a proof built upon *reductio ad absurdum* is sylogistic). Therefore, B. Koichu’s observations merely shows that his students are accustomed to reasoning algebraically and not in a sylogistic way.

A TWO-DIMENSIONAL MODEL

We introduce a new typology of problems (in a certain sense a two-dimensional typology), some of whose components were known previously (Vedernikova & Ivanov, 2002). The main idea consists of using the classification “kind of activity—scheme of reasoning” to assess the process of mathematical education. In the previous section, we introduced such schemes of reasoning, as: *analytical*, *algebraic*, *combinatory-algorithmic*, and *sylogistic* and such activities, as: *using a standard method*, *a mathematical experiment*, *codifying*, *interpreting*, *restructuring*, *setting a hypothesis*, *transforming and transferring*.

If we want to develop different aspects of students’ mathematical thinking such as ability to formalize mathematical material, to generalize it, and others (Krutetskii, 1976; see, also, *Standards for Mathematical Practice in Common Core Standards*, 2013), given problems have to be diverse in terms of the kinds of activities used for their solution and in terms of their schemes of reasoning. In a certain sense we looked for a transition from ‘the tacit expertise’ to ‘the grounded science’ (Ruthven, 1993). The problem is that it is impossible to describe these characteristics in terms of the typologies of mathematical problems that are known in Russia and other countries (see, for example, Sarantsev & Miganova, 2001, and Chamberlin, 2010).

In the following table we present our analysis of the solutions of the discussed problems. When solving highly difficult mathematical problems employment of several complex reasoning schemes are required. Thus it seems important to devolve problems that can be solved by implementation a particular reasoning scheme.

#	<i>Kind of activity</i>	<i>Scheme of reasoning</i>
1	restructuring	analytical
2	codifying; interpreting	algebraic
3	restructuring	algebraic
4	experiment	combinatory-algorithmic
5	transforming and transferring	analytical
6 ₁	using a standard method	analytical
6 ₂	transforming and transferring	algebraic
7	experiment; setting a hypotheses	analytical
8	experiment	sylogistic

As you can see, there are no problems with coinciding pedagogical characteristics; all of these problems are distinct. Therefore, this set in particular may be used successfully by a teacher for assessment of pupils’ mathematical development.

The development of mathematical thinking should be one of the main goals of teaching mathematics in schools, especially, at an advanced level. We gave problems

1-7 to pupils aged 15-16 who started to learn mathematics at the advanced level only in the autumn of 2012. Here is the description of one of their works.

One pupil gave an excellent solution for Problem 3; he restructured the given number and factorized the obtained numerical expression. He codified Problem 2 correctly; however, he made mistakes in operations with fractions. He made two common mistakes in the solution of Problem 1, namely, he concluded that if $a \in [-2,3]$, then $a^2 \in [4,9]$, and, consequently, the interval $[-2,13]$ is the range of the expression $a^2 - 2a$. He gave the correct solution for Problem 6 (the algebraic one). Through this process, a teacher is better able to understand strengths and weaknesses of the pupil's mathematical knowledge and development.

PAIRING PROBLEMS

In the last part of our paper, we develop the approach outlined in the section “Instead of a Conclusion” of the book by Ivanov, 2009. The main (and well-known) idea is that “What you have been obliged to discover for yourself leaves a path in your mind which you can use again when the need arises.” George Christoph Lichtenberg (1742-1799).

The first example deals with problems which may be called *pre-tasks*. In a situation when your pupils are unable to solve the suggested problem, it is worthwhile giving them another one. To be more precise, you suggest that your pupils handle another problem with the same kind of activity and scheme of reasoning used in its solution (according to the table above).

For example, suppose you gave Problem 3. It is likely that they cannot solve it. You may suggest going on to the next problem by saying something like “Never mind, try to solve another problem”.

Problem 9. Check whether or not for any positive integer n the number $n^5 + n^3 + n^2 + 1$ is a composite.

The point is that when factorizing a polynomial one is restructuring an expression. In our case, since $n^5 + n^3 + n^2 + 1 = n^3(n^2 + 1) + n^2 + 1 = (n^2 + 1)(n^3 + 1)$, this number is a composite for any positive integer n .

It is likely that the majority of your pupils will be able to do this exercise successfully, since most pupils are accustomed to factorizing polynomials. Your next sentence should be: “Surely you have guessed how to solve the previous problem...” The point is that the same kind of activity and the same scheme of reasoning are used in the solutions of Problems 3 and 9. Thus, you have given your pupils “a hint”, but only “an implicit hint”.

There are also problems which may be called *post-tasks*. Consider the following problem.

Problem 10. Examine the behaviour of the function $f(x) = \frac{x+a}{2x+b}$ (here both a and b are positive numbers) on the interval $[0, +\infty)$.

The solution is rather standard. For example, one can find the derivative, $f'(x) = \frac{2x+b-2(x+a)}{(2x+b)^2} = \frac{b-2a}{(2x+b)^2}$. Thus, if $b > 2a$, then $f'(x) > 0$, which implies that this function increases on the given interval; similarly, if $b < 2a$, then $f'(x) < 0$ and the function decreases. It is worth noting that the condition $b > 2a$ is equivalent to the condition: $f(0) = \frac{a}{b} < \frac{1}{2}$.

Now, ask pupils the following question: “Can you see some relationship between this problem and the problem within the given set?” The point is that Problem 2 is a straightforward corollary of Problem 10. And the number 0.5 in the answers of these problems appears because of the fact that the line $y = 0.5$ is the asymptote of a hyperbola which is the graph of the given linear-fractional function.

Do you agree that it is useful to pair problems?

CONCLUSION

A famous Soviet psychologist S. L. Rubinstein said that: “Man’s development does not coincide with the content of his knowledge and skills and is not determined by the coherence of operations inherited to man, but by the culture of his internal intellectual processes.” We cannot judge the situation in other countries, but in Russia teaching mathematics even at the advanced levels often means simply broadening the scope of familiar mathematical notions, methods and algorithms. However, as mentioned at the conference “Teaching Mathematics in Mathematics and Science High Schools” (Saint-Petersburg, 2012), we cannot attain a deep understanding of mathematics merely by giving our students a lot of problems to solve, most of which are exercises in applying known methods and algorithms. As a result, the majority of our pupils are only able to apply standard methods and become helpless even in a simple situation in which they are required to use two techniques in order to solve a problem. We hope that the results of our research will be useful for teachers, providing them with tools which can help them to analyse and enrich their pedagogical strategies as well as help them in constructing concrete lessons.

To conclude, the proposed ideas may also be instructive in pre-service and in-service mathematics teacher education (see, Ivanov & Il’ina, 2001, and Ivanov, 2009).

MATHEMATICAL PROBLEMS FOR THE GIFTED: THE STRUCTURE OF PROBLEM SETS

Alexander Karp

Teachers College, Columbia University

This paper discusses the structures of problem sets from textbooks for the mathematically gifted and suggests ways to analyze these structures. It is argued that seemingly purely technical details, such as the presence and quantity of simple problems or the grouping of problems, reflect important aspects in the understanding of gifted education, and more broadly, of the education of all students. An analysis of existing textbooks along the lines proposed here, it is argued, is useful for working teachers and textbook authors. But it may also interest a wider circle of mathematics educators, making it possible to pose a series of questions that may lead to new research.

Keywords: textbooks, gifted students, problems, problem sets, schools with an advanced course in mathematics.

INTRODUCTION

This article is part of a large study of Russian mathematics textbooks in which I am currently engaged. The analysis of textbooks and their history constitutes a complex methodological problem (Schubring, 1987). It is notable, however, that researchers usually focus on the theoretical material presented in a textbook, as it were, while devoting less attention to problems. In part, this is explained by the fact that problems were quite slow to appear in textbooks in general. On the other hand, even today, despite the fact that the importance of problem solving has become universally recognized, problems in textbooks are often seen as mere exercises, whose aim is to develop various skills, and which are consequently more or less typical and traditional, and therefore of little interest for discussion.

Here, we will briefly discuss the distinctive features of the structure of problem sets from textbooks for the mathematically gifted (or from special problem books for these students). For this category of students, problems are especially important (although they are, of course, important for all other students as well). The discussion will focus on details that may be regarded as technical, but which are founded, as we will argue, on important considerations about the philosophy and organization of education. Note that the present study is not yet completed and represents only a relatively small part of the research being conducted, or more precisely, offers only certain examples of this research.

ON THE PRINCIPLES AND GOALS OF THE STUDY

The principles (methodology) for analyzing problem sets are insufficiently developed. The analysis of problem sets is sometimes confined to simplistic quantitative parameters (how many problems are given per topic) and in the best cases to indications of different types of assignments -- multiple choice, short answer, or essay question. Although no complete theoretical generalization of methodological approaches is offered in this paper, examples of deeper analysis will be demonstrated.

The research question which this study attempts to answer is: what are the differences between sets of problems from textbooks for the mathematically gifted and sets of problems from "ordinary" textbooks. Important characteristics of the problem sets which need to be analyzed to address this question include (but are not limited to) the following:

- *Quantity.* As mentioned above, this characteristic is frequently analyzed. It is important, however, to go beyond simply identifying the numbers of problems in different sections, and to connect these parameters with others. The quantity of problems in a textbook has changed over time. At a certain point, historically, textbooks contained no problems at all for students to solve on their own. Gradually, the number of such problems grew, and separate problem books began to appear as supplements to textbooks. The increase of the quantity of problems was, of course, not necessarily the same across all topics, and specific distinctions between different cases deserve to be analyzed. The same number of problems in two sections can be achieved in very different ways, say, by providing identical or similar tasks or by posing original questions every time; one more direction of study is consequently the deeper exploration of quantity in each case. Another interesting theme for analysis is the relation between the main, theoretical part of a textbook, as it were, and the number of problems in the textbook, as various problems were moved over into the theoretical part and vice versa -- various theoretical concerns were shifted to the problem section, and so on.
- *Difficulty of problems.* This very notion requires a definition. Sometimes a distinction is drawn between difficulty as a psychological characteristic, which consequently can be determined only through empirical investigation, by offering students a problem to solve, and difficulty as a particular characteristic of the text, for example, the number of operations involved in the most widespread algorithms for solving a problem. Certainly both types of difficulty present interesting topics for study; in the work described here, however, we will focus on the second of them.
- *Arrangement in groups.* Identifying different groups of problems within each section, we can explore how different the groups are across the entire book. By

looking at the whole set of problems in a textbook or in some section of it as one mega-assignment, we can study the relations between different groups of problems given in the textbook. The theoretical principles of the organization of the groups can be identified (even if the textbooks' authors did not explicitly express these principles), and so on.

- *Mathematical subject matter.* It is natural to expect that problems' subject matter will correspond to the syllabus and this is, of course, typically the case. However, more precise quantitative analysis usually reveals that certain topics occupy special positions—the problems corresponding to them are incomparably more numerous and sometimes they are present, in one way or another, in virtually every section.
- *Structure of problems.* This question is highly significant. The structure of a problem is in fact a complex phenomenon, in particular, because the givens of a problem may be stated in highly dissimilar ways. Studying a problem's structure, for example, includes studying the relations between different possible forms of the representation of the mathematical material used in the problem.
- *Interconnectedness of problems.* This parameter also effectively pertains to structure, but the structure in question here is that of the set of problems as a whole (or the mega-assignment). Researchers have often attempted to represent the structure of an assignment in the form of a graph (Stolyar, 1974). Likewise, one may attempt to depict the whole set of problems belonging to a section in a similar fashion, representing the problems themselves as vertices linked by edges with other problems to which they are linked in one or another manner. The resulting picture is often informative. However, the fact is that reality is even more complicated and substantive. Not only is the resulting graph a directed one (the order of the problems is important), but the connections between the problems can vary greatly: a problem may serve as a hint for the problem that follows it, or it can represent the translation of another problem into a different mathematical language, and in both cases the two problems will be connected, but connected in different ways.

In addition to these characteristics, a few other are of interest, such as *non-mathematical subject matter*, which includes, for example, historical and political information incorporated in the problems; or *pedagogical characteristics*, such as are manifested in special forms of delivering content to students or even in the special selection of data in the problems with a view to making them more accessible for students. As has been said already, this paper presents only a small part of the research, and no full analysis of even the characteristics mentioned above will be undertaken below.

A BIT OF HISTORY

Let us state in somewhat greater detail which books will be analyzed and under what conditions these books are used. At the end of the 1950s, so called specialized mathematics schools appeared in the USSR (Karp, 2011; Vogeli, 1968; 1997). Sometimes these schools are called schools for the mathematically gifted, and this is justifiable, since many of their students have belonged to this category; however, it seems more correct to refer to them more neutrally as schools with an advanced course in mathematics.

These schools built their own curricula and traditions of teachings with the participation of leading Russian mathematicians, including Kolmogorov, Gelfand, Smirnov, Lavrentyev, and many others. Students were admitted to these schools on a competitive basis, often being selected from a whole large city or region. From the 1960s on, textbooks for teaching in these schools began to appear in one or another format.

Later, the number of such schools grew substantially. Special textbooks and problem book for such schools began to be published, sometimes in quite large numbers (for example, Alexandrov, Werner, Ryzhik, 2006a, b; Vilenkin, Ivashev-Musatov, Shvartsburd, 1995a, b; Galitsky, Goldman, Zvavitch, 1997; Karp, 2006). While at the beginning of their existence schools with an advanced course in mathematics included only the two upper grades, later a four-year course of advanced study, encompassing grades 8 to 11, became widespread.

It must be said that the curricula of such schools, whether provided by the Ministry of Education or formulated in the schools themselves, usually include many advanced sections that are either not studied in ordinary schools at all or studied there in incomparably less depth and detail. Below, we will subject those sections to analysis which at least in name correspond to those studied in ordinary schools. This will make it easier for us to draw comparisons and contrasts. Note that aside from textbooks and standard problem books, there also exists a vast supplementary literature for mathematics schools, which includes, for example, Olympiad problem books. These will not be analyzed below.

PROBLEM BOOKS FOR GRADES 8-9

Let us look in more detail at one of most widely used problem books in schools with an advanced course in mathematics: the problem book for grades 8-9 by Galitsky et al. (1997). This text began to be published in the mid 1990s and has gone through many editions since. Reflecting the curriculum that existed at the time of its publication, the problem book contains the following chapters:

Review; Divisibility of integers; Square roots; Quadratic equations; Inequalities; Powers with integer exponents; Functions; Equations and systems of equations; Word problems;

Powers with rational exponents; Sequences and progressions; Trigonometric expressions and their transformations.

Practically all of these topics (except perhaps the divisibility of integers) were covered in one way or another at certain points in ordinary schools as well. We will see many more distinctive features, however, if we compare separate groups of problems. Consider, for example, the small and auxiliary section "Incomplete quadratic equations."

This section contains 16 assignments, each of which except the last four includes several—from three to six—problems. The assignments united under one number are not necessarily identical. For example, the first of them (5.1.) contains incomplete quadratic equations of the form $ax^2 = b$ with coefficients of different types (fractional, negative, etc.) as well as equations that are reducible to them, including equations that may be reduced to incomplete quadratic equations by introducing a new variable (for example, $4 - 9(2 - 5x)^2 = 0$). The remaining assignments are devoted to the following questions:

Solving incomplete equations of the form $ax^2 + bx = 0$ and equations reducible to such equations; Incomplete equations with letter coefficients; Rational equations reducible to incomplete quadratic equations; Incomplete equations with absolute value notation; Problems on investigating equations with parameters; Word problems.

For comparison, consider an analogous section from the textbook by Dorofeev et al. (1999), written somewhat later than the problem book just cited and for ordinary schools. The problems in this textbook are divided into two groups, A and B, the second of which is addressed to stronger students. Section A contains 14 assignments, half of which contain six problems each (this time, the problems are, if not completely analogous to one another, then very similar). These problems are devoted to solving various types of incomplete equations and equations that are reducible to them. We should note the inclusion of problems—nonstandard for such a section—in which students are asked to solve incomplete cubic equations on the model of incomplete quadratic equations (for example, $x^3 - x = 0$). The remaining problems in this section are word problems.

Section B contains 12 assignments, which include equations that are reducible to incomplete quadratic equations, including those that may be reduced to incomplete quadratic equations by introducing a new variable, solving equations with letter coefficients, investigating equations with letter coefficients, and once again, word problems.

It may be noted at once that even if the topics in the two problem book are the same, a problem from Galitsky et al. (1997) is usually more difficult, if only in the sense that its solution requires more steps. Compare, for example, problem 490 (b) from Dorofeev et al. (1999) and 5.3. (d) from Galitsky et al. (1997). In the former, students

are asked to solve the equation $ax^2 - x = 0$; in the latter, the equation $a(x^2 - 6x + 9) + 4 = 0$. Another factor, however, is probably even more important.

Even in comparing the problem book by Galitsky et al. (1997) with the text by Dorofeev et al. (1999), which is also written in such a way as to allow students who are gifted and interested in mathematics to use it, we can see that the differences between them consist not only in the technical difficulty of the problems, but in the different principles underlying their organization. The following three distinctive characteristics may be identified in books for mathematically advanced students:

- Fewer problems in which students are asked to directly apply and practice employing an algorithm that they have studied;
- Greater attention to developing some idea or transferring it onto other objects;
- More connections with other, previously studied sections.

BOOKS FOR GRADES 10-11

Textbooks for grades 10-11 with an advanced course in mathematics, as has already been said, contain many extra sections by comparison with ordinary textbooks. (For example, Vilenkin et al., 1995a, 1995b contains sections on limits and continuity, complex numbers and operations with complex numbers, elementary combinatorics and elementary theory of probability, while the textbook by Alimov et al., 1996 does not cover any of these topics.) Let us again compare sections that are present in both types of textbooks. For example, solving exponential equations and inequalities.

This section in the textbook by Vilenkin et al., 1995b is very short. Students are given only 14 equations and inequalities (arranged in two groups). The textbook by Alimov et al., 1996 offers 107 problems arranged in 26 groups. A comparison between these numbers, of course, tells us little if we do not also take into account the number of problems in each textbook overall (the textbook for ordinary schools also has more problems in general).

It is noteworthy, however, that in Alimov et al., 1996 the problems are arranged in such a way as to be next to problems that are very similar to them conceptually (within the same group). Sometimes, there is a certain development within a group.

For example, group № 15 begins with the equation $3 \cdot 9^x = 81$ and ends with the equation $6^{3x-1} = 6^{1-2x}$. In both cases, naturally, the solution is based on the use of the fact that if $a^b = a^c$ (where a is a positive number not equal to one), then $b = c$. Nonetheless, the assignments are not identical.

They differ, however, far less than the assignments in the corresponding group in Vilenkin et al., 1995b. Here, the first equation is $4^{x-1} + 4^x = 320$, but already the third equation is $2 \cdot 3^{x+1} - 5 \cdot 9^{x-2} = 81$, in other words, an equation of a completely different type. Note also that Vilenkin et al., 1995b contains no completely elementary

equations or inequalities such as $a^x = a^b$ or $a^x > a^b$ at all, while Alimov et al., 1996 contains quite a number of them.

On the other hand, Vilenkin et al., 1995b does contain assignments that connect the topic being studied with topics studied earlier. These include, for example, the following, in our view rather artificial, equation and inequality: $5^{2+4+\dots+2x} = 0.04^{-45}$ and $\left|2^x - 2\right| - \left|2^x - 1\right| \geq \left|2^x + 1\right| - 5$, in order to solve which students must know how to find the sum of a geometric progression and to solve modulus inequalities. In other words, the distinctive characteristics that we noted earlier are present here as well.

DISCUSSION

Above, we deliberately discussed two typical algorithmic (technical, computational) sections. Neither solving quadratic equations nor solving exponential equations and inequalities can be considered topics that throw into some special relief the kind of conceptual understanding and depth that we would like to regard as typical manifestations of mathematical giftedness.

Of course, it is not difficult to cite examples from other topics, or problems characteristic of another way of organizing instruction. Probably the most vivid example of such a special way of organizing instruction is the system of instruction used in several Moscow schools that makes use of "leaflets" or "sheets" (Davidovich, Pushkar', Chekanov, 2008). The problems used in this system of instruction are selected in such a way as to allow students themselves to arrive at the recognition of the fundamental theoretical principles of the course being studied, deriving and proving the corresponding propositions on their own.

In the West, a similar system has been called the "Texas method" or the "Moore method," since it is often associated with R.L. Moore, who made use of it (Parker, 2005). The fact that this system may be used only with highly gifted students, and even then only under special conditions, is obvious (for example, in Moscow's school № 57, at a class being conducted according to the system just described, in addition to the teacher-supervisor, there are four or five teaching assistants to whom students present their solutions, who clarify certain details, etc.). The discussion above, however, concerned no special sections and no special conditions.

The three distinctive characteristics of the structuring of problems in the educational literature for the gifted that we have identified need to be theoretically interpreted and viewed in the light of other theoretical insights into the gifted. The distinctive characteristics of the thinking of the mathematically gifted were already identified by Krutetskii (1976), who took into account the opinions of practicing teachers. It may be said that practicing authors of textbooks rely on the following notions about the thinking of the gifted (which are reflected in the distinctive characteristics of the structures of problem sets discussed above):

- Gifted students grasp rules and algorithms more quickly and retain them better;
- Gifted students more easily make connections with other sections of mathematics that they have studied and are studying, more freely transferring what they have learned to other fields.

Here, we might ask to what degree these considerations (which largely parallel those formulated by Krutetskii) are borne out not only by practical experience, but also by organized studies. Let us note that the practical question concerning the number of assignments-exercises that students should be given for the purpose of practicing the application of some rule deserves serious investigation in general. It is not difficult to point to situations in which students are given literally hundreds of identical assignments so that they might memorize rules sufficiently thoroughly. On the other hand, one may also cite textbooks that offer only two-three identical problems. Of course, sometimes this is done because the authors in principle do not approve of memorization and consequently do not set themselves the task of facilitating it. But sometimes this is not the case—the authors think that certain things do have to be memorized thoroughly, but believe that even two same-type, one-step problems will suffice, while the rest will be learned in the course of working on more difficult assignments. Whether this is the case, or whether it pertains only to mathematically gifted students, or even whether this is not always true even for these students, or whether the outcome depends not on giftedness but on some other facts, are questions that, in our opinion, have not been sufficiently investigated.

In another paper (Karp, 2007), we discussed the notion that possession of great knowledge is evidence of talent. As can be seen, the authors of textbooks assume that gifted schoolchildren remember more than ordinary ones, and boldly weave into problems materials covered earlier. On the other hand, one could say that authors do this because they make it their goal to get schoolchildren to remember more than is demanded of them under ordinary conditions (and as experience shows, they achieve this goal). It would be interesting to collect data (experimental or drawn from teaching experience) about the success—or conversely, failure—of such an approach with "ordinary" students. What happens if they are treated in the same way as those who are recognized as gifted?

In the assignments analyzed above, individual ideas are developed only to a modest extent (which cannot be compared, for example, with the way in which ideas are developed in the aforementioned "sheets"), although this still goes beyond what is found in "ordinary" textbooks. More generally, shifts from one group of assignments to another are usually based on rather simple considerations—usually, they are due simply to the fact that another topic is being covered, that is, another type of assignment and another algorithm for solving such assignments. In another paper (Karp, 2002), we pointed out that the structure of problem material may be quite complex and discussed the importance of studying the "morphology of the problem

set." It is noteworthy that, despite the virtually universal recognition accorded to the importance of creating opportunities for independent discovery by the students, in practice such opportunities, which are opened up by the nonstandard structuring of problem sets, are not very numerous in textbooks. This points to interesting directions for improvements in working both with gifted and with interested students, and, indeed, with all other students as well.

CONCLUSION

The practice and theory of working with mathematically gifted students are, we would argue, not infrequently divorced from one another (which happens often in mathematics education in general). Working teachers often do not know about the work of psychologists, although it would be useful for them, while theoreticians in their turn not always consider it necessary to become familiar with the work of working teachers. Meanwhile, comparisons and contrasts between different approaches are evidently fruitful.

The composition of textbooks is undoubtedly based on definite theoretical principles, even if these are not always explicitly formulated, and perhaps not even fully recognized by the authors themselves. Analyzing existing experience and identifying such principles, we would argue, is useful to working teachers and theoreticians alike.

LEARNING WITH PLEASURE: TO BE OR NOT TO BE?

Romualdas Kašuba

Vilnius University, Lithuania

Creative education often addresses the question what are students able to understand immediately and what can they not. Importantly, to answer this question, teachers need not only consider students' knowledge and abilities, but their feelings and motivation as well. Therefore, the issue of pleasure in the process of learning deserves to be studied. It is hardly possible (at least at this stage) to present a rigorous quantitative study of relevant facts, but still, this paper aims to present some thoughts in identifying some principles for working with students. The paper offers a summary of decades of teaching practice in action.

Keywords: Learning with pleasure, interest, motivation, problem solving, proof.

THE LEARNING WITH PLEASURE: AWAKENING INTEREST

The goal of this paper is to analyze the practice of writing problems and organizing working sessions on students' problem solving activities. Challenging problems were a focus of a special ICMI study (Barbeau and Taylor, 2009). This work to some extent continues along the same lines, concentrating on one specific theme – making problem solving enjoyable. The definition of pleasure and enjoyment in general and in mathematics education specifically has been the subject of many studies which hardly can be reviewed here even superficially (let's just remind that the famous book of Rademacher and Toeplitz (1957) was called in English translation *The Enjoyment of Mathematics*). The author would limit himself to saying that the pleasure which we are feeling in process of dealing with mathematics is an intellectual pleasure often associated with the accomplishment of an important task (it can be compared with the pleasure that one feels after finishing building a house).

To understand the issue in question better, we need to formulate some general pedagogical assumptions about students and their learning in general. Based on our observations we assume a child can achieve astonishingly much when properly instructed and motivated.

CASE STUDY OF AN *OPTIMISTIC NUMBER*

Let us start with the analysis of one problem. Let us name a natural number *optimistic* if it has more than one digit and if these digits, taken from the right to the left, are strictly decreasing. So in this case 12 is the first *optimistic* number and, obviously and consequently, the number 123 456 879 is the last *optimist*. We ask to multiply the *optimistic* number by 9 and then count the sum of its digits. For

instance, taking that first optimistic number 12 and multiplying it by 9 we'll get 108 with 9 as the sum of digits $1 + 0 + 8$.

So what else could we get? For another example take the largest optimistic number 123 456 789. Multiplying by 9 we'll get $123\ 456\ 789 \cdot 9 = 1\ 111\ 111\ 101$ – again with 9 as the sum of its digits

$$1 + 1 + 1 + 1 + 1 + 1 + 1 + 1 + 0 + 1.$$

What more could we get? Or do you already believe that only 9 as the sum of its digits is the uniquely possible? What to do and how to start?

AWAKENING THE NATURAL CURIOSITY

It is very unlikely that the student is not impressed by these "strange" results. How can it be? Is it a miracle? Typically, students consider more numbers and try to check the statement. Whatever their next step will be, students will be engaged in thinking. Their natural curiosity is awakened.

Why is it here and not in many problems offered in school? Probably, the reason is that the problem starts with a very clear and observable result. Understanding the problem is the first stage among Polya's four stages (Polya, 1973), and is really important. The problem can and even should be challenging but we need to prepare students by starting with something what student can see right there in the classroom. The first principle is "start with something known and understandable". The second principle is also here: "try to say something unusual and unexpected". The cognitive conflict between clearness and unexpectedness awakes the curiosity.

CASE STUDY OF *DISTRIBUTING COINS*

The problem to be discussed below was reported to the author by the famous Latvian professor, problem composer and educator Agnis Andžans. The author of the problem and the author of this paper presented the problem many times to different audiences, starting from students of Grade 3 and 4 and finishing with students of Vilnius University. The process of the solution is the same.

Firstly, the lecturer asks how to distribute 12 identical coins between two purses putting in one purse twice as many coins as in the other one. The clear answer – 4 and 8 – in all audiences is given immediately, without the slightest delay.

And now the lecturer proposes to take 10 coins instead of 12 and achieve exactly the same result – that in one purse there would be twice as many coins as in the other one. It needs to be added that to divide coins into parts is not permitted.

The audience is puzzled. Those more educated even write the equation $x+2x=10$ which can not be solved in integers (and dividing coins is not permitted). Those less experienced simply say "No, it is not possible!" The lecturer is supposed to behave in such way as to insist that a solution is still possible. Sometimes somebody finds

the solution. If this is not case then the lecturer announces that he will now make two “moves” and some people will immediately, unavoidably present the answer. The two “moves” are simple: the first movement imitates some small circle (purse) and another – another circle (purse), large one.

Immediately, some listeners come with the solution: one purse with 5 coins must go into another purse which holds already the remaining 5 coins. The audience is happy. The pleasure of problem solving is achieved.

WHY WAS THE SOLUTION PLEASURABLE?

The task was selected according to the principles formulated above -- the situation is clear as well as the cognitive conflict. The next step comes with the solution -- it is enjoyable. Why? First, it is understandable -- no person in the room can say that he or she do not see how it works even if he or she did not solve the task. Second, it is unexpected. The person solving the problem had some limitations, some stereotype in the mind. This limitation was removed -- the feeling of intellectual freedom makes the problem solver happy.

CONSIDERING MORE CHALLENGING PROBLEMS: CASE STUDY OF THREE BROTHERS

The previous problem is just a puzzle and although some mathematics is involved it hardly relies on any sophisticated knowledge. Let's consider a situation that is a bit more challenging.

Let's take any person and assign to this person any number – positive, negative, or zero. The most natural way to model this process with a real world situation is considering a financial capacity of the person. Indeed, a person can have a positive banking account, have nothing, or, unfortunately, even be in debts, that is have a negative account. In line with it we define the financial capacity of any group of persons (maybe containing a single person only) as the sum of numbers assigned to each person in that group. A financial capacity of any group of persons (again, maybe containing a single person only) is said to be *remarkable* if, and only if, that sum in question is positive. And now the problem comes.

Consider any group of three brothers with the *remarkable* financial capacity. Prove that there is a pair of brothers with the *remarkable* common financial capacity.

The formulation of the problem is as required simple and understandable. The solution is also clear -- let's just assume that the statement is not correct. In other words, let's assume that

(A) The total financial capacity of all three brothers is *remarkable*.

(B) The total financial capacity of any pair of all three brothers is not *remarkable*.

Now some mathematical language should come in the play. Let x , y and z be correspondingly the numbers assigned to these three brothers or these are their single

financial capacities. Then the first condition that their total financial capacity is *remarkable* means that the sum of all x , y and z is positive. But, according to the second condition all three pair-wise sums $x + y$, $y + z$ and $z + x$ are not positive, because, as told, all total financial capacities of any possible pair are not *remarkable*. Adding these three non-positive sums we'll get the double sum of all three numbers x , y and z , or

$$2(x + y + z) \leq 0.$$

But then $x + y + z \leq 0$ what is clear contradiction to the given fact that the total financial capacity of all three brothers is *remarkable* – or to the condition 1.

EXTENDING THE PROBLEM

Are you happy? Well, it is a nice problem, but it is not a surprise. Neither the result, nor the method was unexpected. The point, however, is that once we familiarized ourselves with the situation we can go further. The next question comes if we "slightly" change the word -- instead of asking about *one* pair ask about *all* pairs.

A problem with three brothers now sounds like that: Given that the total financial capacity of three brothers is remarkable, is it necessarily true that the total financial capacity of all pairs of these brothers is remarkable?

The solution is even easier than the previous one but of very different nature. Let's simply consider an example; let the first brother have 6, the second 5 and the third brother -10. Obviously, the sum of all three numbers is positive, while two sums of two numbers are negative. The answer to the problem is no, it is not necessarily true.

In solving this problem we solved one more about having two pairs of brothers with the total remarkable capacity. Even having them is not necessarily true.

The case of three brothers is explored but now the time for the four brothers comes. Now the list of questions might be longer and contain the following questions in addition to the question about one pair which is answered affirmatively:

- (A) Are there necessarily at least two pairs with the common *remarkable* financial capacity?
- (B) Are there necessarily at least three pairs of brothers with the common *remarkable* financial capacity?

Then you can pose a general question about n brothers with the total *remarkable* financial capacity (this problem was offered in one Olympiad in Belarus).

THE PLEASURE OF ACTING AS A MATHEMATICIAN

The author of this paper discussed the problem in many audiences. Obviously, the financial model for this problem helps solvers to understand the problem better and feel more comfortable with it. It would be wrong, however, to attribute the interest which the audience has to the matter of money only. Clearly not. The reason for the pleasure is again purely intellectual: participants enjoy the process of asking

questions and extending the problems. Typically, this work is done by the research mathematicians, while students are assigned to the lower job of answering somebody's else questions (the analysis of problem posing from the social point of view is offered by Brown and Walter, 1990, and by Watson and Mason, 2005). Here they can act as a mathematician and, again, this new freedom is enjoyable.

A FEW "MINOR" DETAILS: CASE STUDY OF *DOUBLY THRICE-SMART NUMBERS*

The problem is supposed to be attractive. In writing attractive problems a teacher should remember that children likes games, they like tales, they like unusual situations and words. It is advisable to combine the mathematical side with the play.

For example, it is well known that for any large integer it is possible to write it as the sum of a few summands. It can be done in several ways. If the number gets smaller the degree of freedom “gets smaller”. Applying some special and unusual terminology, we may try to make the situation to appear more attractive.

Let us call the number *doubly thrice-smart* if it is possible to write it as the sum of three addends in two ways with no of those six attracted addends being used twice.

Clearly 111 or 21 is *doubly thrice-smart* because of

$$111 = 100 + 10 + 1 = 104 + 4 + 3, \quad \text{and} \quad 21 = 1 + 9 + 10 = 2 + 4 + 15.$$

On the other hand, it is clear that 6 is not *doubly thrice smart* because of

$6 = 1 + 2 + 3$ is clearly the only possibility to write 6 as the sum of three different addends. So the question – where is the boundary between these integers that are *doubly thrice smart* and which are not, might be interesting for the arithmetical investigation.

The solution of the problem, although technically not difficult, contains some substantial ideas. It may be helpful to apply Polya's strategy of working backwards and think what can be the numbers involved in the sums for our number (let's call it x). Obviously, six smallest positive integers are

$$1, 2, 3, 4, 5, 6.$$

Assume that this *doubly thrice smart* x is obtained using these numbers in any order and in any way twice. That implies that $2x$ equals the sum of these numbers which is

$$1 + 2 + 3 + 4 + 5 + 6 = 21.$$

Two conclusions are following. First, we cannot operate with these numbers only -- the number 21 cannot equal $2x$. Second, numbers smaller than 11 are not *doubly thrice smart* -- even operating with the smallest possible numbers we obtain something greater. It means that the smallest possible candidate to be *doubly thrice smart* is a number 11. And 11 is indeed such a number because 11 can be written either as

$$11 = 2 + 4 + 5 \quad \text{or as} \quad 11 = 1 + 3 + 7$$

so 11 is indeed the smallest such integer and the rest follows.

OBSERVATIONS FROM THE CLASSROOM

This problem according to the experience of the author, is understandable for children of the age of 10. Importantly, they even are already able to understand the concept of proof.

By saying this, the author doesn't mean that the abstract reasoning is necessarily developed by all or even by many third-graders. When teaching this problem in Grade 3, the author faced the situation that the conclusion that no number smaller than 11 can be *doubly thrice smart* was taken as the one established by authority of the teacher. Still, students realized that the statement had to be somehow supported and validated (the authority of the teacher was one of the possibilities, particularly when the practical experience also demonstrated to the children that there are no required representations for the numbers smaller than 11). In Grade 4 at the same school it was possible to achieve much more: evidently, a good proportion of pupils present were able to understand even the abstract part or the proof.

In any case even those who missed the abstract part enjoyed the task. The atmosphere of the game rather than the dull and routine school activity was helpful, and the funny wording was useful in establishing this atmosphere. Another important feature was that the problem permitted actions on the different levels of cognition. While some students were concerned with more abstract tasks, other could enjoy the more practical and concrete search for numbers. The opportunity to work differently seems to be an important characteristic for making problem solving a pleasurable activity.

WHAT IS AN EFFECTIVE HINT?

THE CASE STUDY OF THE ST. PETERSBURG PROBLEM

The problem sounds as a task for the low grade. Nine numbers are given:

15, 16, 17, 18, 19, 20, 21, 22 and 23.

We need to put them into 9 entries of a 3 x 3 table in such a way that the sum of any pair of neighboring integers is always different (neighboring cells are those sharing the side).

Let us note that placing them in the order is not suitable. Indeed in that case 16 shares the common side with 17, as well as 15 with 18 do. Because both pairs have the same sum 33 that way of placing them is not the required one.

15	16	17
18	19	20
21	22	23

Again, the teachers can find themselves in the situation similar to the one with the purses described above. The audience does not see the way to solve the problem. It would be desirable to give a hint, but still, not providing the entire solution. One way to do this may be to suggest thinking about how to make the sides more like diagonals so that neighbors will not be neighbors anymore. The hint although very small and more emotional than practical can suggest the right direction of thoughts. Indeed, imagine that the table given above is rotated around its center. We will obtain the following table in which no "wrong" pairs are visible.

15	17	20
16	19	22
18	21	23

Indeed, all 12 of neighboring pairs prove to provide different sums:

$15 + 17 = 32$, $17 + 20 = 37$, $15 + 16 = 31$, $17 + 19 = 36$, $20 + 22 = 42$, $16 + 19 = 35$,
 $19 + 22 = 41$, $16 + 18 = 34$, $19 + 21 = 40$, $22 + 23 = 45$, $18 + 21 = 39$, $21 + 23 = 44$.

The effect of achieving much by undertaking practically nothing is quite memorable. This little hint proves to be very efficient - students learn to consider their "vague" feelings and make them more accurate.

THE SUPPORT AND ENCOURAGEMENT OF THE TEACHER MEANS A LOT!

This paper deals mainly with the mathematical side, identifying criteria for a good problem and for a good solution. The pedagogical dimension is, however, at least equally important. The pedagogy has already been mentioned when talking about the wording, but the behavior of the teacher is of major value too. The paper was started with the problem about the optimistic number. Now, near the end of the paper, we should praise the optimistic teacher: a teacher who believes in the students' abilities and interests and shares these interests with them. This disposition of the teachers is felt in the classroom and influence the audience.

CONCLUSION

The author spent many years teaching how to solve problems and has written several books in three languages trying to report some of his impressions (Kasuba, 2008a, 2008b, 2009, 2012). This experience represented in the discussion above leads to posing two questions.

The first one deals with regular school mathematics: the tasks discussed above are usually considered to be part of so called extracurricular mathematics, or mathematics for the circle. It is important to consider what can be done with regular school mathematics about the equation of the straight line and the law of sines to be

pleasurable. The author strongly believes that the principles for the teacher are the same as stated above:

- start with something known and understandable;
- try to say something unusual and unexpected;
- provide the feeling of intellectual freedom;
- give the chance to act as a mathematician;
- make use of minor details being age appropriate;
- be optimistic and provide a supporting behavior.

It is another story that, surprisingly, the experience of pleasurable learning in the regular classroom is not very often discussed. The author believes that such experiences should be collected and analyzed. Also, the samples of activities and problems which proved to be helpful in this work should be made broadly available. The question here is not just a technical issue -- making the learning pleasurable in the context of a regular classroom includes some important reorganizations permitting specifically the happiness of intellectual freedom.

It is important to emphasize here the difference between "pleasurable" activity and easy activity as well as non-mathematical activity. Unfortunately, too often in order to keep students engaged and make them have fun mathematics is substituted with some irrelevant stories or pictures or videos. The job of the mathematics educator is to make mathematics education pleasurable, not to provide pleasure instead of mathematics education. Open and critical discussion of the existing controversies is badly needed.

The second question deals with the methodology of research in mathematics education. This paper represents the notes of the practitioner attempting to generalize his observations. Given the development of methodology and research instruments in mathematics education (Schoenfeld, 2007), it would be desirable to find some ways to complete more rigorous studies on the issue of learning with pleasure. Clearly, we have some instruments which permit measurement of the satisfaction of the group. The author, however, is afraid that so far these instruments cannot distinguish the highest levels of intellectual pleasure (just as it is difficult to distinguish by means of questionnaires the difference between good and entertaining performance and major events in the history of theater).

The author believes that we need to make use of qualitative studies but rigorously organized. Specifically, we need to collect episodes of learning mathematics with pleasure at different levels, starting probably with those who later became involved in mathematics, but not limited to them. What was pleasurable? How was the pleasure achieved? What was the role of the teacher?

Answering all these questions seems to be both of practical and theoretical importance. The author would like to think that this paper contributes to raising these questions.

THE CONNECTION BETWEEN MATHEMATICAL CREATIVITY AND HIGH ABILITY IN MATHEMATICS

Miri Lev and Roza Leikin

University of Haifa

This paper presents part of the findings from a large-scale study that explores the relationship between mathematical creativity, mathematical expertise and general giftedness, a relationship which is not obvious. We distinguish between relative and absolute creativity in order to evaluate mathematical creativity in school children. This paper demonstrates that general giftedness and excellence in mathematics has a major effect on secondary students' creativity associated with production of multiple solutions to mathematical problems. However, these effects are task-dependent. Thus, we conclude that different types of Multiple Solution Tasks (MST) can be used for different research purposes.

Key words: Mathematical Creativity, Multiple Solution Tasks (MST), General Giftedness, High Level of Mathematical Instruction.

RATIONALE

This study employs multiple solution tasks to explore students' creativity in mathematics. It continues a series of studies that were directed towards the design and validation of the research tool used herein. (Leikin and Lev 2007, Leikin 2009, Leikin & Lev In press-2013 , Levav-Waynberg and Leikin 2012, Guberman and Leikin 2012). These earlier studies also examined the relationship between mathematical creativity and the level of the participants' mathematical ability. All the studies led to several hypotheses which we are currently examining in this large-scale study. We hypothesized that (1) between-group differences are task dependent and (2) in the originality-fluency-flexibility triad, fluency and flexibility are of a dynamic nature, whereas originality is of the "gift" type.

BACKGROUND

Creativity

There is no single, authoritative perspective or definition of creativity (Mann 2006). Our study follows Torrance's (1974) definition of creativity with four components: *Fluency* refers to the continuity of ideas; *Flexibility* is associated with changing ideas; *Novelty* is characterized by a unique way of thinking; *Elaboration* refers to the ability to generalize ideas. Of these four components, novelty, or originality, is widely acknowledged because creativity is viewed as a process having to do with the generation of original ideas.

While drawing a connection between high abilities and creativity, researchers express a diversity of views. Some claim that creativity is a specific type of giftedness (e.g., Sternberg 2005), while others feel that creativity is an essential component of giftedness (Renzulli 1978), and still other researchers suggest that they are two independent characteristics of human beings (Milgram and Hong 2009). Thus, analysis of the relationship between creativity and giftedness, with a specific focus on the various fields of mathematics, is important for better understanding of the nature of both mathematical giftedness and mathematical creativity.

Mathematical creativity

One of the complexities related to the relationship between mathematical giftedness and mathematical creativity is rooted in the contrast between viewing mathematical creativity as a property of the professional mathematician's mind (Ervynck 1991) and the opinion that mathematical creativity can and must be developed in all students (Sheffield 2009). Naturally, creativity in school mathematics differs from that of professional mathematicians. Mathematical creativity in school students is evaluated with reference to their previous experiences and to the performance of other students who have a similar educational history. Leikin (2009) suggested that viewing personal creativity as a characteristic that can be developed in schoolchildren requires a distinction between *relative* and *absolute* creativity. *Absolute creativity* is associated with discoveries at a global level. Our work deals with *relative creativity*, which refers to mathematical creativity exhibited by school students when evaluated in relation to their previous experiences and to the performance of other students who have similar educational histories. The current study accepts the relative perspective on creativity while evaluating originality of students' solutions.

THE MODEL FOR EVALUATION OF MATHEMATICAL CREATIVITY

Multiple solution tasks

A multiple solution task (MST) is an assignment in which a student is explicitly required to solve a mathematical problem in different ways. Solutions to the same problem are considered to be different if they are based on: (a) different representations of some mathematical concepts involved in the task, (b) different properties (definitions or theorems) of mathematical objects within a particular field, (c) different properties of a mathematical object in different fields.

Table 1 demonstrates an example of a multiple solution task (Jam problem) and depicts 10 different solutions to the problem.

Table 1: Jam problem-Multiple solution task

Jam Problem	
<p>Mali produces strawberry jam for several food shops. She uses big jars to deliver the jam to the shops. One time she distributed 80 liters of jam equally among the jars. She decided to save 4 jars and to distribute jam from these jars equally among the other jars. She realized that she had added exactly $\frac{1}{4}$ of the previous amount to each of the jars. How many jars did she prepare at the start?</p> 	
Group of solutions	Description
A	System of equations -1 $\begin{cases} xy = 80 \\ 1.25x(y - 4) = 80 \end{cases}$ System of equations -2 $\frac{x}{y} \Rightarrow \frac{x}{y-4} = \frac{5x}{4y}$
B	Equation -1 $\frac{4}{x} = \frac{1}{4}$ Equation -2 $\frac{4}{x-4} = \frac{1}{4}$ Equation -3 $1.25x = x + 4$
D	Equation in 2 variables $4x = \frac{1}{4}x(y - 4)$
E	Diagram
C	Insight: Fractions/ Percents $\frac{1}{4}$ of initial amount is $\frac{1}{5}$ of the new amount. 4 jars are $\frac{1}{5}$ of all jars, thus there were 20 jars at the start.
F	Insight Solution 4 jars equals one quarter of the remaining amount of jam \rightarrow 20 jars in total
G	Insight Solution Jam from each of the 4 jars was distributed among 4 jars – overall all the jam from 4 jars went into 16 jars. Thus there are 20 jars in total

The scoring scheme

The evaluation model was first introduced by Leikin (2009) and then employed in the research of Levav-Waynberg and Leikin (2012) and Guberman and Leikin (2012).

Table 2: Scoring scheme for evaluation of creativity (based on Leikin 2009)

	Fluency	Flexibility	Originality	Creativity
Scores per solution	1	$Flx_i = 10$ - for the first solution $Flx_i = 10$ - solutions from a different group of strategies $Flx_i = 1$ - similar strategy but a different representation $Flx_i = 0.1$ - the same strategy, the same representation	$Or_i = 10$ $P < 15\%$ or for insight/unconventional solution $Or_i = 1$ $15\% \leq P < 40\%$ or for model-based/ partly unconventional solution $Or_i = 0.1$ $P \geq 40\%$ or for algorithm-based/ conventional solution	$Cr_i = Flx_i \times Or_i$
Total score	$Flu = n$	$Flx = \sum_{i=1}^n Flx_i$	$Or = \sum_{i=1}^n Or_i$	$Cr = \sum_{i=1}^n Flx_i \times Or_i$

n is the total number of appropriate solutions

$P = (m_j / n) \cdot 100\%$ where m_j is the number of students who used strategy j

Fluency (Flu) refers to the pace at which solving proceeds and the switches taking place between different solutions.

To evaluate *flexibility* (Flx), we established groups of solutions for the MSTs. Flexibility embedded in a problem is evaluated according to expert solution space. Two solutions belong to separate groups if they employ solution strategies based on different representations, properties or branches of mathematics.

Originality is evaluated by comparing individual solution spaces with the collective solution space of the reference group.

In the decimal basis we used in scoring, the total score indicates the originality and flexibility of the solutions in the individual solution space of a participant. For example, if the total flexibility score for a solution space is 21.3, we know that it includes 2 solutions that belong to different solution groups (based on different solution strategies), 1 solution that uses a solution strategy similar to a former solution but differs in some essential characteristics, and 3 solutions that repeat previous ones.

The *creativity* (Cr) of a particular solution is the product of the solution's originality and flexibility: $Cr_i = Flx_i \times Or_i$. The use of the product of flexibility and originality scores enables evaluation of the most creative solutions, with the highest score ($Cr_k = 100$) given for a flexible and original solution. This also addresses the fact that previously performed solutions cannot be considered to be creative. The total creativity score on an MST is the sum of the creativity scores for each solution in the individual solution space of a problem:

$$Cr = \sum_{i=1}^n Flx_i \times Or_i .$$

The model for evaluation of creativity applied with a particular set of MSTs constitutes the research instrument in this study.

THE STUDY

Research goals

There are two main interrelated goals in this study:

- (1) To examine relationships between mathematical creativity, general giftedness, and mathematical excellence.
- (2) To explore the power of different types of MSTs for the identification of between-group differences related to mathematical creativity as reflected in multiple solutions produced by the students.

The test

The problems included in the test differed with respect to:

- (1) *Mathematics topic* to which the problem belongs in the school curriculum

- (2) *Complexity*
- (3) *Conventionality* of the problem and conventionality of the solutions, requiring insight in order to produce the solutions (following Erynk 1991).

The test consisted of five problems (Leikin & Lev, accepted). We focus here on 2 of these problems (see Table 3) to discuss task dependency of the effects of G and EM factors on mathematical creativity (see the Population section below).

Correctness of the solution for a problem was evaluated according to the complete solution produced by the student to the problem. For a complete solution a student received 25 points. Creativity components were evaluated according to the scoring scheme (Table 2).

Table 3: Two problems on the test

Topic	Problem
Word problems 	Jam problem: Mali produces strawberry jam for several food shops. She uses big jars to deliver the jam to the shops. One time she distributed 80 liters of jam equally among the jars. She decided to save 4 jars and to distribute jam from these jars equally among the other jars. She realized that she had added exactly $\frac{1}{4}$ of the previous amount to each of the jars. How many jars did she prepare at the start?
System of equations	$\begin{cases} 3x + 4y = 14 \\ 4x + 3y = 14 \end{cases}$

Population

A sample of 191 students was chosen out of a population of 1200 10th -11th grade students (16-17 years old). The sampling procedure was aimed at investigating the effect of G and EM factors (see Table 4).

G factor: Students for G groups were mainly chosen from classes of gifted students (IQ>130). Additionally, the entire research population was examined using Raven's Advanced Progressive Matrix Test (RPMT) (Raven, Raven & Court, 2000) (see Table 4 for the sampling criteria).

EM factor: All 1200 students studied mathematics at high and regular levels (HL, RL). The level of instruction is determined by students' mathematical achievements in earlier grades. Instruction at HL differs from that at RL in terms of the depth of the material learned and the complexity of the mathematical problem-solving involved. Additionally, excellence in mathematics is examined using the SAT-M (Scholastic Assessment Test in Mathematics, adopted from Koichu, 2003). (See Table 4 for the sampling criteria).

After completion of this stage, 191 of the initial 1200 students were subdivided into four experimental groups, determining the research population according to varying combinations of the EM and G factors, as presented in Table 4.

The fifth group of students – S-MG (super gifted in mathematics) students included G-EM students who were members of mathematical Olympiad teams or who study university mathematics while attending high school. These students received recommendations from research mathematicians familiar with their achievements.

Table 4: Target population

	Gifted (G) IQ>130 Raven > 27/30	Non-Gifted (NG) Raven < 26/30	Super Gifted (S-MG)	Total
Excelling in math (EM) SAT-M >26 or HL in mathematics with math score > 92	G-EM N=38	NG-EM N=51	S-MG N=7	96
Non-excelling in math (NEM) SAT-M <22 and RL in mathematics with math score > 90 or HL in mathematics with math score < 80.	G-NEM N= 38	NG-NEM N=57		95
Total	76	108	7	191

Data analysis

A multivariate analysis of variance tests (MANOVAs) were used to compare the scores on each component of creativity that participants received in each problem.

Between-subjects differences were examined for each one of the problems and each one of the creativity components for G factor, EM factor and interactions between G and EM factors.

Within-subjects differences were examined for their performance on the different tasks.

FINDINGS

As mentioned earlier, we present herein our findings related to the two problems. These two problems are regular curriculum-related problems which have unconventional (insight-based) solutions.

Table 5 presents the percentage of students with different levels of fluency (the number of overall solutions produced by a student) and flexibility (the number of different solutions produced by a student). We learn from this data that students in all the groups were more successful, fluent and flexible in solving the system of equations than in solving the word problem. This may be due to the fact that in contrast to the system of equations, word problems similar to the Jam problem are seldom used for mathematics lessons in 10th-11th grades. From Table 5 we learn that, although there is a connection between fluency and

flexibility in students' problem solving performance, these two parameters measure different mental abilities. Production of multiple solutions does not mean production of different multiple solutions. Clearly students from the G-EM group (including S-MG students) differed significantly in their flexibility when solving both problems. Statistical analysis – comparisons of column means – (which we do not present here due to space limitations) supports this observation: participants from the G-EM group differ from participants of all other groups in the fluency and flexibility of their problem solving performance.

Table 5: Fluency and Flexibility

%		Jam problem						System of equations						
No. of solutions (Flu) / No. of groups of solutions (Flx)		0	1	2	3	4	6	0	1	2	3	4	5	8
G-EM (N=38)	Flu	5.3	15.8	23.7	55.2			0	0	7.9	71.1	21		
	Flx	5.3	29	52.5	13.2			0	5.3	36.8	50	7.9		
G-NEM (N=38)	Flu	28.9	31.6	13.2	23.7	2.6		5.3	0	5.3	68.4	15.8	2.6	2.6
	Flx	28.9	44.7	26.4				5.3	5.3	47.3	39.5			
NG-EM (N=51)	Flu	27.5	23.5	21.6	27.4			2	2	9.8	78.4	7.8		
	Flx	27.5	47	23.5	2			2	9.9	47	47.1			
NG-NEM (N=57)	Flu	50.9	24.6	17.5	7			1.8	14	21	54.4	7	1.8	
	Flx	50.9	33.3	15.3				1.8	28	43.9	26.3			
S-MG (N=7)	Flu			14.3	85.7						42.9	57.1		
	Flx		42.8	14.3	42.9					28.6	71.4			

Table 6, which presents Means and SD that we obtained for all the examined criteria on both problems, provides additional support for the observation of the specific qualities of mathematical reasoning in G-EM students.

MANOVAs demonstrate effects of EM and G factors on all the examined criteria (Table 7). Significant main effects of G and EM factors were found for Cor, Flu and Flx criteria on Jam problem, while only the G factor had a main effect on Or and Cr criteria. In the system of equations, significant main effects of G and EM factors were found for Flx, Or and Cr. Only the G factor had a main effect on Flx criteria. For the system of equations we found an interaction between EM and G factors with respect to students' flexibility related to solving the system of equations: G factor strengthens the effect of EM factor; that is, excelling in mathematics students who are gifted in mathematics are significantly more flexible than their non-gifted counterparts, whereas no significant differences appear in the flexibility of EM and NEM students among NG students.

Table 6: Means and SD

N		G-EM		G-NEM		NG-EM		NG-NEM	
		38		38		51		57	
		Mean	SD	Mean	SD	Mean	SD	Mean	SD

SUMMARY

This study examines relationships between mathematical creativity, general giftedness, and mathematical excellence. It also explores the power of different types of MSTs for the identification of between-group differences related to

mathematical creativity as reflected in multiple solutions produced by the students. Five groups of 10th grade to 11th grade students who varied in their level of general giftedness and in the level of mathematical instruction participated in this study.

The study demonstrates that G students have higher scores on all the examined criteria. Both EM and G factors have a main effect on students' fluency and flexibility associated with MSTs. The G factor has a main effect on originality. G and EM factors interact on the flexibility criterion: the EM factor has a more significant effect on flexibility and originality criteria among G students.

The effects of EM and G factors are task-dependent and are related to the level of insight embedded in the task and the familiarity of the conventional solution. Task dependency of the findings, as well as different effects that were discovered in the study, demonstrate that EM and G factors are interrelated, but different in nature.

ACKNOWLEDGMENTS

This project was made possible through the support of a grant from the John Templeton Foundation. The opinions expressed in this publication are those of the author(s) and do not necessarily reflect the views of the John Templeton Foundation. We are thankful to the Israeli Ministry of Education and the University of Haifa for their generous financial support of this project.

MATHEMATICAL CREATIVE SOLUTION PROCESSES OF CHILDREN WITH DIFFERENT ATTACHMENT PATTERNS

Melanie Münz

University of Frankfurt/ IDeA Centre

In research about mathematical creativity seldom the early childhood is taken into count. The paper investigates the mathematically creative solutions of Kindergartners (in Germany children between 3-6 years attend Kindergarten). Starting point is the longitudinal study MaKreKi (mathematical creativity of children) in which theories of mathematics education and psychoanalysis are amalgamated for the investigation of mathematical creativity. In this paper two episodes of two children between 4 and 5 years old are presented, while they cope with a mathematical task. It focuses on the mathematical creative ideas emerging in the interaction between the involved children and the accompanying person and how the children deal with the mathematical instructions.

Keywords: mathematical creativity, attachment theory, early childhood mathematics

INTRODUCTION

Attempts to define mathematical creativity seem to lead to more than 100 contemporary definitions of creativity (Mann 2006), but mathematical creativity in early years is rarely examined. Thus the central research question is, how does mathematical creativity express itself at the age of preschool and how is it observable?

Following Urban (2003) a theory of creativity has to consider the “4P-E Structure” of creative thinking and acting, which embodies the interactive structure of the factors: problem, person, process, product and environment. The existence, the range and recognisability of possible problems to be solved creatively are determined by meta- environmental factors like evolutionary and social-historical developments, macro-environment like economic, material, cultural and political conditions and micro-environmental factors such as socioeconomic conditions of the family (Urban 2003). From a socio-constructivist point of view, the individual ability of mathematical creativity develops in the course of many interactions with other members of the culture. The paper focuses on the mathematical process while children are working on mathematical tasks in mathematical situations of play and exploration. Therefore it highlights on the negotiations of meanings (Brandt & Krummheuer 2001) between the children and the accompanying person during the interactive process while coping with mathematical task and in a specific cultural system. Beside this situational, micro-sociological access the paper also refers to psychoanalytically- based attachment theory, in which a function of the culture is understood as an aspect of the relationship between mother and child. Bowlby’s

theory of attachment suggests that children come into world biologically pre-programmed to form attachments with others, because this helps them to survive (1969). The neonate develops special relationships with her parents. In the first years of life the child develops an ‘inner working model’ through child-parents-interactions (Bowlby 1969). This ‘inner working model’ contains the early individual bonding experiences as well as the expectations, which a child has towards human relationships, derived from these experiences. They conduce to interpret the behavior of the caregiver and to predict his or her behavior in certain situations. So the attachment between mother and child has a great impact on the social- emotional and cognitive development of the child. After the first year of life this ‘inner working model’ becomes more and more stable and turns into a so called attachment pattern.

Children are confronted with mathematical tasks and contents from different domains of mathematics as they appear in their everyday life. In the MaKreKi project these contents are presented in form of mathematical situations of play and exploration (Vogel 2013) for the children regarding their assumed mathematical competencies. Within in these situations a competent adult guides the children. He has some knowledge about the mathematical contents, which are intended and a minimal set of instructions like questions or allegations. The competent adult also has some hints of possible reactions and expressions of the children, so that he is somehow prepared for possible mathematical tasks and solutions emerging in the context of the mathematical situation of paly and exploration. All these information for the accompanying person are documented in ‘didactical design patterns’ (ibd.). On the situational level the presentation of these mathematical situations of play and exploration initiate processes of negotiations of meanings, which necessarily do not be in in accord with the described mathematical domain nor the activities that are expected in the design pattern.

Following Urbans idea of the “4P-E Structure” this article examines macro-environmental factors like cultural conditions e.g. the intended mathematical domains/contents and the expected mathematical tasks and solutions presented in the mathematical situations of play and exploration as well as the interactive negotiations of these themes (micro-social factors). Beside this the paper also involves psychodynamic aspects of early childhood development (micro-environmental factors). In the research design of the MaKreKi project children are dealing with mathematical problems and tasks guided by a competent adult. This adult can be seen as a representative for the parents, because it might be reasonable to assume that children shows similar behaviour in this situation like they would with their parents, because of their stable ‘inner working model’ and their attachment pattern. The attachment system is now widely studied in the life cycle, but little is said about creativity as a concomitant of this system (Brink 2000). Therefore the second research question is, which correlation exists between the attachment pattern of children and their mathematical creativity?

THEORETICAL PERSPECTIVES

The following section introduces theoretical perspectives of mathematical creativity in early childhood and offers psychoanalytical considerations about attachment theory and the connection to creativity.

Mathematical Creativity

Mathematicians and researchers in mathematics education as well as psychologists have examined mathematical creativity under their various scientific viewpoints (Hadarmard 1954, Sriraman 2004). A clarification of concepts of creativity is difficult and additionally complicated by its relationship to the concepts of intelligence, giftedness and problem solving. According to Urban and Sriraman, who offer a definition of mathematical creativity, which keep in mind the “4P-E Structure” of creative thinking, creativity is understood as the ability of creating a surprising, meaningful product, which extends the body of knowledge and as the process that results in unusual/novel/insightful solutions to a given problem (Urban 2004; Sriraman 2011). Sriraman (2011) notices the difference between creativity at the professional and school levels and suggests that the ability to produce original work can be regarded as mathematical creativity at professional level whereas the process that results in unusual solutions can be seen as mathematical creativity at school level. For mathematical creativity at preschool level exists no definition.

Because of the relative lack of current research in mathematical creativity in early childhood, this article deals with the following four aspects of mathematical creativity (Sriraman 2004) regarding the presented definition of mathematical creativity at school level:

- *Choice*: Poincaré (1948) described as a fundamental aspect of mathematical creativity the ability to choose from the huge number of possible combinations of mathematical propositions a minimal collection that leads to the proof. With regard to the age group of interest under this *choice* aspect of mathematical creativity the production of (unusual) relations between mathematical examination and experiences and the playful contact with mathematical methods is understood.
- *Non-algorithmic decision-making*: According to Eryvynck (1991), mathematical creativity articulates itself not when routine and/or standard procedures are applied but when a unique and new way of solving a problem emerges. With regard to the age group one is able to shift the accentuation and speak of the “divergence from the canonical” (Bruner 1990, p.19).
- *Adaptiveness*: Sternberg & Lubart (2000) characterize creativity, as the ability to present an unexpected and original result that is also adaptive.
- *De-emphasizing details*: In his study, in which he investigates the ideas and thoughts to mathematical creativity from famous mathematicians, Liljedahl (2008) has discovered that detail does not play any role during the incubation phase of

creativity. Many of the participants mentioned how difficult it is to learn mathematics by attending to the details, and how much easier it is if the details are de-emphasized.

Attachment theory

Attachment theory originates from Bowlby (1969) and postulates the central role of attachment behaviour for individual development. Bowlby perceives the attachment system as the central source of motivation. In his approach the antagonism between attachment and exploration has a highly relevant explanatory power. Both systems cannot be simultaneously activated. If a child feels secure, it can activate his exploration system and explore his surroundings. If it perceives a danger, the attachment system is activated. The child interrupts its exploratory behaviour and seeks safety by its parent. Four attachment patterns are described (Ainsworth et al. 1978): *Insecure-avoidant*: The ‘insecure-avoidant’ child (A) experiences that its mother feels best when it shows no intense affects itself and behaves towards her in a controlled, distanced manner with a minimum of affect. *Secure*: The securely attached child (B) has, thanks to its sensitive mother, a chance to build up a secure relationship to her in which the whole spectrum of human feelings in the sense of communication with another, that can be perceived, experienced and expressed. *Insecure-ambivalent*: The ambivalently attached child (C) has spent its first year with a mother, who sometimes reacts appropriately, and is at other times rejecting and overprotective, i.e. on the whole, inconsistent and for this reason she reacts in a way that is unpredictable for the child. *Insecure-disorganized*: The disorganized/disoriented attached child (D) could not build up a stable inner working model, as its mother (or father) suffered under the consequences of an acute trauma (for example, the dramatic loss of an important person). They were psychically so absorbed by this loss that they could hardly take up a coherent relationship with their infant.

Relating this approach to the topic of mathematical creativity of young children, the results of empirical attachment research point to the fact that the shaping of domain-specific (mathematical) creativity can not only be localized in the potentially stimulating mathematical contents in the child’s milieu but also in the type of attachment of the child to its parents. Grossmann describes the link between the attachment pattern of the child and the ‘successful cooperation’ (in German: *gelingende Gemeinsamkeit*) in a child-parent play situation more detailed (Grossmann 1984). The ‘successful cooperation’ of these play situations correlates with the delicacy feeling of the mother and a more delicacy feeling leads very often to a secure attachment pattern of the child (ibid.). Mothers of secure attached children seem to be more reserved, gentle and they show more efforts in handing over the lead to their children in play situations instead of mothers of insecure attached children. Mothers of insecure attached children are often strict and controlling and they have more instructional ratio in play situations than mothers of secure attached children (ibid.). Significant differences between children with a secure attachment

pattern and children with an insecure attachment pattern in play situations are also described in the study of Grossmann. Secure attached children are more often initiators of the common play and they seem to be rather extroverted instead of insecure attached children, who wait for instructions.

METHODOLOGY

Regarding the theoretical considerations and the attempt to identify mathematically creative moments in mathematical interactions of preschool children, in the following there is conducted an analysis of interaction, which based on interactional theory of learning (Brandt & Krummheuer 2001). It focuses on the reconstruction of meaning and the structure of interactions. Therefore it is proper to describe and analyze topics with regards to contents and the negotiation of meaning in the course of interactional processes. The negotiation of meaning takes place in interactions between the involved people. These processes will be analyzed by an ethno methodological based analysis, in which is stated that the partners co-constitute the rationality of their action in the interaction in an everyday situation, while the partners try constantly to indicate the rationality of their actions and to produce a relevant consensus together. This is necessary for the origin of own conviction as well as for the production of conviction with the other participating persons. This aspect of interaction is described with the term ‘accounting practice’ (Lehmann 1988, p. 169). To analyze these ‘accounting practice’ of children in mathematical situations, the reconstruction and analysis of argumentation of Toulmin (1969) have proved to be successful. Four central categories of an argumentation are "data", "conclusion", "warrant" and "backing". The general idea of an argumentation consists of tracing the statement to be proven back to undoubted statements (data).

For the diagnosis of the attachment pattern the MaKreKi project apply the Manchester Child Attachment Story Task, so-called MCAST (Green et al. 2000). This is a story telling test that has good reliability and validity.

FIRST INSIGHTS

The following section presents extracts of interpretations of two children Nina and René of the MaKreKi project while they are participating in the mathematical situation of play and exploration called ‘Ladybug’. Both children are examined paired with one of her/his closer friends and at least one adult person, who acts as nursery teacher.

The ‘Ladybug-situation’

In this situation the children can differentiate between similar objects, which differ according to their size and color. The objects are pictures of ladybugs, which differ in size (small and large), in color (red, green, yellow), and in the spots on ladybugs in three ways (shape, amount of spots, size). The design pattern suggests the following mathematical activities to the children through material and designated instructions

and impulses: Counting and determination of quantity; Arrangement and comparing of sets e.g. in respect of the number of elements on the back of the ladybugs; Identifying mathematical structures. The ‘Ladybug-situation’ consists of two parts. In the first part the children are dealing with little ladybug cards. Typical instructions of the accompanying person are: ‘Look what I brought.’; ‘Put together all ladybugs which belong together’; ‘Can you find further groups or families of ladybugs?’; ‘Why do these ladybugs belong together?’ In the second part the children are dealing with big ladybug-cards, which have small and large spots on their backs. Usually the accompanying person offers a triplet of big ladybug-cards and asks: Which one does not belong?

Case study one: René’s solution process in the ‘Ladybug-situation’

René is a four years and 9 months old boy who lives with his parents and his older sister in a small city. His father works fulltime in a computer firm and his mother remains at home. He shows insecure-avoidant attachment pattern (A). The attachment pattern is measured by the MCAST (Green 2000).

Beside René there are two persons involved: Lisa, a four years old girl from René’s preschool and a member of our research team, who conducted the conversation with the two children. The following interpreted episode refers to the end phase of a collective processing of the task. René, Lisa and the member of the research team invented a familial system of description: The small ladybugs represent kid-bugs and the big one mom-bugs, dad-bugs, or parents-bugs. All little ladybugs lie around the carpet.

The guiding adult has put a triplet of 3 red ladybug cards in the centre of the carpet:

Figure 1: Triplet of ladybug-cards

René has mentioned that the ladybug with 19 little triangles and Marie has mentioned that the bug with seven big triangles does not belong to the group:

René comes up with the solution that *both* bugs with many and small triangles do not belong. His justification has two aspects:

- Comparing the figures of the small and the big ladybug-cards, he concludes, that the bugs of the small cards should also only possess small figures on their tops.
- The two cards with the many and small triangles cannot exist in the system of the cards at all.

If one understands the figures of the ladybugs to be people’s hands, René’s argument

is that parents do not have hands of the size of kids, this is impossible. They cannot be parents and children “at the same time”, as he says. With respect to the three aspects of mathematical creativity mentioned one can conclude: René’s solution is based on a surprising choice of a familial system of description for the comparison of the ladybugs. Hereby he does create a somehow non canonical combination of size and family-members. Furthermore on the level of speech, he expresses this unusual choice by a linguistic adaption of the size of ladybugs by using a familial metaphor. He says that the big ladybugs would be “already big”. The wording of “big” can appear in the size-system of description and in a familial system of description. The guiding adult seems to have difficulty in comprehending René’s approach. Possibly she shares Marie’s solution. So she asks René for an explanation two times (‘why’ and ‘what do you mean by saying this’). With respect to the interactional setting it is René, who takes the part as the competent partner and explains his position to his counterpart. In this situation he presents a very deep argumentation as the toulmin scheme shown:

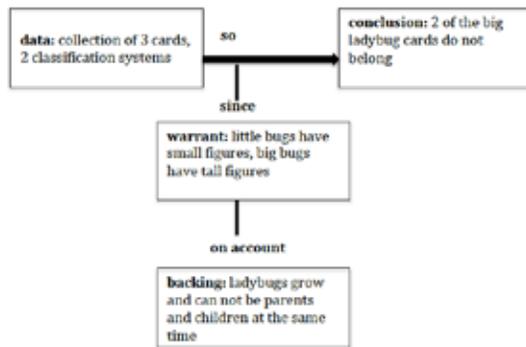

Figure 2: Toulmin scheme of René's argumentation

In René’s argumentation one can see that he connects the first part (finding family members, making groups of little ladybugs because of their relationships regarding their spots (amount, shape) or their colors) with the second part (separate big ladybugs, which do not belong together) of the mathematical situation. So he transforms two operations into one under disregarding the detail that only one ladybug does not belong to the triplet. In the end the guiding adult forces an agreement and asks if it is all right for René to take Marie’s solution.

Case study two: Nina’s solution process in the ‘Ladybug-situation’

Nina is a five years and five month old girl who lives with her mother in a German major city. Her parents are divorced. Nina shows secure attachment pattern (B).

Beside Nina there are two other persons involved: Samira a five years old girl from Nina’s preschool and an accompanying person from the research project. At first the children and the adult person have dealt with the little ladybugs. They have discovered various families of ladybugs where the color and the number of spots determine to which family a ladybug posse. At the end of this phase Nina mentioned

that all ladybugs of the same family are grown in the same stomach. After that the little ladybug cards are moved to the edge of the table. The presented scene begins with the second part of the ladybug situation: The guiding adult has put a triplet of big yellow ladybug cards on the table and asked: Which one does not belong?

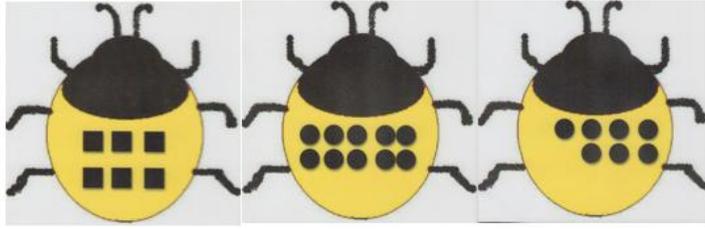

Figure 3: Triplet of ladybug-cards

Nina comes up with the solution that two big ladybug cards are wrong and only one ladybug card is right. The right one has ten circles on his back, which correspond to the number of little yellow ladybugs. She creates a non-canonical solution. Her surprising choice includes aspects of relationships similar to a mathematical function: The number of elements on the back of the ladybug and the quantity of babies, which appertain to the bug. Each spot represent one of his babies. She extends her functional relationship by determining the color as a feature of the functional relationship between the ladybugs: The big yellow bug can only have little yellow ladybug kids. By reconstructing Nina's argumentation it is obvious that she connects the first part of the mathematical situation (finding families/groups of ladybugs) with the second part (which one does not belong?):

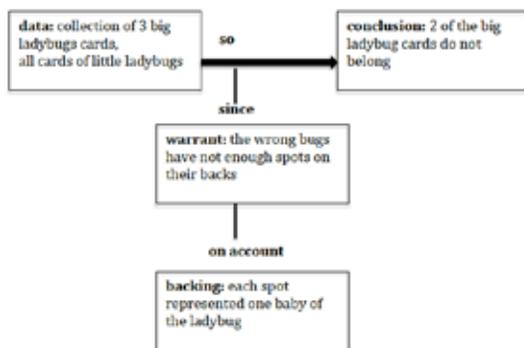

Figure 4: Toulmin scheme of Nina's argumentation

Nina disregards the detail, that only one ladybug does not belong to the triplet. On the level of speech Nina is able to formulate her non-canonical solution with appropriate expressions, so the identification of the little yellow ladybugs as babies of the big yellow ladybug can be seen as a linguistic achievement to describe the functional relationship between the little and the big ladybugs in an adaptive way. Samira shares Nina's solution, but the guiding adult seems to be surprised. Similar to René, Nina has to give an explanation of her one card solution, what is expected by the guiding adult.

Summary and Prospect

Two cases of the MaKreKi study were discussed and it has been shown that the approaches mentioned in the theoretical perspectives are useful to describe creative mathematical processes of young children at preschool age. The cases illustrate that children who can be seen as mathematical creative are able to change the perspective on a mathematical task, although a clear instruction from the guiding adult focuses another perspective. Nina as well as René offered an one card solution instead of the expected two card solution, because of the connection they have discovered between the two parts of the ladybug situation. As seen in the two episodes the final definition of the problem situation is a matter of the negotiation of meaning in the concrete situation of interaction. Instructions may have a strong impact on children's interpretation of mathematical tasks and so only mathematical creative children are able and have the confidence to see more possibilities and perspectives than the canonical solution, which is forced by the comments of the guiding adult. Both children are initiators (Grossmann 1984) of their non-canonical solutions. In case of Nina as a child with a secure attachment pattern this observation is in accord with Grossmann's results. Following Grossmann children with an insecure-avoidant attachment pattern like René are often less autonomous in play situation. In the mathematical situations of play and exploration this is not the case for René. He often is the initiator, too. So the behaviour of children in play situations may be linked to the context of the situation as well as to their attachment pattern.

Regarding the construction of children's mathematical thinking it is important to understand and honour their non-canonical solutions, which might be the first steps of the development of mathematical creativity in early childhood. Additional analysis of young children's non-canonical solutions can help to describe, understand and identify the mathematical potential of young children. Till now the connection between mathematical creativity and the attachment pattern in early childhood is not satisfactorily investigated. Therefore a conceptual framework has to develop which examines the cultural and the situational impact as well as the influence of the attachment pattern on the development of mathematical creativity in early childhood and connects with creative mathematical abilities of young children.

TWICE EXCEPTIONAL CHILDREN - MATHEMATICALLY GIFTED CHILDREN IN PRIMARY SCHOOLS WITH SPECIAL NEEDS

Marianne Nolte

University of Hamburg, Faculty of Education, Psychology and

Inclusion in Hamburg leads to joint school education of disabled and non-disabled children. The goal is full development of the potentials of all children. Gifted and twice-exceptional children in particular are at risk that their potential is not recognized. Based on four case studies in the article, the problem of non-recognition is demonstrated by both, special talents and developmental impairments.

INTRODUCTION

Children differ in many ways. They have different interests, show a different attitude to work and come from different familiar backgrounds which is why they speak different native languages and have different genetic potentials. Compensatory education, heterogeneity, diversity and inclusion are keywords which arose in different times of the German pedagogical discussions. All these terms have in common that they were intended to develop the awareness of these differences. In all times these key-terms were, and they are still today, the foundation for constructing concepts in order to give all children an adequate access to education. The “CONVENTION on the RIGHTS of PERSONS with DISABILITIES of the UN (2006)” lays a legal basis for people with functional limitations and handicaps. The goals of this convention, which in the meantime is signed by many states, are the following:

“(a) The full development of human potential and sense of dignity and self-worth, and the strengthening of respect for human rights, fundamental freedoms and human diversity;

(b) The development by persons with disabilities of their personality, talents and creativity, as well as their mental and physical abilities, to their fullest potential.”
(Bundestag 21. Dezember 2008, p. 18)

At the moment, in Germany approaches for the implementation of the idea of inclusion are discussed. The realization of inclusion in Hamburg for example means that all children with or without disabilities¹ are taught together. Based on special conditions, this is already implemented in various schools under the heading "integration". This concept demands a lot of effort and care. Many teachers do not know whether they have sufficient practical knowledge for being able to teach children with such diverse conditions appropriately.

¹ Excluded are blind and deaf children.

Particular attention is paid to children with disabilities. But we should not neglect gifted children with special needs. In particular, a high intelligence enables these children often to compensate limitations and peculiarities. However, this is often associated with the fact that a special talent is not easily recognized.

Since school year 1999/2000, at the University of Hamburg we are fostering mathematically talented children of the third and fourth grade within the framework of our project called PriMa². After a talent search process we foster about 50 children of grade three until the end of grade four at the University. This project is regularly attended by children with specific performance deficits, diseases or impaired developmental processes.

How many children are affected?

Although we ask the parents to provide us with additional information in case of such impairments, this information is only given voluntarily. Therefore, until now we do not have accurate data about the whole sample of children participating in our fostering project. This year there are five out of 50 children with special needs, of whom we know that for sure. Furthermore, the results of a questionnaire which was answered by 115 parents of our project show that more than 14% of our children are affected by partial performance disturbances or impairments.

		Frequency	Percentage	Valid percentage	Accumulated percentage
Valid	No	97	84,3	85,1	85,1
	Yes	17	14,8	14,9	100,0
	Total	114	99,1	100,0	
Missing	System	1	,9		
Total		115	100,0		

Table 1: Partial functional-performance disturbance

What do these children need?

Method

To learn more about the needs of the children and to acquire more practical knowledge, case studies have been proven to be an appropriate approach. In this article four children are presented. All children were tested as mathematically gifted. For our considerations several results were taken into account:

² PriMa is a cooperation project of the *Hamburger Behörde für Schule und Berufsbildung* (u.a. *BbB*), and the *William-Stern Society* (Hamburg), the University of Hamburg. (for further information you are invited to visit the website <http://blogs.epb.uni-hamburg.de/nolte/>)

- a) Individual observations conducted during the fostering lessons.
- b) Records of the children written while solving mathematical problems.
- c) Discussions with the parents gave us information about the learning biography of their children.
- d) The school report of the second class gives insight in the observation of the teachers and their assessment of the children's performance.
- e) The results of the children collected during the talent search process. These include half standardized observations during trial lessons, the results of a mathematics test developed by us, the results of intelligence testing and results of testing verbal competences.

For measuring the IQ we used CFT 20 R in combination with a vocabulary test and a number sequence test. As an academic achievement test in mathematics we used DeMat 2+. The stumbling words test is based on finding useless words. The reading test proves the degree of understanding of a short story. For observing the performance in the trial lessons (MTR) we developed special lists which contain cognitive components of problem solving and patterns of action which are important in solving mathematical problems (Nolte 2006; 2012a; 2012b). We constructed the maths test based on complex problems which enabled us also to show cognitive components of problem solving and patterns of action.

Justin, 8 years old

Justin participated in the project during our third year. Because we were still in the process of developing the talent search process, we do not have as many information about him as with the other children. Additionally Justin did not participate in the intelligence test.

Sometime after starting with our fostering program, Justin lost his motivation. He was no longer in the mood to come to the university and did not feel well. The tutors reported that he had difficulties to understand our problems and that he did not start working on his own. Justin did not like to explain his solving process in writing. But this is also the fact with many other children. After talking with his mother we supposed that perhaps his reading capabilities were not as good as it is normal for a gifted child. Therefore we conducted further diagnostics and tested his reading skills. By that we have found out that his reading skills were lower than the average rank.

His school report tells that Justus is a high-performing student in all subjects. His capabilities in the acquisition of writing and reading are just as positive as those shown in mathematics. He is described as an inquisitive, thoughtful and socially well-integrated boy. Some hints about problems are given by the advice to speak

clearly, and to write stories more detailed. He is learning Italian in school. Here it is pointed out that it takes practice to learn new words.

Why is Justin unhappy and unmotivated?

Our tasks for mathematically gifted children are presented with little redundancy. The language is demanding due to this fact and because we pay a special attention to mathematical correctness. Although the problems are presented orally and with examples, to work on them requires an understanding of the texts of the worksheets. These kinds of phrasings differ from those normally used in school. The mixture between everyday language and special mathematical language is called “Bildungssprache” (‘academic discourse’ or ‘academic language’: Gogolin 2009; Gogolin and Lange 2011). Understanding our phrasings is even more difficult due to the complexity of the mathematical content, the low redundancy and the high level of mathematical correctness. Therefore, reading and understanding the text in our problems is significantly harder for Justin than for other children.

In school Justin is able to participate in reading contests, but it is difficult for him to understand our tasks. He gets the impression to be not intelligent enough to understand the mathematical contents. Therefore, he feels unsafe and withdraws. His tutors get the impression that he is no longer interested in solving mathematical problems. His mother notices that he does not feel well. She thinks his performance in reading is not as high as expected. Since his performances in school are in an above average range, his teacher thinks, his mother is too ambitious.

Reading Test	Trial lessons (MTR)	Math-Test
ca. PR 35	One of the best	34 th of 135

Table 2: Justin Test Results

The test clearly shows discrepancies between his mathematical capabilities and his reading capabilities. Justin felt this discrepancy between his superior mathematical skills and his less than average performance in reading, but could not cope with them. We talked with him about his weakness and developed with him mechanisms to compensate them. The tutors were informed and the mother took care for additional support concerning his weaknesses in reading.

Justin is a child with a dissociated performance profile, which results from a partial impairment of performance.

Justin needs:

- Understanding of others for his behavior
- Understanding his situation and developing methods to compensate his weakness
- Strategic support in the current situation to compensate his weakness
- Long-term professional support in the field of reading acquisition

Lars, 9 years old

Lars is a shy and cautious boy. At the beginning of our lessons Lars was motivated, but usually more and more he lost his interest. First interaction and communication with others was difficult, perhaps also due to the fact, that his workplace and his way of problem solving were chaotic. Before two meetings he changed his place and went to another group of children. First the children got into contact and showed only a weak interest in working. Obviously Lars accepted and enjoyed the situation. During the last session he worked excellent. He seemed very motivated and very attentive even in plenary discussion.

His school report tells that Lars is a high-performing student in all subjects. Also his capabilities in the acquisition of writing and reading are nearly as positive as those shown in mathematics. Only his spelling is described as good, not as very good. Hints to show more efforts are given for keeping his working place in order. He is described as well integrated and supporting, but not always controlling anger.

IQ	Vocabulary	Number sequences	Academic achievement test	Stumbling words test	Reading test	Trial lessons (MTR)	Maths-Test
151	118	136	PR 97	PR 58	41 of 50 points	Place 95 of 370	Place 76 of 226

Table 3: Lars' Test results

Also with Lars discrepancies between his high intelligence and his verbal capabilities can be observed. Comparing the IQ with his verbal capabilities there was a difference of about more than two standard deviations. His performance in a mathematical school test was very high (PR 97). Nevertheless the observer during the trial lessons did not propose him for participation in the project.

His writing is not appropriate for a third grade child, especially of his intelligence.

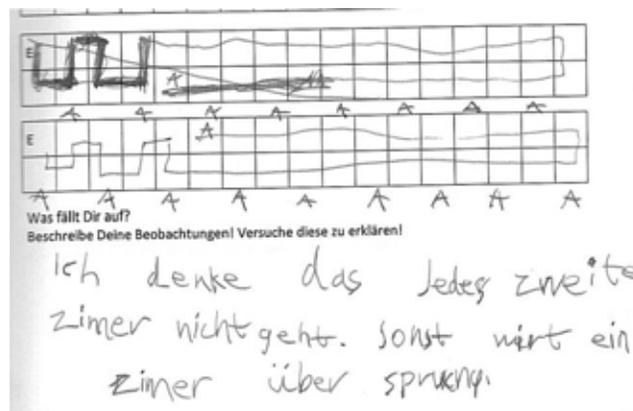

Table 4: Lars' writing

How can these discrepancies between his school reports and his performance in our tests be explained?

Lars goes to school with a very high proportion of children with a migration background. In these situation his weak writing and reading skills are not that much noticeable because many children have very poor performance in the acquisition of reading and writing.

But Lars was unhappy and shy, and we got the impression that he needs further support. The parents told us, that Lars shows weaknesses in the auditory perception. This partial impairment of performance has an important impact on his capabilities of understanding verbal / auditory information. It also influences the development of skills in reading and writing. That might be the reason for misunderstandings in communication processes and furthermore means more effort and stress in participating in school (Nolte 2000; 2004). We confirmed the parents in our opinion, that their son has very high potentials but needs additional support concerning his impairments. Obviously Lars can take care for himself and we hope that he will continue working with motivation.

Lars *needs*

- In the current situation, people who insure that communication and interactions shall be clearly
- Support to develop metacognitive competences for organizing his work
- Long term intervention for the development of his auditory perception and his written language skills.

Karen, 9 years old

Karen is a quiet and reserved student. She works very carefully and is keen to make any mistakes. After getting used to the situation at the university she is actively involved in the plenary discussions. She writes only sophisticated solutions, which show excellent considerations. She seems not to feel being under pressure. Her meticulous work can be regarded as the reason for working sometimes very slowly. Also Karen's reading capabilities did not match with her mathematical performance. In the stumbling words test she reached a percentile rank of 58. Due to her slowness she could not finish the whole test. The results of other tests did not match with her remarkable performance during the trial lessons and the maths test. Here results show a discrepancy of nearly two standard deviations between the total IQ and the result of the vocabulary test. The good results in the reading tests can be explained by the possibility to get the necessary information from the context.

IQ	Vocabulary	Number sequences	Trial lessons (MTR)	Math-Test	Academic achievement test; Mathematics	Stumbling words test	Reading test
120	91	112	Place 12 of 370	Place 36 of 226	PR 97	PR 58	46 of 50 points

Table 5: Karens' test results

Analysing her worksheets, it is striking that she works very carefully. She expresses herself well and seems to have a remarkable memory.

With Karen we see a discrepancy between the test results concerning IQ, verbal capabilities, and the mathematical achievements in the teaching process. A spelling mistake gave us the crucial evidence. This was an error typical for children with impairment of phonological processing. In the meetings with parents, we learned that Karen needed several surgeries between one and seven years old because of problems with her ears. This affects the auditory development and thus about phonological consciousness. Her very good results in our fostering program show her ability to compensate her weaknesses by very carefully and reflected approaches. But this is the reason for very slow work which does not allow time limitations. So we suppose that her test results do not show her real capabilities.

Karen's needs

- more time than other children
- no more pressure

Dissociated performance profile

All three children can be regarded as an example for children with specific performance deficits. Their test profile show significant variations. In all cases, these discrepancies are not identified in school. All children need additional support to develop their potential.

Leon

At the beginning of our fostering program the parents informed us that Leon is autistic.

“In addition, gifted individuals and those with autism are also similar in the way they sometimes have a compulsive preoccupation with words, ideas, numbers and foods; perfectionist personalities; a rigid fascination with an interest; a need for precision; intellectual rigidity; a lack of social skills; the need to monopolize conversations and situations; the ability to concretely visualize models and systems; an intense need for

stimulation; difficulties in conforming to the thinking of others; and a tendency toward introversion” (Cash 1999, p. 23).

IQ	Vocabulary	Number sequences	Trial lessons (MTR)	Math-Test	Academic achievement test in Mathematics	Stumbling words test	Reading test

Table 7: Leons’ Test results

Leon feels completely comfortable working with us at the university. He is fascinated by doing mathematics. His achievements are impressive. Most of his considerations he does on mind using an almost unlimited number space. He prefers to work alone and can be distracted by anything when it comes to mathematics. Talking to others he explains very precisely his ideas at a very high level of language. But due to his need for precision the participation in discussions with others is difficult. Also plenary phases are a challenge for him, especially if other contributions are not as exact and completely as his considerations. It's hard for him to endure that others are not as fast as him and also not as capable as him in understanding mathematical content deeply.

For the tutors, working with him it is a pleasure and a challenge at the same time. He takes everything what is said literally.³ Therefore, the tutors check their communication with him constantly. Furthermore, his brilliance in mathematics requires emotional support for other children. His rigidity in conversations is a challenge to cope with and they are confronted with the fact that their contributions often are at a lower level of mathematical insight. Due to this experience some of the other children got the impression of being less able as they are.

Dissociated development

With Leon the cognitive skills and the social-emotional skills differ strikingly. He gets therapeutic support and continuously develops his skills to behave in a group.

Discussion

At the university we are used to children who are exceptional in different ways. We are well aware of the requirements arising from the fact that some children do experience the first time, not to be the best. Rather, they must learn to work in a

³ One day, when his mother picked him up after the lesson she said: "Today we have to rush home!" That for him was the signal quickly to go home. He took the elevator, he found the subway station, the correct line, get off to the right place, the right bus. We got a call that he was at home at the very moment when the police wanted to start searching for him.

group with similar interested and talented children. It is very important to us to support the children in developing their social and emotional skills as well as their mathematical competencies.

The cases lead to the question whether high abilities allow hiding developmental disorders and impairments during regular classroom lessons, and also the other way round whether developmental disorders and impairments can hide high cognitive abilities. Apart from Leon where a clear diagnosis was present, our observations were not always consistent with school reports.

We assume that the children come voluntarily to us because they are interested in mathematics. So it is an important signal for us, when they lose motivation. Also discrepancies in test results can be faced as hints for problems concerning development. Both Justin and Lars showed by their awareness that something is wrong by behaving not appropriate. This was different with Karen. She behaves very well, works very hard, but she stresses herself. Perhaps there are different ways to compensate such irritations with boys and girls. Because we have experience in the context of giftedness and developmental disorders, we are cautious in judging behaviour and performance.

“To reach their full potential, twice-exceptional students need a balanced educational program that nurtures their gifts and talents while providing intervention for their disabilities.” (Schultz 2012, p. 120) and later “Many school programs seem designed to either remediate weaknesses or develop gifts and talents but are unable to address both simultaneously (Schultz 2012, p. 120).

Intervention as well as the development of challenging learning environments is based on the information of teachers about normal and abnormal development. Interpretations of behaviour or performance are as broad and as good as the knowledge of the observer. For working with children with developmental disabilities the knowledge of the nature of the problem is essential. Knowledge about developmental disorders as possible causes of unclear or even contradictory observations in the classroom is a prerequisite for the development of appropriate methods. Here we need the balance between searching for impairments and overlooking them. Not every problematic child is ill or disturbed. The first step in analysing a children’s problem should begin with looking for rational reason for the shown behaviour. A lower motivation to work on mathematical problems can also be caused by the situation in the classroom or that a child would rather play football. With the next step, however, questions should be asked concerning the learning preconditions of the child in connection with a particular task. After this the responsibility of the teachers lies in the construction of appropriate methods to match as well as possible the strengths and the weaknesses of the child. To meet the high demand of working with impaired and / or twice exceptional children additional support for teacher is necessary.

TEACHING HIGHLY ABLE STUDENTS IN A COMMON CLASS: CHALLENGES AND LIMITS OF A CASE-STUDY

Ildikó Pelczer

Concordia University

Cristian Voica

University of Bucharest
Romania

The case-study presented in this paper is built around a middle school teacher's beliefs. The paper focuses on identifying links between self-efficacy beliefs, content knowledge, classroom practices and mathematical beliefs of a professional who teaches in a mixed-ability class. The data come from a semi-structured interview, group discussions, and individual work on a problem-posing task. The results revealed a mismatch between the teacher's self-efficacy beliefs and his specialized content knowledge. The teacher was found to possess most of the expert features except theory and schema change – a capacity to change mental frames due to an inquiry process. These findings might explain both his success in training high ability students and failure to address adequate tasks for orchestrating students' understanding.

Keywords: Self-efficacy beliefs; Specialized content knowledge; Mental frames; Mixed ability class; Expert thinking

INTRODUCTION

Instructional practices are strongly influenced by teachers' beliefs. On the one hand, we consider beliefs about mathematics, its teaching and learning and, on the other hand, affects and beliefs regarding personal efficacy. The study of teachers' beliefs continues to represent a strong line of research, as many surveys and publications can witness about (for example, Maasz & Schloeglmann, 2006). It has been shown that teachers who regard mathematics as a static body of knowledge, with procedures and rules to apply, also consider the skillful application of these as goal of mathematics learning, and will focus much less on aspects of understanding the origin of the procedures or that of the concepts (Thompson, 1992). This "traditional view" of mathematics will manifest in classroom practices as the direct transmission of the rules, followed by solving problems as illustrations to the rules and practicing them on a new, but structurally identical problem (Stigler & Hiebert, 1997). Such findings of strong interdependence between beliefs and classroom practices were confirmed by more recent studies, too (for example, Stipek, Givvin, Salmon, & MacGyvers, 2001).

Teacher self-efficacy belief has been defined as teacher's belief in his/her abilities to organize and execute courses of action to bring about desired results (Tschannen-

Moran, Woolfolk-Hoy, & Hoy, 1998) and has been related to student motivation, achievement, student's self-efficacy beliefs and, also, to teacher's classroom practices (for a review, see Tschannen-Moran and Woolfolk-Hoy, 2001). Teachers with high self-efficacy beliefs might think of themselves as highly effective teachers – a thought that, in turn, influences their need to reflect and adjust their classroom practices. A way to inspect the concordance of such belief with reality is to focus on teachers' specialized content knowledge (SCK) as part of the mathematical knowledge for teaching (Ball, Thames, & Phelps, 2008). The construct of mathematical knowledge for teaching refers to the knowledge teachers need in their practice. It has several components: common content knowledge, specialized content knowledge, knowledge of content and teaching, knowledge of content and students, and knowledge of curriculum. SCK represents a body of mathematical knowledge beyond the one taught to students and different from mathematical knowledge used by research mathematicians or applied in professions where mathematics is a tool. It is mathematical knowledge that is specifically needed in teaching. It is needed in carrying out tasks such as: “recognizing what is involved in a particular representation, finding an example to make a mathematical point, modifying tasks to be either easier or harder” (Ball, Thames, & Phelps, 2008).

The interplay between beliefs construct, the mathematical knowledge for teaching and the classroom practices, in all its complexity, has not been studied, as far as we know. However, a huge body of research indicates that the interactions are not one-way, simple causal relationships, but rather they are characterized by continuous feedbacks, often pulling in opposite directions.

In our article we look at the case of a middle-school teacher, habituated in training high-ability students in regular settings. Our interest is on identifying links between his self-efficacy beliefs, his SCK, his classroom practices and mathematical beliefs, both on concordant and discordant cords, and to look at the ways in which his practices might impact the students' learning and understanding of mathematics.

METHOD

Design and procedure

The paper presents a case study. The data were collected through participant observation, semi-structured interview, and documentation (as defined by Yin, 1994). We describe the circumstances of data collection in the next paragraphs.

The authors of the paper organized a 3-day interactive seminar on the topic of problem posing. In all, 43 mathematics teachers of various levels of education, from primary to upper-secondary, participated in that seminar. The seminar proceeded as follows:

In an initial session, teachers were shown several examples of problems and a discussion was initiated about the formulation of a problem. Then, the trainers undertook a qualitative analysis and discussed techniques for problem modification and/or posing.

During the next phase of the seminar, the participants had the task to pose, individually or in groups of 2-3 people, multiple-choice problems. For this assignment, a special requirement referred to defining the distracters: they should reflect, as much as possible, typical mistakes – including erroneous strategies, misconceptions, computing errors, etc. Each posed problem had to include an indication/hint for its solving and a brief comment addressed to the student regarding the choice of each of the distracters.

On the last day of the seminar, every participant presented a problem, posed by the person or selected from those posed by his/her group. These problems were analyzed and critically evaluated during interactive discussions between all the participants at the seminar. Several criteria were taken into consideration: the level of difficulty, the quality of formulation, solution hints, etc.

The present study idea came from the experiences within this seminar. One of the participants (referred hereafter as Mr. T.) got remarked for his perspective on mathematical knowledge and teaching strategies. We concentrated on his case: we analyzed his interventions during the group discussions, we invited him to an interview, and we documented on his personal history as a teacher.

Intervention during the seminar

We start by listing below the problem that Mr. T. presented for the seminar discussions, along with his given solution. This problem was selected by Mr. T. as being the most relevant for the posed problem activity of him and his team. Some other of his interventions will be presented within the discussion section.

Problem 1. *The number of integer solutions for the equation $|x - |3x - 2|| = 8$ is:*

A) 1; B) 2; C) 3; D) 4; E) 0.

We include below the idea of the solution of this problem as Mr. T. presented it:

Equation $|x - |3x - 2|| = 8$ is equivalent with $x - |3x - 2| = \pm 8$.

$$x - |3x - 2| = +8 \Rightarrow |3x - 2| = x - 8 \geq 0 \begin{cases} 3x - 2 = x - 8 \Rightarrow x = -3 \in \mathbf{Z}, \text{but } -3 < 8 \\ 3x - 2 = -x + 8 \Rightarrow x = \frac{5}{2} \notin \mathbf{Z} \end{cases}$$

$$x - |3x - 2| = -8 \Rightarrow |3x - 2| = x + 8 \geq 0 \begin{cases} 3x - 2 = x + 8 \Rightarrow x = 5 \in \mathbf{Z}, \text{and } 5 \geq -8 \\ 3x - 2 = -x - 8 \Rightarrow x = \frac{-3}{2} \notin \mathbf{Z} \end{cases}$$

In conclusion: $x = 5$.

Interview

The starting point in the interview was the following problem:

Problem 2. *In the sequence 1, 4, 7, 10, 13, ... the numbers are counted by three's, meanwhile in the sequence 4, 9, 14, 19, ... the numbers are counted by fives. Which are the first four common terms in the two sequences?*

The interviewers firstly addressed questions related to teaching, such as: "For what grade would you consider this problem appropriate? In what chapter/content would you include it? What goal could it serve? What helping/bootstrapping questions would you address to your students?" Later, Mr. T. was asked to modify Problem 2 and, then, to explain the criterion used for modification.

The interview was coded using codes referring to beliefs and knowledge approach: a. What is a "good class"; b. Who is a "good student" (how should he/she behave, what should he/she do); c. What does it mean "solving a math problem"; d. What alternate ways of solving might be; e. How should a solution be communicated and noted down; f. PP techniques; g. Criteria for judging the posed problem; h. Explicitly state the purpose of problem modifications actions. We consider the codes a-e as relevant to the teacher's mathematical beliefs, meanwhile the codes f-h as being relevant to his SCK.

Documentation

Given our interest in his personal history as a teacher, we collected information from a diversity of sources: mass-media; autobiographic file, and discussions with a school district responsible who supervises Mr. T.

Mr. T. is a middle school teacher, from a small town in Romania. He has been teaching for 33 years. Lately, one of his former students (now college student) had exceptional results at national and international contests, being a medalist at the International Mathematical Olympiad (IMO) and at the Balkan Mathematical Olympiad (BMO). The student asserted, in interviews given to mass-media that his middle school teacher had an important role in his development as mathematician.

Mr. T. considers himself a successful teacher in preparing students for mathematical competitions, as he revealed it in the interview. He said about his student: „I'm helping him to *understand* mathematics. He is a really good student.”

RESULTS AND DISCUSSION

We focused on the following research questions: Is there any relationship between high personal efficacy belief and the specialized content knowledge (SCK)? In what ways mathematical beliefs and personal efficacy beliefs relate to classroom practices? To answer these questions, we analyze the data gathered from Mr. T's interventions during the seminar, the interview, and other sources of documentation.

Beliefs on teaching and learning

During the interview, we asked Mr. T. about the level of difficulty he would associate to problem 2 if using it in class. Mr. T. insisted that this problem has an above average level of difficulty, proper for classes with highly able students and earliest possible to be tackled it is in grade 5. He justified this assertion as follows:

I consider it is an above average difficulty problem, because it asks the student to write a general expression of a term...because, like this, step by step, you have given 4 elements, but I could give 444 [*common elements*].

For Mr. T., a problem needs to hide a challenge, and in this case, the problem is seen as consistent only if we take into account its potential for generalization. By having this perspective, he thinks from the very beginning to “take away” the intuitive support. Mr. T. gave an algebraic solution to this problem instantly. Indeed, in the presence of an algebraic solution, the numerical exploration of the problem might become uninteresting. The question is: does exploration have value for children’s learning? As expressed in the interview, Mr. T. thinks that such exploratory initiative should be reprised in students. As such, at our question about the possibility that some students might first observe the regularity in the succession of common terms and then extrapolate that in order to obtain the 444 common terms, Mr. T. made a refusal gesture and said:

We don’t tell stories at mathematics. The student must have the capacity for synthesis, to write just what is strictly needed, nothing more. Along with the required arguments!

Mr. T. perceives the above problem as difficult because the only solution method accepted by him is the formal, algebraic solution. Consequently, for his classroom practice, essential is to transmit the mechanisms of formal solutions, which, it is, of course, difficult for 5th graders. By his attitude of refusing simple explorations, Mr. T. gives the impression that he focuses only on the high performing students, ignoring the others. Moreover, this exclusion seems conceptually automatized in him: he was unable to come up spontaneously with a simpler problem of the same type; his proposals, made at the insistence of the interviewers, were still complicated.

Returning to problem 1, posed by Mr. T., we assume that his goal was to force a case-analysis on the student’s behalf in order to identify possible variants and exclude the impossible ones. It seems that Mr. T. carefully defined the numbers in the problem, so that the solution phases allow highlighting possible errors.

The solution algorithm given by him is, of course, correct, but the learning of the algorithm is not necessarily leading to the understanding of the reasons for the unique solution. From a didactical point of view, this solving might not be a proper one. From mathematical perspective, the exercise can be identified as one of finding the solution of a polynomial equation. In such problems, establishing the domain of the involved functions is essential and conditions the solution of the equations.

We observe that Mr. T. evaluates the problem based on an algorithm that is correct from mathematical point of view, but loses the profound justification for which certain conditions appear. This justification is linked, in fact, to the understanding and explicit use of the concept of function.

During the seminar discussion, it was suggested to solve this problem through a graphical representation, which would better reflect the involved mathematical phenomena (see Figure 1). Moreover, if the representation is done on a grid, the integer solutions could be visualized. Such visualization would help to avoid errors that could occur during a formal solution.

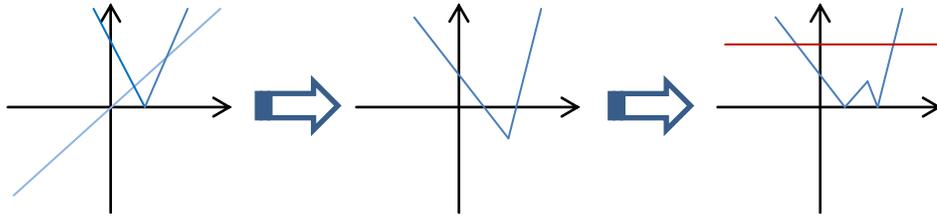

Fig. 1: A graphical solution for the Mr. T's posed equation: Compare x to $|3x-2|$, draw the graph of $x \rightarrow x - |3x - 2|$, then visualize the equation $|x - |3x - 2|| = 8$.

Mr. T. demonstrated no interest for the graphical solving: his answer was that the other approach (algebraic, presented by him) is more interesting. We hypothesize that his reaction was determined by the fact that a graphical solution would eliminate the traps hidden in the “algebraic” solution.

Specialized content knowledge

We now analyze the solutions proposed by Mr. T. to problems 1 and 2 in more detail, in order to reveal his underlying knowledge and understanding.

For the first problem, the solution consists of an algorithm of repeated steps in which the critical elements are: checking the non-negativity conditions, and checking if the partial results belong to the set requested in the problem. We compared this solution with the ones given to the same problem by five mathematicians, teaching at the university level. We noticed that the ideas mathematicians used for solving problem 1 were the same as Mr. T. used, eventually containing some not-so important shortcuts. We can assert that in solving problem 1, Mr. T. behaves as an expert mathematician.

In solving problem 2, Mr. T. wrote down the generic terms of the two arithmetical progressions, and then he arrived to a Diophantine equation and identified the set of solutions. It is clear that Mr. T. knows the general solution mechanism of Diophantine equations and he can particularize that one for the current problem. Therefore, when he was asked to formulate a more difficult problem, he modified the question by asking for 10 common terms of the given sequences that, besides being common terms, are also divisible by 13. He asserted that the solution strategy will not change, because we will still arrive to a Diophantine equation. Again, his

behavior exhibited a level of mathematics expertise. According to Glaser (1997), an expert possesses: structured, principled knowledge (the expert rapidly accesses the underlying meaningful patterns) and principles stored in coherent chunks of information and proceduralized and goal-oriented knowledge (recalling a principle or a rule and efficient implementation of it). In addition, an expert makes use of an effective problem representation, which allows a qualitative assessment of the nature of the problem and the development of a mental model that reduces and organizes the problem space. Relevant is also automaticity to reduce attention demands. Another dimension of expert behavior refers to self-regulatory skills (Glaser, 1988, 1997). Experts develop metacognitive skills that control their performance in particular areas of knowledge, they learn to monitor their problem solving by predicting the difficulty of problems, allocating time appropriately, noting their errors or failures to comprehend, and checking questionable solutions.

The solution strategies of Mr. T. for the presented problems bring evidence for the above features identified for an expert by Glaser. Mr. T. spontaneously framed the problems into more general classes. This assertion is reinforced by one of his seminar interventions that we present below.

During the initial session of the seminar, the following problem, given at the admission exam to the Faculty of Mathematics, was analyzed:

Let $G = \{(a, b) \mid a, b \in \mathbf{R}, a \neq 0\}$, and the algebraic operation defined by $(a, b) * (c, d) = (ac, ad + b)$. Show that G is a group that is non-abelian.

Some of the students enrolled to this exam proved that the operation $*$ is not commutative, without verifying that $(G, *)$ was indeed a group, and consequently have lost most of the score for this subject. The majority of the participants at the seminar agreed that the solver's omission was generated by the use of the word "that", which, in this case, filters the correct decoding of the problem. Several modified formulations were proposed, considered as more accessible/ recognizable by students, like: "G is a non-abelian group"; or in two steps: a) "G is a group; b) G is not an abelian group". Mr. T. had a different opinion. He sustained that the wording is mathematically correct and that any discussion about reformulation is a waste of time, since a "serious" student, in the context of such problem, will automatically prove both.

Mr. T. has the conviction that a student who created routines of solving problems of that category (verification of the properties of an operation) will prove first that the structure exists and, then, will prove certain properties of it. Such a student will be not deviated by the preposition used in the problem text: he will correctly solve even those problems with fuzzy formulations, because he knows that type of problem. In other words, he expects students to behave also as experts without considering the process for becoming so – a quality indispensable for classroom teaching.

Creativity training versus competition training

Mr. T. is, in certain interpretation, an efficient and successful teacher, if we focus on some of his students' performance in math competitions. We saw, in the above discussion, that Mr. T. focuses his classroom practices to promote a formal understanding of mathematical concepts, refusing the idea of explorations /investigations. The refusal of a gradual approach is expressed by a classroom practice strongly related to his views on mathematics and knowledge of mathematics. His inability to simplify a problem and use it as starting point for learning illustrates that his SCK is at imbalance with his self-efficacy beliefs.

From his conceptual thought it seems to be missing what Glaser calls *theory and schema change* (Glaser, 1988) – that is: a dimension of expert thinking that reflects a process of interrogation, confrontation, conflict, and discovery. Mr. T. is reluctant to explorations in problem solving but also in changing his personal approaches of various issues. Therefore, we ask, what explains then his success in the creativity and/ or competition training? In order to answer, we analyze the manner in which Mr. T. changes a given problem. For example, at the request to modify problem 2, he proposed the following:

I could keep one of the sequences, and for the second we consider one with a bigger ratio. I'm thinking to still ask for the first 4 common terms or the first 10, to extend them more and to force them to...for example, 2, 22, 42, 62 ...[with a ratio of 20].

Mr. T. keeps one sequence unchanged. With regard to the problem question, for him, requesting the first 4 common terms, or the first 10 is the same thing because, due to the low number of terms, the students could still proceed by trial and error. The choice of the second sequence with a higher ratio has the purpose to farther the terms from the origin of the axis such that the numbers with which the students should work are bigger. Such situation would force the student to take an algebraic approach and (eventually) to accept the necessity of an algorithm in solving the problem. Moreover, Mr. T. chooses the ratio as 20 (multiple of 5). Why 10 (number of terms) and 20 (ratio)? We suppose that he is governed, subconsciously, by a certain mathematical aesthetic, a sense of beauty that rises from the fundamental nature of the base 10 that leads to “beautiful”, “elegant”, “round” numbers.

In a previous study (Voica & Singer, 2012), we discussed the relationship between problem posing and mathematical creativity in terms of cognitive flexibility. We concluded that, in problem posing, high performing students express a functional type strategy – they vary one single element of the starting problem, to control the quality of the newly obtained statements. Mr. T. proceeds similarly, because he keeps unmodified a part of the data and varies a single parameter – the ratio of the second sequence. It is possible that this “mono-dimensional” cognitive flexibility of the teacher, similar to the one of high performing students, allows him to do an efficient training of creative students. This behavior properly fits a way of thinking that

focuses on efficiency in problem solving, an aspect requested within mathematics Olympiads.

CONCLUSIONS

Mr. T. has strong positive self-efficacy beliefs. He proves to have a mathematical content knowledge similar to an expert mathematician; however his SCK mismatches his perception of efficacy. As solver and trainer for International Olympiad style competitions, Mr. T. is interested in efficiency. From this point of view, Mr. T.'s objective is the acquisition of solving algorithms for classes of problems. More complex these are more are the chances that the student turns into a highly performing one. However, from a teaching perspective, a practice focused on algorithms leads to a failure on profound understanding of mathematical ideas and concepts. The algorithms targeted by Mr. T. are of high level of abstraction and complexity. He seems to have “cut off” SCK and kept only those mathematically “delicate areas” that he teaches in a systematic manner to highly performing students. These students are trained, for example, in avoiding “traps” such as the ones concerning checking initial constraints over the data and results.

However, a fundamental problem might be his “traditional” view of mathematics: mathematics is a set of formalized knowledge where performance is essential. This view explains his belief that knowing a complex algorithm means knowing mathematics – there is nothing more to look into there. Such beliefs lead to specific classroom practices, where the children should be the ones to “keep the rhythm” (as some performing students do). To be a good student means, for him, to work a lot after you have been taught the algorithm. However, such an approach can have a negative impact on students in a mixed ability class and, maybe, even on high performing children.

Problematic issues derive from the fact that he has no way of knowing if the students really “understood” (because the question does not address this target) and if the students really develop their own creativity (because the lack of opportunities for exploration could lead to inhibition and misunderstandings). He perceives learning as a product, not as a process: Mr. T. does not accept that a child can be coached towards the solution with helping hints that deepen understanding – it is a one-chance approach for him: “either you get it from the first moment, or you don’t”. Such view can have a counteractive impact on students’ self-efficacy perceptions, as the feedback they receive is a negative one. Besides the existence, in general, of a traditional view of mathematics, the source of such beliefs can be linked to the vision the general public (including parents and students) share about what it means to be good at mathematics: for most, the only criteria is the performance in competitions.

In the same time, high-ability students can have additional sources of information or interest in individual learning: in general they receive training from multiple sources. They can overcome certain deficiencies in understanding by being exposed to

diverse training practices. Even the former student of Mr. T. admitted that, besides his middle-school teacher, he had also other trainers, including parents.

Contrary to the case of the students with high potential and interest in mathematical performance, the other students are usually ignored by such teacher. Breaking the vicious circle asks for much more than highlighting ways to increase teacher's SCK; there is a need to change teachers' mentalities and beliefs. Beyond Olympic preparation, all the students, gifted or less gifted, should be prepared for a successful professional life and optimum social inclusion; in today's dynamic world, a training on problems typologies and complex algorithms is far from being enough.

MATHEMATICAL CREATIVITY AND HIGHLY ABLE STUDENTS: WHAT CAN TEACHERS DO?

Bernard Sarrazy¹⁾, Jarmila Novotná²⁾

Laboratoire Culture, Education, Sociétés (LACES EA4140)

¹⁾ Université Bordeaux Segalen (France), ²⁾ Charles University in Prague (Czech Republic)

The text focuses on the effects of didactical heterogeneisation on students' creativity, namely on students' ability to propose such solutions to problems that are novel for them. The key questions for mathematics education are: Should the teacher direct his/her teaching towards good mastery of algorithms or towards development of students' creativity? Should all students or only the highly able ones be given the opportunity to work creatively?

Keywords: Didactical heterogeneisation, didactical differentiation, students' creativity, teachers' didactical culture.

INTRODUCTION

Formulation of the question addressed by this text is relatively simple: If learning of mathematics is based on coming up with new solutions to new problems (from the student's perspective) and not only on mere reproduction of algorithms, then mathematical creativity is undoubtedly in the center of mathematics education; some students feel freer in allowing themselves to come up with innovative solutions. Who are these students and should they (often termed "intelligent", "highly able" or "gifted") be regarded as an additional problem in the teacher's work (sadly this perception of the situation is not rare)? One must not forget that it may not be possible for the teacher to work with differences in their students' abilities as is recommended by didactics. This is the thesis that we will defend here.

When Alfred Binet (1857-1911), the French psychologist and inventor of the first usable intelligence test (known at that time as Binet test and today as IQ test) (1905) was asked for a definition of intelligence, he answered: "Intelligence, it is what my test measures."; if he had been asked for possible grounds of a talent in mathematics, he would have probably answered with the same irony: "Intelligence!". Such an answer would have left teachers skeptical as to the way of dealing with differences in creativity (i.e. the ability to create "something new") of their students when teaching. More precise definitions, presented by psychologists – e.g. Julian de Ajuriaguerra, who introduced the term "over-gifted" – will all be enigmatic to the question of the origin of giftedness; they will stay faithful to its evangelic origin (Matthew, XXV, 14). We are neither psychologists nor neuropsychiatrists; as didacticians we will approach the problem of highly able students independently of any ideology (e.g. of the type "for" or "against"); indeed, even if a didactician is not able to state whether

specific educational policy of differentiation is profitable for one or another category of students, his/her work can still contribute to clarification of the intentions and probable outcomes brought about by this organization.

ORGANIZATION OF THE EXPERIMENT

This research uses a larger set of observations. The aim of this set of observations was to explore the impact of teachers' didactical variability (i.e. their ability to organize situations – and therefore knowledge – for teaching arithmetic) on students' mathematical culture (Novotná, Sarrazy, 2011).

The following paragraphs describe the conditions of these observations.

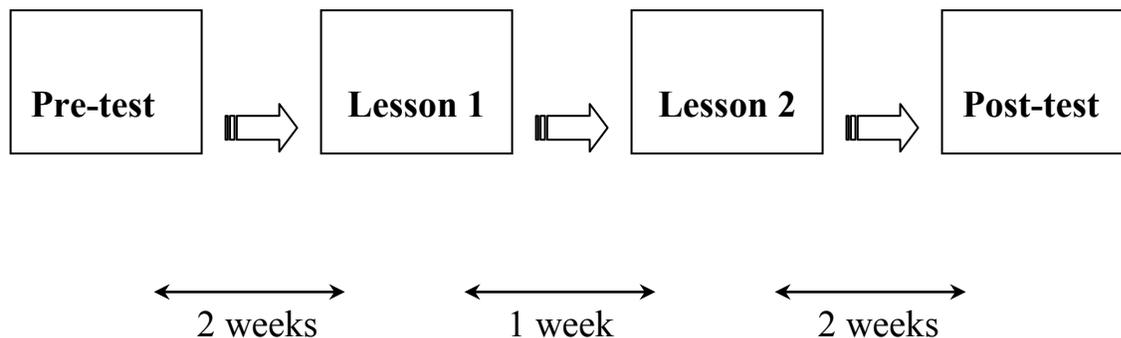

The studied population

The representative sample participating in the experiment consisted of 112 French pupils aged 9-10 from 7 primary school classes. Their school level was evaluated using a standardised test enabling us to position the pupil's level in relation to the French school population. The pupils were then divided into three groups corresponding to the criteria developed by the authors of the test: "Good": the mark (x) in TAS is in the interval $<8; 10>$; "Average": $x \in <5,5; 8>$; "Weak": $x \in <0; 5,5>$. There is a strong correlation with the teachers' evaluation (χ^2 ; $p < .001$).

The conditions of the observation

The conditions of the teachers' teaching were meant to be as close to their usual work as possible; the conditions were discussed in two perspectives: a) the topic of the lesson; b) the time of the observation. The teachers had to perform two one-hour lessons; there also was a pre-test and a post-test.

The course of the experiment was standard; it proceeded according to the following scheme:

The topic of the lesson

The topic taught was meant to be appropriate to the pupils' level and simultaneously was meant to be of novel nature in order to avoid deviations possibly caused by what

the teachers had already taught, in other words in order to limit the effects of didactical memory of the class (Brousseau, 1997).

The topic selected for the two lessons corresponds to the fourth additive structure of Vergnaud (1983) because it allows integration of the two above described methodological restrictions. This structure works only with positive or negative transformations (“gain” or “lose”) without any indication of the initial numerical status. The following is an example of such problem:

Lou plays two rounds of marbles. She plays the first round and then the second. In the second round, she loses 4 marbles. After the two rounds she wins 6 marbles. What happened in the first round?

The pre-test and post-test consisted of 22 problems of this type (selected from 24 types of problems for this type of structure); each problem contained at most two numbers smaller than 10. The level of difficulty of these problems depends on the position of the unknown (possibilities: 1st transformation, 2nd transformation or compound transformation) and on the transformations that can be either of the same sign or of the opposite sign. For example, the above given problem *Lou* is very difficult for 9-10-year old pupils, while the below given problem *Dominika* is much easier, although a non-negligible proportion of the pupils produces an incorrect answer anyway (“*She has 2 marbles altogether*” instead of “*She won 2 marbles altogether.*”)

Dominika plays two rounds of marbles. She plays the first round and then the second one. In the first round, she wins 6 marbles. In the second round, she loses 4 marbles. What happened in the whole game?

To avoid any influence on the teachers’ organization and structuring of the lessons, the teachers had no access to evaluation before the post-test – this condition was negotiated as part of the research contract.

This paper does not give us enough space for description of the observed lessons (and it is not necessary for our purposes)¹: for our purposes we focus on the consequences of pupils’ learning as a function of the initial level (shown in the pre-test). Thus we want to find the possibilities the teachers have (whatever their teaching style is) for differentiation of teaching with respect to their pupils; cognitive abilities.

ANALYSES AND RESULTS

Figure 1 represents the distribution of success in the pre-test:

¹ For a more detailed description of teaching activities focusing on this type of knowledge see (Chopin, 2011).

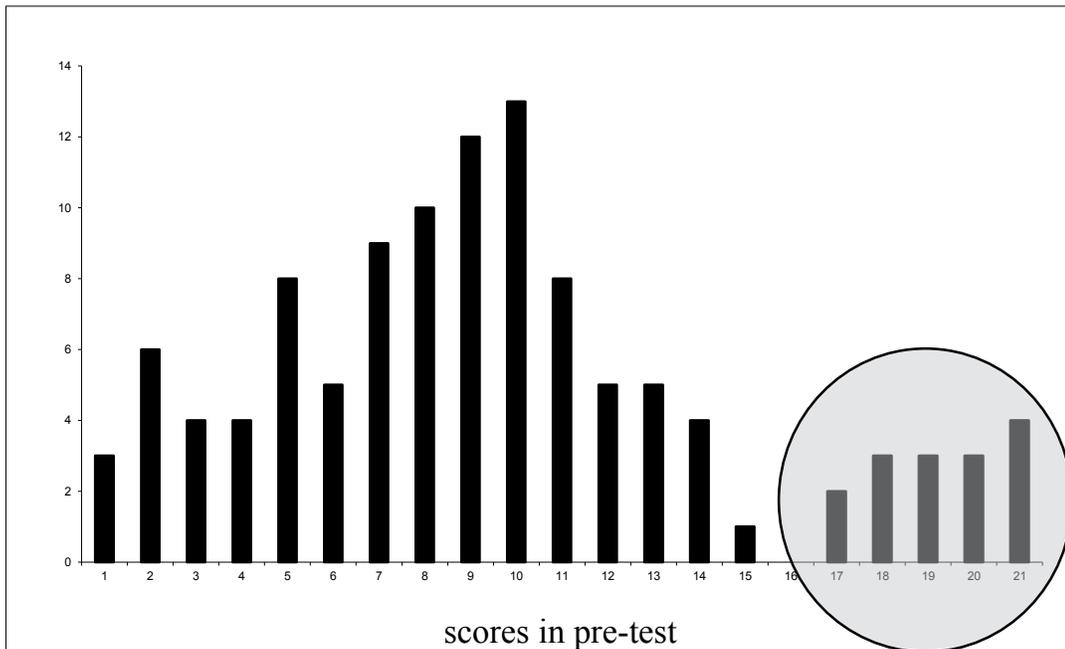

Figure 1: Success in the pre-test

In the following analyses 15 pupils who were successful in the pre-test at least in 17 problems out of the given 21 are considered as highly able.

Who are they?

They represent 13.4% ($n = 15$) of the participating pupils. There were more boys (73.3%) than girls (26.7%) – out of 51% boys and 49% girls in the whole set of pupils ($\chi^2 = 2.64$; ns; $p = .11$). The majority of them come from higher social classes (54%), 46% to middle classes. All parents of the pupils involved are secondary school graduates and 2/3 of them have a university degree. A questionnaire for the families confirmed that the parents' practices in the process of their children's upbringing were flexible (their children could negotiate the rules) and “curiosity” and “critical approach” were the dominant values in their educational approaches. To put it briefly, these are all students who succumb to rules which, whatever their degree of precision, must nonetheless be applied differently according to the context and situations.

In the context of the class the psychosocial status of these pupils is high in case of 87% of them and their majority are well aware of it (they neither underestimate nor overestimate their abilities). Unlike the majority of pupils, they always ask the teacher as soon as they do not understand something in mathematics lessons. They do not interact more than other pupils ($t = 0.11$; $p = .91$) but their interactive profile is significantly different from the others ($\chi^2 = 10.74$; $p = .005$): they do not ask to speak, they simply speak.

Theoretical model of the study

Didactical treatment of heterogeneities of competences by the teachers

It is a generally accepted fact that all teaching and learning, at least in the school environment, tries to develop knowledge of maximum possible number of pupils in the limited amount of time. This development surfaces as a decrease in the number of pupils' errors; in other words, as a reduction of heterogeneity of pupils' decisions on how to proceed, answers etc. that are acceptable for the teacher. But the teacher has no tools for *direct* handling of heterogeneities of pupils' differences in their giftedness, the differences in their attitudes to mathematics, of the time and attention they are ready to devote to it etc. What he/she does in his/her teaching in the beginning is that he/she complies with this original heterogeneity, trying to optimise it. In fact, no matter what the level of the class is (weak, advanced or very advanced), a too ambitious lesson would be too difficult for a considerable proportion of the pupils and a too simple lesson would also be unacceptable (loss of time). Individual pupils are often more than happy and comfortable in their positions of "good pupils", "weak pupils" etc. For several reasons, these categories of classification must be considered as functioning of didactical systems as such, independently on the initial abilities of individuals (Brousseau, 1997).

Let us now explore the following two questions:

1. Did the teaching enable learning for the largest possible number of pupils?
2. Is this learning equally distributed with respect to the pupils on different levels?

Results

1. Not all the pupils benefitted equally from the teaching: pupils of the above average and average levels profited most (about 58% of pupils) – see Table 1:

	<i>School level</i>			
	<i>Highly able</i>	<i>Good</i>	<i>Average</i>	<i>Weak</i>
<i>Number</i>	15	17	48	32
<i>m</i>	0,7	4.45	6.55	2.32

Table 1: Means of success in the post-test

2. Those good and average pupils who were the worst in the pre-test made the biggest progress in the post-test (and vice versa). This shows a strong correlation between the level of success in the pre-test and in the post-test. This does not hold for weak pupils.

<i>School level</i>				
	<i>Highly able</i>	<i>Good</i>	<i>Average</i>	<i>Weak</i>
ρ	-.57	- 0,78	- 0,73	-0,34
$p.$.02	2.10^{-5}	.0001	.15

Table 2: Correlation of success pre-test/improvement (Spearman's rho)

Conclusion: Teaching is efficient only when we start from the threshold of the initial abilities; this can be called according to A. Marchive (1997) and referring to Vygotsky a “zone of proximal teaching”, in which the teacher can teach with reasonable outcomes.

The presented results allow us to acknowledge the following two statements. No matter what the level of the considered class ($F(\text{pre-test}) = 2.60$; $p. = .02$) is:

- if the difficulty is lower, more pupils advance and heterogeneity decreases ($r = -.87$; $s.$; $p. < .001$);
- if the difficulty is high, the progress pupils make results in an increase of heterogeneity ($R = +.83$; $S.$; $P. < .001$).

DISCUSSION

Would the principle of didactical differentiation (using different things according to the students' initial level) allow us to support the conditions of creativity for all students, i.e. to support their learning?

As indicated in the previous text, regardless of the initial level of the class, any progress in knowledge in the class leads to an increase in heterogeneity. The lower the progress is, the more the heterogeneity is reduced. This implies that grouping pupils according to their level of giftedness does not bring optimisation of their learning, whatever their initial abilities are (there are researches that support this hypothesis – e.g. Duru-Bellat, 1996 ; Mingat, Duru-Bellat, 1997). The fact is that when teaching, the teacher must inevitably differentiate among pupils. We must be aware of the fact that the fall of very good pupils to weak positions if they attend large, above average classes will result in loss of courage, decrease in self-confidence etc. This is the price we must be ready to pay for an increase of the average level of the class. The following scheme (Fig. 2) illustrates this phenomenon: If a class A is divided into two groups, one group consisting of good and rather good students and the other of weak or rather weak ones, then the first group's level will be higher than the level of the second group; but it is interesting that the teacher will be forced to adjust his/her level of teaching according to the level of the group and will therefore create a new heterogeneity in the group. From the perspective of heterogeneity, we can see the same phenomenon in the two groups although the level of the first is higher than of the second.

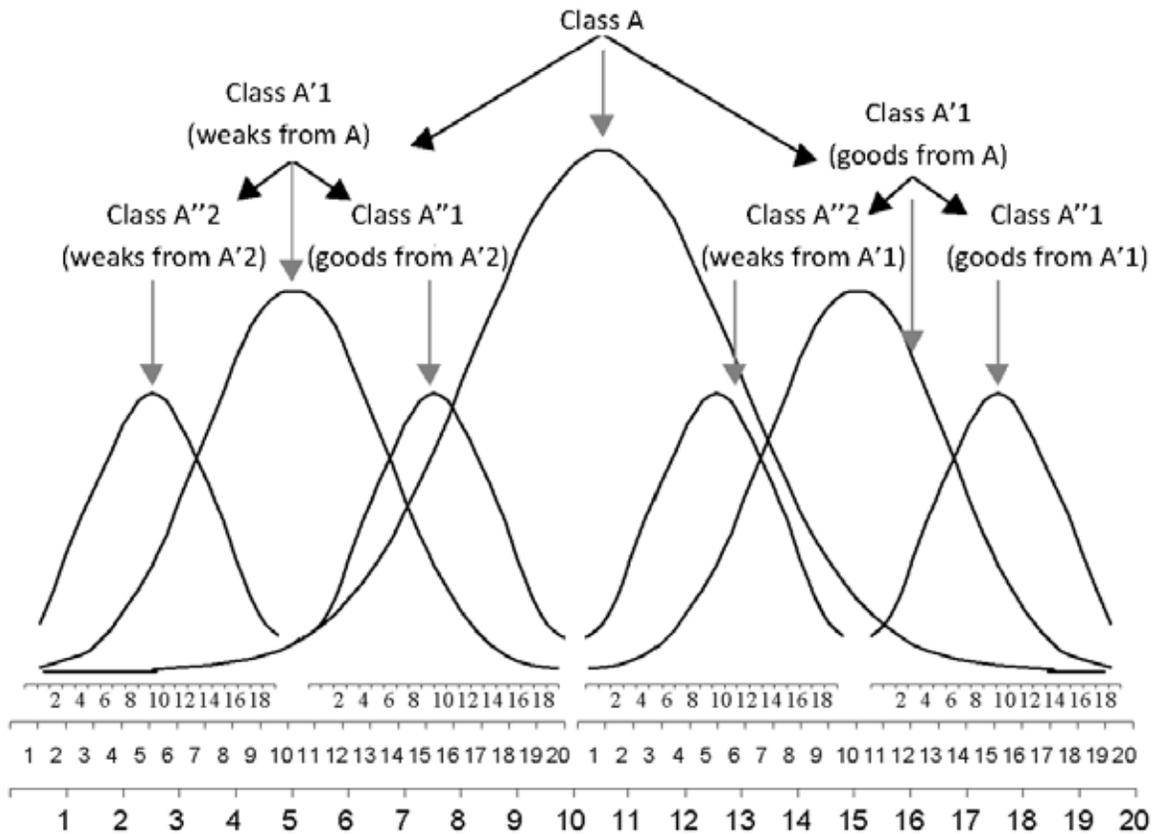

Figure 2: Division into classes according to students' giftedness

The decision to teach in such a way as to improve the performance of the best pupils at the expense of weaker pupils is political. It is not the task of mathematics educators to judge this choice. Their role is to help clarify this situation. As McDermott & Varenne (1995, 343) claim the place that is reserved for pupils from cultural minorities says much more about how our institutions work, about the values they bring than about the expected cognitive priorities. These ideas are “clearly adapted to the functioning and institutions that, across a formal educational system, serve to political and economic goals”. This is certainly not the question of glorification of egalitarianism or of radical elitism. We only warn of the dangers of the situation when modern democracies produce categories of individuals who are not able to communicate outside the boundaries of their own cultural community. Our results suggest that research motivated by legitimate concerns about effectiveness and equality is of great potential, as long as it pays sufficient attention to the conditions of organization of such teaching/learning situations in which everybody can adjust the knowledge to make it useful for his/her life. We are fully convinced that there exists a happy medium between acceptance of *indifference to differences* (P. Bourdieu) and its total refusal. It is the task of didactics to show this happy medium or at least to help to clarify it.

The set of these results evokes the fundamental question of orientation of education: Should it orient towards good mastery of algorithms or allow students to be creative in application of these algorithms in new situations (for this is the core of creation: it does not lie in rediscovery of some algorithm but in how the student really applies it in new situations)? It seems that both these orientations must be present simultaneously, which causes a paradoxical relationship: The more the teacher makes his/her teaching algorithmic, the more he/she limits the opportunities for creation for his/her students; the less he/she makes it, the less the students' knowledge is important and the less the students have the opportunity to create something new (as shown e.g. in (Sarrazy & Novotná, submitted to ZDM for 2013) the best students allow themselves to create new relations).

The Theory of didactical situation is born from the theorization and the scientific study of conditions enabling to overcome this paradox; although its recognition in the scientific community is high¹, its dissemination and its use in teacher training remain strongly limited, as it is shown by Marchive (2008). Should it be regretted? Certainly, as teacher training shows to be an important lever allowing teachers to leave this pointless debate. For the teacher, it is fundamental to trust students' creativity, but this pedagogical belief often leaves them helpless when they are to prepare conditions for: pedagogical intention itself is powerless face to face students' incomprehension.

We believe that it is desirable to increase teachers' didactical culture; in fact, if a didactician contributes to clarification of the conditions under which a student may be given the chance to create new knowledge (this contribution does not depend on the student but on the mathematical culture itself), the teacher's responsibility remains to manage the socio-affective conditions that allow the student to get involved in the adventure, which nobody can experience instead of them: the adventure of grasping the whole world in one day on their own, gaining the profit from it. How can one imagine that students would be able to produce something new, had they never had any opportunity to experience it? This is our noble mission: to organize the conditions for such mathematical creativity; the fact that some of them succeed in this adventure better than others is not, as we tried to show, the teachers' responsibility as long as he/she creates the conditions allowing the possibility of this adventure for all students.

ACKNOWLEDGEMENT

The research was partially supported by the project GAČR P407/12/1939.

BRAIN POTENTIALS DURING SOLVING AREA-RELATED PROBLEMS: EFFECTS OF GIFTEDNESS AND EXCELLENCE IN MATHEMATICS

Ilana Waisman, Mark Leikin, Shelley Shaul and Roza Leikin

Faculty of Education, RANGE Centre, University of Haifa, Israel

This event-related potentials (ERP) study investigates the impact of general giftedness (G) and excellence in mathematics (EM) on behavioural performance and cortical brain activity while solving geometric area-related tasks. We report on findings of comparative data analysis based on 74 right-handed male students. Effects of the G and EM factors emerged at the behavioural and the neuro-cognitive level. We found that giftedness is expressed in more efficient brain functioning. EM does not guarantee success in solving the problems and exerts a different effect on the cortical brain activity in G as compared to NG subjects. When performing area-related tasks, G can compensate for the lack of EM.

Key words: Geometric reasoning, Area, Event related potentials, General Giftedness, Excellence in Mathematics, Neural efficiency

INTRODUCTION

A considerable body of research has been conducted towards understanding the neural foundation of mathematical cognition (e.g., Santens et al., 2010). In addition, extensive neuroscience research has focused on human intelligence including individual differences in general intelligence (e.g., Neubauer & Fink, 2009; Deary et al., 2010) and on mathematical giftedness (O'Boyle, 2008). However, these studies have not gone beyond arithmetic, logic and spatial mental ability. That is why we have chosen to focus our attention on electrical brain activity (by means of Event Related Potentials – ERPs) associated with solving advanced mathematical tasks.

Additionally, to the best of our knowledge, differences between giftedness and expertise in mathematics have not been addressed in brain research to date. This observation resulted in the integration of 4 research population groups, divided according to varying combinations of general giftedness and mathematical expertise.

BACKGROUND

Studying areas of figures in school

Studying geometry in high school involves analysing geometric structures, characteristics and relationships (NCTM, 2000). Mental images of geometrical figures represent mental constructs possessing simultaneously conceptual and figural properties (Fischbein, 1993). Geometrical reasoning is usually associated with visual and logical components which are mutually related. The area of figures overlaps with content areas of geometry and is considered to be a significant topic of school mathematics (NCTM, 2000). Mathematics researchers and educators have suggested that knowledge of the properties of the basic shapes and congruence, geometric

motions and area measurement concepts are all closely interrelated (Clements et al., 1997). Moreover, the integration of geometric knowledge and area measurement can be important for the conceptual understanding of area measurement (Huang & Witz, 2011). Problems involving comparison between the areas of two figures can be solved without using area formulae, thus enabling researchers to study student's purely conceptual understanding (Huang & Witz, 2011).

Mathematical abilities, cognitive skills and brain research

Literature review demonstrates quite consistent findings that connect different mental operations associated with mathematics and the location of brain activation. For example, research shows that attention control processes and general task difficulty (Delazer et al., 2003) are associated with the prefrontal cortex, while mental rotation (Heil, M., 2002) and visuo-spatial strategies in mathematics (Sohn, et al., 2004) are associated with the parietal cortex. The brains of the mathematically gifted show enhanced development and activation of the right hemisphere (Prescott et al., 2010) as well as enhanced brain connectivity and an ability to activate task-appropriate regions in both brain hemispheres in a well-orchestrated and coordinated manner (O'Boyle, 2008). There is strong evidence for special development of prefrontal and posterior parietal regions of the brain and their enhanced intra-hemispheric connectivity (e.g. Jung & Haier, 2007).

The goal of the current study was to investigate the impact of general intelligence, as well as of excellence in mathematics, on performance in short area-related geometric problems using electrophysiological measures.

MATERIALS AND METHODS

Participants

Seventy-four right-handed male high school students from northern Israel (16-17 years old) participated in this study. The students were sampled as shown in Table 1.

Table 1: Research population

	Gifted (G) IQ>135, Raven >28 of 30	Non-Gifted (NG) 100<IQ<130, Raven < 26 of 30	Total
Excelling in mathematics (EM)			
SAT-M >26 of 35 or Math score > 92 in high level mathematics	20	17	37
Non-Excelling in mathematics (NEM)			
SAT-M <21 of 30 or Normal level of mathematics instruction	20	17	37
Total	40	34	74

Stimuli and Procedure

A computerized geometry test was designed using E-Prime software (Schneider, Eschman, & Zuccolotto, 2002). The test included 60 tasks. Each task on each test was presented in three windows with different stimuli (S1 – Introducing a situation stage, S2 – Question presentation stage, and S3 – Answer verification stage) that appeared

consecutively. Figure 1 presents the sequence of events and an example of a task. Time periods were determined by a pilot study with 15 participants.

Participants received a drawing of a geometric object. Part of this drawing was shaded. The participants had to determine what area of the drawing was shaded or what the area of the geometric object was in reference to the shaded part.

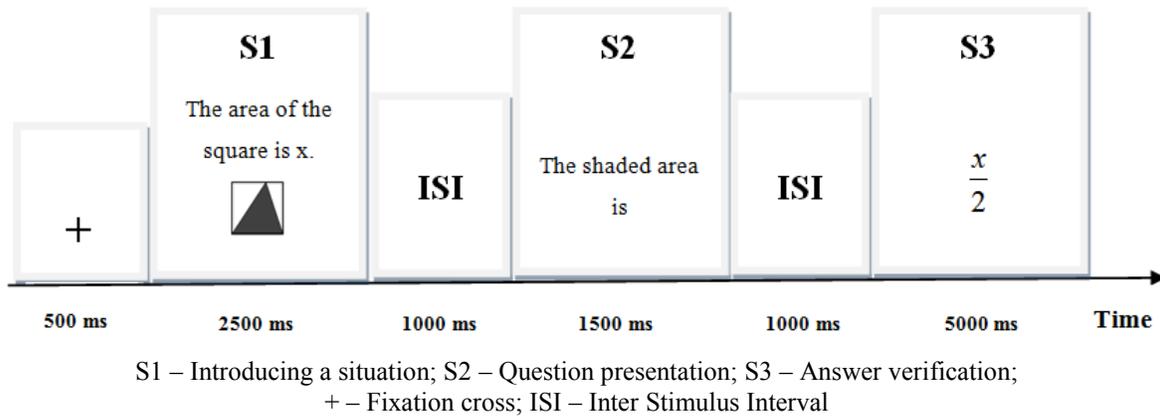

Figure 1: The sequence of events and a task example

Behavioural data analysis

MANOVA was applied to reaction time for correct responses (RTc) and accuracy (number of correct responses - Acc) of the performance in order to examine effects of between-subject factors (G factor and EM factor).

ERP Recording and Analysis

Scalp EEG data were continuously recorded using a 64-channel BioSemi ActiveTwo system (BioSemi, Amsterdam, ND). [We do not present the technical details of data recording and analysis due to the space constraints of this paper]. ERPs (Event Related Potentials) are electrophysiological measures reflecting changes in the electrical activity of the central nervous system related to external stimuli or cognitive processes occurring in the brain. The ERP waveforms were time-locked to the onset of S1, to the onset of S2 and to the onset of S3. The grand average waveforms (average of students waveforms) were calculated for each stage.

Early components (P1 and P2) and late potentials, as well as the electrodes and time frames for statistical analysis, were chosen based on a preliminary examination of grand average waveforms and ERP topographical maps (electrical voltage distribution) (Table 2).

Table 2: Electrodes chosen for statistical analysis

	Time frame (ms)	Selected electrodes
P1 component	S1, S3: 100 – 180; S2: 100 – 200	P3, Pz, P4, PO3, POz, PO4, O1, Oz, O2
P2 component (for S1 only)	180 – 250	AF3, AFz, AF4, F3, Fz, F4, FC3, FCz, FC4
Late potentials	250 – 500, 500 – 700 and 700 – 900	AF3, AFz, AF4, F3, Fz, F4, FC3, FCz, FC4, P3, Pz, P4, PO3, POz, PO4, O1, Oz, O2

We performed the following statistical analysis related to early components and late potentials.

(1) In order to examine early differences in amplitude and latency of early components associated with perceptual processing of each stage, we conducted repeated measures MANOVA for each task's stage using Laterality (3 levels: P, PO, O) as a within-subject factor, G factor (2 levels: G, NG) and E factor (2 levels: EM, NEM) as between-subject factors. **(2)** In order to examine the mean overall activity we performed repeated measures MANOVA on RMS (i.e., the square root of the mean of the squared potentials from each common referenced electrode) using Time (3 levels: 250-500, 500-700 and 700-900 ms) as a within-subject factor, G factor (2 levels: G, NG) and E factor (2 levels: EM, NEM) as between-subject factors. **(3)** The mean amplitudes were averaged over six electrode sites (ELS) (PR - right posterior (P4, PO4, O2), PM - middle posterior (Pz, POz, Oz), PL - left posterior (P3, PO3, O1), AR - right anterior (AF4, F4, FC4), AM - middle anterior (AFz, Fz, FCz) and AL - left anterior (AF3, F3, FC3)). In order to examine the differences in electrical activity in the aforementioned electrode sites, the repeated measures MANOVA was performed on the ERP mean amplitude considering the ELS (6 levels: 6 electrode sites – PL, PM, PR, AL, AM and AR) as within-subject factor, the G factor (2 levels: G, NG) and EM factor (2 levels: EM, NEM) as between-subject factors. This was done for each stage of task problem solving. *P-values* were corrected for deviation from sphericity according to the Greenhouse Geisser method.

RESULTS

We report here only the main effects and significant interactions.

Behavioral data

Table 3 demonstrates reaction times for correct responses and accuracy (mean and SD) of the performance on geometric tasks found for the four groups of participants.

Table 3: RT for correct responses (RTc) and Accuracy for different groups (Mean, SD)

	Acc (%)			RTc (ms)		
	G	NG	Total	G	NG	Total
EM	81.9 (7.1)	75.4 (9.0)	78.9(8.6)	1223.0(314.9)	1344.5(419.4)	1278.8 (366.4)
NEM	81.3 (6.8)	73.3 (8.6)	77.7(8.5)	1453.4 (441.2)	1218.4 (382.0)	1348.9 (426.9)
Total	81.7 (6.9)	74.4 (8.7)	78.2 (8.7)	1328.2 (395.9)	1283.4 (400.5)	1309.8 (391.5)

Acc – Accuracy; RTc – Reaction time for correct responses

The MANOVA showed a main effect for the G factor ($F(2, 68) = 9.137, p < .001$). The follow-up ANOVA analysis showed a main effect of G factor on accuracy ($F(1, 69) = 15.285, p < .001$) and marginally significant interaction of $G \times EM$ factors

involving RTc ($F(1, 69) = 3.741, p = .057$). Figure 2 demonstrates these effects and interactions.

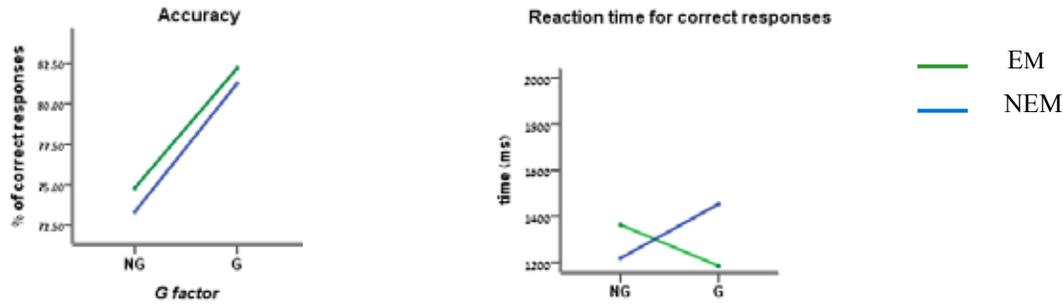

Figure 2: Accuracy and RT for correct responses in the four experimental groups

G participants were significantly more accurate than their NG counterparts. The accuracy of G-NEM individuals was similar to the accuracy of G-EM and much higher than those of NG-EM. However, the RTc of G-NEM was the longest of the four groups of participants.

Electrophysiological scalp data

The grand average waveforms for four experimental groups for each task's stage are displayed in Figure 3.

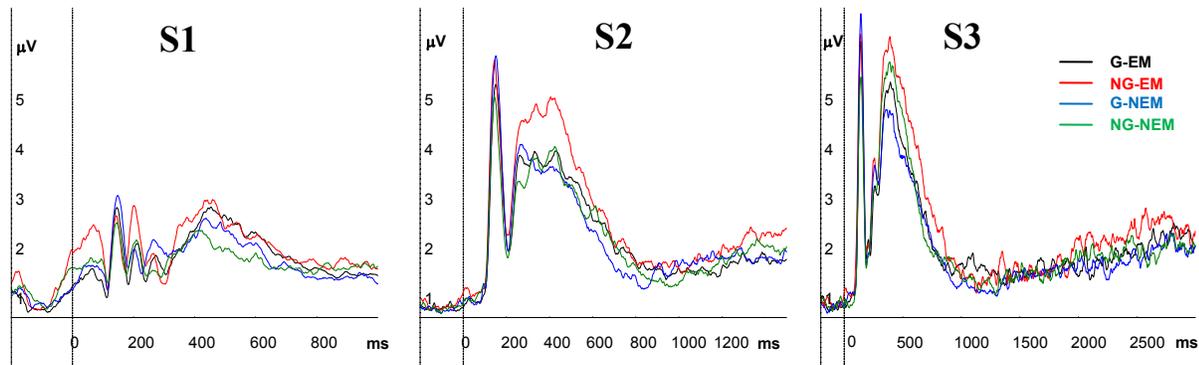

Figure 3: The grand average waveforms at each stage

From the grand average waveforms observed in Figure 3, one can see that posterior P1 is elicited in each of the three task's stages: S1 – Presentation of a situation, S2 – Question presentation and S3 – Answer verification. Anterior P2 is elicited only at Stage 1.

The significant effects on latency and amplitude of P1 and P2 are shown in Table 4.

Table 4: Main effects and significant interactions of latency, amplitude of P1 and P2

Stage	Peak	Latency		Amplitude
S1	P1	N.S.		Laterality × EM at P electrodes $F(2, 140) = 4.464^*$
	P2	Laterality × G at AF electrodes	$F(2, 140) = 3.464^*$	Laterality × G at F electrodes $F(1.730, 121.088) = 4.918^*$
		G factor × EM at AF electrodes	$F(1, 70) = 6.712^*$	Laterality × EM at F electrodes $F(1.730, 121.088) = 3.750^*$
		at F electrodes	$F(1, 70) = 5.285^*$	Laterality × EM at FC electrodes $F(1.811, 126.757) = 3.232^*$
S2	P1	Laterality × EM at O electrodes	$F(1.611, 112.782) = 3.985^*$	N.S.
		G factor at O electrodes	$F(1, 70) = 6.613^*$	
S3	P1	N.S.	G × EM at O electrodes	$F(1, 70) = 4.852^*$

* $p < .05$ (p -values with Bonferroni correction)

The aforementioned results suggest that different participants groups perform early processing of an object in different ways. These differences were expressed in latency and amplitudes of P1 and P2 as well as in laterality of these peaks. Space constraints of the paper do not allow us to explain all of these findings in detail. Following the P1 and P2 components, we analysed late potential components. Table 5 represents main effects and significant interactions followed by pair-wise comparisons.

Table 5: Main effects, significant interactions and pairwise comparisons for each stage

Stage	RMS – root mean square	ELS – at electrode sites	
S1	EM factor	5.373*	
	500-700 ms	4.838*	
	700-900 ms	6.422*	
	for NG: RMS(EM) >> RMS(NEM)	8.162**	for NG: Amp(EM) >> Amp(NEM)
	250-500 ms	4.409*	for NG at PM: Amp(EM) >> Amp(NEM)
	500-700 ms	7.481**	250-500ms 4.911*
	700-900 ms	7.037**	500-700ms 8.886**
S2	EM factor	5.298*	
	for NG: RMS(E) >> RMS(NE)	5.132*	N.S.
	250-500 ms	5.093*	
S3	N.S.	G factor 500-700ms 4.911*	

(1)* $p < .05$; ** $p < .01$ (p -values with Bonferroni correction); (2) $df: (1, 70)$; (3) Amp – Mean Amplitude;
(4) RMS – Root Mean Square

We found a main effect of the EM factor at S1 and S2 stages for RMS, which is the measure of overall mean electrical activity. RMS of EM was larger than that of NEM participants. Further investigation of this effect showed that a significant difference

between EM and NEM exists only for NG participants (for S1 stage see Figure 4). Interestingly, EM and NEM displayed similar RMS activity amongst G participants.

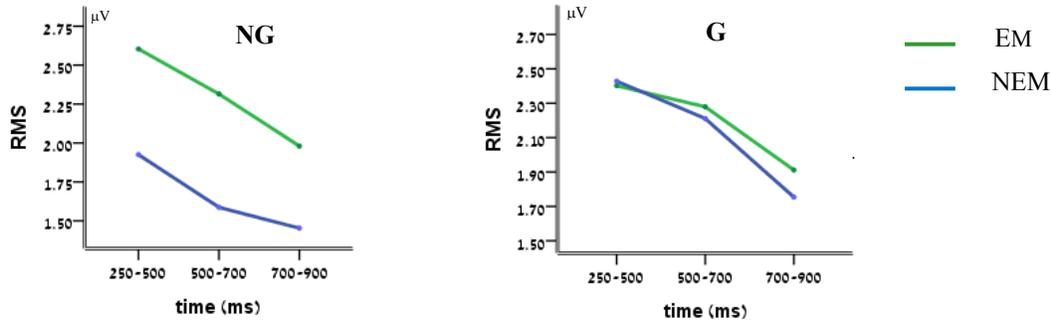

Figure 4: RMS activity at S1 stage for G and NG participants

To investigate more precise topographical distribution of the electric potential, we carried out an examination of the mean amplitude in the electrode sites defined above (AL, AM, AR, PL, PM and PR).

The statistical analysis found significant $G \times EM$ interaction at S1 stage (250-500 and 500-700 ms time frames). At these sites the mean amplitude of NG-EM participants was significantly higher than their NG-NEM counterparts. However, the mean amplitude in G-NEM students was only slightly different from that of their G-EM counterparts.

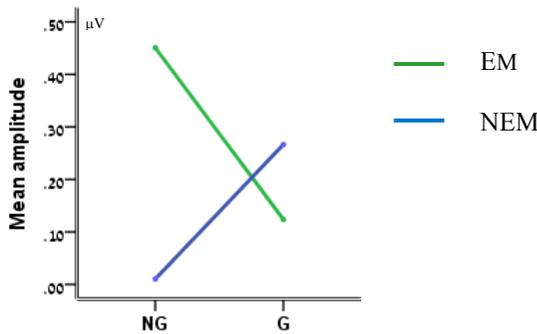

Figure 5: Mean amplitude at S1 stage (500-700ms) for the four groups

The most prominent difference between NG-EM and NG-NEM was at middle posterior (PM) electrode site (Figure 6).

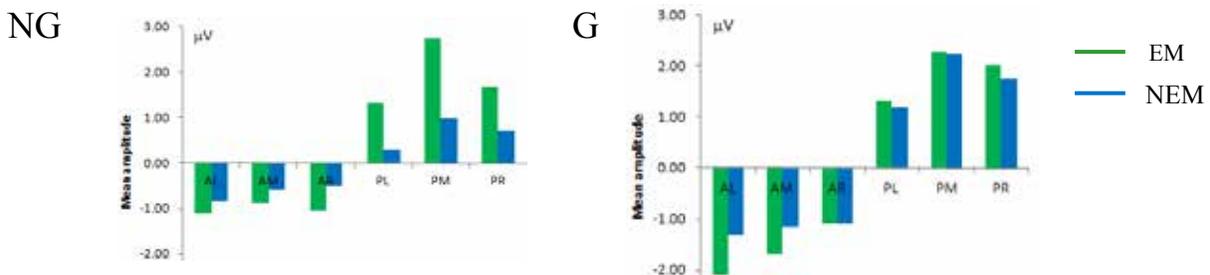

Figure 6: Mean amplitude at S1 stage (500-700ms) for G and NG students at six electrode sites

The statistical analysis revealed a main effect of the G factor at the S3 stage – answer verification. At 500-700 ms, G participants had a lower mean amplitude in the predefined electrode sites compared to their NG counterparts (see Figure 7). Pairwise comparisons revealed marginally significant differences between G and NG participants only amongst EM participants ($F(1, 70) = 3.676, p = .059$).

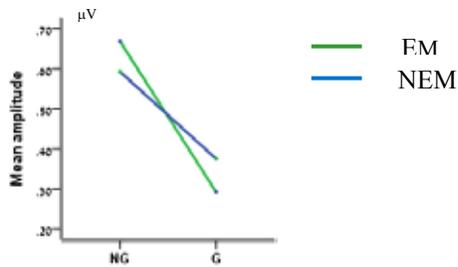

Figure 7: Mean amplitude of students in the four groups at S3 stage (500-700ms).

Figure 8 displays the scalp topography of participants in four groups at 500-700 ms as it is manifested in the answer verification stage (S3).

Figure 8: Scalp topography of participants in four experimental groups (500-700 ms).

From Figure 7 and Figure 8 we observe that G-EM participants have the lowest mean amplitude, whereas the NG-EM have the highest mean amplitude at the rear parts of the scalp. This suggests that G-EM devoted the least effort in solving area-related tasks. On the other hand, NG-EM struggled to solve this kind of tasks.

CONCLUSIONS

The present study investigates the differences in brain activity in gifted versus non-gifted and excelling versus non-excelling male adolescents when performing area-related tasks involving transition from a mathematical object to its property.

Behavioural data of the study demonstrated that the accuracy of gifted students was significantly higher than those of non-gifted. The accuracy of G-NEM individuals was similar to the accuracy of G-EM but much higher than that of NG-EM. Therefore, we can conclude that excellence does not affect accuracy in solving geometry area problems amongst G individuals. On the contrary, the RTc of G-NEM was the highest amongst the four groups and significantly differed from the RTc of G-EM. However, G-NEM participants were slightly slower but more accurate than NG-EM. Therefore, from the behavioural data it can be concluded that giftedness exerts a strong impact on performance in NEM participants. Thus, giftedness can compensate for the lack of excellence in mathematics in area-related problems.

Furthermore, electrophysiological data revealed significant differences between participant groups as it was manifested in latency and amplitude of early components (P1 and P2) and their lateralization. Thus, the analysis of early components suggests that early processing of the mathematical object amongst the participant groups was different.

The analysis of late potentials revealed that participants excelling in mathematics had higher overall mean activity (RMS) than their non-excelling counterparts. However, further pairwise comparisons detected that this difference was significant only amongst NG participants. The RMS measure was similar between EM and NEM amongst G participants. Similar findings were obtained from analysis of electrical activity at six predefined electrode sites during the S1 stage. At these sites the mean amplitude of NG-EM participants was higher than their NG-NEM counterparts. On the other hand, the mean amplitude of G-NEM participants was slightly different from that of their G-EM counterparts. The significant difference in mean amplitudes between EM and NEM participants was found only for NG students. This difference was most prominent at the middle posterior (PM) electrode site. Therefore, we can conclude that G-NEM and G-EM participants process the stage of introducing a situation (geometric figure with shaded area) and the stage of question presentation in the same way. This leads us to the conclusion that in area-related problems excellence loses its influence amongst the gifted participants.

The electrophysiological results demonstrated that in time period 500-700 ms at answer verification stage (i.e., S3) gifted students have lower overall mean amplitudes for correct responses at six predefined electrode sites. That is, they seem to exhibit more efficient brain activation during this task (e.g., Neubauer & Fink, 2009). The lowest electrical activity at the S3 stage was amongst G-EM participants, whereas the NG-EM had the highest electrical activity. This indicates that that NG-EM invested a great deal of cognitive resources in order to verify the given answer.

The present study provides evidence that different levels of giftedness as well as different levels of EM are reflected in the amount of cortical activation and in the behavioral measures. The electrophysiological data can provide a level of measurement and analysis that is difficult to approach by behavioral means. This may be relevant for conducting educational interventions for individuals with different abilities skills and for evaluating the effects of these interventions.

ACKNOWLEDGEMENT

This study was made possible through the support of a grant from the John Templeton Foundation and the University of Haifa. The opinions expressed in this publication are those of the author(s) and do not necessarily reflect the views of the John Templeton Foundation.

MATHEMATICALLY ABLE BUT UNDERACHIEVING IN SCHOOL MATHEMATICS

Elisabet Mellroth

Karlstad University, Sweden

Teacher observation has shown that some pupils achieve very high on the Kangaroo Competition test (KC) but very low on the Swedish National test in Mathematics (SNM). This study will investigate the number of pupils who have high achievement scores on the KC (top 10%) but low achievement scores on the SNM (bottom 50%). Individual results on the SNM given in grade 6 (age 12) will be compared to results on the KC given in grade 7; concerning approximately 700 individuals. Results will give an example of the quantity of mathematically able pupils who underachieve in School Mathematics in Sweden. Data interpretation will connect this study to international research concerning mathematical abilities and mathematical achievement among mathematically able pupils.

BACKGROUND

Research stresses that early identification of giftedness, stimulation and support are important to prevent underachievement (Seeley, 2004). Sweden therefore has to support and stimulate those pupils who are mathematically able in early ages to prevent underachievement. TIMMS show less high achieving students in Sweden (Skolverket, 2009).

The Swedish curricula claim that teaching in mathematics should give pupils opportunity to develop mathematical abilities mentioned in the curricula (Skolverket, 2011). The purpose of the SNM is to measure abilities according to the Swedish curricula connected to different topics in mathematics; it aims to give the teachers support in equal and fair assessment and grading (Skolverket, 2012).

Mathematical abilities discussed in international research can often be connected to Krutetskii (Krutetskii, 1976). Krutetskii's definition can be used to analyse the problems in the KC (Pettersson, 2011). The purpose with the Kangaroo Competition test is to awake curiosity and inclination to learn mathematics (Nationellt centrum för matematikutbildning, 2013).

However, are those two ways of measuring mathematical abilities compatible? What if a pupil achieves high on the KC but low on the SNM, that pupil may attain low grades in mathematics and may not continue to study advanced mathematics.

So far in Sweden no research has investigated additional methods to find mathematically able pupils. Therefore this study will investigate if mathematically able pupils who underachieve in the Swedish school system can

be made visible through the KC. These pupils could with accurate support and stimulation continue to study mathematics, technology or science at university advanced level; people who are needed for society in the future.

AIM AND METHOD

The aim of the study is to investigate the number of pupils who are high achievers on one mathematical test, in this case KC, but are not high achievers on the SNM. The SNM has a large impact on pupils' grades in mathematics, which in turn will guide pupils in their future choice of education. Thus there is a risk that the Swedish school system loses mathematically able pupils who with accurate support and stimulation could have had a successful education within mathematics, technology or science. The results will imply a discussion about differences in achievement in the two tests. The discussion will be framed by the how mathematical abilities are defined and measured in different contexts (the Swedish curricula vs. Krutetskii).

Individual results of the SNM given in grade 6 (age 12) will be compared to results of KC given in grade 7. The study covers a whole municipality (approximately 700 individuals). Pupils' results will be compared relatively to each other, which will give ranked data. Data will be analysed with non-parametric tests using SPSS. Data interpretation will connect this study to international research concerning mathematical abilities and mathematical achievement for mathematically able pupils.

CAN WE JUST ADD LIKE THAT?

Alv Birkeland

University of Tromsø

The aim of this qualitative study is to analyse the mathematical reasoning of a group of teacher education students, and ask if their mathematical reasoning can be categorised as creative mathematical reasoning. The students were not selected for mathematical giftedness or excellence. After an introduction, the research question is formulated and the methodology indicated. Finally, an excerpt from the transcripts of the study is given with a discussion and initial findings indicated.

Keywords The Four-C Model · Imitative reasoning · Creative mathematically founded reasoning · Dialogical approach.

INTRODUCTION

The Four-C Model of Creativity proposed by Beghetto and Kaufman (2009) recognizes the discoveries created by students when learning something as personal novelty, and thus to be creativity at a personal level. Lithner (2008) uses the terms imitative reasoning (IR) and creative mathematically founded reasoning (CMR). The basic idea here is that rote learning reasoning is imitative reasoning (IR), while the opposite type of reasoning (CMR) is creative and mathematically founded, meaning that the reasoning has personal novelty, is plausible and anchored in the mathematics of the given problem.

Research question:

How can the mathematical reasoning of teacher education students, not selected for mathematical giftedness or excellence, be described as creative mathematically founded reasoning?

METHODOLOGY

A group of teacher education students were given the following sequence:

0, 4, 10, 18, 28, 40...

They were asked to find an explicit expression for the n 'th term a_n of the sequence. I recorded the group working on this problem on video and prepared transcripts based on the recording. The transcripts will be analysed using the theoretical framework of Lithner (2008). To analyse the collaborative work in small groups I will follow the dialogical approach found in Bjuland (2004). Initial findings indicate that some of the reasoning of teacher education students is not imitative and hence creative mathematically founded reasoning, where the creativity is on the personal level.

THE STUDY

To solve the problem the students had to find the sum: $2 + 3 + \dots + n$. The students were familiar with the triangular numbers, but found that something was missing as indicated in the following transcripts.

1 Student 3: We are missing 1,

2 Student 2: we are missing 1, yes if we add,

3 Student 1: add 1 to each side,

4 Student 2: we have to add 2 ... 2 ... 2 times 1 ... to both sides, because we have the number two Yes, if we try that, add 2 times 1, then you get an plus 2 times 1 equals 2, and then we get 1 plus 2 plus 3 plus 4 plus ... plus n.

5 Student 1: yes don't we?

6 Student 2: yes,

7 Student 3: can we just add like that?

The students add 2×1 to both sides of the equation $a_n = 2(2 + 3 + \dots + n)$ which gives the equation $a_n + 2 \times 1 = 2(1 + 2 + 3 + \dots + n)$. Since they are familiar with the triangular numbers, the problem is solved. Student 1 suggests in line 3 that they should add 1 to each side of the equation. In line 4, student 2 suggests that they should try to add 2×1 to both sides of the equation. This means that they make their own choices and try out their own ideas, which indicates that their reasoning is not imitative. Student 3 in line 7 asks if one can just add like that. One way to interpret this question might be that student 3 does not understand equations and the fact that one can add to both sides of an equation, but for student 3, the problem is rather that 1 is missing as indicated in line 1. Another way to interpret the question is that the idea used by the students to solve the problem, has personal novelty to student 3. The transcripts indicate that the mathematical reasoning of the students is not imitative and hence creative mathematical reasoning (CMR).

PROPOSING A THEORETICAL FRAMEWORK FOR STUDYING MATHEMATICAL EXCELLENCE

Sérgio Carlos

Ph. D. Student at Universidade da Beira Interior, Portugal

The excellence phenomenon has been fascinating mankind since ever. In particular, excellence in mathematics is an intriguing thing – why some are capable of a math performance at excellent level, and some aren't? What do this very restrict group do differently from everyone else that sets them apart? What contextual variables, personal characteristics and math specific abilities need to be present to allow the potential to do math at top level? These are some of the questions that can arise in the researcher's mind when trying to unravel this phenomenon. But the very different factors involved and the connections among them may constitute a difficulty. This poster is proposing a theoretical framework that attempts to give consistency to this array of concepts and the links between them.

OUR RESEARCH

We are attempting to clarify the components of mathematics excellence in university students, and to characterize their math reasoning. Relating to math reasoning, in particular, our interest lies in perceiving their creativity. To attempt to shed light on those issues we will invite some excellent mathematics university students to participate in an empirical study.

Besides those more practical aims we have another goal: to propose a theoretical model for studying mathematical excellence. To do so more effectively we intend to work in two phases. Firstly, we've examined the existing literature on the field and we developed a model (the one that can be seen here) based on previous research; Then, after conducting our empirical study – which isn't done yet – and both, understand the influence of the different external variables that affect the participants performance, and studying their inner qualities, we intend to go back to the initial model and refine it in the way that better fits the observed components and procedures. This later version of the model will be proposed to the research community to be used in future mathematical excellence research.

EXISTING MODELS

Among the existing theoretical models intended to the comprehension and development of talent and superior performance, there are two main perspectives. Some models emphasize the natural abilities while associating some personal traits and contextual factors, while others privilege the importance of long deliberate practice and self-monitoring.

OUR FRAMEWORK

Due to the diversity of the constituents of excellence and the different views on it, we think it's worthy to build a framework that takes in consideration the different beliefs and domains relevant to this phenomenon, and consequently allows a holistic approach on math excellence understanding. Therefore we suggest an umbrella framework, as seen in figure 1.

By observing the diagram, the central role of motivation is evident: as part of the needed general personality traits (other valuable traits are, e. g., intellectual curiosity, positive attitude towards math,...), as a couple together with talent that can lead to knowledge and also providing the necessary drive to engage in deliberate practice. We see the conjunction of abilities specific to mathematics (e.g., ability to generalize and to approach a problem in different ways, mathematical memory and intuition,...) and general personality traits as a potential to talent. There are considered personal catalysts in the form of self-regulation mechanisms (e.g., strategy choice, self-evaluation, adaptations,...) and social catalysts as a response to the combination of talent and motivation.

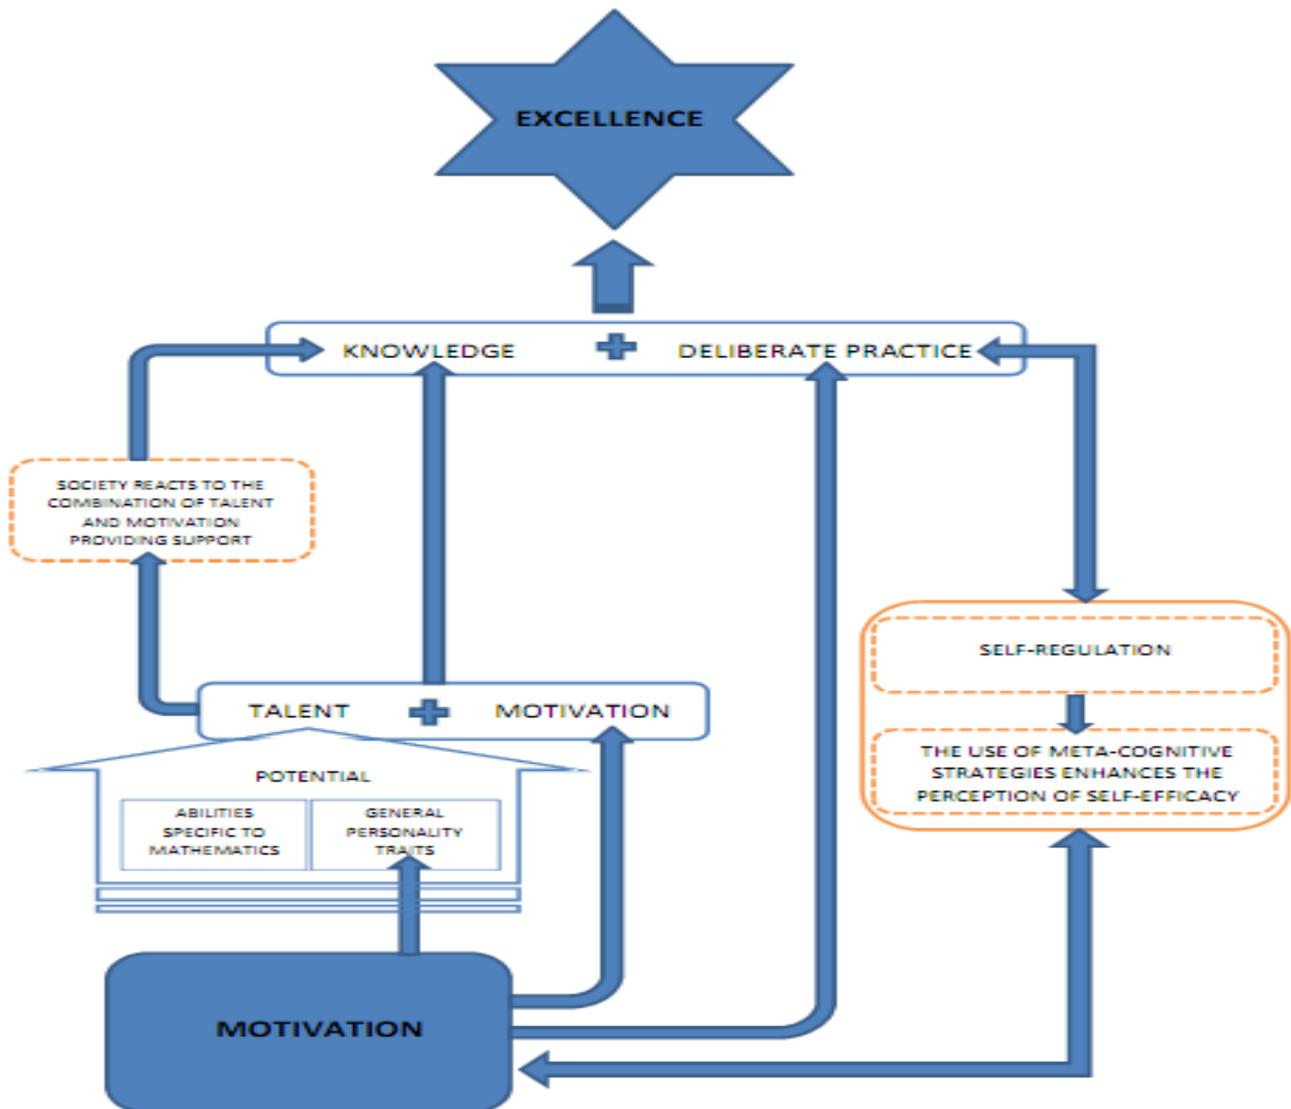

Figure 1: Purposed model of the concepts involved in math excellence

CREATIVITY AND CRITICAL THINKING IN SOLVING NON-ROUTINE PROBLEMS AMONG TALENTED STUDENTS

Einav Aizikovitsh-Udi

Beit Berl Academic College, Israel

The aim of this pilot study is to examine the extent of creativity and critical thinking in solving non-routine problems at a reasonable level, among students in the Mathematically Talented Youth Program. The study was conducted to answer following research question: What was the degree of creativity and critical thinking skills in problem solving among students who attended the Mathematically Talented Youth Program?

BACKGROUND

In general, creativity is defined as "the cognitive skill of proposing a solution to a problem or making something useful or novel from ordinary" (Hwang, Chen, Dung, & Yang, 2007). Mathematical creativity in school mathematics is usually connected with problem solving or problem posing (Silver, 1997).

Modern literature has provided a range of definitions of varying specificity in an attempt to describe and characterize what "Critical Thinking" is (Innabi & Sheikh, 2007). To cite just a few examples, McPeck (1981) defines it as the "skills and dispositions" necessary to "appropriately use reflective skepticism," while Paul (1999) offers a more extensive description as "thinking that enables judgment, is based on criteria, corrects itself, and is context-sensitive."

The purpose of the current study is to analyze connections between creative and critical thinking. I present here shortly the study method and initial results.

METHOD

The questionnaire was handed out to three classes of eight-grade students in their second year in the Mathematically Talented Youth Program in central Israel. There was no time limit for the students to solve the problem. The students were encouraged to write their explanations on how they came up with the solution and to provide justifications of their thinking. All their written responses were first analyzed qualitatively to identify the types of reasoning used to solve the problem. The number of correct responses for each type of reasoning was calculated.

RESULT

The majority of the subjects (40.4%) were found to be at the most basic level of creativity and critical thinking. Students who developed a method from a given situation (17.5%) were found to be at the second level of creativity and critical thinking. Students who knew how to relate to the given figures in non-pre-defined manner and used their proofs in their solutions (15.8%) of the subjects were found to

be at the third level of creativity. A high degree (64.1%) of clarity was found in these subjects' solutions: the arguments that they provided tended to be simple and straightforward. During the analysis some answers (26.3%) were categorized as "other" because they did not fit to any of the other categories.

Skills	Skill of Creative thinking	Skills of Critical thinking
Level 1: <i>Comparison</i>	Create new or original criteria comparison	Analyzing the characteristics of the objects of comparison
Level 2: <i>Raising points of view</i>	Developing the ability to step into the shoes of others and see things from a new angle	Justification and evaluation of points of view
Level 3: <i>Argument</i>	Raising a variety of reasons that can support the claim	Taking a detailed personal position

Table 1: Categories of Creativity & Critical Thinking

DISCUSSION

It comes to no surprise that creative thinking is more inherent among students who exhibit mathematical accuracy and fluency, especially in the context of working with non-routine and novel mathematical tasks, requiring them to pose original and meaningful solutions (Binder, 1996). Students relied heavily on prerequisite knowledge and although presented their solutions with high clarity, they failed to express simplicity, structure, and cleverness in their solutions. Although the research literature on talented students support the notion that talented students are more creative, no specific high level of creativity and critically was found in this segment of the population.

INTRODUCTION TO THE PAPERS AND POSTERS OF WG8: AFFECT AND MATHEMATICAL THINKING

Marilena Pantziara, (Chair) Cyprus Pedagogical institute, Cyprus

Kjersti Wæge, Norwegian University of Science and Technology, Norway

Pietro Di Martino, University of Pisa, Italy

Bettina Rösken-Winter, Ruhr University Bochum, Germany

Keywords: Beliefs; motivation; attitudes; security; identity; goals; uncertainty orientation; problem solving

INTRODUCTION

In the field of mathematics education, there has been an increasing interest in affect within the last fifteen years (Pantziara, Di Martino, Wæge, & Schloeglmann, 2011). At Cerme 8, the 25 participants of the Working Group 8 contributed to an inspiring and motivating discussion: 22 research papers and 3 poster presentations were initially submitted to the group and 17 papers were finally presented and discussed during the conference. In the proceedings, 17 papers and one poster presentation are included, each of which investigated some specific aspect of the complex world of affect.

We scheduled five of the seven conference sessions based on the themes of the presented papers: 1) Teachers' beliefs and self efficacy beliefs, 2) Teachers' beliefs and attitudes, 3) Teachers' and students' goals, security and identity, 4) Motivation, and 5) Students' emotions, beliefs and attitudes, and problem solving. Each participant's paper was presented and discussed within the whole group. Further discussion was encouraged by discussants who took up the role of a responder to the single paper in order to stimulate interaction. The five sessions were organized in such a way that enables the discussion to go beyond the scope of an individual paper to refine the conceptual frameworks of affect and to focus on its dynamic nature.

In the last two sessions, further discussion was stimulated in small sub-groups in order to explicate the relation between new concepts in the field and more traditional ones, to discuss the role of methodology in the investigation of affective issues, and to trace new directions of the research on affect. In particular, the discussion was inspired by the following questions: (a) How are the new affective constructs developed and what is their relationship to the more traditional constructs in the field? (b) How do the instruments and the context influence students' and teachers' affect? How can we reduce this influence? (c) Which directions of research on mathematics-related affect have not yet been explored sufficiently?

The structure of the affective domain

Much of the discussion in this affect group has focused on conceptual frameworks and terminology. The discussion was grounded in the graphic representation of the conceptual field of affect first introduced by Op't Eynde in Cerme 5 (Hannula, Op't

Eynde, Schloeglmann & Wedege, 2007). The figure identifies three main conceptual categories (cognition, motivation and affect) and their partial overlap while it positions different affective constructs in relation to each other and in relation to the three main conceptual categories. This figure also identifies the socio-constructivist perspective on learning characterized by its focus on the situatedness of learning and problem solving and by the close interaction between (meta)cognitive, motivational and affective factors in students' learning.

The discussion was also initiated by Hannula's (2011) framework which focuses on the need to deepen our knowledge of the structure and dynamics in the affective domain. The framework can be seen as a meta-theoretical foundation for research on mathematics-related affect since it helps to identify similarities and differences between studies in the field, and it is probably useful for relating a variety of theories to each other. The most important notions in this framework are: (a) a distinction between trait and state-aspects of affect; (b) perceiving emotions, cognition and motivation in a synergistic relationship and (c) the identification of biological, psychological and social levels of affect.

Teachers' beliefs about mathematics and its teaching and learning were investigated extensively in the group (Arslan & Isiksal, Fauskanger & Mosvold, Pantziara & Philippou, Mosvold et al., Erens & Eichler). Revealing the long lasting discussion about the definitions and characteristics of beliefs, authors provided some of the more commonly used terms related to the terminology of beliefs like beliefs systems, conceptions, considerations, personal convictions, identity, knowledge and values. They also discussed categorizations of mathematics teachers' beliefs about the nature of mathematics, mathematics teaching and mathematics learning. Specifically, Fauskanger and Mosvold investigated the ways in which focused discussions based on Mathematical Knowledge for Teaching (MKT) items can be used to tap into teachers' beliefs about aspects of MKT. Pantziara, Karamanou and Philippou's study was concerned with teachers' beliefs and knowledge related to the Cyprus mathematics curriculum reform, while Erens and Eichler explored teachers' beliefs concerning the calculus domain to understand their teaching practices. Mosvold, Fauskanger, Bjuland and Jakobsen used two approaches of content analysis in order to learn more about pre-service teachers' beliefs from transcripts of focus-group discussions prior to field practice.

In relation to beliefs, teachers' self-efficacy beliefs were also introduced in the group by Arslan and Isiksal as well as Sarac and Aslan-Tutak. These authors used Bandura's (1997) framework to define self-efficacy beliefs as individuals' judgments regarding the capability of a specific behaviour. Sarac and Aslan-Tutak shared with the group the process of investigating teachers' trigonometry teaching efficacy and of categorizing them in terms of their efficacy levels. Arslan and Isiksal revealed the effects of an elective origami course on preservice teachers' beliefs and perceived self-efficacy beliefs in using origami in mathematics education.

Fuentes Rivera and Gómez-Chacón explored teachers' attitudes towards mathematics as a first approach to researching affective factors in the teaching and learning process within the Telesecundaria educative subsystem. They define attitudes as evaluative predispositions (negative or positive) that determine the personal intentions and influences on the behavior.

Other concepts related to affect were introduced by participants (Liljedahl, Charalambous & Rowland, Sánchez Aguilar et al., Gebremichael). Liljedahl provided a taxonomy of five goals that teachers own when they come to professional development programs and discussed with the group how teachers move from one goal category to another while being engaged in these programs. Charalambous and Rowland introduced a new concept to the group, the feeling of security, which mathematicians can draw from mathematics. They perceived security in terms of Riemann's (1970) four types of fear which correspond to four types of personal needs that are organized into two opposing pairs: (a) fear of *assimilation* versus fear of *isolation* and (b) fear of *change* versus fear of *stagnation*. Identity was discussed in the group as it serves to explain what makes a person feel like an able mathematics student and get involved and engaged in mathematical activities. The term was used by Sánchez Aguilar et al. in their study of factors that motivated Mexican female students to choose mathematics as a career. Ethiopian students' perceptions of the relevance of mathematics to their learning goals was described and analyzed by Gebremichael using the Engeström model (Cole & Engeström, 1993). The model depicts the activity system, which involves the interaction between the subject (students) and the object (motives, goals, learning school subjects including mathematics and material resources) mediated by tools and artifacts. As discussed, this interaction is also mediated by rules, the division of labor, and the community.

Based on the work done since Cerme 5, Wæge and Pantziara presented an overview of five motivational families of social cognitive constructs, identifying similarities and differences between self determination theory and achievement goal frameworks. Reviewing the research on the relationship between teachers' practice in the mathematics classroom and students' motivation, they revealed overlapping issues concerning teachers' practices that promote students' motivation in mathematics. Enhancing students' motivation was further discussed by Edwards and Deacon who explored the influence of classroom grouping on students' motivation. Specifically, they revealed the influence of grouping based on close friendships, and friendships by association on students' motivations to engage with mathematics. Di Martino and Zan focused on students' negative emotions towards mathematics, in particular by tracing students' fear of mathematics. Analysing students' narratives, by giving voice to the students about their relationship with mathematics, they revealed the origin of fear of mathematics. Also in this direction, Ader and Erktin investigated student's coping with negative emotions when faced with difficulties in mathematics.

Students' mathematical confidence was explored by Jagals and Van der Walt. Specifically, the authors investigated sources of low and high forms of students'

mathematics confidence revealed through social, psychological and intellectual influences. In the same vein, Carreira, Ferreira and Amado described the help seeking and enjoyment patterns reported by students participating in an inclusive mathematics competition. They concluded that help seeking and enjoyment seem to be problem-dependent and that students seek help mainly from teachers and family. Students' preferences for solving tasks with multiple solutions and modelling were further explored by Schukajlow and Krug. In their study, the authors introduced uncertainty orientation (Sorrentino & Roney, 1999) which describes a person's typical way of dealing with complexity, uncertainty and abundant information. The authors assessed students' preferences for solving tasks with multiple solutions and uncertainty orientation before and after a five-lesson teaching unit promoting modelling competency.

Methodologies for investigating affect

Various methodological approaches, both quantitative and qualitative, were applied to investigating the complex and multifaceted nature of affect. Some papers developed questionnaires for studying teachers' beliefs, self-efficacy beliefs and attitudes (Arslan & Isiksal, Sarac & Aslan-Tutak; Rivera & Gómez-Chacón). The development of such instruments is basically related to also defining the concepts and their relationships. Other papers (Pantziara et al.) adopted questionnaires to apply them in a different socio-cultural context, revealing differences in the different settings. Questionnaires were also applied to gather students' uncertainty orientation, their preference for tasks with multiple solutions (Schukajlow & Krug) and their enjoyment while they are involved in challenging problems (Carreira et al.)

Other studies used qualitative methods to approach their goals. Focus group interviews were used (Fauskanger & Mosvold and Mosvold et al.) to investigate teachers' epistemic beliefs assuming that these give more realistic accounts of what people think. Semi-structured interviews were used in the study by Erens and Eichler and the study by Charalambous and Rowland while structured interviews were used in the study by Jagals and Van der Walt. Di Martino and Zan used a narrative approach referring to students' essays about their experiences related to mathematics. This approach was introduced as an interpretative approach capturing students' affect towards mathematics by giving voice to the students.

The use of a multi-method approach was adopted by several papers as a fruitful way to explore the affective domain. A combination of questionnaires and interviews was used by several presenters (Sarac & Aslan-Tutac, Aguilar et al., Gebremichael, Edwards & Deacon). Liljedahl gathered data from field notes, interviews and survey data to investigate teachers' goals. An intervention was applied by Schukajlow and Krug and questionnaires were used to measure the results of the intervention on students' affective constructs.

In the discussion, we focused on how the instruments and the particular context in which the study is conducted influence students' and teachers' affect and in what

ways we can reduce this influence. Comparative studies were addressed and the issues of language and culture were further elaborated.

Discussion and further considerations

In our discussion, the development and clarification of the concepts and instruments in the domain remained an important focus. How do the studies presented in the group contribute to the theoretical frameworks and the refinement of existing affective constructs? In this discussion, the input of a combination of qualitative and quantitative methods was stressed. In particular, the methodological approach proposed by Mosvold and Fauskanger seemed promising to give deeper insight into teachers' beliefs. Erens and Eichler's methodology traced teachers' central and peripheral beliefs related to the teaching of calculus. Pantziara et al. applied a methodology for exploring dimensions related to teachers' inquiry and traditional beliefs while in Sarac and Aslan-Tutak's study an alternative methodology was employed as a more efficient mean to investigating teacher's efficacy beliefs. In the discussion of beliefs and efficacy beliefs, the robustness of these constructs was also considered. Are teachers' beliefs and efficacy beliefs stable across different mathematical domains (e.g. geometry, calculus), different social contexts (e.g. national and school level), and different populations (e.g. pre-service teachers, new teachers, in-service teachers)?

In an attempt to produce unity in the language and constructs of the affective domain, the second focus in the group concerned the relation between new constructs (e.g. security and uncertainty orientation) and more traditional ones (beliefs, attitudes, emotions, identity). What is the relation between mathematicians' security (Charalambous & Rowland), their mathematical identity, and their beliefs? How are students' uncertainty orientation (Schukajlow & Krug), beliefs and motivation related? Is uncertainty orientation part of identity?

Another focus of the group was to identify and interpret different affective constructs in relation to individual and social levels. In his study, Gebremichael adopted a social perspective in order to investigate students' perceptions of the relevance of mathematics to their learning goals whilst Di Martino and Zan relied more on psychological frameworks and applied a more in-depth analysis in identifying students' origins of fear of mathematics. Other studies (e.g. Sánchez Aguilar et al.; Jagals & van Der Walt) attributed the origins of female students' attraction to mathematics-related careers and to students' confidence on both individual and social levels. In the same vein, a number of studies in the group highlighted the contribution of both individual and social characteristics to students' affective constructs like motivation (e.g. Edwards and Deacon; Carreira et al.; Schukajlow & Krug).

A focal point in the discussion was also the relation between different constructs in the affective domain and their connection to other areas in the realm of mathematics education. The complex nature of these relations was also discussed. In Liljedahl's study, teachers' goals may express what they believe and, conversely, beliefs

presuppose and incorporate goals. In the study by Di Martino and Zan, the deep bidirectional interplay between emotions and cognition is stressed. The relation between students' motivation and achievement in mathematical areas like problem solving and modelling was incorporated in other studies presented in the group (e.g. Carreira et al., and Schukajlow & Krug).

Ultimately, the concluding remarks of the group included the necessity to deepen our knowledge of structure and dynamics in the affective domain by investigating further the theoretical framework proposed by Hannula (2011). Comparative studies on affect were also initiated by group participants. In addition, the comparison of studies investigating constructs related to different theoretical perspectives in a domain, for example motivation, was also suggested. Lastly strong longitudinal studies on affect were also welcomed.

THE EFFECT OF THE ORIGAMI COURSE ON PRESERVICE TEACHERS' BELIEFS AND PERCEIVED SELF-EFFICACY BELIEFS TOWARDS USING ORIGAMI IN MATHEMATICS EDUCATION

Okan ARSLAN and Mine IŞIKSAL

Middle East Technical University, Turkey

Origami began to capture more attention in mathematics education literature because of its mathematically beneficial uses. This characteristic of origami affected the teacher education programs and some universities began to offer elective origami courses for preservice elementary mathematics teachers. In the current study, the effects of the elective origami course on preservice teachers' beliefs and perceived self-efficacy beliefs in using origami in mathematics education are investigated. Paired sample t-test results revealed that, there is not a significant change in the beliefs of preservice teachers but there is a statistically significant increase in preservice teachers' perceived self-efficacy beliefs with large effect size.

Key words: *origami in mathematics, beliefs, perceived self-efficacy beliefs*

Origami, which enables to fold various models from paper, is known as the Japanese art of paper folding (Franco, 1999). Although origami originated as a hobby more than 1200 years ago (Tuğrul & Kavici, 2002), in recent years, it has become a commonly used instruction tool for mathematics lessons (Boakes, 2009).

Origami could be used to promote the geometry knowledge of students since in the folding process, geometric principles are used and moreover, it is possible to fold two and three dimensional geometric models from paper (Cipoletti & Wilson, 2004; Georgeson, 2011). Although the most known application of origami in mathematics education is geometry teaching, origami could be used for the fields of algebra (Georgeson, 2011; Higginson & Colgan, 2001); calculus (Wares, 2011) and the list could be extended. In addition to the possible usage fields of origami in mathematics education, origami also helps to gain some skills for mathematics education. For instance, paper folding exercises would lead to an improvement on students' spatial visualization skills which are accepted as an important skill in mathematics education (Boakes, 2009). Furthermore, it helps to gain mathematical problem solving ability and using mathematical terms in the folding process would improve the mathematical language of students (Cipoletti & Wilson, 2004; Robichaux & Rodrigue, 2003).

Possible benefits of origami for mathematics education have affected some countries' mathematics education programs and Turkey is one of these countries. The Ministry of National Education (MoNE, 2009) defines origami as an instruction method which has various mathematical benefits such as improving mathematical problem solving skills, geometry knowledge and spatial visualization skills. In accordance with this view, origami activities to be used in mathematics education are given a place in the national mathematics education programs. However, treatment effects of origami were investigated in the national context with little research. In one of these studies, Kavici (2005) investigated the effect of origami exercises on preschool children's mathematical abilities and visual perception and it was found that children who had origami exercises for 11 weeks had significantly higher scores on mathematical ability and visual perception tests when compared with the children in the control group. In another study, Çakmak (2009) investigated the effect of origami on 4th, 5th and 6th grade students' spatial ability. According to the results, she concluded that origami exercises significantly improved students' spatial visualization skills. Similar to the findings of Kavici (2005) and Çakmak (2009), in the study of Akan-Sağsöz (2008) it was found that 6th grade students who had origami based mathematics instruction performed significantly higher on the test about fractions than the control group students who had not such instruction. Although research studies related with origami are limited in number, these studies found results in favor of using origami in mathematics education.

Consistent with the place of origami in the national curriculum of Turkey and the results obtained in the origami related research, some universities began to offer elective origami courses for preservice elementary mathematics teachers. In these courses, preservice teachers learn how to use origami effectively in mathematics lessons and experience how to overcome difficulties which may occur during paper folding activity. Although origami takes part in mathematics education programs and teacher education programs, it has not been studied much in terms of affective issues in the accessible literature. However, studies regarding the affective issues have an important place in mathematics education (Hannula, 2011). Among a wide range of affective issues, beliefs are attributed as an important component of mathematics education (Philipp, 2007). In spite of the consensus on the importance of studying beliefs, there is not a single belief definition in the literature (Pajares, 1992; Philipp, 2007). In the current study, the belief definition of Richardson (1996) was used as basis: "Psychologically held understandings, premises, or propositions about the world that are thought to be true" (p.103). Therefore, in its simple definition, beliefs towards using origami in mathematics education refer to individual considerations regarding the use of origami in mathematics education that are thought to be true. Although it is difficult to claim that there is a linear, unidirectional relationship between beliefs and behavior, it is generally accepted that beliefs shape

predispositions towards behavior (Philipp, 2007). Therefore, investigating preservice teachers' beliefs could give a valuable view on their teaching decisions and thus, have a great importance (Pajares, 1992; Timmerman, 2004). In accordance with these views, it is believed that investigating beliefs of preservice teachers towards using origami in mathematics education and the effect of elective origami courses on their beliefs would lead to gain some insights regarding their future origami related teaching decisions.

In addition to beliefs, research on specific types of beliefs such as self-efficacy beliefs, provides important educational benefits (Pajares, 1992). Perceived self-efficacy beliefs refer to individual judgments regarding the capability of a specific behavior (Bandura, 1997). According to Bandura (1997), there are four basic sources of perceived self-efficacy beliefs: mastery experiences, vicarious experiences, verbal persuasion, physiological and affective states. Mastery experiences are personal interpretations on one's own experiences whereas vicarious experiences are interpretations on others' observed behaviors (Joet, Usher & Bressoux, 2011). Furthermore, perceived self-efficacy beliefs are affected from verbal persuasion which refers to verbal feedbacks that one gets from the people in their close environment and also affected from physiological and affective states which refer to one's physical and emotional situation at that moment (Bandura, 1997). In these four sources, mastery experiences are interpreted as the most influential source. In the literature, perceived self-efficacy beliefs' influence on future behavior and perseverance on doing that behavior are widely mentioned (e.g., Bandura, 1997; Brand & Wilkins, 2007; Joet et al., 2011). Therefore, investigating preservice teachers' perceived self-efficacy beliefs towards using origami in mathematics education could give some clues on their origami related possible teaching decisions. Furthermore, examining the change on perceived self-efficacy beliefs after participating in an origami course would enable the interpretation of the effect of these courses.

In brief, origami is seen as an effective way of teaching mathematics and when the issue is mathematics education, affective factors are interpreted as important components of mathematics education. Therefore, the current study aims to investigate the effect of the elective origami course on preservice teachers' beliefs and perceived self-efficacy beliefs towards using origami in mathematics education. For that purpose, the following research questions are investigated with the current study:

- Is there a statistically significant effect of the elective origami course on preservice teachers' beliefs in terms of the benefits and limitations of using origami in mathematics education?
- Is there a statistically significant effect of the elective origami course on preservice teachers' perceived self-efficacy beliefs regarding the use of origami in mathematics education?

METHOD

Research Design and Sample of the Study

The current study aims to examine the effect of elective origami course on preservice elementary mathematics teachers' beliefs and perceived self-efficacy beliefs towards using origami in mathematics education. In accordance with this purpose, one group pre-posttest experimental research was selected as the research design for this study.

In Turkey, there are five universities which offer elective origami courses for preservice elementary mathematics teachers and participants of this study were selected from one of these universities. In that course, preservice teachers are firstly trained to fold origami models and learn origami diagrams. Subsequently, they learn how to choose appropriate origami model and relate folding steps to mathematical concepts. Furthermore, they learn how to change the language of origami into the language of mathematics. Subsequently, teacher candidates prepare origami activities to teach different mathematical concepts and carry out these activities in that course in order to gain experience in origami based mathematics activities. There were 36 possible teacher candidates who participated in that origami course but data for the current study was collected from 33 preservice teachers since some were absent during the data collection process. Most of the participants were in the third grade of their university education and there were just three participants from 1st, 2nd and 4th grades. Furthermore, in accordance with the general profile of education faculties in Turkey, most of the participants were female and there were just 5 male preservice teachers in that course.

Data Collection Instruments and Process

In the data collection process, Origami in Mathematics Education Belief Scale (OMEBS) and Origami in Mathematics Education Self Efficacy Scale (OMESS) which were developed by Arslan (2012) were used as the data collection instruments. OMEBS is composed of two dimensions called benefits of origami in mathematics education with 19 items and limitations of using origami in mathematics education with 7 items. All the items in OMEBS are in 6 point Likert format ranging from strongly disagree to strongly agree. Sample items from OMEBS are given in Table 1.

Table 1: Sample Items from OMEBS

Item	Dimension
Origami is beneficial to make some abstract mathematical concepts more concrete	Benefits of origami in mathematics education
Origami makes easy to teach geometrical concepts	Benefits of origami in mathematics education

Table 1: Sample Items from OMEBS (continued)

Origami cannot be used for mathematics lessons in crowded classes	Limitations of using origami in mathematics education
Using mathematical terms during origami activity helps to improve mathematical language of students	Benefits of origami in mathematics education
It takes long time to use origami activities in mathematics lessons	Limitations of using origami in mathematics education

OMESS is composed of one dimension named as perceived self-efficacy in using origami in mathematics education. There are eight items in 9 point Likert format ranging from insufficient to very sufficient and sample items from OMESS are given in Table 2.

Table 2: Sample Items from OMESS

How well do you feel...
to plan a mathematics lesson in which origami activities will be used?
to use mathematical language during origami activities?
to find solutions to the problems of students while relating origami activity to mathematics topics?

For both of the scales, detailed literature review and expert opinions during the item development process; moreover, high factor loadings in the exploratory factor analysis and good fit indices such as RMSEA, GFI, CFI in the confirmatory factor analysis were presented as the evidences for the validity of the scales (Arslan, 2012). In addition to the validity evidences, Cronbach alpha values were investigated in order to check the internal consistency of the data obtained in pretest and posttest. As can be seen in Table 3, for both of the scales, Cronbach alpha values were calculated above .80 in pretest and posttest. These values could be interpreted as good internal consistency reliability for the data collection instruments with this sample (Pallant, 2007).

Table 3: Reliability Analysis for Data Collection Instruments

	OMEBS		OMESS	
	Pretest	Posttest	Pretest	Posttest
Cronbach Alpha	0.862	0.945	0.958	0.937

OMEBS and OMESS were administered simultaneously to 33 preservice teachers as a pretest before the beginning of the elective origami course in the spring term of 2011-2012 academic year. After 14 weeks, scales were administered again as a posttest. Data obtained from these scales were analyzed

with paired sample t-test in order to investigate whether there is a significant change in beliefs and perceived self-efficacy beliefs of teacher candidates.

RESULTS

Before conducting paired sample t-test, preliminary analyses were performed and one extreme point was removed from the data file. Furthermore, these analyses indicated that, there is no violation of the assumptions of paired sample t-test for the current data set. Therefore, it was decided that, the data file for the current study is appropriate to perform paired sample t-test.

Beliefs of Preservice Teachers in Using Origami in Mathematics Education

Preservice teachers' beliefs regarding the use of origami in mathematics education were investigated with the administration of OMEBS. As indicated in the methodology part, OMEBS has two dimensions which are benefits of origami in mathematics education and limitations of using origami in mathematics education. Paired sample t-test was performed for both dimensions of OMEBS. According to the results given in Table 4, there was an increase in teacher candidates' beliefs regarding the benefits of using origami in mathematics education from pretest ($M=4.80$, $SD=0.50$) to posttest ($M=5.02$, $SD=0.81$). However, this difference was not statistically significant, $t(31)=1.601$, $p=0.119$.

Table 4: Paired Sample T-test Results for the First Dimension of OMEBS

	Paired Differences			t	df	Sig. (2 tailed)
	Mean	Std. Deviation	Std. Error Mean			
postbenefit-prebenefit	,221	,780	,138	1,601	31	,119

Contradictory to the beliefs regarding the benefits of origami, preservice teachers beliefs' regarding the limitations of using origami in mathematics education decreased from pretest ($M=3.48$, $SD=0.85$) to posttest ($M=3.34$, $SD=0.81$). However, paired sample t-test results, which are given in Table 5, indicated that this difference was not statistically significant, $t(31)=-0.727$, $p=0.473$.

Table 5: Paired Sample T-test Results for the Second Dimension of OMEBS

	Paired Differences			t	df	Sig. (2 tailed)
	Mean	Std. Deviation	Std. Error Mean			
postlimitation-prelimitation	-,138	1,076	,190	-,727	31	,473

To sum up, according to the paired sample t-test results, it is possible to conclude that there is not a statistically significant effect of the elective origami course on preservice teachers' beliefs regarding the benefits and limitations of using origami in mathematics education.

The Impact of the Origami Course on Perceived Self-Efficacy Beliefs towards Using Origami in Mathematics Education

Data obtained from the administration of OMESS in pretest and posttest was analyzed with paired sample t-test. Analysis results, which are given in Table 6, revealed that, there is a statistically significant increase in preservice teachers' perceived self-efficacy beliefs in using origami in mathematics education from pretest ($M=3.02$, $SD=1.76$) to posttest ($M=6.59$, $SD=1.56$), $t(31)=8.682$, $p=0.000$. Therefore, it is possible to conclude that preservice teachers' perceived self-efficacy beliefs regarding the use of origami in mathematics education significantly increased after participating in the elective origami course. Furthermore, the eta squared statistic was calculated as 0.71 and it could be interpreted as a large effect size (Green & Salkind, 1997).

Table 6: Paired Sample T-test Results for the Data Obtained from OMESS

	Paired Differences			t	df	Sig. (2 tailed)
	Mean	Std. Deviation	Std. Error Mean			
postefficacy-preefficacy	3,572	2,327	,411	8,682	31	,000

DISCUSSION AND CONCLUSION

In the current study, it was seen that, preservice teachers held similar beliefs towards using origami in mathematics education before and after the course. They strongly believe that origami has various mathematical benefits such as making abstract mathematical concepts more concrete, improving mathematical language, spatial ability and proof ability. In addition to the mathematical benefits, they strongly believe that origami has instructional benefits to make mathematics lessons more effective. Preservice teachers' beliefs of this kind are also consistent with the studies in the literature (e.g., Boakes, 2009; Cipoletti & Wilson, 2004; Higginson & Colgan, 2001). Apart from the mathematical and instructional benefits of origami, preservice teachers do not believe that origami has various limitations to be used in mathematics lessons. They do not believe that, it is difficult to use origami activities in crowded classes and to plan origami based mathematics lessons.

Preservice teachers' beliefs regarding the benefits and limitations of using origami in mathematics education remained relatively stable after the elective

origami course and no statistically significant effect of the course on participants' origami related beliefs was found. The reason might derive from the fact that, preservice teachers held already positive beliefs towards using origami in mathematics education before the course and kept their beliefs after the course. Another reason for this result might be derived from the nature of 'belief' since beliefs are generally resistant to change (Philipp, 2007). Therefore, one term course might not have a significant effect on their origami related beliefs.

When the issue is the effect of the origami course on preservice teachers' origami related beliefs, it should be noted that they did not have a chance to use origami in real teaching environments during the course. In the literature, it is generally accepted that beliefs are influenced from past experiences (Kagan, 1992), but at the same time, beliefs are also shaped by current experiences (Philipp, 2007). Therefore, apart from elective origami course, if teacher candidates had a chance to use origami activities for mathematics lessons in elementary schools, their beliefs regarding the use of origami in mathematics education might be changed. Based on origami related teaching experience, they might have different beliefs regarding the benefits or limitations of using origami in mathematics lessons. Therefore, in addition to the elective course, enabling preservice teachers to use origami in real teaching environments might be beneficial to interpret their beliefs regarding using origami in mathematics education.

Contradictory to the beliefs of preservice teachers, there was a statistically significant increase in their perceived self-efficacy belief levels in using origami in mathematics education. Furthermore, eta squared indicated that there was a large effect size which is interpreted as so important in social sciences (Pallant, 2007).

In the literature it is mentioned that origami based mathematics lessons would be very beneficial if teacher relates origami folding steps to mathematical concepts effectively (Georgeson, 2011). Therefore, teachers should be knowledgeable on how to plan and organize origami activities for mathematics lessons (Cipoletti & Wilson, 2004). Before participating in the origami course, preservice teachers felt slightly efficient to use origami in mathematics education. However, after the course, they saw themselves quite efficient to plan and carry out origami activities for mathematics lessons. Therefore, it is possible to conclude that preservice teachers were not familiar with the own nature of origami based lessons before the course and felt slightly competent to use origami in mathematics education. However, posttest results revealed that origami course was rich enough to enhance preservice teachers' knowledge and efficacy regarding the use of origami in mathematics education. Although elective course improved their efficacy level, more mastery experiences are suggested by

Bandura (1997) in order to improve perceived self-efficacy belief levels. Therefore, as stated above, enabling preservice teacher to use origami activities for mathematics lessons in elementary schools during the elective origami course might improve their efficacy level and similarly, using origami in other courses such as teaching practice, method courses might lead to an improvement on efficacy beliefs.

To sum up, current study aimed to contribute to the literature by examining the effects of elective origami course on preservice teachers' beliefs and perceived self-efficacy beliefs towards using origami in mathematics education. However, when the issue is affective factors, longitudinal studies might be beneficial to gain further insight (Hannula, 2011). Furthermore, studies with more participants and research studies comparing different countries would be beneficial to fill the gap in the related literature.

YOUNG STUDENTS SOLVING CHALLENGING MATHEMATICAL PROBLEMS IN AN INCLUSIVE COMPETITION: ENJOYMENT VIS-À-VIS HELP-SEEKING¹

Susana Carreira*, Rosa A. Tomás Ferreira**, & Nélia Amado*

*Univ. of Algarve & Research Unit of the Institute of Education of the Univ. of Lisbon, ** Univ. of Porto & CMUP - Portugal

In this paper, we intend to describe the help seeking and enjoyment patterns reported by the participants in an inclusive mathematics competition. Results suggest that they seek help from a variety of sources, mainly family and teachers, and that they enjoy much the problems in the competition; in addition, help seeking and enjoyment seem to be problem-dependent. Some questions for future research are raised.

Key words: mathematics competitions, problem solving, help seeking, enjoyment.

CONTEXT AND RESEARCH QUESTIONS

Inclusive mathematical competitions as motivational environments

Around the world, the number of regional, national and international mathematical competitions has visibly increased, taking many different forms, contents and durations, and targeting considerably wide groups of students in terms of age and mathematical ability levels. Some competitions target highly talented students, as the International Mathematics Olympiad. Others, like the Mathematical Kangaroo contest, have an inclusive nature, welcoming students with various degrees of aptitude for mathematical problem solving and endorsing feelings of fun, joy, pride and mathematics loving.

Experience indicates that the challenging and competitive nature of enrichment projects is associated with students' positive affect towards mathematics and the development of problem solving skills. In fact, empirical research has proved that students' participation in mathematics competitions has an influence on their motivation for learning mathematics, especially at younger ages. Furthermore, both very good students and those who show some difficulties in school mathematics benefit from participating in such activities beyond the classroom (Freiman & Vézina, 2006).

Based on the review of several studies, Freiman and Applebaum (2011) claim that the advantages of mathematical competitions are strongly connected to affective and emotional factors such as: student satisfaction, self-efficacy, and cooperative skills as well as infused love and interest for mathematics. The context of mathematical competitions is therefore reaching much further than the identification of mathematically gifted students. Inclusive competitions are becoming important sites where mathematics is presented as challenging, exciting, accessible to average students, socially and emotionally engaging, and close to the daily aspects of students' lives.

Online competitions: the setting and the questions addressed

SUB12 is a regional online mathematical problem solving competition supported by the University of Algarve. It has been running annually since 2005, and it is intended for 5th and 6th graders (ages 10-12). It is a web-based competition with two distinct phases: the *Qualifying* and the *Final*. The *Qualifying* phase develops entirely at distance through the website and consists of a set of ten problems, each posted every two weeks. Participants are asked to solve each problem, at home, at school, etc., and to submit their answers by e-mail or using the online form available at the webpage. They can use several resources, approach the problems in different ways, and resort to different representations. Participants have total freedom in presenting their solutions (handwritten and scanned, using the computer to create images or diagrams...). The explanation of the solution process is a fundamental requirement for a complete answer. Regardless of the level of mathematical sophistication, all the correct and complete answers are equally valued.

Feedback is always provided to the participants by a team of senior mathematics teachers. Feedback is formative and encouraging, offering suggestions when needed to help overcoming obstacles, or recognizing successful answers. Students are allowed to submit revised solutions as many times as needed within the respective deadline. Help seeking is approved and even encouraged during the *Qualifying* phase given the inclusive nature of the competition.

Usually 10% to 15% of the total initial participants reach the *Final* phase as they have to submit correct and complete answers to, at least, eight of the ten qualifying problems. The *Final* is held at the university campus. Family members and also teachers accompany the participants but the latter compete individually and on-site.

Acknowledging the role of affective variables within inclusive mathematical competitions, we intend to get a picture of the SUB12 participants' enjoyment and help-seeking behaviour in relation to the problems proposed. In particular, we consider the following questions: (1) What is the significance of the help provided by the several partners that participants in SUB12 can resort to during the competition? (What is the quantitative dimension of this support? What is the most salient source of help and to what extent is the presence of external aid constant or variable over time?); (2) How do participants in SUB12 express themselves in relation to their higher or lower enjoyment with the various problems posed? Is it possible to detect situations of greater preference or dislike towards the problems released? and (3) What trends can be identified combining these dimensions?

THEORETICAL PERSPECTIVES

Challenging mathematical problems

In any learning context, performance must be understood in light of a strong bond between affect and cognition and recent theorizations are not reducible to the identification of causal links between affect and cognition. Understanding affect is

now moving beyond the usual way of seeing it as the other side of cognition; instead, affect is viewed as a part of thinking: “Affect influences thinking, just as thinking influences affect. The two interact” (Walshaw & Brown, 2012, p. 186). In fact,

Affect is as central to understanding the character of educational experiences as are motivation and cognition. Furthermore, affective, motivational and cognitive processes, while they can be separated conceptually and empirically, are interdependent in the ongoing experience of students. (Ainley, 2006, p. 391)

The very notion of challenge reflects how affect must be integrated with the cognitive aspects involved in it. By definition, a challenge presupposes an element of difficulty, raises the need to overcome an obstacle. Barbeau (2009) has thoroughly elaborated on the idea of challenges in mathematics education. His view stresses that mathematical challenges deliberately incite its recipient to attempt a resolution. A good challenge is one for which the individual has the necessary mathematical apparatus but is required to deal with it in innovative ways, thus implying the feeling of being intellectually alive and able to share some of the thrill of devising new approaches as mathematicians usually do. Such mathematical challenges are usually seen by the students as different from the regular problem solving activities in school and, even when perceived as difficult to grapple, the challenges boost feelings of enjoyment (Jones & Simons, 1999, 2000).

The various problems proposed in SUB12 briefly and succinctly describe a context-framed situation, casting a well-defined question, but they are expected to be seen by participants as challenges, which amounts to believing that students feel inwardly compelled to solving them. Therefore we propose a delicate difference between the idea of mathematical problem and the concept of challenging mathematical problem. A *mathematical problem*, usually conceived as a situation from which the initial and the final states are known but the process to move from the first to the last is not immediately available through mathematical techniques and reasoning, has its grounds on the cognitive components of the problem solving activity. In turn, a *challenging mathematical problem* includes a strong affective appeal by involving curiosity, imagination, inventiveness and creativity, therefore resulting in an interesting and enjoyable problem not necessarily easy to deal with or to solve (Freiman, Kadjevich, Kuntz, Pozdnyakov & Stedøy, 2009).

The idea of moderate challenge

Research has stressed the need for balance in the degree of challenging questions (or problems) posed to students and the idea of *moderate challenge* has come to the fore (Turner & Meyer, 2004). The propensity to perform a task seems to decrease in two situations: when one’s expectations about the probability of success are very high (too easy task) or very low (too difficult task). The preference for challenges rests on the situations in which the expected success is around 77%.

The environments in which help seeking is regarded as natural are consistent with those that value moderate challenges. Such challenges seem to be ideal for

persuading students to try and encouraging them to explain alternative strategies, evaluate approaches and appreciate multiple possible solutions. Thus, the use of moderate challenges has much to gain when associated with features that are typical of contexts which value challenge. One of such features is viewing help seeking as legitimate and another is pressing for explanations and accountability for thinking. These two aspects are clearly present in SUB12 – not only is help seeking explicitly encouraged as reporting the solution process is required – and they are precisely the two essential categories that may describe challenge supporting practices, according to Turner and Meyer (2004). Interestingly it is reported that students who are given moderate challenges tend to reveal lower avoidance of help seeking.

On the occurrence of students' help seeking and help avoidance

When a participant seeks help, can we assume that the problem was actually seen by the participant as a challenge? If not, why? We may suspect that the degree of difficulty of the problem was probably too high, leading to the need of seeking help. Moreover, the very act of asking for help can compromise the challenging character of the task in the eyes of the participants since the sense of achievement, namely if it is equated with performance demonstration, may not be as full – the credit for having answered well goes not just to the participant but is shared with others.

Help seeking has been researched from the perspective of a behavioural type of self-regulation and has received increasing attention for its role in the learning process. Zusho and Barnett (2011) highlight some of the developments on the conceptualization of help seeking and help avoidance, namely stressing the social connotations of help seeking in tune with the costs involved: being perceived as needy and admitting failure or incapacity to accomplish a task. There is evidence that self-regulated and confident learners are more likely to display adaptive profiles of help seeking, which means looking for instrumental help: where the reasons to find help are the wish to learn and to understand the material, as opposed to a shortcut to get a task completed. In addition, empirical evidence suggests that help avoidance is a consequence of performance expectancy as help seeking is seen as a threat to self-worth and self-efficacy. In fact, low achievers tend to perceive greater threat in help seeking and therefore report higher levels of help avoidance; reversely, students with higher perceptions of cognitive competence show lower levels of help avoidance.

Furthermore, help seeking is adjustable to contextual factors, and patterns of help seeking are consonant with a caring, supportive and exploratory learning environment. This is also related to students' perception of moderate challenge where conditions of support and accountability for understanding are nourished and where a preference for challenging activities goes together with engagement and enjoyment. In such environments, students' preference for solving problems on their own may rise and help seeking becomes closer to seeking clues rather than answers (Zusho & Barnett, 2011).

On the relationship between challenges and affect

The meaning of moderate difficulty is not universal because different people perceive the same task differently. Even the same person can experience different levels of challenge in a certain task depending on having freely decided to engage with it or on having been required to perform it (Schweinle, Meyer & Turner, 2006). Although acknowledging the relativity of moderate challenge, there are indicators supporting the claim that targeting moderate challenge is a favorable condition to develop positive affect. But other conditions should surround moderate challenge: a social environment that supports enjoyment, self-confidence and value in mathematics – a number of characteristics that SUB12 fulfills, all of which are grounded on the kind of feedback provided, which is a key element, amongst others, that contribute to the inclusive nature of the competition. Inclusiveness is part of the global aim of fostering enjoyment (by easing frustration, giving positive reinforcement, encouraging persistence, valuing cooperation more than competition – as reflected in the opportunity for children to participate in small groups).

Optimal levels of challenge, coupled with affective and motivational support, can provide contexts most supportive of students' feelings of enjoyment, efficacy, and value in mathematics (Schweinle, Meyer & Turner, 2006, p. 289)

There seems to be a highly interactive relationship between positive affect, challenge, and value attributed to mathematics (and more precisely to mathematical tasks). In particular, we can refer to two kinds of threats to students' perceived ability, both possibly combined: the difficulty of the task and the need to seek for help. The two threats, especially when combined, can generate negative affect, which is observed in our study in terms of participants' level of enjoyment regarding different problems proposed in the course of SUB12.

METHODOLOGY

In this paper, we address two dimensions of 5th graders' participation in SUB12 concerning affect and emotion: help seeking and enjoyment in solving the challenging mathematical problems presented throughout the *Qualifying* phase. Data were collected through the participants' answers to a mini-questionnaire consisting of two multiple-choice questions included in the online form available on the webpage to submit the answer to each of the problems posted. The two items were straightforward and the answers were given by choosing a single option: 1) I solved the problem with the help of: a) Teacher; b) Family; c) Friends; d) SUB12; e) Nobody; and 2) I enjoyed the problem: a) A lot; b) So-so; c) Little.

Answering the questionnaire was mandatory when participants chose to use the online form to send their problem solution. However, the right not to respond was assured – alternatively to using the online form, participants could choose to send their answers directly to the SUB12's address using their personal e-mail. All participants in the competition are required to have an e-mail account.

The number of respondents to the questionnaire is slightly below half the number of participants enrolled and basically corresponds to those who used the online form to submit their answers. It is important to notice that as the competition unfolds the number of participants decreases (by attrition) and so does the number of respondents to the questionnaire (there were 469 replies at the beginning and 151 at the end, as shown in Tables 1 and 2).

Our analysis of the data is guided by the research questions and mainly intends to look for patterns that may help to understand the significance of help seeking and the level of enjoyment reported in each problem, and also possible associations between those. Since the mini-questionnaire was only launched on problem #2, the data consist of answers referring to problems #2 to #10. Our approach is mainly descriptive, based on the number of answers and percentages regarding each option per problem, by looking at such values across the series of problems.

DATA ANALYSIS

A first indication on how participants report on help seeking is quantitatively expressed for each of the nine problems in Table 1. Similarly, Table 2 displays the distribution of answers to the item on enjoyment per problem.

Table 2: Enjoyment in each problem

In what concerns the distribution of reported help seeking, the data show that it has a visible expression in all problems. Participants in SUB12 widely vary in their abilities to solve mathematical problems and this is an inherent feature of the inclusive nature of the competition. In general, a large percentage of these participants openly declared to have received help (help seeking was only slightly below 50% in problems #3 and #7). It is also important to recall that help seeking is actually encouraged and stimulated by the organization and explicitly stated at the webpage. Thus, fifth graders (the ones entering the competition for the first time) showed to be willing to seek for help in their problem solving activity during the *Qualifying* phase.

The two major sources of help, family members and teachers, reveal similar percentages, although there are pronounced differences in some of the problems (problems that are more related to daily life may become good opportunities for family members to help their children). It may well be that the same teacher is a source of help to a large number of participants – there are some teachers who reported in interviews that they gave support to their students throughout the competition, and so the help of teachers may cover a lot of participants. The third source of help is the participants' friends, although the amount of inputs from friends is clearly smaller. Finally, as students report it, the SUB12 (i.e. the organization of the competition to whom the participants contact by e-mail) is a residual source of help. However, all participants who sent an initial wrong or incomplete answer to each problem received feedback from the organization in order to reformulate their answer, and eventually this resulted in a correct solution. There is a discrepancy between the percentage of participants who claimed to have received help from SUB12 and the number of cases that actually succeeded after receiving feedback from the organization. A question then comes up: is it true that participants only recognize to have received help when they explicitly asked for it? The participants may not perceive the feedback constantly provided by SUB12 as actual help since such feedback is offered without being requested; it arises as a reaction (and is possibly seen as corrective stance rather than a means to help improving the work already done) to the answer sent by the participants.

The case of Luís (L) is illustrative of the referred situation (Figure 1). Luís sent a first answer to problem #5 which was not completely correct and stated that he had help from family and enjoyed more or less the problem. The SUB12 offered him feedback and some hints. He then reformulated his answer and resent it, claiming that nobody had helped him and maintaining the level of enjoyment. SUB12 answered again indicating a faulty answer and giving more feedback. Finally, Luís got the solution right and resent it, confirming having had no help and a more or less enjoyment.

There are few cases in which participants explicitly address the SUB12 asking for help to start solving a problem. In such rare cases, the fact is that participants declare that they had help from SUB12, recognizing to have sought such help.

To:	L

It is almost correct. You know that each side of the closed table is 60 cm long. You know that each leaf is 30 cm wide. Thus the open table is $60 + 30 + 30$, which is 120 cm, long. But notice that the cloth falls 10 cm on each side, when the table is open. So you have to calculate the length of the cloth, increasing these 10 cm on each side. And the width of the cloth, what is it?

We wait for your correct answer.

Figure 1: Sequence of e-mails between Luís and SUB12

In what concerns enjoyment, the overall manifested feeling shows a general positive emotion of participants in facing challenging mathematical problems. However it can be noticed that in problems #5 and #9 the number of answers stating “much enjoyment” is lower. At the same time, for these problems there is an increase in the number of answers indicating “so-so” and “little” enjoyment. These two challenges are, in a sense, the deviants within the category of the enjoyment felt and are also those in which participants report having sought more help (more than 70%).

Given the volume of help sought in problems #5 and #9, we can infer that these problems raised more difficulties than others to the participants. This complexity seems to be associated with less enjoyment in solving these problems. This greater difficulty for participants also seems to indicate that the challenge was higher and therefore such over-challenging problems led to less positive emotions, namely,

lowering the feeling of enjoyment. The greater search for help in these two problems may also have contributed to a lower enjoyment. There may have been participants asking for help on these two problems who did not feel this need in others, which may have contributed to a sense of weakness and thus to lower enjoyment. The data may also suggest that enjoyment may be problem-dependent, which resonates with the way students perceive the value and interest of different tasks. On the other hand these problems relate to mathematical topics in which students typically have difficulties (geometry and fractions), which may also contribute to explain their help seeking behaviour. So, help seeking also appears to be problem-dependent.

DISCUSSION AND CONCLUSIONS

As research suggests help seeking is an important matter in any learning context, being even more relevant within an inclusive mathematical competition. Our data reveal that participants significantly seek for help. Help provided by different sources positively contributes to the success in the competition and students' sense of accomplishment; in addition it positively influences the quantity and diversity of students enrolled. Participants seek help mainly from two sources: teachers and family. This is a sign of a great family involvement alongside with a presence of the competition in the school environment. Further research should follow to better understand how students perceive help seeking according to the different available sources, in particular SUB12. This source of help is especially intriguing since it seems to be recognized as such only when participants specifically ask for it.

In general, participants do enjoy the challenging problems proposed in the competition, and we believe that most of the problems can be considered of moderate challenge. This seems to resonate with prior studies which indicate that the challenging and competitive nature of enrichment projects such as SUB12 is associated with a positive affect towards mathematics and the developing problem solving skills (Kenderov, Rejali, Bussi et al., 2009). The problems where the level of enjoyment lowers are precisely those for which participants sought most help. Furthermore enjoyment decrease and help seeking increase are located in two specific problems: enjoyment and help seeking are problem-dependent. We argue that the degree of challenge of such problems is higher in that they involve mathematical ideas that are typically difficult in school curriculum. Another question can be raised: is the decrease of enjoyment related to a higher degree of difficulty or is it associated with the need to ask for help?

NOTES

1. This work is supported by national funds through Fundação para a Ciência e Tecnologia, under the projects PTDC/CPE-CED/101635/2008 and PEst-C/MAT/UI0144/2011, and by FEDER funds through COMPETE.

MATHEMATICS SECURITY AND THE INDIVIDUAL

Eleni Charalampous^a and Tim Rowland^{a,b}

^aUniversity of Cambridge, UK, and ^bUniversity of East Anglia, UK

This paper complements a report (Charalampous and Rowland, 2012) regarding the feeling of security which mathematicians can draw from mathematics. The focus of this report is the potential of mathematics to empower the individual, offering possibilities both for distinguishing and transcending one's individuality. The research involved 19 adult mathematicians working in universities and schools in Greece. Semi-structured interviews revealed that the participants distinguished mathematics from other sciences, and valued both the intellectual abilities which it cultivates and its social contributions.

Key words: security, fear, mathematics, individual

INTRODUCTION

It is generally acknowledged that affect plays an important role in mathematics education. The literature has focused largely on negative responses to mathematics and on constructs such as mathematics anxiety, fear of failure, and mathematics avoidance (Zan, Brown, Evans & Hannula, 2006). However, mathematics may also engender positive experiences. For example, Russell asserts that:

The true spirit of delight, the exaltation, the sense of being more than Man, which is the touchstone of the highest excellence, is to be found in mathematics as surely as poetry (Russell, 1919, p. 60).

The topic of positive experiences emerging from engagement with mathematics is under-investigated. This paper continues the discussion on the potential of mathematics to contribute to one's sense of security, as introduced by Charalampous and Rowland (2012). There we explored the concept of security, as it emerges from the relationship of mathematicians to mathematics. We conceptualised security as the absence of existential fears and investigated two pairs of opposing fears: *assimilation* versus *isolation*, and *change* versus *stagnation*. In the previous paper we presented the findings concerning the latter pair, whilst here we focus on the former.

In the next section we draw out conceptions of mathematics that could be appealing to certain individuals in terms of security, and elaborate on our conceptualisation of security for the purposes of this study. We then proceed with an account of our findings from interviews with a sample of mathematics professionals.

THEORETICAL FRAMEWORK

In this section, we frame our investigation in terms of the nature of mathematics itself, and of security as a psychological phenomenon.

The nature of mathematics

A wide range of perspectives about the nature of mathematics has evolved since early Greek civilisation up to the present time (Davis and Hersh, 1980, Friend, 2007). Plato introduced the idea that mathematical objects pre-exist, awaiting human discovery. Early modern philosophy (Descartes, Spinoza, Kant) lent support to this conviction privileging reason over the sense-experience (Hutchins, 1952). Faith in the power of reason culminated in the quest for secure foundations for mathematics, i.e. a system comprising a few axioms and deductive rules from which all mathematics could be deduced. This dream had to be abandoned when Gödel proved that any such system complex enough to include arithmetic is necessarily incomplete. The collapse of the formalist project led to the re-conceptualisation of mathematical practice as a human and unavoidably fallible enterprise (Hume, 1978; Lakatos, 1976). This view of mathematics as negotiable and consensual is emphasised in social constructivism as a philosophy of mathematics (Ernest, 1998). Admittedly, modern epistemologies-ontologies of mathematics seem to place the mathematician on shifting sand, but nevertheless give them agency in an unfolding mathematical story.

Security

Psychology has recognised the need of security in various ways (e.g. Maslow, 1970). In this research, the concept of security is framed in two steps: (i) by reference to dictionary definitions of security as ‘freedom from fear or anxiety’ (e.g. www.merriam-webster.com); (ii) a typology of fear due to Riemann (1970). Riemann proposed four types of fear which correspond to four types of personal need and are organised into two opposing pairs. The first pair concerns the individual, the second their environment over time. Humans must achieve a balance between their need (a) to exist both as individuals and as part of an entity that transcends their restricted individuality and (b) to lead a life marked both by stability and innovation. The associated fears are (a) fear of *assimilation* [our translation] versus fear of *isolation* and (b) fear of *change* versus fear of *stagnation*. The effort to achieve balance also suggests that people try to avoid the extremes of each pair, and is consistent with defining security as absence of fear. More specifically about the fears which are handled in the paper: fear of assimilation is connected with losing one’s individuality, the need to be distinguished from others and define one’s self against others; on the other hand, fear of isolation is connected to avoiding loneliness either physically by belonging to a group of people or metaphysically by participating in an ideal ‘essence’ elevated beyond the human level (e.g. the universe or God).

The following quote illustrates the relevance of security to mathematics education and the potential application of Riemann’s framework in order to interpret this feeling. Here Mendick (2005, p.175) comments on the pleasure that Phil, a young mathematics student, draws from his engagement with mathematics.

Phil finds a security in mathematics that enables him to construct himself as intellectually mature and as distant from his working-class, minority-ethnic self.

Phil's response can readily be construed as a response to fear of assimilation; through his engagement and success in mathematics, he positions himself as distinct and distinctive, in terms of his intellectual capacity and his distance from his origins.

METHODS

We explored the concept of security with an opportunity sample of 19 Greek adult mathematicians. We chose adults because, on the whole, they could be expected to be more articulate about their relationships with mathematics. However, their stories reveal that this relationship began when they were young. So we expect that the results would be pertinent to young persons, as indicated by the earlier reference to Mendick (2005).

Nine of the participants were in university positions and ten were teaching in secondary schools. Among the first group there were five applied mathematicians (Faidra, Paraskevi, Periklis, Themis, and Vasilis) and four theoretical mathematicians (Alvertos, Dimitris, Kleitos, and Sofoklis). Three of the teachers were teaching in lower secondary schools (Marios, Sokratis, and Stamatia), and the rest were teaching in a technical upper secondary school ((Nestoras, Avgoustis, Aris, Eleftheria, Fanis, Loukas, and Thodoris). All the participants had at least an undergraduate degree in mathematics, which is necessary for teaching mathematics beyond the primary level in Greece. Most of them had substantial professional experience (15 years or more); Themis, Vasilis, Sofoklis, Periklis, Faidra and Eleftheria had been in post between 2 and 8 years. The names used in the paper are pseudonyms.

One semi-structured interview was conducted by the first author with each participant. Four issues were considered: the participant's personal history regarding mathematics (e.g. Describe the history of your relationship to mathematics. Is there any memorable incident?); their views about mathematics (e.g. What do you think distinguishes mathematics from the other sciences?); the relevance of mathematics in everyday life (e.g. Would you say that mathematics has helped you deal with your everyday life?); and their feelings about mathematics (e.g. What do you enjoy (or not enjoy) in your involvement with mathematics?). Views about mathematics were included since the history of philosophy of mathematics provides ontological and epistemological links to security, e.g. the mathematical certainty of Platonism. While discussing the participant's relationship with mathematics in a general way, unconscious feelings surfaced, which might have been difficult to access directly (Rubin and Rubin, 1995).

The utterances were coded as relevant to one of Riemann's four types of fear (see above). Several cases of multi-coding arose. Multi-coding *across* pairs is indicative of contribution of the dimension of time (second pair) to one's sense of individuality (first pair); Multi-coding *within* pairs suggests the dialectical relationship between

their components, which is built as the individual strives to reconcile the two opposites. For example, secure sense of group membership can liberate a person to explore and express their individuality. As the data were revisited again and again, a constant comparison method lead to the emergence of broad themes and related sub-themes, associated with each type of fear. The themes and sub-themes associated to *fear of isolation* are listed in Table 1, by way of illustration. Note that themes 1-4 emphasise aspects of mathematics and mathematical activity that have the potential to offer protection against isolation, while themes 5-7 suggest *interconnections* with the other three types of fear and themes 8-10 acknowledge *limitations* in safeguarding against fear of isolation.

Themes	Sub-themes
Omnipresence	mode of thought; tool of all sciences; historical continuity
Social contribution	applications; social empowerment
Communication	conciseness and precision; impartiality and pluralism; real life
Teaching	initiation; communication with children; accessibility
Assimilation	initiation and success; talent and omnipresence; tool for/foundation of all sciences
Change	historical continuity and reliability; precision and one reality; omnipresence and connectedness
Stagnation	isolation and diversity; creation and social contribution
Limitations to isolation	teaching; communication
Limitations to change	omnipresence
Limitations to stagnation	historical continuity

Table 1: Fear of isolation: Themes and sub-themes

FINDINGS

As mentioned earlier, this paper reports on our findings relating to the pair *assimilation-isolation*. Our report is restricted to those themes which are directly related to these types of fear. The participant's views are organised under the corresponding themes starting with fear of *assimilation* (relevant codes: abilities, self-confirmation, mathematical self, superiority to other sciences) and continuing with fear of *isolation* (relevant codes: omnipresence, social contributions, communication, teaching).

Fear of assimilation

First, we report participants' views which indicate how mathematics gave them a sense of being different and distinct individuals. Mathematics enhanced the participants' feelings of uniqueness and self-awareness, and protected them against fear of *assimilation*.

Abilities

The participants perceived the mathematical mode of thought as superior to any other kind. For example:

The mind of the humanities stops; the mathematical mind is unsatisfied if the answer remains concealed, it goes on a discovering spree (Stamatia).

This mode implied the possession of above-average intellectual abilities which had been further cultivated by mathematics and were applicable to everyday life.

. . . the ability to think abstractly requires an above-average capacity (Themis)

. . . mathematics makes you think more; you think more quickly, more easily; you handle some problems in a more correct way (Vasilis)

. . . the way the [mathematician's] mind functions, is rarely restricted to mathematics (Sokratis).

These views suggest that mathematicians enjoy admirable and respectable abilities which can boost one's self-esteem.

I have observed that people who in my opinion have considerable potential, have a good relationship with mathematics (Themis).

Self-confirmation

Successful display of the aforementioned intellectual capabilities bestows a feeling of self-confirmation intensified by the perception that mathematics is difficult. For example:

. . . [solving a problem] is as if you put test yourself to the test and [the 'examiners'] say to you: 'You passed' (Avgoustis)

Sometimes you may think that you've found an original solution, and even though many others may have found it before you, you secretly feel proud; for a moment, you believe that you are the only one that has found [it] (Marios)

[Mathematics] wasn't like history. It presented a certain degree of difficulty; and probably, I felt more successful when I did well in mathematics, while I didn't think it was as important when I did well in history (Faidra).

Some participants asserted that mathematics had increased their self-confidence; mathematics was regarded as a shield against mistakes.

[Mathematics] has made me calm, confident in expressing my opinion without the need to necessarily persuade others (Aris)

You feel confident about the quality of your capabilities . . . I believe that [mathematics] makes you set more and more difficult goals . . . Mathematics protects you against falling prey to lies . . . it saves you from traps (Stamatia)

Mathematicians have confidence in their opinions; it stems from the fact that [in mathematics] you can check the actions you take, see if they are verified (Avgoustis).

Solving problems, either in mathematics or in everyday life, provides a limitless source of self-confirmatory opportunities. Repetitive positive experiences of that kind lead to confidence in one's ability to manage problematic situations.

Mathematical self

Some participants integrated mathematics with their identity. On the one hand, they traced their involvement with mathematics to personal traits and on the other hand, they recognised that this involvement had led to further cultivation of these traits. For example:

One reason, why I like mathematics, is its consistency and its rationality; if they suit to one's character, then one is attracted to mathematics (Nestoras)

Mathematical thought is characterised by strictness, precision, methodicalness and these affect your character as a whole and consequently your everyday life (Thodoris)

I like [mathematics] because it is in my nature to be rational and I like to do things systematically (Marios)

It is in my DNA (Eleftheria).

Most of them had entered the mathematical adventure in an early age.

I knew how to count before I went to school; I also knew about fractions. At preschool age, my father asked me how I could share two apples between three children. I couldn't think of a way, and I answered embarrassedly: "I don't know". Then my father asked me if I knew how to share one apple between three children and I answered: "yes, each child will take $1/3$ ". "Then why can't you share two?" asked my father and I realised what the answer was" (Alvertos).

Mathematics was a means to self-fulfilment and a valuable companion on the journey of self-awareness.

It is a work of art; you don't need anything more, you feel content (Dimitris)

Look at the person who manages to discover something after considerable effort. He exclaims 'Eureka' . . . he feels happy; he feels complete because he has used his intellect (Stamatia)

Mathematics empowers people; it is a great tool, which can help humans reflect on their actions . . . it also offers stimuli for introspection (Nestoras)

Mathematics teaches you how to think rationally, how to order assumptions and draw the best possible inferences. Therefore, up to an extent, it bestows power; [it bestows] the ability of self-evaluation and self-criticism (Fanis)

Doing mathematics is an intellectual activity which leads you to maturation (Nestoras).

These views imply that mathematical skills play a crucial role in the process of shaping a secure identity. Consequently, they are regarded as an indispensable part of this identity.

Superiority to other sciences

Finally, mathematics was believed to occupy a distinguished position in the constellation of sciences: it is independent, it is at the cutting edge of research and it is the foundation of all sciences.

Mathematics has an admirable trait; it is self-contained in the sense that it is not required to know another science in order to understand it (Themis)

Research in mathematics continues; [it] precedes [research in] other sciences and it causes admiration (Fanis)

. . . [mathematics] is the basis of all sciences; it is behind anything you can imagine. Even philologists say that syntax is the mathematics of language” (Marios).

These views indicate ways in which mathematicians experience and benefit from the importance and high status of mathematics. All in all, doing mathematics was connected to their sense of worth and being valued.

Fear of isolation

Here we report the participants’ views which indicate how mathematics enabled them to feel a part of a greater whole. Mathematics enabled the participants to bridge the gap between themselves as individuals and the external world, protecting them against fear of *isolation*.

Omnipresence

The participants believed that mathematics transcends the human being, both statically and dynamically, thus allowing mathematicians to be part of something greater. First, mathematics is all around us, either as the language which discloses the secrets of the universe, or as a mode of thought to tackle problems.

. . . but no matter if it is music, or a building, or the forces we realise around us, or anything, everything is linked to mathematics (Aris)

Mathematics functions without being seen . . . It is the language of nature; there is not a different world of mathematics (Fanis)

. . . the mathematical mode of thought is involved in all sectors of life (Thodoris).

Second, mathematics is an adventure of the human intellect throughout history.

. . . when you learn a theorem, it is as if you communicate with the person that proved it (Avgoustis)

When I teach . . . I try to follow the route that the human intellect has followed (Dimitris)

. . . if you approach [mathematics] enough you can see its associations with other sectors of life and you can understand that [it] is part of the civilisation (Nestoras).

Social contribution

The participants concluded that since mathematics is everywhere mathematicians are useful. They claimed that mathematical progress could be translated into social progress. Mathematical knowledge was perceived as power, not only at the individual but also at the social level.

. . . the various technological instruments which are produced, for example, an x-ray computed scanner. What lies behind its function? Differential equations do (Nestoras)

Even football involves mathematics . . . when I see the ball moving in a trajectory tangent to the ground I know that the opponent must fall in order to intercept it (Aris)

. . . through mathematics we try to interpret what is going on around us and express it in a language that we understand (Sokratis)

. . . if you know a field well, you can promote scientific knowledge [in this field], contribute something, and this can definitely be translated as power (Periklis).

Communication

I'm attracted to mathematics by its concise, symbolic language . . . All around the world, mathematical language has the same meaning for mathematicians (Fanis).

Some participants claimed that use of the precise mathematical language cultivated communicational skills.

Mathematics influences the way I think and the way I organize myself; it has made me able to express myself precisely, examine many perspectives simultaneously; in that sense it has influenced my life since communication is facilitated and misunderstandings are avoided (Themis)

I came to love mathematics when . . . I realised that mathematical training had helped me in comprehending social situations (Stamatia)

Two persons who understand mathematics communicate with one another much better (Avgoustis).

Mathematics was also regarded as an advocate of impartiality and pluralism.

Mathematics perceives its nature as international. Discrimination related to colour, height or hair is absent from mathematics; it plays no role in the process of problem solving. If one is taught by mathematics, then one learns to be free of prejudice (Sokratis)

Multiple dimensions . . . help you see through someone else's eyes . . . [someone else's opinion] can be considered as another dimension (Sokratis).

The participants expressed the opinion that mathematics can bring people together, facilitate communication and solve misunderstandings, creating a better world to live in.

[Modelling all sciences in mathematics] is desirable . . . afterwards we will be able to code life, to communicate better and avoid failures and mistakes. Most human problems are the result of ignorance. When I am ignorant I make mistakes and the more ignorant I am the more ready I am to deify something (Loukas).

Teaching

Teaching is not restricted to mathematics. It is connected to fear of isolation mainly through the opportunities it offers to communicate with young people and to initiate them into a community of experts. Mathematics was believed to offer the additional advantage of being accessible and tangible.

. . . [e]ven though many claim otherwise, mathematics is tangible; . . . if you demonstrate to a logical human being that mathematics is based on logic, then mathematics becomes tangible (Aris)

. . . there is an infinite field of questions even for the simplest rules, there are many applications and many levels of difficulty (Themis).

After all

. . . [d]ifficult things don't exist; we name difficult what we don't know, and the less we know it the more we try to make it look impressive (Paraskevi).

CONCLUSION

In this investigation we regarded feelings of security cultivated through engagement with mathematics. Security was conceptualised as relief from fear by means of a framework based on Riemann's (1970) suggestion of four types of fear organised in two opposing pairs. In this paper we reported on the pair *assimilation-isolation*. The findings provide evidence that mathematics can be used as a means to achieve balance between these opposing fears. As many times before in the history of the philosophy of mathematics, the participants endorsed the belief that mathematics has special attributes which set it apart from other sciences. Mathematics is at the same time the leader and the foundation of all sciences; it is the language through which we translate, comprehend and 'conquer' the world (Guillen, 1995). Moreover, the attributes of mathematics empower the individual, who develops a repertoire of intellectual capabilities such as deriving logical inferences, finding applicable solutions or communicating with precision and conciseness. Mathematics was the tool which allowed the participants to shape a strong and confident identity (offering relief from fear of assimilation) and to connect to the world (mitigating against fear of isolation).

These findings suggest possibilities for further research: both in the direction of other cultures, investigating similarities and differences, and in the direction of younger participants, including mathematics students, to capture the development of feelings of security through the development of one's relationship with mathematics.

WHERE DOES FEAR OF MATHS COME FROM?

BEYOND THE PURELY EMOTIONAL

Pietro Di Martino and Rosetta Zan

Dept. of Mathematics – University of Pisa – Italy

Abstract: *Fear of mathematics is a widespread emotion that has many negative consequences in students: it is a possible factor of local failure (since it prevents the best use of one's competence and knowledge) but also a possible factor of global failure (since it might lead to students giving up any engagement with mathematics). Investigating the cognitive origin of this emotion is fundamental to prevent it and to overcome its negative consequences. In this study we try to understand this origin giving voice to the students, analysing students' narratives about their relationship with mathematics.*

Keywords: *fear of mathematics, cognitive origin of emotions, affect*

INTRODUCTION AND THEORETICAL FRAMEWORK

In the last two decades, the specific field of research on affect in mathematics education has grown recognizing four specific constructs: beliefs, emotions, attitudes (McLeod, 1992) and values (De Bellis & Goldin, 1999).

Scholars have underlined the role of the emotional component in mathematics learning processes (Zan, Brown, Evans & Hannula, 2006) and in particular in problem solving processes (McLeod & Adams, 1989). The deep interplay between emotions and cognition is bidirectional: emotions affect cognitive processing in several ways, for example biasing attention and memory and activating action tendencies (Hannula, 2002); conversely the emotional experience is the result of a combination of cognitive analyses and physiological responses (Mandler, 1984). According to Mandler, it is not the experience itself that causes emotion, but rather the interpretation (influenced by individual's beliefs) that one gives to the experience. Understanding these interpretations is therefore central to answering the question of *where emotions come from*, and then to preventing and overcoming negative emotions towards mathematics (as hatred, anxiety and fear). These emotions may become very stable and have very negative influence on mathematical school performance, but more in general cause math-phobia also in adult age (Tobias, 1978; Buxton, 1981). Schlöglmann (2002) tells about stories of oppressive nightmares that are recalled even in adulthood.

In a longitudinal research study aimed to characterize students' attitude towards mathematics through the analysis of students' narratives (Di Martino & Zan, 2010) we suggested a model for attitude characterized by three dimensions: emotional disposition toward mathematics, vision of mathematics and perceived competence in mathematics. In this study we found recurrent patterns in the stories characterized by

failures: a particularly interesting case - because it may end up in a generalized rejection of mathematics - is the recurrent pattern with the emotional dimension involving *fear*.

Ortony Clore and Collins (1988), proposing a categorization of the basic emotions according to their cognitive source, classify fear as a valenced reaction to events, focusing on consequences for self, and “prospect-based”. With the latter term the scholars mean emotions that are characterized as reactions to the prospect of an event, or to the confirmation (or disconfirmation) of the prospect of an event. In particular, fear arises when the individual is displeased about the prospect of an undesirable event. The variables affecting the intensity of fear are the degree to which the event is undesirable and the likelihood of the event. Then the cognitive component (belief) intervenes in the perception of the event, in the evaluation of the consequences for self (hence in the eliciting of the emotion itself), and in the evaluation of the likelihood of the event (hence in the intensity).

In this contribution we try to understand *where fear of math comes from*, analyzing how students narrate this emotion in their autobiographical essays.

METHODOLOGY

Scholars have used many different approaches to studying affect and in particular emotions: in our theoretical researches about affective constructs and their influence in the process of teaching and learning mathematics, we needed an instrument consistent with an interpretative approach, capable of capturing students’ emotions, beliefs and attitudes towards mathematics, giving voice to the students through the possibility of talking about the aspects they considered relevant for their own experience with mathematics (Di Martino & Zan, 2010).

We recognized in the narrative approach the key to reach our methodological goals. The primary focus of a *narrative approach* is people's expressions of their experiences of life. These expressions emerge in particular from autobiographical narratives, where the narrator tends to paste fragments, introducing some causal links, not in a logical perspective but rather in a social, ethical and psychological one (Bruner, 1990). These links become a bridge between the writer’s beliefs and emotions, highlighting the psychologically central role they play for the narrator.

We claim that in order to grasp the cognitive source of emotion, this pasting process is more important than an objective report of one’s experience:

There is as yet no known objective measures that can conclusively establish that a person is experiencing some particular emotion (...) In practice, however, this does not normally constitute a problem because we are willing to treat people’s reports of their emotions as valid (...) we evaluate them as being appropriate or inappropriate, or justifiable or unjustifiable, not as being true or false. (Ortony, Clore, Collins 1988, p. 9)

Within a National Project in Italy, we asked schools across Italy to participate in a study about the students' attitude towards mathematics. In particular, we asked school directors to help us in collecting students' autobiographical essay "Me and mathematics: my relationship with maths up to now".

Essays were anonymous, assigned and collected in the class not by the class mathematics teacher. The study involved a large sample of students from different school levels: 874 from primary school (grade 1-5), 368 from middle school (grade 6-8), 420 from high school (grade 9- 13). The three different typologies of Italian high school (Technical Institute, Vocational School and Lyceum) were all represented.

In the field of affect the need for social and anthropological approaches, i.e. for studying affect in its natural contexts, is particularly stressed, motivating the use of non-traditional methods, such as narratives (see for example Kaasila, Hannula, Laine & Pehkonen, 2006).

As regards the analysis, we referred to Lieblich, Tuval-Mashiach and Zilber (1998), who identify two main independent dimensions in the process of reading and analysing a narrative: holistic versus categorical, and content versus form. The combination of these two dimensions produces four modes of reading a narrative: holistic – content; holistic – form; categorical – content ('content analysis'); categorical – form.

Our analysis of students' narratives about fear used two of these modes of analysis in two subsequent steps: categorical - content mode to select the stories characterized by *fear of math*; holistic – content mode to analyze in the selected essays the view of math associated with fear, and the *causal* links introduced by pupils (for example through utterances such as 'I am afraid *because...*').

RESULTS AND DISCUSSION

In the collected essays students often report (almost one student out of six) fear of mathematics, using several tokens that refer to fear (the most recurrent are anxiety, terror, nightmare, distress, worry, fright).

Our data shows that fear associated with mathematics is nearly always fear of *not being able*. We might therefore claim that the undesirable event that triggers the emotion is failure in mathematics:

"When Miss Sandra explains something new, I get goose bumps, because I'm afraid I won't be able to do the exercises" 4P.106¹ - grade 4

¹ In the excerpts, the first number refers to the class level, the letter refers to the school level (Primary / Middle / High), the last number indicates the progressive numbering of the essay within the category.

“Problems are the thing I like less because I’m afraid I won’t be able to solve them” 5P.135 - grade 5

If the undesirability of an event (in this case failure in mathematics) seems to be related to an individual’s goals, the probability that this event takes place is based upon two elements: the subject identification of the factors needed to be successful in mathematics, which we call *factors of success*, and the evaluation of one’s competence with reference to those factors. If failure in mathematics is viewed as a highly undesirable event, this subjective probability is, according to Ortony et al. (1988), what determines both the rising and the intensity of fear. In this framework, the individual’s beliefs about the stability/modifiability of factors of success in mathematics and about the indispensability of such factors (i.e. his/her theories of success, Nicholls, Cobb, Wood, Yackel & Patashnick 1990) come to be extremely relevant. As a matter of fact, a low perceived competence with respect to a certain factor of success considered unmodifiable and indispensable may induce a sort of *mathematical fatalism*. This status marks the renunciation to put all the available energies into the attempt to improve the situation (useless effort) and therefore may lead to the rejection of mathematical engagement. Moreover, in these cases, students feel virtually certain that the undesirable event (failure in math) will take place and they will then learn to associate fear to mathematics automatically and independent of the kind of activity they are given, the level of difficulty and any other consideration.

For example, amongst the factors of success that are most frequently associated with mathematics, in the essays we collected, there is intelligence:

“In my opinion, to be good at mathematics one needs to be intelligent.” 5P.120 - grade 5

In general, in the essays that describe unease in the relationship with mathematics and that talk about intelligence as a factor of success, a judgment on one’s intelligence is given that appears definitive and unmodifiable:

“I often think I am not that intelligent and I believe that when they tell me I am, and blame the fact I don’t study, they make me feel even more stupid, thick and useless” 5H.2 - grade 13

In other words students seem to have what Dweck and Bempechat (1983) call an ‘entity’ theory of intelligence, i.e. a vision of intelligence as a rather stable global feature in opposition to a vision of intelligence as a continuously expanding repertoire of abilities and knowledge (‘incremental’ theory).

Recognizing intelligence as a necessary condition to be successful in math has extremely negative consequences on those who fail, because it implicitly carries the message that failing is a proof of scarce intelligence:

“I must say that sometimes I was rather good at some kind of reasoning but then as soon as I got things wrong I convinced myself I was dull. I wouldn't like you to misunderstand the word I've written, I used to think I was obtuse, close-minded, unable to understand and reason. Maybe I had made up in my mind a little image of mathematics, a subject I hate.” 2H.118 - grade 10

The idea that failure in mathematics is a proof of scarce intelligence probably bears on the high undesirability of failure in mathematics with respect to failure in others school subjects, eliciting - as we can grasp by the above excerpt - a strong negative emotional charge towards mathematics. Not surprisingly, this negative emotional charge may lead students to hate mathematics and to choose to avoid engaging with it, rather than repeatedly failing, thus getting a confirmation of being '*scarcely intelligent*'.

From the analysis of the students' narratives another recurrent aspect emerges: in many cases students seem to simply identify mathematics success with school achievement. Therefore the recognition of success or failure is completely delegated to another person (the teacher) that becomes the object of fear, since he/she is an agent of an undesirable event for the student:

“Last year I did not get on well with the teacher because I was rather frightened by him” 2H.51 - grade 10

Sometimes it seems not clear for the narrator himself if fear is related to the teacher, to mathematics or to both:

“My relationship with mathematics is not great, but this does not mean that I don't study it, it's that when I hear the word, even when I see the teacher, I'm terribly scared, and I forget everything. Maybe, my only fear is the teacher and not mathematics, I never understood why” 3M.38 - grade 8

If the student identifies success with school achievement, his/her beliefs about the behaviour rewarded by the teacher come to be determinant in the recognition of factors for success or failure.

What emerges from the analysis of the essays is that success in mathematics is often identified with being quick at solving mathematical tasks (mainly at early school levels) as well as with not making mistakes. Therefore, there is a sort of identification failure – “slowness and mistakes”, which brings about two worrying phenomena.

On the one hand, being slow, sometimes with the additional perception of being slower than others, becomes a proof of inability, with heavy negative consequences on the emotional side:

“While I am tackling a problem and I don't manage to solve it, after some or many minutes I hear the voices of my classmates shouting they have finished. The queue

to get the problem corrected by the teacher becomes longer and longer and this makes me even more anxious” 5P.110 - grade 5

On the other hand, fear of mathematics becomes fear (or even terror) of making mistakes since the very beginning:

“During tests I’m so afraid to make mistakes that I put lucky charms on the desk” 3P.46 - grade 3

“I don’t like mathematics: it scares me a little bit and makes me anxious because I’m always terrified of making mistakes” 5P.77 - grade 5

Sometimes time and mistakes are explicitly linked to each other. On the one hand needing time to do things in mathematics becomes frustrating and may lead students to hurry up and force *distraction errors*:

“What made me really sad was the fact I was able to solve most of the exercises in the tests, but because I was slow I run out of time and couldn’t finish the test. So sometimes I speeded up and then I made mistakes in the calculations” 5H.14 - grade 13

On the other hand, fear of making mistakes may lead students to slow down and does not allow the students to finish what they are doing:

“One thing I really hate is mathematics assessment. I actually HATE it; I can’t stand it because I’m afraid to make mistakes and hence I do everything very slowly and then time finishes before I can complete my work” 5P.170 - grade 5

Such vision of failure in mathematics not only has negative consequences, but it is far from the real experience of anyone who has studied mathematics at higher level, which shows that one needs to take all the necessary time and that in new and non repetitive problems errors are possible and sometimes functional for the process.

In a sense, we might therefore define *epistemologically incorrect* this characterization of failure in mathematics linked to a way of considering errors as something to absolutely avoid, which is so widespread and transmitted in the classroom. But it is most of all a losing vision, since it may not support the effort which is necessary in problem solving, coming to generate the widespread phenomenon of math-anxiety:

“Many times, when there are problems in the classroom, I get anxious, I’m afraid I can make mistakes, also when I am at home I’m afraid to get it wrong, because I don’t like to make mistakes” 5P.63 - grade 5

Moreover, fear of making mistakes has negative consequences from the point of view of the non-optimal exploitation of the cognitive resources (metacognitive aspects), and pupils themselves are aware of that, describing it as the main cause of their difficulties in mathematics:

“My problem is not being unable to carry them out, but rather fear to make mistakes, as a matter of fact up to now in the oral tests I am always afraid of making mistakes, of giving the wrong answer, even though I know things” 2H.52 - grade 10

“I just give up when, even in front of a simple division, only because I’m uncertain or I’m afraid to make mistakes” 3M.61 - grade 8

The influence of fear of making mistakes on the optimal management of one’s own resources, including cognitive ones, is felt by students themselves, to the point that some of them talk about their own fear of being scared:

“When I do some mathematics tests, I am often, actually very often, scared and this causes problems in carrying them out, because I’m afraid that fear will make me make many mistakes, I get stuck because of that” 5P.97 - grade 5

Sometimes this fear of making mistakes works as an inhibitor (one prefers to stay silent rather than answering and risking to make a mistake):

“I remember that when she asked me questions I was terrified not to know anything, and if she asked me something I was afraid to get it wrong, and I didn’t answer the questions” 2H.120 - grade 10

“In the classroom, when we were doing exercises, I was always afraid that the teacher could ask me something I would not have been able to answer and, for fear of making a mistake, I used to staying silent” 5H.29 - grade 13

Fear of math caused by fear of making mistakes may have another negative consequence: it can elicit fear of the new, of anything that may cause difficulties, going beyond the mere repetitive exercise.

“I remember that once, in grade 3, when we started to learn divisions, I was sort of scared of learning, scared of going ahead with the program” 5P.211 - grade 5

This fear of learning and of going ahead is obviously a big obstacle for learning itself (it is particularly dramatic that a very young pupil has this fear) and, moreover, mortifies the possibilities of mathematics education promoting the development of a taste for discovery and for investigating difficult problems.

“When we deal with something new I always fear it is difficult” 5P.125 - grade 5

In the context of school mathematics, easy/difficult and like/dislike are often identified in a perverse way.

The weight of fear of mathematics, its oppressing role and therefore the importance of fighting against this feeling with purposeful teaching interventions, comes up in the stories that narrate how this emotion can be overcome:

“During the past few years my mind changed, and fear of mathematics changed with it. In the first year of primary school, I thought mathematics was a monster,

with difficult numbers, which went around in my head all at the same time, with no rest. In the following years, the monster of mathematics became smaller and smaller and I got bigger and bigger. That tiny little monster later disappeared; and from that moment onwards I started to love mathematics. I was no longer annoyed by all those numbers, on the contrary, it made me happy, I was content, anxious to see the next problem to be tackled. I was there, ready with paper and pencil, ready to rack my brains. I found something in mathematics I had never found before, due to fear which increased and increased and never stopped, until my strength managed to have control over it and push away from my thoughts.” 5P.219 - grade 5

In the stories talking about the overcoming of one’s fear of mathematics, the teacher is often the decisive figure to determine the change:

“I remember that every time I had a mathematics test at school I felt a strong pain in my stomach and in my head, which made me feel not so ready, so that when the day of the test arrived, my uncertainty led me to make mistakes. Fortunately this is not happening nowadays, and I cannot explain this change, but with this teacher I feel more confident and free from my fears.” 2H.119 - grade 10

CONCLUSION

The analysis we carried out shows that fear of mathematics, that is often correlated to fear of failure, has a strong cognitive origin and at the same time, influences the possibility of managing one’s own cognitive resources in the best possible way. Fear of math is a possible factor of local failure (since it does not allow for the best use of one’s competence and knowledge) but also a possible factor of global failure (since it might lead to give up engagement with mathematics).

From the stories of reconciliation with mathematics emerges that getting over fear of mathematics is the primary and essential condition to be able to start a new and positive relationship with the discipline.

All these remarks charge the teacher with responsibilities, since he/she can convey but also modify a particular vision of mathematics: for example, the weight students attach to mistakes is influenced by the teacher’s management and evaluation of mistakes.

In our study, a strong interplay between the rise and the intensity of fear of mathematics (viewed as a prospect based emotion) and the student’s beliefs about success in mathematics (theories of success) and about self, emerges. Within a student’s theories of success, the interaction among his beliefs about those we called ‘factors of success’, about his perceived competence related to these factors, and about their modifiability, appears particularly significant in order to interpret the evolution of fear toward fatalism. Consequently, in order to get over the students’ fear of mathematics we have to work on both the vision of the discipline and one’s

own perceived competence, in particular sharing the modifiability of the *factors of success* in mathematics.

This action needs that the teachers are prepared to eventually modify their own beliefs towards mathematics and its teaching in the first place.

Moreover, another point of interest is the relationship between teachers' emotions towards math and their students' emotions towards math. This appears to be particularly important in the case of primary teachers that are not specialists in math, and often have had a troubled story with mathematics. Recent studies (Di Martino & Sabena, 2011) show that many pre-service primary teachers have fear of math and are terrorized by the idea of having to teach it.

These results confirm the need to go beyond the purely cognitive also in the research about teacher development, trying to provide teachers the theoretical instruments to interpret, analyze and counteract the students' fear of math, but also to overcome their own eventual fear of math.

CLASSROOM GROUPINGS FOR MATHEMATICS LEARNING: THE IMPACT OF FRIENDSHIPS ON MOTIVATION

Julie-Ann Edwards and Debra Deacon

University of Southampton, UK

The importance of small groups as a pedagogical tool in mathematics classrooms is widely researched and acknowledged to be a successful means of engaging students in mathematics learning. This small scale study examines the influence of close friendships, and friendships by association, in mathematics classrooms of 14-15 year olds on students' motivations to engage with mathematics. We use evidence from questionnaires and individual interviews to describe the motivational factors identified in two classes of students. Findings confirm the multi-faceted nature of motivation in interpreting classroom relationships and the differences in working relationships between groups of close friends and those of friends by association.

INTRODUCTION

The rationale for using talk in small groups as a pedagogic strategy in classrooms is well established. In a review of small group talk, Good, Mulryan and McCaslin (1992) describe “clear and compelling evidence that small group work can facilitate student achievement as well as more favourable attitudes towards peers and subject matter” (p. 167). While much research has been undertaken on the composition of small groups in classrooms in relation to gender, levels of mathematical attainment and age (see, for example, Bennett & Dunne 1991), there is little research on group composition by definition of levels of friendship. According to Slavin (1989), for effective collaborative learning, there must be *group goals* and *individual accountability*, but little is known about how social relationships impact on these factors. A review of group processes in the classroom by Webb and Palincsar (1996) identifies two individual actions associated with increased learning; 1) giving elaborated explanations to other group members, and 2) applying explanations (either received or self-generated) to solve problems or perform tasks (p. 854). Yet there is little research on how these group processes are affected by working with friends.

Friendship groupings in mathematics classrooms are a rarely researched phenomenon, yet they are often used as a pedagogical tool in mathematics classrooms, either briefly for a few minutes discussion or over longer periods of time. This study aimed to explore how the use of pedagogical strategies, such as regular and sustained group work, influenced the perceptions students have about doing mathematics. Since Hamm and Faircloth (2005) propose that motivation is subject-specific, students aged 14 to 15, working towards final mathematics

examinations, are therefore in a key phase of schooling for investigation, given that mathematics represents one of only a few subjects students are required to study in England until the end of compulsory education.

Goos, Galbraith and Renshaw (2002) assert that, since the research undertaken on small group arrangements within mathematics have largely focussed on outcomes, there is a need for research examining how students think and learn as they interact with peers in small groups, emphasising the need for an exploration of the processes at work. Whilst much research exists concerning both theories of motivation and the influence of peers on learning, there is less evidence regarding how these areas interact, specifically within friendship groups in mathematics classrooms.

THEORIES OF MOTIVATION

Lord (2005) argues that several elements form learner motivation. He claims motivation is unique to each individual, can be expressed in a variety of ways, and is aimed towards an end point or a goal. How a student engages with learning is recognised by Brown as reflecting knowledge of themselves as a learner and the learning process, describing this as “metacognitive knowledge” (1988, p. 312). This reflects Lord’s definition of motivation, that learning and motivation are both individual at the initial level. For learning to be truly effective, Brown argues that participants need to have reasons for learning and ownership of knowledge.

Ryan and Deci (2000) are adamant that, too frequently, motivation is defined as a single entity, claiming that individuals not only experience different kinds of motivation but how much motivation is experienced depends on situations and individuals. As Hannula (2002) has recognised, only outcomes of motivation are seen in students’ behaviour(s). Therefore, labelling motivation as a single aspect underestimates the varying emotions students experience when completing different mathematical tasks. In analysing data in our study, we utilise Ryan and Deci’s model of a continuum of motivation.

The most basic distinction between the types of motivation individuals experience, as identified by Ryan and Deci (2000, p. 55) is the contrast between intrinsic motivation and extrinsic motivation.

“intrinsic motivation refers to doing something because it is inherently interesting or enjoyable and extrinsic motivation refers to doing something because it leads to a separable outcome”.

Ryan and Deci present a continuum of motivation beginning with amotivation, the lack of motivation, through four stages of extrinsic motivation to intrinsic motivation. The distinctions between the different stages of extrinsic motivation represent the degree of control students experience, moving from amotivation, where individuals feel that control is impersonal, to intrinsic where control is internal and self-directed. The significance of the different levels of extrinsic motivation

demonstrates that, whilst students may value an activity for its own sake, the enjoyment of the task, in and of itself, may not be the goal being worked towards. A student may value a task for its own sake but this is because it allows them to progress, perhaps, to higher education, requiring a particular examination grade. This reflects the notion of tasks leading to external rewards, hence having elements of extrinsic motivation, although the individual is controlling the effort personally.

Grouws and Lembke (1996) recognise that true motivation is intrinsic, coming from within individuals. They also acknowledge the significance of the classroom culture in establishing intrinsic motivation. This brings into focus questions concerning whether students generate motivation for mathematics from within themselves or through their classroom experiences.

Forman and McPhail (1993) take a sociocultural approach to their study of collaborative groups in classrooms. From this perspective, rather than locating the source of individual motivation and understanding within or between individuals, they locate it in sociocultural practices in which children have the opportunity “to observe and participate in essential economic, religious, legal, political, instructional, or recreational activities” (p. 218). Through guided participation, “children internalize or appropriate their affective, social, and intellectual significance” (p. 218). Findings by Skaalvik and Valås (2010) contradict Forman and McPhail in that these former authors argue that both self-concept and motivation develop with age and are closely connected to personal achievement. From very different viewpoints, these studies raise questions about the effect that friendships are likely to have on motivation.

In measuring attitudes students ascribe to different things, Hannula (2002) suggests that it is often difficult to connect what is being seen outwardly with the elements that are not seen. This reflects Pintrich and Schunk’s (1996) arguments that motivation is a process and that only the product is what is seen. Hannula also observes that only when emotions are sufficiently powerful are they outwardly visible. Ollerton (2003) claims that mathematics, unlike other subjects, seems to cause students significant anxiety. Investigating the motivational beliefs students express concerning the ways in which they work in mathematics is important where emotions such as frustration, boredom and anxiety can be observed in outward behaviours. A study of friendship groupings is likely to explore both emotional and motivational relationships. One of the intentions of this study was to identify processes at work leading to the outcomes seen by teachers.

MOTIVATION AND FRIENDSHIP

Research by Berndt (1992, 1999) examines the influence that friendships during adolescence have on adjustment in and engagement with schooling. His 1992 study explored the impact adolescent friendships have on affective relationships with school. He identifies two elements that influence adolescents’ friendships: the

characteristics of the individual friends and the quality of the friendship. Therefore, how each individual is placed within their friendship groups will alter the influence they have. Berndt's (1999) study recognises that areas such as achievement and motivation may not be common features of conversations amongst adolescents, as participants in Ryan's (2000) study also indicated. Berndt also acknowledges the role of trust within friendships and how its presence allows friends to share experiences, emotions and rely on one another. It is possible, therefore, that relationships built on trust may be evident within mathematics classrooms between peers who are not friends.

If students are able to engage in relationships where trust exists, whether these are close friendships or friendships by association, the benefits may be greater than students working in isolation. Furthermore, if mathematics classes are organised around attainment levels, as is usually found in English classrooms, it is likely that each class will generate its own set of friendship relationships, dependent on the particular students within each class. Evidence that the more consistent these classes are over time, the stronger these structures become (Edwards, 2003) means that students in classes established over several years are likely to be aware of those they can trust within this context. However, if classes are arranged using attainment levels, the existence of friendships within these groups may not be utilised in the most beneficial way. Such a claim is highlighted by participants in Nardi and Steward's (2003) study in their descriptions of feelings of isolation and the sense that mathematics is not presented as a subject that allows opportunities to work with friends.

More recently, a large-scale quantitative study by Nelson and deBacker (2008), examined 253 middle school students' assessments of peer classroom climate, beliefs relating to a best friend's influence on achievement, achievement goals and self-efficacy. They found that positive outcomes relating to achievement were reflected by those students reporting a perception of being valued and respected by peers. As in Berndt's (1992) study, these authors also found that the quality of friendship and the relationship of best friends with academic achievement correlated directly with students' motivation for learning.

SETTING FOR THE STUDY

This study was undertaken in a large comprehensive secondary school in southern England with approximately 1700 students, aged 11 to 16. The school is deemed, by national inspection processes, to be successful, with mathematics examination results, at age 16, significantly above the national average. Within mathematics, students are taught in classes arranged by attainment level, determined by testing shortly after students transfer to the school at age 11. Each year group comprises 11 or 12 mathematics classes, with the mathematics classes studied here, at age 14 to 15, being in the middle of these attainment levels. There were a total of 62 students in

these two classes. This age group, in this particular school, represented a gender imbalance of approximately 65% males to 35% females. This imbalance was similarly reflected in the two classes studied.

DATA COLLECTION

A questionnaire was designed to gather students' opinions about elements of their motivation, the influence of their peers which included the reciprocal nature of these relationships, and the use of peer groups as a tool within the classroom. The questionnaire items were allocated to a 'strand', such as *individual motivation*, *influence of environment/classroom culture*, and *influence of peers on motivation/knowledge* or *influence of peers on construction/accessing help*. For example, a statement from the *influence of environment/classroom culture* strand was "My motivation in mathematics can change based on what is happening around me". The questionnaire comprised of fifteen statements in which students were asked to express their level of agreement using a 5-point Likert-style scale. The lowest value (1) indicated "strongly disagree". The middle value (3) was given the description "uncertain" rather than "neutral" to allow students to state that they were unsure about an opinion on the specific statement rather than that they did not hold an opinion. The highest value (5) indicated "strongly agree". At the time the questionnaire was completed, students were offered the opportunity to participate in the interviews that formed the second part of this study.

Students were also asked to classify their relationship with others in the group in which they worked as '*All friends*' or '*Some friends*'. The former of these categories was described, for students, as peers who were friends outside of lessons, with the latter category as friends because of association with them within the mathematics class. The interview schedule was a semi-structured format, based around five broad questions, where the questions and plan for the interview were the same with each participant, but the ordering of questions and the use of specific follow-up questions was sufficiently flexible to probe particular issues identified in individual responses. The questions were structured to identify general elements of students' work in mathematics, their motivation(s), their interpretations of the relationships with their peers, the overlapping elements of motivation and working with peers, including the reciprocal nature of being a collaborative peer to others. Participation in the interviews was voluntary for participants who undertook the questionnaires. Nine participants, four females and five males, volunteered for the interviews.

OUTCOMES – ROLE OF FRIENDSHIPS

Findings from the questionnaire were analysed using the range of scale indicators from the Likert scale, since the sample size of 62 does not warrant the use of percentages. Here, we present those outcomes which focus solely on the friendship categories, self-identified by students as *All friends* or *Some friends* on the questionnaire.

Category	Questionnaire item	All friends		Some friends	
		Range	Scale	Range	Scale
Influence of peers on motivation	5: Working with my peers in mathematics lessons improves my motivation	2	3 – 5	4	1 – 5
Influence of peers on motivation	6: When I don't work with peers in mathematics, it makes no difference to my motivation	1	2 – 3	3	1 – 4
Influence of peers on motivation	7: Working in a group at a table in mathematics lessons improves my motivation	2	2 – 4	2	2 – 4
Influence of peers on motivation	10: Seeing my peers succeed in mathematics motivates me to pursue similar success	3	2 – 5	3	2 – 5
Influence of peers/knowledge construction	8: I understand things better in mathematics when I can discuss new concepts with my peers	1	4 – 5	3	2 – 5
Influence of peers/knowledge construction	9: I make better progress in mathematics when I work in groups	1	3 – 4	2	2 – 4
Influence of peers/accessing help	11: Being able to gain help from my peers in groups motivates me more than gaining help from the teacher	2	3 – 5	3	2 – 5
Peer contexts/ Reciprocal help	12: I am able to positively influence the motivation of my peers	1	3 – 4	4	1 – 5
Peer contexts/ Reciprocal help	13: My actions in mathematics lessons do not influence the motivation of my peers	1	3 – 4	3	1 – 4
Peer contexts/ Reciprocal help	15: My influence on my peers' motivation is no greater when working in groups than when working individually	2	2 – 4	2	2 – 4
Individual motivation	1: My motivation in mathematics comes from within myself	2	2 – 4	2	3 – 5
Individual motivation	14: Working in peer groups does not motivate me any more than working on my own	2	1 – 3	1	2 – 3
Influence of environment/ classroom culture	2: My motivation in mathematics comes from things around me	3	2 – 5	2	2 – 4
Influence of environment/ classroom culture	3: My motivation in mathematics comes from a range of different things	3	2 – 5	1	3 – 4
Influence of environment/ classroom culture	4: My motivation in mathematics can change based on things happening around me	2	3 – 5	2	3 – 5

Table 1: Comparison of ranges between responses for *All friends* and *Some friends*

This comparison of ranges of responses indicates that the *All friends* subgroup has greater consistency in their agreement on different statement categories and in responses to items with the same statement categories. This is shown through both influence of peers/knowledge construction and peer contexts/reciprocal help having a range of 1 for two statements each. The consistent responses to the statements in these categories highlight the learning enhancements that can occur in groups where participants are working with peers who are close friends. This evidence appears to support findings of both Berndt (1999) and Nelson and deBacker (2008) that trustful relationships amongst friends improve motivation for learning. The more varied ranges for the corresponding statements in the *Some friends* subgroup indicates that, whilst students value the contribution their peers are able to make, these are not as strongly held views as in the *All friends* subgroup.

It might be expected that, in groups where only some participants are friends, students place a greater emphasis on individual motivation. Evidence of this is seen where the statements reflecting individual motivation reflect greater agreement amongst the *Some friends* category. This is paralleled by the range of 1 for questionnaire item 14, where a low value might be expected; however, *Some friends* did not express disagreement as strongly as *All friends* about the difference not working with peers makes to their motivation. An inference of this finding might be that when students are working in peer groups, where only some members are their friends, they are required to generate more motivation from within themselves, rather than this coming from the closer friendships that they have elsewhere.

Using the category distinctions of *All friends* and *Some friends*, in groups where participants considered all members to be their friends, the responses are more consistent. A greater degree of individual motivation is expressed in peer groups where participants considered only some group members to be their friends. Evidence from the students' interviews indicates that their motivation in mathematics is also changeable, not necessarily linking to elements of the classroom culture, but rather to external factors, such as time of the day or week, or prior experiences in lessons in other subjects: "And I probably work harder on the Mondays than Thursdays [last mathematics lesson of the week] ... cos on, like, a Monday I'm, like, all ready for work cos it's Monday morning ... and then on Thursdays, it's a bit more laid back cos it's Thursday". The choice of working peers was also considered important to individuals: "I chose people that I knew, but at the same time I knew I could work well with them ... through things like sports teams and things outside of school".

The findings from the interviews also indicate that students working in mathematics at age 14 to 15 view their peers as a valued resource for learning: "If they're your friends and, umm, maybe you can talk to each other which, like communication ... you can help each other, which may help my motivation"; "I think it motivates me more if I ask my peers ... they're easier to talk to sometimes ... and they understand

you more ... as opposed to teachers who sometimes don't ...". Students emphasised the contribution the classroom environment makes and how it influences changes within their motivation: "If you're not having a good day then it [motivation] doesn't, you don't really feel very motivated, just want to get the lesson over with ... and if you're having a fine day, you don't mind learning and being motivated". They expressed a strong level of agreement over the benefits of being able to discuss new concepts with their peers: "If you don't want to ask the teacher, then asking them [friends] works as well". The interview responses also highlight how the physical arrangement of groups allows for greater flexibility and ease of accessing help from peers: "If you're in a, like, square table, then you can talk to anyone around the table ... I think it motivates me more if I ask my peers ...". In general, the students indicated a preference for gaining help from peers, rather than the teacher, due to understanding peers better and not appearing foolish through publicly requesting help. Such need for public acceptance amongst adolescents is identified by Warrington and Younger (2011).

DISCUSSION

Students in this study indicate that their motivation for mathematics is affected by several factors, supporting Lord's (2005) research. Evidence from questionnaires and interviews suggest that students place considerable emphasis on the classroom culture as a source of motivation for mathematics. However, whilst students recognise the influence the environment can have on their motivation, the personal element to motivation, described by Lord is also acknowledged.

In terms of Ryan and Deci's (2000) study, in which they argue that individuals not only experience different kinds of motivation but the extent of this depends on situations and individuals, all students in our study displayed some form of intrinsic motivation for mathematics. However, questionnaire responses also indicate that this is more likely to be a form of extrinsic motivation on Ryan and Deci's continuum of motivation. It is also evident in student interview responses that motivation for mathematics is not a single feature, supporting Valås and Søvik's (1993) research. These interview responses broadly reflect variations of extrinsic motivation moderated by an internal locus of control, as described by Ryan and Deci (2000).

These 14-15 year old students express an awareness of a relationship between their motivation for mathematics and their relationships with their peers, though the nature of this relationship is not explicitly identified in the interviews. What is highly evident, despite the small scale of this study, is that relationships with peers have a significant influence on these 14-15 year old students' motivation to work in mathematics.

RECONSTRUCTING TEACHERS' BELIEFS ON CALCULUS

Ralf Erens and Andreas Eichler

University of Education Freiburg

The teachers' instructional planning, their classroom practices that impact on their students' knowledge and beliefs could be understood as individual beliefs systems dependent from their actual teaching and learning experience. This individual experience might be contradictory when we regard different teachers or one teacher concerning different mathematical disciplines. For this reason, this report focuses on teachers' beliefs with different levels of experience about their teaching of a specific mathematical domain, i.e. calculus that is a central part of the (German) curriculum at upper secondary level. After a brief outline of the theoretical framework and methodology of this research project, results of the qualitative reconstruction of different types of teachers' beliefs on calculus will be explained.

INTRODUCTION

The importance of gaining knowledge towards mathematics teachers' thinking or beliefs has been emphasised by many researchers in mathematics education in various settings and projects for some reasons: on the one hand teachers' beliefs about mathematics and the teaching and learning of mathematics have a high impact on their instructional practice (Philipp, 2007; Eichler, 2011), on the other hand teachers' instructional practice, which is considerably determined by teachers' beliefs about their professional world (Calderhead, 1996), has a high impact on students' learning and beliefs concerning mathematics (Hiebert & Grouws, 2007). Moreover, the possibilities of changing the teachers' thinking about mathematics education depend on the teachers' beliefs towards teaching and learning mathematics (Franke, Kazemi & Battey, 2007). On these grounds there has been much effort in investigating mathematical beliefs of teachers all over the world in the recent two decades (Philipp, 2007). In this huge body of research, most of the study approaches concern teachers' beliefs on *mathematics* and the learning and teaching of *mathematics*. It is rarely considered though that – similar to the classification of mathematical subjects into fields such as algebra or probability theory – teachers' beliefs on different mathematical domains such as geometry, stochastics or calculus may vary and may be associated with specific beliefs (Franke et al., 2007).

Research on (intended) curricula of experienced calculus teachers is rare (e.g. Tietze, 2000). Recent works aim primarily at investigating calculus lessons with the use of technology (e.g. Kendal et al., 2005) or look at calculus curricula of undergraduate courses at university. Although there is plenty of research on algebra teaching (Kieran, 2007), deeper investigations which focus on the development of teachers' intended curricula independent of technology aspects are scarce.

As there are few investigations about calculus, which is a central part of the German secondary curriculum, domain-specific beliefs of secondary teachers referring to the

teaching and learning of calculus are the main focus in this paper. Our specific interest primarily concerns the structure of beliefs that characterise calculus teachers' instructional planning (teachers' intended curricula) and, thus, impact on the teachers' classroom practice (teachers' enacted curricula), and the students' learning (Eichler, 2011). Reconstructing this structure possibly facilitates to partially identify which constituents are more central than others (Green, 1971). Further, regarding the system on calculus teachers' beliefs, we search for relations between different clusters of calculus teachers' beliefs that we call views (Grigutsch et al., 1998). We refer our findings to existing results for teachers of other mathematical disciplines. As part of a larger research programme it can be asked whether the degree of professional experience might have an impact on characteristics of the teachers' belief systems. Before we address the mentioned questions for this paper, an outline is given about the theoretical framework of the research programme, and a brief description of those parts of the method being relevant for this paper.

THEORETICAL FRAMEWORK

Research on teaching and curriculum has brought forward that a significant difference exists between the curriculum as represented in specifications by national or regional governments, sometimes accompanied by instructional materials, and the curriculum as it is actually enacted in the classroom by teachers and students. The various meanings of curriculum have been conceptualized by the work of Stein, Remillard and Smith (2007), who provide a curriculum model including four phases of a transformation process to describe a mathematical teacher's planning, the teacher's classroom practice and his students learning (see fig. 1).

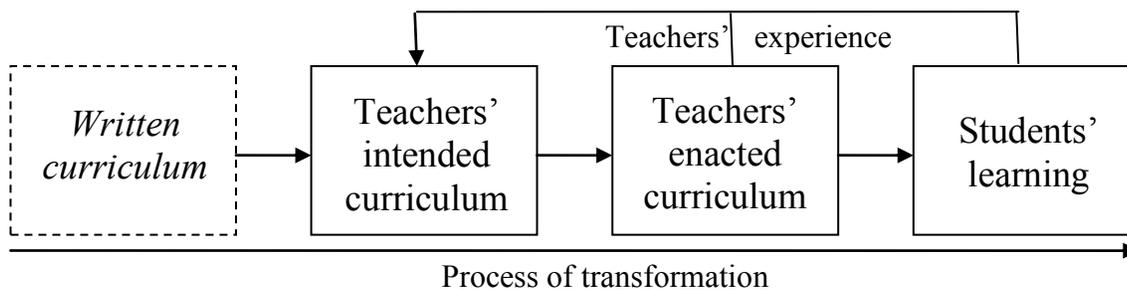

Figure 1: Four phases of the curriculum according to Stein et al. (2007)

The *written curriculum* involves both instructional content and teaching goals, often prescribed by national governments. The way the teachers interpret a written curriculum concerning content and goals is called the *intended curriculum*. The classroom practice involving interactions of a teacher with his or her students, and the instructional content “create something different than what could exist [...] in the teacher's mind” (Stein et al., 2007, p. 321). This transformation of the intended curriculum is called the *enacted curriculum*. The individual students learning outcomes that are not necessarily intended by their teachers is called *students' learning*. In this article, the discussion is restricted to teachers' intended curricula.

A teacher's intended curriculum represented by content and goals can be understood as specific form of beliefs, if beliefs are defined as an individual's personal conviction concerning a specific subject, which shapes an individual's way of both receiving information about a subject and acting in a specific situation (Pajares, 2007). Regarding this definition, content and goals portray a teacher's conviction about an appropriate way of teaching mathematics. Thus a teacher's intended curriculum can be understood as a belief system that is characterised by a quasi-logical system of beliefs with different grades of importance or centrality (Green, 1971, Philipp, 2007). Another theoretical feature of a belief system involves that belief systems consist of several clusters of beliefs that may be contradictory. We hypothesise that a teacher's intended curriculum concerning the teaching of mathematics consists of clusters representing different mathematical domains that need not coincide with each other if the teaching goals are regarded, but are mostly consistent, if a specific mathematical domain, e.g. calculus, is regarded (Girnat & Eichler, 2011). In this paper, we restrict discussion of results on teachers' intended curricula concerning the teaching and learning of calculus.

In the following, belief systems of secondary teachers are characterised towards the teaching and learning of calculus as views representing the main instructional goals of the teachers (Philipp, 2007). There are four main categories which can be characterized by different features regarding the perception of mathematics in general (Grigutsch, Raatz & Törner, 1998) and calculus in particular:

- A formalist view stresses that mathematics/calculus is characterized by a strongly logical and formal approach. Accuracy and precision are most important and a major focus is put on the deductive nature of mathematics or calculus.
- A process-oriented view is represented by statements about mathematics being experienced as a heuristic and creative activity that allows solving problems using different and individual ways.
- An instrumentalist view places emphasis on the “tool box”-aspect which means that mathematics is seen as a collection of calculation rules and procedures to be memorized and applied according to the given situation.
- An application oriented view accentuates the utility of mathematics for the real world and the attempts to include real-world problems into mathematics classrooms.

Usually teachers' belief systems might consist of a mixture of all the four views outlined above. However the weight of each aspect varies from teacher to teacher. Although we assume that a teacher's belief system consists of parts of different views, our research shows patterns of views when we investigate teachers' beliefs referring to a specific mathematical domain: e.g., the research of Eichler (2011) yields that stochastics teachers primarily refer to application oriented teaching goals when they analyse both their instructional planning and their classroom practice. By contrast, teachers mostly disregard a direct connection of school mathematics and

real world problems, if geometry is considered (Girnat & Eichler, 2011). Accepting the hypothesis, like Franke et al. (2007), that teachers' beliefs referring to the teaching and learning of mathematics differ, if they have geometry, stochastics or calculus in mind, it is worthwhile to investigate teachers' beliefs concerning the calculus domain to understand their teaching practice.

METHOD

Concerning the teaching and learning of calculus, we analyse teachers in different stages of their professional development including 10 pre-service teachers, 10 teachers in a practical phase after university studies (teacher-training college) that lasts 18 months and 10 teachers with a professional experience of at least five years. All the teachers are employed or would be employed at upper secondary schools (Gymnasium) in Germany.

In the first part of our research that we address in this paper, data were collected by semi-structured interviews comprising clusters of questions concerning several subjects: contents and goals of instruction, teaching and learning calculus, institutional boundaries and the nature of mathematics and calculus at school level in particular. Within these obligatory clusters, the teachers gave distinction to the interviews by describing their own typical examples but also had to react to specific prompts. These prompts include, for example, evaluating statements about adequate teaching, students' statements about calculus or different tasks from calculus text books. In addition, the teachers were asked to respond to questionnaires concerning mathematical beliefs (Grigutsch et al. 1998) and their teaching orientation (Staub & Stern, 2002).

The interviews were transcribed verbatim. Each transcript has a length of 30 to 40 pages. The first step of the analysis was to split the transcripts into episodes and label them in terms of the question clusters outlined above. Further, the episodes were analyzed by coding. Coding guidelines were adapted in compliance with qualitative data analysis (Kuckartz, 2012). First the relevant coding units were determined and then supplemented by inductive codings. This approach enables both the consideration of empirically-based individual content items (inductive aspects) and the significance and reconstruction of contents and goals (deductive aspects) that have been shown to be relevant in previous work on individual curricula e.g. of stochastics teachers (Eichler, 2011). Finally, the characteristics of each teacher were systematically arranged and summarized with respect to the projects' research questions. Furthermore case summaries were compiled to highlight essential characteristics of each individual teacher.

RESULTS

In order to categorize and illustrate teachers' beliefs concerning the planning and teaching of calculus by means of qualitative analysis, the deductive aspects of four different views (see above) were chosen. This method has been efficient in previous studies of intended curricula for other mathematical domains with respect to patterns

of beliefs as well as to describe these views in depth. This involves the subjective teachers' definition of a specific view that represents the teachers' overarching teaching objectives. We illustrate a coherent view, in this case a formalist view concerning the subjective definition of Mr. C.

Mr. C.: „In general, exactness is crucial for me. That means to fit a necessary formalism as I know from my university studies. This also means that it must be possible to recognise a logical rigor. Sometimes I do more in that sense than the textbook actually demands.”

Taking this teacher as a paradigmatic example, he did not mention aspects like to apply mathematics in real world problems or to learn problem solving, which means to emphasise the process of developing mathematical concepts. By contrast, for Mr. C., the main goal of calculus teaching seems to be emphasising the stringent and logical construction of a mathematical domain.

The identification of specific teachers' views is always established in various parts of a single interview and we report only teachers' views that are in some sense coherent throughout the whole interview. We illustrate this concerning this exemplified teacher. When Mr. C was asked to regard the expectations and needs of his students, he agrees consistently with a formalist view. For instance, Mr. C was asked to rate the statements of students shown in figure 2.

Which of the following comments on calculus would your students most often make?
Why? Which of these are the most important in your view?

I like calculus, because there is a connection to real life problems.

I like calculus, because hard nuts must be cracked and difficult problems can be solved.

I like calculus, because many exercises can be solved by similar procedures/patterns.

I like calculus, because the logic is clear and it follows strict mathematical rules.

Figure 2: Statements of students concerning calculus

As expected, Mr. C attaches particular importance to the last statement that represents a formalist view. Mr. C further explains his goals concerning his students' beliefs towards calculus:

Interviewer: How should your students characterise calculus?

Mr. C: Precise mathematics. Thus, on the one side that it is possible to understand how one develops mathematical ideas and how it is possible to build up a theory on the foundation of few basic ideas.

Summarising the beliefs of Mr. C concerning the teaching and learning of calculus, there exist several unambiguous examples of evidence for Mr. C's formalist view. The high degree of coherence in different parts of the interview leads to the hypothesis that this formalist view is dominant and thus central in the belief system on calculus.

Regarding teachers' beliefs on calculus, our study has so far revealed one particular aspect as some teachers stressed their need for formal and deductive nature of calculus which is characterised by accuracy, precision and a strongly formal and logical approach. However, in contrast to Mr. C, most of the teachers show a mixture of different views.

In particular, if teachers' hold beliefs that represent different views, we analyse relationships among the different views. We describe this analysis exemplarily by regarding Mr. A and Mr. B starting at the subjective definitions of their possibly central beliefs. In contrast to a (central) formalist view, these two teachers firstly delivered an insight on their views on applications:

Mr A.: „I quite agree with the emphasis on applications in the given example. That is certainly a way to motivate them (students), but nevertheless one should not reduce genuine calculus or the teaching of calculus to that topic. “

Mr. B.: „Examples for applications are quite suitable here, and with applications I always associate modelling of real data, [...] increasingly introducing relevant applications into lessons may, for the students, succeed in a deeper insight into the concepts and ideas of calculus.“

Both teachers have nearly completed their teacher training and have taught the first class of upper secondary level independently i.e. without being accompanied by a senior teacher. Mr A. supports the integration of applications as a principle of learning calculus at school for reasons of (student) motivation. In contrast Mr. B reckons that introducing real-world problems into calculus is a part of his system of aims and goals concerning his calculus teaching. The difference between the instructional goals of motivation on the one side, and solving real problems on the other, is stated by Förster (2011) concerning teachers who teach modelling, but, however, has not been reported in domain-specific research about teachers' intended curricula so far. The aforementioned aspect seems to be relevant independent of the professional status of the teachers interviewed. Both views on applications can be found in all three groups of our sample.

In addition, the explicitly expressed goal of Mr. B. of integrating modelling tasks into his lessons is connected with another statement about dealing with the “formal logic” as a characteristic property particularly in calculus.

Mr B.: “...because I think that the formal derivation of integrals by limits is of no avail for secondary level students. It's just too complex for most of them.”

However, a general conclusion that applications are implicitly of primary importance than formality and logic cannot be drawn as the following quotation of Mr A. demonstrates:

Mr. A: “Calculus is more than just dealing with application-oriented tasks. Then, for example, one would not regard the precision and exactness of calculus and use applications as a means to an end.”

Our hypothesis on basis of the present data is the following: If teachers hold a consistent formalist view on calculus, they do not mention any applications. The reversal conclusion, however, is not possible. Teachers who primarily favour applications in their calculus courses, e.g. Mr. A and Mr. B (see above), cannot be described as non-formalist. This example already demonstrates the abundance and need to differentiate the views of teachers on calculus.

As another aspect of relationships among different views or rather cluster of beliefs we describe in the following contradictory belief clusters that we call conflicts (of instructional goals). We reckon that the teachers' system of beliefs may have a quasi-logical structure and could involve contradictory clusters of beliefs with the paradigmatic example of Mr. E. Throughout the whole interview he speaks about the central role of logic in calculus lessons offering his perspective that exactness and logical rigour are necessary ingredients of secondary level calculus courses. Again, the degree of coherence of favouring formalist elements could provide an indication for a core belief. Yet, as he describes representative classroom situations, his subjective experience surfaces a conflict between his belief system about calculus and pedagogical processes in his calculus course.

Mr. E.: „ In my view it is quite important that there are formal definitions of concepts because you need them for proofs later on and it's the tiny details that are particularly important...

In my class I clearly notice that students come to their limits concerning the degree of abstraction. [...] Remembering my own calculus course at school I can't remember any bad experience with these formal aspects. So far I haven't seen such a mismatch between teacher and students in maths.”

Mr E. can be identified favouring a formalist view but probably will not enact his formalist view on calculus in the classroom in a predominant way because there is a conflict with the real situation he encounters in the classroom i.e. the students' ability to understand the formal way of developing calculus ideas. Therefore this situation can be characterized as a conflict of objectives between his view on calculus and his teacher authority and responsibility. In particular when teachers are asked to reflect on representative examples of their actual teaching processes of specific elements of their calculus courses, the interview transcripts provide a deep and concrete insight of teachers' subjective notions of their intended and enacted curricula and sometimes yield conflicts of a teacher's system of instructional goals. We hypothesise that a conflict of teaching objectives gives evidence for a central belief since peripheral beliefs might be superimposed if they show a conflict with central beliefs.

In addition to predominant beliefs that teachers show in different parts of the interview in a coherent way, the teachers also provide insights into some peripheral goals. These peripheral goals are neither coherent nor do they produce any conflicts between the intended and enacted curriculum. For example, the teachers indicate in some interviews the peripheral goal that calculus and the teaching of calculus is a

collection of rules and procedures (i.e. toolbox) although their beliefs cannot be categorized globally as an instrumentalist view.

Mr. F.: The main goal of every student is to perform well in his final exams – therefore calculation rules and procedures have to be thoroughly practised in class. Especially the calculus part of final exam tasks are alike in some respect, so practising is a substantial guideline for my course.

Often these views are motivated by normative aspects such as final exam tasks, yet seem to have a considerable impact on their actual teaching of calculus.

It is apparent though that for all teachers in our sample the preparation of the final exam (so called “Abitur”) does indeed play more than a subordinate role in their calculus beliefs as an inductive feature. The driving force of the written curriculum and a focus on student achievement scores has a particular influence on the realisation of learning processes and, thus, the enacted curriculum.

DISCUSSION

Certainly the scope of this paper could not present an exhaustive discussion on teachers’ beliefs on calculus. We discussed two views with the teachers’ subjective definitions, the formalist view and the application view. Concerning all teachers one of these views seem to be central in the calculus teachers’ intended curricula since other beliefs, in particular the instrumentalist view with respect to exams, have become apparent as peripheral goals. We further discussed two indications of central goals, i.e. the coherence of beliefs concerning different aspects of the teachers’ teaching and the existence of conflicts of teaching objectives.

The results of this study of teachers’ (central) beliefs on calculus as one important mathematical domain at upper secondary level suggest that the assumption (occasionally stated, e.g. Tietze, 2000) of a biased instrumentalist orientation of calculus teachers is not valid.

The establishment of a causal relationship between different clusters of teachers’ beliefs on calculus is an effort to reconstruct the network structure. At the current state of our analysis, it is striking that a formalist view could be a key factor to understand the calculus teachers’ intended curricula: Those teachers who favour a formalist view as a central goal neglect any application-oriented view. We hypothesise that the individual characteristic of the formalist view considerably forms the calculus teachers’ intended curricula.

Having outlined that teachers’ beliefs on calculus and its teaching are inherently different from the domain-specific beliefs of stochastics or geometry teachers, comparisons to other domains have to be drawn carefully, since we did not investigate the teachers’ beliefs concerning to all mentioned mathematical disciplines. From a pragmatic perspective this would not have been possible as a single interview on calculus took about two hours. On the basis of present evidence we assume that differences in belief systems in the aforementioned domains surface

in every secondary teacher. However, regarding the larger research programme, it has been conclusively shown that there exist differences depending on the mathematical domain being looked at.

At this point, the analysis of the present data cannot yet give a reliable answer whether e.g. pre-service teachers show a higher preference of collaborative activities in their pedagogical practice than experienced teachers who are assumed to favour a more instructivist view of learning. The development of teachers' belief systems depending on their degree of professional experience as well as some verification whether expressed beliefs are guiding factors in actual classroom practice will be considerably analysed after a further collection of data.

With regard to the previous argument this qualitative study will turn towards the question by means of subsequent interviews in what way pre-service teachers' beliefs are subject to change in the course of their professional development and whether there will appear a cohesion or fraction of their intended or enacted curricula.

Furthermore an attempt will be made to quantify relevant aspects of our sample with respect to the results of the qualitative approach, which will be evaluated by relevant quantitative data interpretation.

However, up to the present stage, our studies already underline the importance of a differentiated investigation of teachers' beliefs referring to specific mathematical domains like calculus. The focus on a deep and valid understanding of intended and enacted curricula of calculus teachers might further facilitate to understand teachers' classroom practice and to identify approaches to change both teachers' intended curricula, and teachers' enacted curricula.

ANALYZING FOCUSED DISCUSSIONS BASED ON MKT ITEMS TO LEARN ABOUT TEACHERS' BELIEFS

Janne Fauskanger and Reidar Mosvold

University of Stavanger¹

The mathematical knowledge for teaching (MKT) measures have become widely used among researchers both within and outside the U.S. The measures as well as the underlying framework have, however, also been subject to criticism. One aspect of the criticism relates to the MKT framework failing to include teachers' beliefs. This paper has a methodological focus and discusses in which ways discussions based on MKT items can be used to tap into teachers' beliefs about aspects of MKT. Two example studies will be used to indicate how analyses of teachers' focused discussions can provide researchers with important information about teachers' epistemic beliefs related to aspects of MKT.

Keywords: MKT, epistemic beliefs, focus group discussions

INTRODUCTION

Familiarity with the participating teachers' mathematical knowledge for teaching (MKT) is beneficial for teacher educators when planning and implementing professional development (e.g., Ball, Thames, & Phelps, 2008). Since beliefs influence teachers' interpretation, application and implementation of pedagogical approaches (Philipp, 2007)—as well as their approach to professional development and eventual gains from attendance (Fives & Buehl, 2010)—teacher educators will also benefit from being familiar with the participating teachers' beliefs. Teachers' beliefs about knowledge (including teaching knowledge)—often referred to as epistemological beliefs (e.g., Fives & Buehl, 2010)—are particularly important. According to Buehl and Fives (2009) distinct beliefs about different aspects of teaching knowledge exists, such as the source of teaching knowledge, the stability of teaching knowledge and the structure of teaching knowledge. In the present paper we focus on practicing teachers' beliefs about a fourth aspect: the content of teaching knowledge (as in Fives & Buehl, 2008)—in particular methodologies that can be used to gain insight into teachers' beliefs about teaching knowledge.

We study the adaptation and use of the MKT measures (Fauskanger, Jakobsen, Mosvold, & Bjuland, 2012). These measures have been used among researchers both within and outside the U.S. The measures as well as the underlying framework have been used and referred to by many, but they have also been subject to criticism. One aspect of the criticism is related to how the MKT framework fails to acknowledge the importance of teachers' beliefs (Petrou & Goulding, 2011; Schoenfeld, 2011). The importance of including beliefs in studies of teachers' knowledge has been emphasized, and some even argue for the equivalence of beliefs and knowledge (e.g., Beswick, 2011). Beswick (ibid.)

suggests that beliefs about mathematical content and pedagogy should be included in the MKT framework. Schoenfeld (2011) supports the idea of including teachers' beliefs, and he argues that this would increase the validity of studies on teachers' knowledge.

Despite the amount research on teachers' beliefs (e.g., Philipp, 2007), relatively few studies have focused on teachers' beliefs about teaching knowledge in general—teachers' epistemological beliefs (e.g., Fives & Buehl, 2010); even fewer studies focus on teachers' beliefs about the knowledge they need to teach mathematics in particular—their epistemic beliefs (e.g., Fives & Buehl, 2008). The MKT framework does not acknowledge the importance of teachers' beliefs (Petrou & Goulding, 2011), and we intend to investigate if and how teachers' reasoning—expressed in writing as well as in focus group discussions—may elicit their beliefs about MKT.

We invited teachers to participate in our studies, where we aimed at exploring how discussions based on MKT items can be used to study teachers' beliefs about aspects of MKT (See figure 2 for an example item). For the purpose of this paper, we will focus on methodological issues related to these FGIs in order to answer the following research question:

In which ways can focused discussions based on MKT items be used to tap into teachers' epistemic beliefs?

We use two of our own studies as starting point for making this methodological discussion. Seven focus group interviews (FGIs) were conducted as part of the first example study, and the 15 participating teachers in these FGIs were selected from a larger sample of teachers. They had all given their responses to a set of 61 MKT items in a testing situation prior their participation in the FGIs. In the second study, six FGIs were conducted with 26 teachers based on their responses and written reflections related to ten MKT items.

CONCEPTUAL FRAMEWORK

Ball and colleagues (2008, p. 395) define MKT as “the mathematical knowledge needed to carry out the work of teaching mathematics”, and this represents a further development of Shulman's (1986) theories of teacher knowledge. In his seminal paper, Shulman (ibid.) distinguished between ‘Subject Matter Knowledge’ (SMK) and ‘Pedagogical Content Knowledge’ (PCK). The MKT model builds directly upon this initial distinction (Figure 1).

In the MKT “egg”, SMK is divided into three sub domains. ‘Common Content Knowledge’ (CCK) describes the mathematical knowledge that is common outside as well as inside the teaching profession. ‘Specialized content knowledge’ (SCK), on the other hand, represents a mathematical knowledge that is unique to the work of teaching. The third sub domain of SMK, ‘horizon content knowledge’, is mathematical knowledge not directly deployed in instruction.

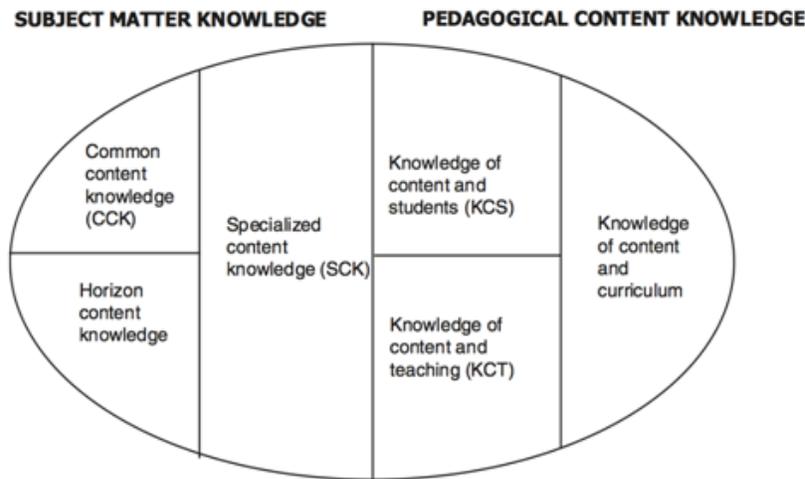

Figure 1. Domains of MKT (Ball et al., 2008, p. 403).

The right side of the oval contains three different categories of knowledge related to Shulman’s PCK. The first category—‘knowledge of content and students’ (KCS)—is focused on students’ mathematical thinking, knowledge and learning of mathematics. ‘Knowledge of content and teaching’ (KCT), which is the second category, refers to the knowledge used by teachers when designing mathematics lessons. The final category, ‘knowledge of content and curriculum’, includes (but is not exclusively related to) knowledge of grade levels where particular topics are typically taught, assessments and educational goals.

The MKT framework does not include beliefs. This has been criticized, and Beswick (2011) argued that beliefs about mathematical content and pedagogy should be included in the MKT framework. Philipp (2007), on the other hand, suggested that beliefs are closely related to knowledge, but he argued that a distinction should still be made between the terms. In this paper, we follow Philipp’s suggestion and distinguish between knowledge and beliefs. We focus on the beliefs that teachers have about MKT, and we consider this to be an aspect of teachers’ epistemological beliefs (e.g., Fives and Buehl, 2008). Teachers’ epistemological beliefs are considered important by several researchers and several competing models that describe the nature of epistemological beliefs have been proposed, but general epistemological beliefs still seem to refer to “individuals’ belief about the nature of knowledge and the processes of knowing” (Hofer & Pintrich, 1997, p. 112). In their attempt to clarify the research in this area, these researchers proposed that epistemological theories are composed of “certainty of knowledge, simplicity of knowledge, source of knowledge, and justification for knowing” (ibid., p. 133).

In order to avoid confusion, we use ‘epistemological beliefs’ with reference to teachers’ general beliefs about knowledge and knowing in this paper. ‘Epistemic beliefs’ refer to teachers’ domain-specific beliefs about knowledge and knowing—in particular teachers’ beliefs about aspects of MKT.

Most of the research on MKT has been related to the measurement of MKT by the use of multiple-choice items, and the MKT items themselves are strongly connected with—and can even be seen as manifestations of—the MKT construct. When attempting to investigate teachers’ beliefs about MKT, it might therefore be a good idea to use MKT items as a starting point for focused discussions. In the following, two studies will be presented as examples of ways in which focused discussions based on MKT items can be used to tap into teachers’ epistemic beliefs.

Bryman (2004, p. 348) suggests that FGIs may give “more realistic accounts of what people think, because they [interviewees] are forced to think about and possibly revise their views”. The use of activity-oriented questions in FGIs is highly recommended as productive supplements to oral questions and the importance of asking the participants to do something before the FGI is emphasized (Colucci, 2007). Inspired by other researchers who have used similar items in this way, we included MKT items that were well known for the teachers to focus the discussions. Below is an example from the public released MKT items that focuses on definitions. In the first example study the teachers discussed definitions, and in one of the items the main issue was whether or not 1 is defined as a prime number. The MKT item in Figure 2 is not the exact same, but it also has a focus on the definition of prime numbers.

2. Ms. Chambreaux’s students are working on the following problem:

Is 371 a prime number?

As she walks around the room looking at their papers, she sees many different ways to solve this problem. Which solution method is correct? (Mark ONE answer.)

- a) Check to see whether 371 is divisible by 2, 3, 4, 5, 6, 7, 8, or 9.
- b) Break 371 into 3 and 71; they are both prime, so 371 must also be prime.
- c) Check to see whether 371 is divisible by any prime number less than 20.
- d) Break 371 into 37 and 1; they are both prime, so 371 must also be prime.

Figure 2. Item 2 from the set of released items (Ball & Hill, 2008, p. 4).

In the second example study, an item focusing on place value and decomposing numbers was discussed. Since we are discussing two example studies in this paper, we have chosen to make separate presentations of the methodological issues and results for each study below.

STUDY 1—METHODS AND RESULTS

In the first study, 15 teachers participated in seven semi-structured FGIs. These teachers were selected from a convenience sample of 142 teachers. All the participants had a special interest in mathematics and mathematics teacher education and worked individually with a set of MKT items before they participated in the interviews. A complete form (Elementary form A, MSP_A04) with items from the LMT project² was used. This form had been translated and adapted for use among Norwegian teachers (Fauskanger et al., 2012), and it contained 30 item stems and 61 items in total. The form consisted of the following three sets of MKT items: number concepts and operations (27 items), geometry (19 items), and patterns, functions and algebra (15 items).

After the teachers had taken the test, they were given a short break before groups of two or three teachers' were invited to discuss the items. The initial aim with these discussions was to investigate whether or not our adaptation of the MKT measures was successful by bringing in the voices of the test-takers. In our previous analyses of these interviews, we learned that the practicing teachers also discussed different aspects of the knowledge they found relevant and irrelevant for their work as teachers—including aspects related to mathematical definitions (Fauskanger, 2012). This inspired us to analyze the FGIs with a focus on beliefs about MKT definitions. The results from this study was presented at the 2012 AERA conference in Canada (Mosvold & Fauskanger, 2012), and the main focus then was on what teachers' reflections on MKT items reveal about their epistemic beliefs concerning mathematical knowledge for teaching definitions.

The transcripts from these interviews were analyzed in two steps. First, directed—often called theory driven—content analysis (Hsieh & Shannon, 2005) was applied to the data. We began by identifying all that was discussed related to MKT-items focusing on definitions, and all that was said related to definitions when discussing other items as well. Both authors first searched the transcripts for occurrences of the words 'define', 'definition' and derived terms. When reading the transcripts, we discovered that words like 'concept' and 'formula' were used more or less as synonyms of 'definition'. We therefore searched the transcripts for these terms as well. In our separate analyses, we ended up with an almost perfect overlap of excerpts from the transcripts. Second, these excerpts were subject to further qualitative analysis to uncover subcategories related to what was said about definitions. For a subcategory to be established, the aspect in focus had to be discussed by the teachers in at least 2 separate interviews. Two researchers carried out independent content analysis of the data to ensure reliability.

Mathematics teachers need to know something about mathematical definitions, and the focus on definitions was present as one of the mathematical tasks of teaching in Ball and colleagues' (2008) presentation of the MKT framework.

When “choosing and developing useable definitions”, teachers need to know the actual definitions.

A directed content analysis approach followed by qualitative analyses of data from these FGIs revealed different epistemic beliefs from the teachers concerning the relevance of MKT definitions as well as the task of teaching mathematical definitions. In our analysis, two categories emerged. The first category was: *Knowledge of definitions is an important part of teachers’ MKT?* This category refers to teachers’ common content knowledge and included the following two subcategories: *Definitions are important* and *Remembering definitions is not important*. Below is an excerpt from the transcripts that illustrates the first subcategory:

Interviewer: You suggest, in a way, more of the kind of tasks that focus on definitions, and less of the kind of tasks that focus on calculations, then?

Betty: Yes, I think that is correct.

Benjamin: Definitions are incredibly important as a pre-requisite, because if you don’t have clear definitions and know a little about it, then you will easily be out of track.

Betty: And, what was said after the TIMSS study, what I have heard anyway, is that we score low on concepts. So, I believe it is more important to be clear about this than to be able to calculate correctly.

The teachers in our study seemed to agree that knowledge of definitions is important. Quite a few teachers suggested, however, that teachers do not have to remember the actual definitions—only know about them. Some teachers even claimed that knowledge of definitions—although it is arguably part of teachers’ knowledge—is not crucial.

The second main category that emerged from our analysis was: *Choosing and developing useable definitions*—a category referring to teachers’ SMK as well as PCK. It contained the following subcategories: *Adjusting to different groups of students*—highlighting teachers’ knowledge of content and students—and *Inclusive definitions are confusing*—referring to teachers’ common content knowledge. In the FGIs, some teachers suggested that certain definitions are less suitable for the lower grades—which is an example of the first subcategory—as represented by the following excerpt from the transcripts:

Karen: I think they [the MKT measures] should have been differentiated... As an example if one can have a rectangle that is not a parallelogram and that stuff [definitions of quadrangles]. (...). But we do not have [teach] it [definitions of different quadrangles] for the younger ones [students] we teach.

Ken: No, exactly.

This can be seen as supporting the claim that “choosing and developing useable definitions” is a relevant mathematical task of teaching, however the definitions chosen should—based on teachers’ knowledge of content and students—be adjusted to different groups of students. This example study indicates that such a methodological approach—i.e. inviting teachers to respond to MKT items in a testing situation followed by focused discussions—might be a fruitful way to tap into teachers’ epistemic beliefs related to MKT definitions. However, for future studies it is important to discuss if the teachers being interviewed after having conducted a test might bias the results.

STUDY 2—METHODS AND RESULTS

The second study was presented at the Norwegian conference “FoU i praksis” (Fauskanger & Mosvold, in press). In that study, our focus was on teachers’ beliefs about MKT place value. This second study was conducted on the basis of what we had learned from the first study—indicating that FGIs based on teachers’ responses to MKT items are suitable for eliciting teachers’ views on which aspect of the MKT they consider relevant and/or irrelevant. In the second study, 26 teachers were asked to give written responses to ten MKT items from the “number concepts and operations” scale at home. Follow-up questions were added to the items, and they were asked to reflect upon which items best captured MKT that was important for them. Based on these written reflections interviews were conducted.

The interviews were recorded and transcribed, and the transcripts were analyzed in three steps. First, a double content analysis was made in order to reduce data. The first author read through all the transcripts and identified all that was said related to the item in focus. The second author conducted an independent content analysis in which the transcripts were analyzed by counting words in the text with the purpose of understanding the contextual use of words related to place value. Second, utterances were chosen as coding units, and the context unit was defined to be two utterances before and after each coding unit in which a key word was found. This was followed by a comparison of what was included in the first sample and not in the second, and the union of the two samples was used in the further analyses. In order to analyze teachers’ beliefs about MKT, we decided to use the aspects of MKT as presented in Figure 1 as codes in this second part of our content analysis, and the sample was then coded by both researchers. In a third and final step, all the coded parts were analyzed in relation to aspects of MKT place value as highlighted in the research literature.

Our analyses indicate that the teachers as a group emphasize all aspects of MKT (Figure 1) when describing what is important for them as teachers. They agree that place value is an important base for students’ future learning of mathematics, indicating that the teachers highlight several aspects of their PCK. When trying to make the teachers identify why it is important, one of the teachers responded:

Interviewer: What makes the place value system so important?

Doris: It is the foundation for counting and arithmetic. It is the basis for everything. The numbers wouldn't even have the names they have if it wasn't for the place value system.

Doris draws on her horizon content knowledge as well as knowledge of content and curriculum. Our findings also indicate that the teachers' utterances—in the FGIs—in some cases contrast important research findings. As an example, the teachers indicate column value to be more important than quantity value, whereas research emphasize that both are important related to multi-digit calculation (e.g., Thompson, 2003). A second example is that the teachers in this example study emphasize a decomposition of multi-digit numbers following the positions, whereas research emphasizes non-standard decomposition as an important base for multi-digit calculation (e.g., Jones et al., 1996). This is interesting since e.g. the standard Norwegian algorithm(s) for multi-digit subtraction includes non-standard decomposition, and it might indicate that this aspect is important to discuss in future professional development. Teachers' beliefs about MKT place value might thus provide a relevant starting point for professional development initiatives.

As in the first example study, this second study also indicates that using MKT items in FGIs might be a fruitful way to tap into teachers' epistemic beliefs about important aspects of MKT—such as their MKT place value. A three step content analysis of data from these FGIs as described above revealed different epistemic beliefs concerning the MKT place value. In conclusion, this example study indicates that inviting teachers to respond to MKT items and reflect upon the items in writing, followed by FGIs including the items might be a fruitful way to tap into teachers' epistemic beliefs.

CONCLUSIONS

Preliminary analyses of teachers' focused discussions related to MKT items in these two example studies indicate that such analyses can provide researchers with important information about teachers' epistemic beliefs related to aspects of MKT—in particular about the knowledge needed to teach place value (example study 2) and their epistemic beliefs about mathematical definitions (example study 1).

Different methodological approaches can be used when studying beliefs and the two example studies presented in this paper exemplify how focused discussions based on MKT items can be used to tap into teachers' beliefs about aspects of MKT. We have learned that analyzing these FGIs using different forms of content analysis can illuminate aspects of teachers' epistemic beliefs about MKT important for future professional development. Knowing, for instance, that teachers believe decomposition following the positions to be most important,

professional development can be developed that allows us to discuss teachers' epistemic beliefs about decompositions.

So far, there is a scarcity of research related to epistemic beliefs about MKT (Fives & Buehl, 2010), and more research is needed. Our preliminary results indicate that different approaches to content analyses of teachers' reflections in FGIs based on MKT items can be particularly useful in this connection. Despite the obvious limitations of these two example studies, they support the argument that epistemic beliefs about MKT are important. Further studies of teachers' epistemic beliefs about aspects of MKT are called for, and we believe that such studies might have a potential to inform the further development of the MKT construct as such.

NOTES

1. Our research project has been supported by OLF, The Norwegian Oil Industry Association.

ATTITUDES TOWARDS MATHEMATICS OF TEACHERS IN SERVICE OF TELESECUNDARIA: AN EXPLORATORY STUDY

Maricela Fuentes Rivera

Inés M^a Gómez-Chacón

Complutense University of Madrid (Spain)

The results of a research carried out with in-service teachers of federal “telesecundarias” in the area of the city of Xalapa Veracruz, Mexico, will be shown in this article. The research explored the teacher’s attitudes towards mathematics as a first approach on the research of affective factors in the teaching-learning process within this educative subsystem. The overall results showed no negative attitudes coming from the teachers but rather neutral with positive charge and slightly positive. However, in the subscales analysis the presence of a negative disposition in items related to anxiety and a low self confidence in some teacher’s mathematical skills can be seen.

Keywords: Teachers in-service, telesecundaria, attitudes,

INTRODUCTION

The recognition of the importance of affective factors (emotions, beliefs, attitudes and values) in the quality of learning (Goldin, 2002; Gómez-Chacón, 2000; Hannula, Evans, Philippou, & Zan, 2004) and assessment processes of learning of mathematics has led to include these aspects in educational reforms in many countries in recent years (Martínez Padrón, 2008). Such is the case of Mexico with the secondary education reform in 2006 which has mainly focused on the competence-based learning, giving attitudes a leading role as well as conceptual and procedural contents. In recent years there has been an increasing emphasis on the development of better researching methods in attitudes (Leder & Forgasz, 2006). A particular point of interest was the measurement of some dimensions of self-concept (Bandura, 1997; Malmivuori, 2001), conceptual clarification (Di Martino & Zan, 2003; Ruffell, Mason, & Allen, 1998) and development in college stages (Galbraith & Haines, 2000; Gómez-Chacón & Haines, 2008; Liston & Odonoghue, 2008). As it comes on training future primary and secondary teachers some descriptive studies on attitudes were found. These focused on different aspects: mathematics as an object of study, its role in the society and science, its application in real contexts and the teaching-learning process of mathematics and the proposal of some measuring instruments on conceptions, beliefs and attitudes towards mathematics (Beswick & Callingham, 2011; Camacho, Hernández, & Socas, 1995; Hernández, Palarea, & Socas, 2001; Rico & Gil, 2003).

There is not a consensus in the definition of attitude among researchers in mathematics education (Di Martino & Zan, 2003, 2011; McLeod & Adams, 1989). For this job, we adopt Gómez-Chacón (2000) definition, who accurates it as:

Evaluative predisposition (negative or positive) that determines the personal intentions and influences on the behavior. Therefore, it consists of three components: one cognitive that manifests on the mentioned attitude underlying beliefs, another one affective, that manifests on the work or matter acceptance or rejection feelings and one intentional or trending to a certain behavior. (p. 23).

And thus a multidimensional perspective was adopted for this paper.

This paper is focused on the teacher's attitudes towards mathematics. There are many factors that make this research important in order to clearly understand what is happening in this educational subsystem; first of all, the lack of enough research in this matter in the Mexican context (Juárez, 2010). Second, the contrasting results of previous researches. For instance, some authors have pointed out that teachers' beliefs and emotions towards mathematics influence the achievement of their students, as well as their beliefs and attitudes towards this discipline (Caballero, Blanco, & Guerrero, 2008; Ernest, 1989; Pezzia & Di Martino, 2011). It is indicated that the development of positive attitudes towards mathematics depends on the teaching style. Thus, negative attitudes may be appear when the teacher teaches instrumentally and the student attempts to learn relationally (Amato, 2004). On the other hand, other researches stated that affective variables such as conceptions, beliefs and attitudes towards mathematics play a determining role in the development of teaching practice (Frade & Gómez-Chacón, 2009; Hodgen & Askew, 2006; Philippou & Christou, 1998, 2003).

It is important to highlight the teaching context in this subsystem. In Mexico secondary schooling is provided in four modes; general, technical, for workers and "telesecundaria". This last one was founded in 1968 to provide coverage to rural areas where technical or general high schools are not built due to its high operation costs. Unlike the other secondary schools, "telesecundaria" teachers are in charge of all the subjects, likewise primary teachers. People with mayors in the "Normal Superior" with specialties such as English, Natural Sciences, Social Sciences, Math, Arts, etc.; and university courses in Physics, Biology, English and Mathematics are hired. Also professionals with other university mayors may be accepted, as long as they take complementary studies of Normal Superior or any Masters Degree in Education. To back up the teachers work a 15-minutes-long class is satellitaly broadcasted. This class is repeated daily during a learning sequence, giving the teacher the freedom to use it whenever it is more convenient. The methodology of this subsystem also includes the

use of a book for each subject, one for the student and another one for the teachers. These books are distributed Nationwide, just as it happens in primary schools as well.

As the teaching context in primary schools and “telesecundarias” is quite similar, as stated before, some findings that researchers have reported in other countries on training primary school teachers will be used. It was found that many people at university stages have weak knowledge and negative attitudes, being some of them even afraid about mathematics (Beswick & Callingham, 2011; Frade & Gómez-Chacón, 2009; Philippou & Christou, 1998). While others have revealed moderated to positive attitudes among teachers in training and currently working (Caballero et al., 2008; Eudave, 1994). Additionally, a low performance in mathematics can be clearly seen in this subsystem as it has been shown by the international results in PISA 2006 and nationally in the results of ENLACE for its initials in Spanish (National Assessment of Academic Achievement in School centers). Therefore the need of researching on the telesecundaria teachers’ attitudes towards mathematics in order to set the ground for future researches that may be carried out. The research question we have raised is then the following: What are the attitudes towards mathematics of Telesecundaria teachers who do not have a training profile in math?

Teachers who have a mayor in mathematics were not taken into account in this research since it was assumed their attitude towards mathematic should be positive.

METHODS

Subjects

35 teachers attached to the Federal Telesecundarias of Xalapa, Veracruz, Mexico. 70 teachers with many different specialties compose the complete staff. As indicated before teachers with specialty in math according to the aim of the study, and also those teachers who due to their administrative functions (directors, supervisor, etc.) are not teaching classes were not included.

Instrument

The Likert scale, ATMAT by its initials in English of Ludlow y Bell (1996) was carried out. It was designed to measure attitudes and experiences related to mathematics and its teaching. This scale consists on 29 items, with options for three levels of agreement and three of disagreement. It was piloted with 240 undergraduate and graduate students in a mathematics teacher training institution in New England. Cronbach’s alpha coefficient as well as a factorial analysis were carried out in order to validate this scale. Cronbach’s alpha coefficient was 0.96

As the scale was applied in a Spanish-speaking context it was translated into Spanish and in order to avoid understanding problems from which it was piloted. This lead to separate item 1 in two, so that the final scale was composed of 30 items. Each one of

them had five options ranged from “strongly disagree” to “strongly agree”, including the neutral or of indecision option, since we consider that in this way we would obtain more descriptive results. Cronbach’s alpha coefficient was verified for this version of the scale, obtaining a 0.754 value, which continues being a good reliability index, even if diminished with division of item 1.

The scale was divided into three subscales according to the three components of the multidimensional model of attitudes: Cognitive Subscale (C), Affective Subscale (A), Behavioral Subscale (B). The Affective Subscale is formed by items that refer on one side to the liking/disliking towards mathematics and on the other side to the anxiety caused by mathematics itself and the resolution of mathematical problems and also by the possibility of their teaching in different educational levels. The Cognitive Subscale is formed by items that refer to the beliefs about mathematics, mathematical problems, and self-efficiency and competitiveness beliefs. Finally the Behavioral Subscale is formed by items that show the tendency to act in concordance with their perspective of mathematics in learning and problem solving. This classification was validated by the criterion of two experts in research on attitudes in Mathematics Education. The drafting of the items in the subscales were of two types: positive (because they reflect a positive attitude) and negative (because they reflect a negative attitude). In the following table we present an item from each subscale according to the type of drafting as an example.

NO. ÍTEM	SUB SCALE	DRAFTING TYPE	STATEMENT
1	C	Positive	Mathematics is very interesting to me.
16	C	Negative	I have forgotten many of the mathematical concepts wich I have learned.
2	A	Positive	I enjoy math courses.
4	A	Negative	I feel a sense of insecurity when doing math.
17	B	Positive	I learn mathematics by understanding the underlying logical principles, not by memorizing rules.
12	B	Negative	I do not attempt to work a problem without referring to the textbook or class notes.

Table 1: Example of items in each subscale

After evaluating each teacher intervals were established to classify their attitudes as it is shown in the table 2. So if a teacher, for instance, obtained a score of 68, he/she would be in the interval of 60-74 and his/her attitude would be considered neutral with negative charge, symbolized as “I—”

Intervals	CLASSIFICATION OF ATTITUDES	SYMBOLGY
30-44	Strongly negative	NN
45-59	Moderately negative	N
60-74	Neutral with negative charge	I--
75-89	Neutral with slight negative charge.	I-
90-104	Neutral with slight positive charge.	I+
105-120	Neutral with positive charge	I++
121-135	Moderately positiva	P
136-150	Strongly positive	PP

Table 2: Intervals, attitudes and symbols classification

Application

The schools of participating teachers were visited with their authorities' consentment. Teachers taking part in this research gathered in a classroom where they were given the necessary indications. They were invited to answer honestly as their names would be kept private. Afterwards it was proceeded to deliver the printed scale, giving them plenty of time to answer.

RESULTS

The results are presented in two sections, the first of them called global results. The total scores of the participants were addressed, which allowed us to characterize their attitudes. In the second section, results for subscales, a more detailed analysis according to the three components of attitude was done.

Global Results

According to the classification of attitudes raised, 23 teachers exhibit neutral attitudes, 4 of them are neutral with slight positive charge and 19 neutral with positive charge, the 12 remaining ones present positive attitudes, 11 moderately positive 1 strongly positive. It can finally be seen that they do not present negative attitudes.

To sum up it can be said that most teachers have neutral with positive charge and moderately positive attitudes towards mathematics (30 teachers). This is somehow consistent with the results obtained by Caballero et al., (2008), who found that Primary School teachers in training in the Extremadura University had not negative nor rejection attitudes. Eudave (1994), also found neutral with slight positive charge attitudes within high school in-service teachers. On the other hand, this is contrasting with results showing negative or even frightening attitudes among Primary School prospective teachers, especially at early training stages (Beswick & Callingham, 2011; Frade &

Gómez-Chacón, 2009; Philippou & Christou, 1998). We have compared our results with the ones obtained on studies over primary professors, because of the context similarity as we anticipated on the introduction.

Subscales results

Valuable information on the affective, cognitive and behavioral areas has been gathered after this research.

Affective subscale. Unlike what was found by Philippou y Constantinos (1998), who stated that “an alarmingly high proportion of students brought very negative attitudes to Teacher Education” (p. 196), most of the teachers show from moderately positive to positive attitudes on the different items that form this scale, specially on those about liking of mathematics, where no negative attitudes are shown. However, despite this positive tendency, we find high anxiety levels on 20% of the participants on items referred to “it makes me nervous to even think about having to do a math problem”. Also on items referring the possibility of teaching mathematics on the next educational level, we find negative attitudes on between the 16.7 and the 33.3% of the participants.

Cognitive subscale. Most teachers showed favorable conceptions about mathematics, math problems and classes as well as self-confidence regarding their capacity of facing mathematical problems and their background on the subject. However, a 16.7% of the teachers of this study show a very low self-efficiency referring problem solving, for example the “I can draw upon a wide variety of mathematical techniques to solve a particular problem” kind of items. Similar results are to be found on items related with professional training, where from a 13% to a 20% of the teachers show a very low sense of competence. This is coherent with the results obtained by Caballero et al., (2008).

Behavioral subscale. In this topic there are neutral with positive charge attitudes. It can be stated that most teachers prefer learning through the real understanding of the logical intrinsic principles rather than memorizing rules although 26.7% manifests indifference. Many of them would be willing to work with problems which go beyond the difficulty level prepared for class while some other were undecided or reluctant to do so.

DISCUSSION AND CONCLUSION

We can observe on the global results that on one side, no negative attitudes are shown and on the other side the teachers attitudes are to be found mostly between neutral with a slight tendency to positive, to moderately positive. Watching the graphic carefully, it is to be noticed that the highlight occurs on the neutral attitudes (23/30) instead of the positive (7/30) ones. So the obvious question that comes out is, why does the highlight occur on the neutral attitudes? We can find the explanation on the results by subscales analysis, where some dimensions like the value and liking of mathematics are highly scored, while others, despite of being positively scored, negative and even very negative

attitudes appear on percentages that go from 16.7% to 33% of the participant teachers. These issues can be grouped in two topics: The first one refers to the mathematical problems along the three subscales and the anxiety caused by facing them and a low self-efficiency perception at solving them, that seems to be caused by the feeling of not being secure of their previous knowledge and developed skills. Just as it was pointed out by Philippou & Constantinos (1998), who stated that the lack of confidence to solve problems is directly associated with negative attitudes. The second one refers to the possibility of teaching mathematics in different educational levels, particularly in the immediate superior level, where the 33% show a high insecurity level.

On the other hand and returning once again to the relationships among attitudes (cognitive, affective, behavioral) dimensions, we recognize some external factors that can influence each teacher's internal perspective. We consider that the attitude is part of this internal perspective. The external factors to consider are: teacher characteristics and teaching characteristics, in particular the method or problem solving (Wilkins & Brand, 2004; Wilkins & Ma, 2003). Let's consider each one of these factors (cognitive, affective and behavioral) more closely to obtain a better understanding of the teacher's perspective. Complementary to these scales, the information obtained from informal interviews, highlights the external factors that affect their perspective and their attitudes towards mathematics. The first external factor that emerged from the obtained information belonged to characteristics of the teachers when they were students. We see these characteristics as some of the most important, since teachers often have the power to affect other factors. These teachers described memories of nice teachers, funny teachers and devoted teachers. They also underlined personal attention that some students received from their teachers and the effect this had on such students' attitudes. So their "views" are related with the influence a teacher's behavior had on their attitude towards the class.

The second external factor of teaching characteristics is clearly related to the teachers' characteristics and their capacity to solve problems. The participants were encouraged to reflect on their mathematical experience and talk about their attempts to solve problems. Their knowledge of mathematics were insufficient to solve all the given problems, causing them anxiety when dealing with students and work at different levels. Significantly fewer teachers claim they have to memorize ideas. A medium-high percentage of teachers consider a dynamic and social perspective of mathematics. It is not a subject about concepts and procedures they have to memorize and they indicate the importance of working a problem-solving approach ("I learn mathematics by understanding the underlying logical principles rules, not by memorizing rules"). We note the apparent discrepancy in their responses when asked about their beliefs regarding themselves (self-efficiency). They indicate that their tendency is not to be able

to solve problems. Whereas when they responded to beliefs about mathematics itself, their responses are more suited to social desirability.

All these findings and information supporting our statement that this group needs specific course in problem-solving, in order to improve the cognitive dimension of attitudes from mathematics as a body of procedures to be learned, to mathematics as a process of thinking. These courses shall also reinforce their knowledge and mathematical skills, so that they manage to perceive themselves as more capable to solve problems and as consequence, their anxiety levels will diminish. This way, we may be able to reverse and prevent poor attitudes towards mathematics in “Telesecundaria” Teachers. Besides, since the secondary reform in Mexico on the mathematics subject is focused on problems solving, teachers have to be prepared, both, in knowledge and attitude, in order to the reform to be successful, as regards to improve the mathematics teaching and learning.

ETHIOPIAN PREPARATORY STUDENTS' PERCEPTIONS OF THE RELEVANCE OF MATHEMATICS TO LEARNING GOALS

Andualem Tamiru Gebremichael

University of Agder

This study investigates Ethiopian students' perceptions of the relevance of mathematics to their learning goals. Interview, classroom observation and survey were used to examine students' perceptions in the cultural, economic, historical and social context they are situated. The results indicate that participants in this study hold perception of the relevance of mathematics which is characterized by unknown future, trust, identity, empowerment to make informal decision and exchange value, which are held to various levels of strengths, with the characterizations trust, unknown future, and exchange value being strongly held. They are motivational factors to students' engaging in mathematics, and emotion is intertwined with them.

Key words: emotion, Ethiopia, identity, motivation, perception of relevance

INTRODUCTION

In Ethiopia the transformation of schooling from indigenous to modern one occurred on a contradictory situation: the religious and cultural background of the country on the one hand and the need for modernizing the country on the other (Wagaw, 1979). The contradiction seems to have contributed to the society's perception of schooling as a means of getting job rather than a means to solve societal problems. The students find themselves in this historical context of schooling. Literature suggests that students' perceptions about the relevance of tasks to their goals are motivational factor to their engaging in it (Wigfield, Hoa & Klauda, 2008). Students' goals are motivational factor for engaging in mathematics (Goodchild, 2001). Students' motivation to engage in mathematical tasks affects their performance, and their perceptions about accessibility of the goals affect their motivation (Hannula, 2006). Students regulate their emotions in order to achieve their goals (ibid). According to Wigfield, et al (2008) the importance of a task is associated with the individual's identity. There are diverse ways to motivate students to engage in mathematics. The rationale for their learning of mathematics could be one way (Wæge, 2007). This study is carried out in a school in the capital of Ethiopia. A preliminary result from a pilot study which exposed the characterizations of students' perceptions of the relevance of mathematics was reported in Gebremichael, Goodchild & Nygaard (2011). A questionnaire was designed and survey was undertaken based on this result. The purpose of this paper is to report on characterizations of students' perceptions of the relevance of mathematics with respect to their learning goals. The research questions I addressed are 'what are the characterizations of Ethiopian students' perceptions of the relevance of mathematics with respect to their learning goals; how strongly are these perceptions held, and do these perceptions have the same distribution across different categories of students. This paper is structured in

such a way that the theoretical perspective is followed by methodology. Then, the qualitative and quantitative data analyses are presented, followed by the conclusion.

THEORETICAL PERSPECTIVES

In this study the theoretical perspective adopted is sociocultural theory, particularly, cultural historical activity theory (CHAT), which is discussed in more detail in Gebremichael et al. (2011). The Engeström model (Cole & Engeström, 1993) is used as an analytic tool to describe and analyze the students' perceptions of relevance. The model depicts the activity system, which involves the interaction between the subject (students) and the object (motives, goals, learning school subjects and the material resources) mediated by tools and artifacts. This interaction is also mediated by the rules, division of labor, and community (ibid). In their participation in the activity of schooling, students have motives. They belong to a community of natural or social science streams. The members of the school community are governed by the school rules. The school rules enforce that they should take school subjects including mathematics. They should cover certain topics over the year based on a mandatory textbook, which is a mediating artifact for their learning and the resulting perception.

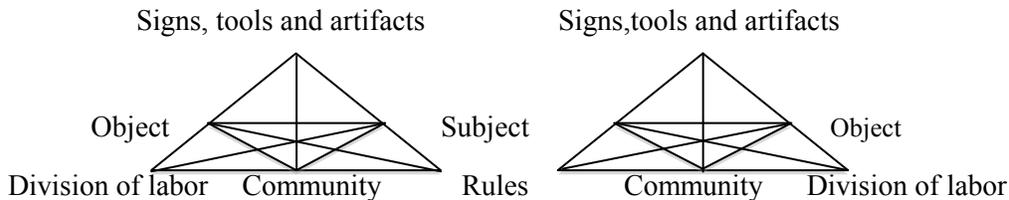

Figure 1: Interacting activity systems adopted from Roth & Lee (2007).

The students participate in a network of activity systems (Roth & Lee, 2007), and see figure 1. In their out-of-school lives students participate in the activity of family life where members of the family as a community share a common motive of survival of the family and a goal of enhancing the personal development of the student. According to the division of labor in the local activity system, students have responsibilities of mentoring their younger siblings as they are mentored by their elders. The rule enforces following and obedience to the elder. For many students, their parents are unlikely to know what they are learning, as the parents may not have the appropriate education. The preparatory school system is new which was only introduced in 2003 and replaced the freshman program of universities. The students in this study are situated in a historical context of schooling and learning mathematics. They have been learning mathematics before they were enrolled in preparatory school and their elders might have learnt preparatory mathematics. The school and the local activity systems interact; the model is dynamic and the components might embrace different entities that might change (Roth & Lee, 2007). Tension might arise within and between the components (Ibid). Emotion, motivation and identity are integral to each other and are distributed all over the activity system (Roth, 2007). It is in such a framework that the students' perceptions develop.

Following Vygotsky (1978) perception is understood in this study as a formation of meaning and making sense of encountered mathematical experiences.

METHODOLOGICAL ISSUES

This study employs a mixed approach, in which interviews and questionnaire are used to collect data in a school where I taught more than a decade ago. The students of this school are both sex. They are divided into two grade levels and two streams. The teacher further divided them into levels of achievement. These student categories were used for sampling both in the qualitative and quantitative data collection. They are of age 16 - 18, with a possibility of few exceptions. I undertook a pilot study using group interview, supported by classroom observation. A total of 24 students were selected for interviews by homeroom teachers (teachers who have a firsthand responsibility for a class of students). The department head selected 4 homeroom teachers who also teach mathematics, and they selected 6 students from their respective classes. 3 students of the same sex who are high, medium and low achievers were interviewed together. Analysis of the data resulted in the characterizations of students' perceptions. Using results of the pilot study, questionnaire was developed. The characterizations emerged were used as Likert scale items, and 335 students completed it. The data analysis is discussed next.

QUALITATIVE DATA PRESENTATION AND ANALYSIS

The five themes pertaining to students learning goals and the mediational process that regulated the development of these perceptions are presented here.

Mathematics is relevant because it is useful in an unknown future

The students are preparing for university studies and they have goals associated with it. Students form perception of the relevance of mathematics related to this.

Andualem: Is math useful for your future? How about the math you are learning now?

Habtu: I want to study astronomy and my brother told me that in addition to mathematics, physics is the base.

Abebe: I don't know the detail about astronomy and how much mathematical capacity it requires. Since mathematics is important in our everyday activities, it would be the same at that level. I think it would be important.

Meseret: [Mathematics] is a mother tongue. ... In economics there is slope. We learnt it in 7th or 8th. We didn't know then that it has this use.

Makida: In books we don't see where to apply [it]. [It] has relation with other subjects and we apply it on them... at tertiary level.

As Habtu is participating in the activity of family life, he is mentored by his elder brother towards enhancing his personal development. The local community mediates his perception. Meseret considers her prior experience and projects it to her future. They perceive that preparatory mathematics is relevant to their future goals. The

other subjects, school rules and artifacts mediate their perceptions. The school curriculum and the textbook do not give a rationale for learning the topics with respect to their future; their perceptions are motivational factor for engaging (cf. Goodchild, 2001; Wæge, 2007). It is discussed in “identity” that students set goals based on their relationship with mathematics, and in “exchange value” that mathematics determines their access to what they intend to attain in the future.

Mathematics is relevant because I trust the curriculum

There is a sense of trust by the students in the curriculum and/or the teacher.

Andualem: Why are you learning mathematics? Is it useful?

Asad: It is mentioned in the objective of the textbook. ... I do not exactly remember specific examples. ... I think it is because we should learn it.

Meada: In the objective it says ‘at the end of this lesson you will be able to understand’. ... [Limit] is used in derivative.

Ruth: Our teacher usually tells us.

Azenegash: [The teacher] is our eye... If it were not relevant we wouldn’t have been taught. I think it is useful.

Asad perceives that they learn mathematics because they should learn it. In his participation in the activity of schooling to realize his motive of joining the university, he undertakes actions such as engaging in mathematical tasks and attending mathematics lessons. These actions are directed towards the goal of learning mathematics. He forms certain perception about the relevance of mathematics, which in this case is characterized by trust for the curriculum. When he is engaged in mathematical tasks the textbook is an artifact he uses. The textbook mediates his perceptions about the relevance of mathematics. Following Asad, another member of the same group, Meada explains what the objective informs and he gives a specific example. My review of the chapter on limits in the textbook confirms Meada’s statement. In one of the bullet points that lists the objectives it mentions that the concept of limit gives a basis for differential calculus. This provides a sense of rationale for their learning of the concept of limit if they know what differential calculus is for. The textbook tells what the student should expect to learn by the end of a chapter. This might prepare the students to what they should learn and what they should pay attention to. However, the textbook does not give a clearly articulated rationale for their learning of the concept of limit, particularly with respect to the students’ future goal. The perception emerged as a development from the tension between the object and the rules. The students have a high assumption of the teacher and the tension is mediated by the teacher. This is seen in Ruth’s and Azenegash’s narratives. The teacher and her/his practice mediate their perception which is characterized by trust. The rules, the division of labor in the school, where their role is to listen to the teacher, mediate their perceptions.

Mathematics is relevant because it gives an identity

Students form their identity in relation to mathematics and their future goal.

Andualem: Is math useful for your future? How about the math you are learning now?

Debesh: I want to study Banking and Insurance because it has mathematics I like mathematics ... it is not difficult for me.

Essayas: I want to study law because my brother told me that it doesn't involve mathematics ... economics, but [it] has mathematics; so I don't like.

Andualem: Do you find problems or examples which indicate that math has application?

Ruth: ... Most social science students do not like mathematics. Only few students work hard. Thus our teacher always advises us.

Debesh perceives himself as someone who can do mathematics well. Essayas, on the other hand, perceives himself as someone who does not want to deal with mathematics. They are identified by their teacher as high and low achievers, respectively. In order to realize their motive of becoming university student, they attend classes and study school subjects towards achieving the goal of learning. There is emotion intertwined with their object and their decisions (cf. Roth, 2007). Their perceptions are mediated by the local community, and their emotion towards mathematics. Their emotions and identities are motivational factors in engaging in mathematics, and towards making a decision about their future study. Ruth is a high achieving and in other discussions as well she refers to the whole of students, and the social science when locating herself in the mathematics classroom. She is situated in the community of social science students who generally do not like mathematics and are taught by a mathematics teacher whose background is natural science. In the division of labor the teacher has the role of providing advice about working hard while the students have to listen to it. The teacher could tell them to work hard on mathematics and that it is important for their educational career. But, the student could not know how the mathematics they are learning would help them. The tension that Ruth experiences within her community seems to lead to a development of perception that is characterized by identity. Emotion is involved in here as well because the advice was initiated because of the social emotion exhibited among students (cf. Roth, 2007).

Mathematics is relevant because it empowers one to make informal decisions

Some students make judgments about what mathematics is for. Some perceive that mathematics and the other subjects are there for them to expose their talents.

Andualem: Why do you need to learn the mathematics you are learning now?

Erikahun: I want to study language or philosophy. ... I am doing well in language. ... Math and most of the subjects we are learning now might not be related to

what we learn in the future. But, they help us to identify/know our interest and direct us to the future. We used to learn music; it is not important but if you have the interest then you will know. Some of us may end up in a field that doesn't involve math at all but others may need it.

In his history of participating in the activity of schooling he has been undertaking actions towards the goal of learning. In particular, he was attending to school subjects including mathematics, before he was enrolled in preparatory school. He is still attending to some of these subjects. He perceives that the other subjects are competing with mathematics for students' choice. Since he made other choices, he perceives that he doesn't need mathematics for his future, but he has to learn it because others in his group need it. The school rule enforces the topics that the student should cover in a year, and it has to enable him to understand why he is learning the subjects. His perception is mediated by other subjects, the school rules and community. It is motivational factor, and negative one (cf. Wigfield, et al, 2008). His emotion determines his future direction and is intertwined with his perception (cf. Roth, 2007). This characterization of perception is a development from tension within the object: the learning of mathematics and future goal are in tension.

Andualem: Do the mathematics textbooks reflect that math is useful? Do you see examples that show applications?

Netsanet: Before we use formulas, there are items which we do simply by observation, by looking at it attentively. That helps you to think and analyze; it broadens your mental capacity.

Netsanet perceives that mathematics is there to broaden her mental capacity. Her perception is mediated by the school curriculum, artifacts, the formula, and the prior meaning established in her about formula and other mathematical artifacts. Her perception of relevance about the mathematics she is learning observed to be exciting for her and seems to motivate her to work on mathematics.

Mathematics is relevant because it has exchange value

These students are supposed to score a qualifying grade to be admitted to the university, and Ethiopia is a poor country in which success in education and securing a job relates to sustaining the life of the individual as well as parents.

Andualem: Tell me your history in schooling and your experiences in mathematics?

Beza: We used to hear that 10th is the turning point for life. ... [Studying] any social science would be ok [to be a hostess]. ... Mathematics is compulsory.

She plans to become a hostess, and she perceives that the school that offers the training requires social science background of university. She perceives that success in mathematics is the gate keeper to joining the university and to achieving the goal of securing a job – becoming a hostess. This perception of relevance she attaches to mathematics motivates her engaging in mathematics.

Andualem: What do you plan to study? Is mathematics useful for your plan of study?

Ruth: Earlier I wanted to study law but it is 5 years. [I] study economics ... then I can help my parents. ... If I do not have the basis in mathematics I can't do it.

Ahadu: I want to become a [medical] doctor. ... Whether one becomes a medical doctor or something else, learning mathematics is part of the process.

Ruth learns mathematics to sell it at the marketplace of learning economics so as to get job at the end, which enables her to sustain her family and study law which she really likes to study. The division of labor in her community – her responsibility to support her parents – mediates her perception of relevance. Her perception of relevance is a motivational factor for being engaged in mathematics. Ahadu perceives that one cannot make her/his way to the future without dealing with mathematics. His perception is mediated by the rules.

Andualem: What do you plan to study? Do you see application of mathematics?

Yirdaw: I want to be a private accountant. ... Mathematics books from abroad are better at applications than domestic ones. ... I prefer the [latter] for success in exams. But, for my interest I prefer the [former]”.

Andualem: Do you find learning mathematics useful? Are the concepts you learnt this year of interest to you?

Alewi: I am not interested in it but it is required ... I liked polynomial at the beginning. ... when I scored poor at the first test, I turned my back to it again”.

We see the tension between the mediating artifacts that are available for Yirdaw and the school rules that he has to succeed in examinations which are pertinent to the text book. The tension results in the development of his perception. Emotion that is associated with the artifacts is exhibited in Yirdaw's interest in using some of the artifacts than the others. Emotion also mediates students' perceptions. Though Alewi did not like it, because of the exchange value mathematics has, she put effort to succeed. Cognizant of the fact that her effort is in vain she dropped it as less relevant (cf. Hannula, 2006). Emotion is integral to and affects her perception of relevance. Her motivation is also seen to decline as a result.

PRESENTATION OF QUANTITATIVE DATA ANALYSIS

The quantitative data analysis and results are presented here. A large proportion of the students' parents do not have education that enables them help the students in their education. More than 63% of the mothers do not have any training above secondary level, while only 15% of them have training above secondary level. Only less than 6% of the mothers have university degrees. Their fathers' do not seem to be far different from their mothers'. More than 52% of the fathers do not have any training above secondary level, while 25% of them have training above secondary

level. Only less than 16% of the fathers have university degrees. About 22% of the students mention neither their fathers' nor their mothers' levels of education. On the other hand, the students hold the five characterizations of perception to various degrees of strengths. The proportion of students who held perceptions characterized by trust is 71%; unknown future, 68%; exchange value, 63%; identity, 43% and decision, 33%. The first three are strongly held. Though the perceptions characterized by identity and decision are not strongly held, a significant proportion of students hold these perceptions. Identity especially is significant, when compared to the proportion of students who do not hold this perception, which is 31%. The item on future use of mathematics is about something which the students did not experience yet. A follow up question was asked, about their sources of information. For 64 % of the students their teacher is their source of information. Their mothers, fathers, brothers, sisters, or relatives are very rare sources.

Three of the five characterizations of students' perceptions did not show any significant difference based on the categories of gender, grade level, stream and levels of achievements. The distribution of items such as "preparatory mathematics is useful to get access to my future plan" is the same across all categories. This was tested using bar graphs as well as the Mann - Whitney U Test (and Kruskal-Wallis Test in the case of three categories) (Field, 2009). But, the students' responses for the item 'preparatory mathematics is useful in what I plan to learn in the future' had different distributions across the two streams. The results obtained from SPSS using the Mann-Whitney U test suggests that the null hypothesis that this characterization is the same across categories of stream should be rejected because its significance value is less than the significance level, 0.05. Similarly, the item "Preparatory mathematics is important because it helps me make decisions" does not have the same distribution across grade levels. 11th grade students held more strongly. There seem to be other variables such as economic benefit than mathematics which influence their decisions, because of students' economic backgrounds and the absence of appropriate information. Moreover, the 12th grade students need to make decisions about their future studies sooner, as they have to choose the fields of study before they are enrolled into the university. The distributions of these characterizations are the same across the other categories. The mandatory use of a single textbook together with the teacher's guide at each grade level, might make students' prior experiences with respect to schooling and mathematics classroom more or less the same. The natural science and social science students use the same mathematics textbook, which is prepared by experts and taught by teachers who have natural science backgrounds. Although there are subjects and few chapters in mathematics which are different for the two streams, the students' experiences in mathematics is more or less uniform. On the other hand, there are distinct differences in students' fields of study when they join the university based on their streams. This could be a possible reason for the difference in distribution of perception across the two streams about the relevance of mathematics to their future plan of study.

The situation of female and male students in schools is changing overtime. Over the past four decades there have been affirmative actions towards increasing the number of females in learning institutions and workplaces to compensate for the historical situation that disadvantaged the female. The number of female and male students in the preparatory school is balanced. The gender gap is becoming narrow, through years, in universities as well as workplaces. The number of female mathematics teachers is now increasing. A year before the data was collected the school principal was a women. During the data collection one of the two deputy school principals was a woman. These situations might have a part in creating a balanced sociocultural context for both sexes. The levels of achievements also had uniform distributions of perceptions, probably because of the high competition to join the preparatory school and very high success rate to join the university. These students were screened by a national examination and are considered as elites of their age group. The number of public and private higher learning institutions and intake rate is increasing. This being an important success indicator for the government, it highly publicizes it on the limited number of media the country has. This data was collected about four months ahead of the national and regional elections in the country, and these were major campaign instruments for the ruling party. The students get such information both in and outside the school. They are hopeful of joining the university.

CONCLUSION

For these students mathematics has exchange value, which transcends beyond the success in joining the university. The students perceive that mathematics is useful in their intended future field of study. The absence of clear idea about their future studies and what it requires in relation to mathematics on the one hand and the lack of information about why they are learning mathematics on the other, seems to lead the students to make their own speculations or accept that it is useful based on trust. Their trust for the curriculum seems to be affected by the lack of information as well as their regards for the teacher. Besides, for most of the students the sources of information about the future use of mathematics are their teachers. This has implications for the curriculum and/or textbook preparation as well as the teachers' role in designing the school curriculum of mathematics classrooms in Ethiopia. Though direct application problems to the students' future plan of study may be difficult to provide, it is important to inspire them by providing the rationales for their learning of the concepts (cf. Wæge, 2007). The necessary familiarization to their future fields of study with respect to mathematics needs to be done at the preparatory level. The mathematics teachers can be instrumental in enhancing the students' motivations by boosting their perceptions. Students' emotion, Identity and motivation are intertwined to each other. The former two influence one another and affect the later (cf. Roth, 2007). Popularizing mathematics, particularly, with respect to social science students needs attention. Understanding how students motivate themselves in order to engage themselves in the learning of mathematics is

important. The characterizations of perceptions of relevance of mathematics have motivational effect on students engaging in mathematics. Future studies need to investigate the strengths of these characterizations as motivational factor for students.

MATHEMATICS CONFIDENCE: REFLECTIONS ON PROBLEM-SOLVING EXPERIENCES

Divan Jagals and Marthie van der Walt
North-West University, Potchefstroom – South Africa

The purpose of this paper is to present the findings of a qualitative inquiry into Grade 8 and 9 learners' mathematics confidence. Learners reflect on experiences with mathematics that have influenced their levels of confidence in the social, psychological and intellectual domains. A convenient purposive sample of four participants, individually interviewed with reflective questioning, provides insight into their reflective accounts on experiences with mathematics problem solving. Through content analysis, the researchers' findings confirm the dimensionality of mathematics confidence and present sources of participants' mathematics confidence.

Keywords: *Mathematics, mathematics confidence, reflection, metacognition, anxiety*

INTRODUCTION

Maree et al. (1997, p.95) classifies problems in study orientation as cognitive, external, internal and intrapsychological causes influencing achievement in mathematics. Sherman and Wither (2003, p.138) documented a case where a psychological factor, mathematics anxiety, caused an impairment of Grade 8 learners' mathematics achievement. There is a scarcity on literature focusing on metacognitive aspects and its link with affect in mathematics learning and teaching (Efklides, 2006, p.6). However, aspects of affect, such as values, beliefs and motivation do not primarily form part of this paper, although these aspects are considered in the larger study. Instead the focus is on mathematics confidence and the metacognitive reflections learners have on problem-solving experiences.

The findings of Bormotova (2010) confirm this link between metacognitive reflection and mathematics confidence. The current paper explores the nature of four Grade 8 and 9 learners' mathematics confidence by focusing on their reflections on experiences with mathematics problem solving.

In mathematics, an affect such as anxiety causes personal distrust of intuition and a consequent lack of effort, which are seen as learners' greatest barrier to achievement (Aschraf & Kirk, 2002, p.2; Thijsse, 2002, p.18). John (2009) proposes a model for metacognitive reflective practice and explains this as looking into one's own thoughts and feelings as a guide and aid to problem solving. According to John (2009), reflective practice consists of two phases. The first, where the learner recalls problem solving experiences, identifying the goals and achievements as reflected upon. Through such reflection, learners begin to understand their use of approaches towards mathematics problem solving. In the second phase they describe accompanying feelings and emotions that surrounds their memories and selected strategies. A deeper

form of reflective account is established once the learner recognises how he or she feels, what they did and why. These emotions are metacognitively collective and could lead the learner along either of two different paths (Bormotova, 2010, p.29). The first gives rise to faulty beliefs that cause apprehensive thoughts about mathematics and threaten performance, thus interfering with the learner's thinking, memory processing and reasoning. Along the other road, confident learners may experience symptoms that are opposite to mathematics anxiety (Strawderman, 2010; Sheffield & Hunt, 2007, p.2). These include feelings of relief, fun, enjoyment and support, which aid with the solving of mathematical problems in a wide variety of contexts. Metacognitive reflection could ease mathematics anxiety, foster confidence and promote achievement in mathematics.

Some conscious and unconscious social, cognitive and personal evaluation practices are explored. The sources for low and high forms of mathematics confidence are scrutinised and contextualised.

CONCEPTUAL FRAMEWORK

Experiences with mathematics problem solving are either successes or failures and are accompanied by feelings of high or low confidence. Three integrated components feature in Strawderman's model for mathematics anxiety. In her study she adapted the model to include the opposite affect – mathematics confidence – in the social, intellectual and psychological domains (Strawderman, 2010, p.1). A natural overlap occurs between the boundaries where these domains coincide and our current study reflects upon these overlaps as portrayed in the conceptual framework. The discussion that follows provides insight into the theoretical influences in each domain. Metacognitive reflection, in this study, was seen as summative cognitive processes and involves thinking, examining, differentiating, detaching and serves as a self-exploratory action (Kaune, 2006, p.350) and regards social, psychological and intellectual aspects of experiences with problem solving.

Social influences

Bergh and Theron (2009, p.86) explain the social domain in terms of Bronfenbrenner's model for ecological systems. The environment includes four levels where human influences develop. The first is a macro system, consisting of persons and organisations with the most frequent contact with the individual. A second is the meso system, consisting of interactions with groups such as schools. The exo system involves aspects outside immediate contacts, such as hospitals, social groups, chat rooms and clubs. The fourth system involves the micro system. This includes habits, socio-economic and political influences. The social domain represents external factors outside of the individual's control, which are contributed by persons such as family, peers and teachers (Strawderman, 2010, p.2).

Psychological influences

Reinforcement, from the psychological behaviourist view, has a positive or negative motivational effect on individuals and the outcomes of their actions (Bergh & Theron, 2009, p.156). Rewarding the correct action, approach or behaviour and punishing the incorrect has completely diverse consequences. Positive motivation involves setting goals and helping problem solvers to achieve those goals, which leads to the successful handling of more tasks that are complex. However, negative motivation can cause undesirable effects such as hostile behaviour and avoidance of certain tasks. It may also suggest alternative ways of doing the same wrong thing differently and instigate fear, which reduces the willingness to continue with a task. Hattie (2009), however, has found low correlations between motivation and achievement. The psychological region linked to internal processes involves the individual's behaviour and varies between becoming involved in and avoiding mathematics problem solving situations. The psychological domain extends further, relating affective factors – emotional history, familiar experiences and stimulus reactions associated with the individual's feelings of confidence, anxiety or discomfort, and pleasurable experiences. This includes skills and knowledge of the problem-solving procedures and strategies selected. Personal performance measured in this domain associates with the region of personal achievement and the perception thereof.

Intellectual influences

The intellectual domain entails cognitive influences. Reflecting on success or failure, the individual evaluates the appropriateness, acquirement and use of mathematics skills and concepts learnt, and consider aspects of their higher-order reasoning and reflective questioning. Guilford's structural model of intellect (Bergh & Theron, 2009, p.149) reviews the intellectual domain as a combination of various aspects involving visual, auditory, symbolic, semantic and behavioural constructs. The operations involved with these aspects appear mainly to be cognitive (memory, divergent production, convergent production) and metacognitive (evaluation and monitoring) in nature. The product of these operations is found to influence group settings, relationships, social systems, transformation of knowledge and it has implications for problem solving.

The three domains have individual characteristics as well as a natural overflow between their components; due to the cause and effect that one component has on another. In the social domain, family members, friends (peers) and society influence the values, beliefs and views the learner might develop. The result is a motivated or demotivated individual with positive or negative emotions. The engaging or avoiding of mathematics tasks and the intellectual components involved, either allows the individual to succeed or fail in his/her use of strategies or approaches.

Combining the components of social, psychological and intellectual domains, lead to an affective product in mathematics problem solving, namely mathematics

confidence. This overflow and connection of the three domains can be observed in the theoretical framework illustrated below.

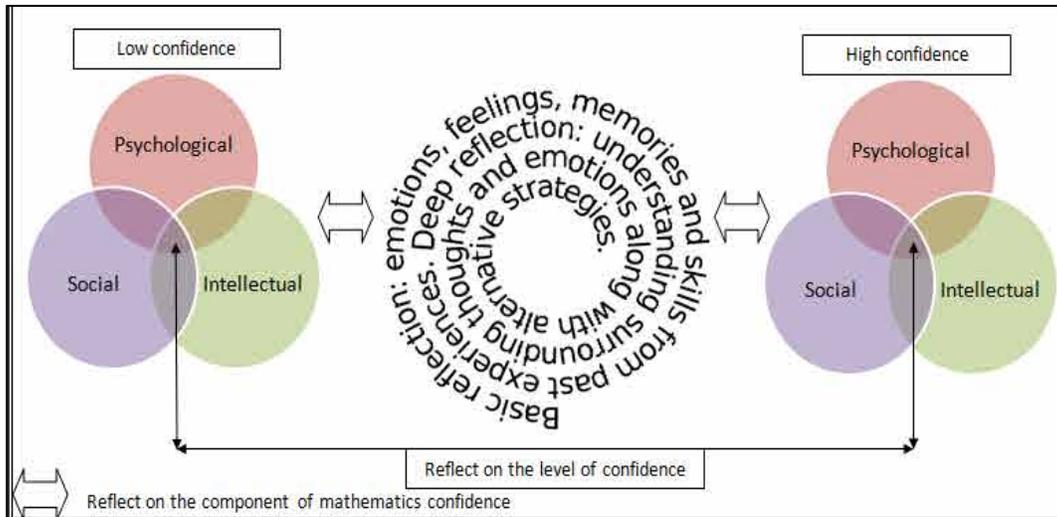

Figure 1 Conceptual framework for reflection on mathematics confidence domains
Source: Adapted from Strawderman (2010) and John (2009)

The primary research question this study seeks to answer is: what does learners' mathematics confidence entail when reflecting on mathematics problem solving experiences? To answer this question, the following methodology was employed.

METHOD

Three invited schools from the North West province in South Africa took part in the current study. This paper focuses on one aspect of this study, namely learners' confidence emanating from experiences with mathematics problem solving. As part of this qualitative, interpretive research design, data was gathered by interviewing four participants from the invited schools. According to their teachers, the purposively selected participants could express themselves verbally and would not be shy to share information about themselves. As arranged with appropriate authorities, the interviews were conducted in one of the classrooms at the participants' respective schools. The participants included three girls and one boy. Some biographical information of the participants is summarised in Table 1.

Table 1 Biographical information of participants

Participant	Age	Grade	Average achievement in 2010
Learner A	15	9	70%
Learner B	15	8	80%
Learner C	14	8	76%
Learner D	13	9	96%

Insight into their experiences with problem solving allowed the researchers to explore the sources and constructs of mathematics confidence. Interview questions, taken from the work of Wilson and Clarke (2004), Bormotova (2010) and Swanson (2006) included questions such as: Are you good at solving mathematical problems? How do you feel when solving problems in the classroom? Do your parents help or advice

you in problem solving? The questions promoted participants' thinking about experiences with problem solving and determined their perceptions about whether the sources contributed to their psychological state before, during and after such as experiences. The verbatim transcribed responses, analysed and coded, supported the themes identified by Strawderman (2010).

A-priori categories were determined in the theoretical framework and included the themes of the three domains: social, psychological and intellectual. The study involved an interpretive natural approach (Bormotova, 2010, p.73) towards an understanding of the research topic. Through content analysis, responses were categorised according to low and high traits in the three dimensions of mathematics confidence.

The results that are discussed in the next section point out that mathematics confidence has at least some roots in mathematics tuition during the primary school years – the effect of such tuition therefore has implications for senior phase mathematics problem solving.

RESULTS

Through reflection on past and more recent occurrences, participants 'made connections' with their feelings regarding mathematics problem solving. They identified the commencement of their confidence in the problem solving and developed an understanding and awareness of its foundations and variations. When asked when they first noticed a change in their mathematics confidence, all participants reflected on experiences in Grades 5 and 6. Their reflections on mathematics confidence could be traced back to incidents that had occurred between the ages of ten and fourteen years. Reflective responses included low and high confidence regarding social, psychological and intellectual aspects of mathematics problem solving.

Reflections on social aspects

Social interaction related to the context within and around mathematics problem solving. Participants compared their self-reflective knowledge with that of their peers. The social structure of the classroom, the arrangement of desks and teaching practices influenced the confidence of learners as social aspects.

The contributions of peers and family members were of a contrasting nature. According to the participants, parents who motivate and support their children and assist with homework do not always help to improve the latter's maths understanding.

Parental influences seemed to be minimal as one participant appeared to believe:

Learner C: I didn't enjoy the work, even if my parents explained it to me.

Comparing themselves with peers, participants fused beliefs and views about their own capabilities. One participant stated a personal disliking of this quality:

Learner B: I don't like to compete against someone.

This self-reflective knowledge promotes low and high confidence in problem solving. It is noteworthy that one participant in this study completely disagreed with the statements made by his peers and confidently said:

Learner D: I was like one with the group. Most kids would say that I don't like it and it's boring. Other people are still doing it, but not me. They don't have the passion, so they think, why should I do it? This year everybody tells us, our marks will drop because its high school...

Teachers' role in the social domain is evident:

Learner A: Most of them taught me something that wasn't maths...my math teacher was a real down-to-earth person that I could relate to.

Reflections on psychological aspects

Psychological traits of the learners' behaviour included a variation of feelings and emotions. Key aspects of the psychological state of participants' mathematics confidence included emotions and preferences with regard to likes and dislikes. Reflections on experiences integrated positive and negative emotions, feelings and associated thoughts, and an understanding of those sentiments. Participants disliked word problems the most. When asked what they liked and disliked about mathematics problem solving, three of the four participants indicated that their past and current teachers' teaching approaches and methodology contributed to their like or dislike of mathematics. Some of their reflections on the instruction methods included the following:

Learner A: Some say what you must do, they just give you the facts. Others make it practical.

Learner B: I liked the teacher but not the way he did it.

Participants seemed to understand, from experience, the characteristics of mathematics anxiety. It appears that their view on mathematics confidence revolves around their self-belief, pride and being scared of mathematics or failing the subject. One participant mentioned a high-confidence trait when comparing problem solving tasks in mathematics with tasks such as tests in other subjects:

Learner D: I just don't feel stressed like in other subjects. Maths is just there, it comes natural. I don't feel stressed. I feel excited to see what questions to expect. Anxious to see what's happening in the test [task].

Participants mentioned various teaching factors that they had experienced and to which they attributed their achievement in and understanding of mathematics during problem solving. One participant claimed:

Learner A: I couldn't understand, she [teacher] jumped around using different methods

Reflections on intellectual aspects

When asked what learners thought would make problem solving difficult or easy, all four participants responded with some regard to metacognitive components. Participants reasoned why they did not avoid mathematics:

Learner A: Even if you get it wrong, you still try to get it right. I just keep trying over and over again.

Learner B: I think it will boost my marks and I will become a better person.

A metacognitive trademark source of confidence was noted:

Learner A: When I know I can do it in another way, it's easy. When I know there's another way to solve the problem, I know I understand it.

Reviewing the steps used in problem solving contributed to the learners' selection and employing of strategies:

Learner C: I go through my work, wondering what I did wrong.

Avoiding mathematics was also an issue, as Learner C remarked:

Learner C: My body just gets into sleep mode. When the bell rings, I'm all energetic again.

It appears from the statement of at least one participant that dislike (psychological) and understanding (intellectual) of mathematics problem solving is related:

Learner D: Word problems are just something I don't like. I don't like it, because I don't understand it.

It is noteworthy that Learner D, in particular, seems to experience both low and high levels of confidence depending on the psychological and intellectual sources.

DISCUSSION

The findings suggest that it is possible that metacognitive reflection may regulate mathematics confidence in the social, psychological and intellectual domains. According to their reflections, participants recalled not only low confidence connected to unsuccessful experiences with problem solving, but also moments when their confidence was high and performance successful. The following discussion focuses on Strawderman's (2010) three domains of mathematics confidence.

Social aspects of mathematics confidence

Learners' attitude towards the subject can either be positive or negative (Maree et al., 1997) with strong correlations to achievement throughout the senior and further education phase (Grades 7-12) (Hannula, Maijala & Pekkonen, 2004, p.18). A number of other researchers (Ernest, 2002; Bormotova, 2010; Strawderman, 2010) confirm social aspects as a psychological factor empowering mathematical problem solving. It therefore seems that the academic environment must be of such a nature that it allows learners to learn how to learn.

Learners face and have to cope with the social context at school. According to McFarland (2011, p.3), learners in the senior phase experience changes associated with puberty, and have to make social and psychological adjustments in their everyday lives. Stankov, Lee, Luo and Hogan (2012) argue that social attributes include values and attitudes originating from society, and in particular from peers, parents and teachers. McFarland (2011, p.4) explains that adolescents focus on their

peers and are greatly concerned about social acceptance. The findings of the current study seem to agree. The effect that peers might have on an individual's mathematics confidence involves a comparing of attitudes towards mathematics problem solving in particular.

Psychological aspects of mathematics confidence

Experiences involving Grade 5 and 6 learners indicate that, for these participants, mathematics confidence seems to start to change at around age ten or eleven, having its foundations in primary school years. Learners' dislike of teachers' approaches (Thijsse, 2002) towards problem solving and their preference for participating in group activities attest to the constructive role that reflection on mathematics confidence plays in respect of achievement in problem solving. Bormotova (2010, p.32) found that positive feelings and emotions enhance the learning process. These feelings keep the learner focused on the task and inspire new learning. Malmovuori (2006) found a connection, in terms of positive experiences, between regulating skills and strategies, and participants' enjoyment of mathematics problem solving.

Intellectual aspects of mathematics confidence

The knowledge and skills of problem solving strategies, as well as content knowledge, is vital in order to perform in mathematics. Participants reflected on their successes and failures with problem solving, and identified the level of difficulty or ease of using approaches learned and taught. Varying between complex and diverse components (Legg & Locker, 2009, p.471), learners reflected on the approaches used during problem solving and the experiences that contributed to their selection and use of strategies and knowledge. Typical traits (Learner C) displayed by learners with low mathematics confidence included avoidance of problem solving or metacognitive components such as evaluating and monitoring. Reflecting on metacognitive and mathematics skills occurred on a subconscious level. This regulative skill (Garrett, Mazzocco & Baker, 2006) differs between individuals. Strategies selected are acquired from knowledge of experiences in similar contexts, as suggested by Pantziara and Philippou (2011).

RECOMMENDATIONS

Several aspects of mathematics confidence and reflection require further investigation. These aspects include possible affective and metacognitive connections to mathematics problem solving. The following might serve as potential considerations for both researchers and teachers involved in mathematics education.

For researchers

The assessment of reflection on affect in mathematics – by using explorative and convergent mixed methods – may confirm and increase literature on the traits of the origins of mathematics confidence. It is suggested that the development of assessment methods to measure mathematics confidence might include social, psychological and intellectual factors. According to Bormotova (2010), journal-writing experiences as self-reflective reports may serve as a basis for reflection and could provide a narrative of the participants' mathematics confidence. Cultural and

socio-economic differences could also be explored to determine the possible relationships between environmental backgrounds and their relation to mathematics confidence and reflection.

For teachers

Learners who experience low mathematics confidence or anxiety may build confidence in the presence of a supporting teacher (Thijsse, 2002, p.25). Symptomatic descriptions and identification of participants' mathematics confidence, especially during primary school years (Hannula, Maijala & Pekkonen, 2004), could alter the foundational challenges that learners experience with mathematics and possibly improve their attitude towards the subject. The use of standardised tests can assist with the measuring of learners' confidence in mathematics, identify and diagnose causes and resources to reduce the level of anxiety, and increase confidence. This, in turn, could guide the planning and implementation of relevant interventions. Curriculum development could perhaps cater for the social, psychological and intellectual needs of learners and aim to nurture ambition for mathematics, mathematics problem solving and math teaching.

CONCLUSION

Some of the most noticeable social sources include teachers' approaches to the teaching of problem solving strategies and learners' self-comparison with peers. Psychological aspects include feelings of stress when the learner does not understand the problem or what approach to use. A feeling of excitement is expected when maths comes *naturally*. As learner B mentioned, the social and psychological domains are connected with liking the teacher, but disliking the approach. Intellectual sources for learners' confidence appear to include persistence and an understanding and use of multiple strategies.

The results of this study indicate that confidence in mathematics has certain implications for the individual, and that the social, psychological and intellectual success of the community as a whole has its roots in diverse experiences with mathematics.

WHAT TEACHERS WANT OUT OF PROFESSIONAL LEARNING OPPORTUNITIES: A TAXONOMY

Peter Liljedahl

Simon Fraser University, Canada

Teachers do not come to professional learning opportunities as blank slates. Instead, they come to these settings with a complex collection of professional learning goals. The research presented here takes a closer look at these goals across five different professional learning settings. The results indicate there exists a taxonomy of five categories of goals that teachers may approach professional learning with.

keywords: professional development, teacher goals, taxonomy

INTRODUCTION

Current research on mathematics teachers and the professional development of mathematics teachers can be sorted into three main categories¹: content, method, and effectiveness. The first of these categories, *content*, is meant to capture all research pertaining to teachers' knowledge and beliefs including teachers' mathematical content knowledge, both as a discipline (Ball, 2002; Davis & Simmt, 2006) and as a practice (Hill, Ball, & Schilling, 2008). Recently, this research has been dominated by a focus on the mathematical knowledge teachers need for teaching (Davis & Simmt, 2006; Hill, Rowan, & Ball, 2005) and how this knowledge is developed within preservice and inservice teachers. Also included in this category is research on teachers' beliefs about mathematics and the teaching and learning of mathematics and the ways in which these beliefs change within the preservice and inservice setting (Liljedahl, 2010a). Some of the conclusions from this research speaks to the observed discontinuities between teachers' knowledge/beliefs and their practice (Skott, 2001; Wilson & Cooney, 2002) and, as a result, calls into question the robustness and authenticity of these knowledge/beliefs (Lerman & Zehetmeir, 2008).

The second category, *method*, is meant to capture the research that focuses on a specific professional development model such as action research (Jasper & Taube, 2004), lesson study (Stigler & Hiebert, 1999), communities of practice (Wenger, 1998), or more generally, collegial discourse about teaching (Lord, 1994). This research is "replete with the use of the term inquiry" (Kazemi, 2008, pg. 213) and speaks very strongly of inquiry as one of the central contributors to teachers' professional growth. Also prominent in this research is the centrality of collaboration and collegiality in the professional development of teachers and has even led some researchers to conclude that reform is built by relationships (Middleton, Sawada, Judson, Bloom, & Turley, 2002).

¹ These categories, although presented separately, are not entirely distinct from each other.

More accurately, reform emerges from relationships. No matter from which discipline your partners hail, no matter what financial or human resources are available, no matter what idiosyncratic barriers your project might face, it is the establishment of a structure of distributed competence, mutual respect, common activities (including deliverables), and personal commitment that puts the process of reform in the hands of the reformers and allows for the identification of transportable elements that can be brokered across partners, sites, and conditions. (ibid., p. 429).

Finally, work classified under *effectiveness* is meant to capture research that looks at changes in teachers practice as a result of their participation in some form of a professional development program. Ever present in such research, explicitly or implicitly, is the question of the robustness of any such changes (Lerman & Zehetmeir, 2008).

As powerful and effective as this aforementioned research is, however, it can no longer ignore the growing disquiet that somehow the perspective is all wrong. In fact, it is from this very research that this disquiet emerges. For example, the questions of robustness (Lerman & Zehetmeir, 2008) come from a realization that professional growth is a long term endeavour (Sztajn, 2003) and participation in preservice and inservice programs is brief in comparison. At the same time there is a growing realization that what is actually offered within these programs is often based on facilitators (or administrators or policy makers) perceptions of what teachers need as opposed to actual knowledge of what teachers really want (Ball, 2002). But not much is known about what teachers really want as they approach professional learning opportunities. The research presented here provides some answers in this regard.

METHODOLOGY

As articulated in Liljedahl (2010b), working in a professional development setting I find it difficult to be both a researcher and a facilitator of learning at the same time. As such, I generally adopt a stance of noticing. This stance allows me to focus on the priorities of facilitating learning while at the same time allowing myself to be attuned to various phenomena that occur within the setting. It was through this methodology that I began to notice that there was a distinct difference between the groups of teachers that came willingly to the professional development opportunities that I was leading and the teachers that were required, often by their administrators, to attend. This was an obvious observation. Nonetheless, it was as a result of this observation that, I began to attend more specifically to other differences. In doing so I began to notice, subtly at first, that the teachers who came willingly came with an a priori set of goals. With this less obvious observation I changed my methods from noticing to more directive research methods. I began to gather data from five different professional learning contexts over a period of two years.

Master's Programs

Teachers in this context are practicing secondary school mathematics teachers who were doing their Master's Degree in Secondary Mathematics Teaching. This is a two year program culminating in either a comprehensive examination or a thesis depending on the desires of the teacher and the nature of the degree that they are seeking. From this group I collected interview data and field notes during two different courses I taught in the program.

Induction Group

This group began as an initiative to support early career teachers (elementary and secondary) as they make the transition from pre-service teachers to in-service teachers. In truth, however, it also attracted more established teachers making it a vertically integrated community of practicing teachers of mathematics. Although this group now meets every second month for the duration of the study we met monthly. From this group I collected interview data, field notes, as well as two years of survey data.

Hillside Middle School

Hillside (pseudonym) is the site of a longitudinal study. For the last five years I have meet with a team of three to six middle school teachers every second Wednesday for an hour prior to the start of the school day. This group began as an administration led focus on assessment of numeracy skills, but after the first year took on a self-directed tone. The teachers in this group lead the focus of the sessions and look to me to provide resources, advice, and anecdotal accounts of how I have seen things work in the many other classrooms I spend time in. For the two year period that constitutes the study presented here I collected field notes and interview data.

District Learning Teams

Very much like the professional learning setting at Hillside, district based learning teams are self-directed. Teachers meet over the course of a year to discuss their classroom based inquiries into teaching. This inquiry runs throughout an entire school year, but the teams themselves only meet four to six times a year. The data for this study comes from three such teams that I facilitated in two different school districts. One of these teams ran during the first year of the study, the other two teams ran in the second year of the study. Like at Hillside my primary role is to provide resources, advice, and insights into their plans and reported classroom outcomes. The data from these teams consisted of field notes, interviews, and survey results.

Workshops

During the two years that I collected data for this study I was also asked to do a number of one-shot workshops. These were workshops designed around a variety of different topics either decided by myself or the people asking me to deliver the

workshop. They ranged in time from 1.5 hours to 6 hours with no follow-up sessions. Data, consisting of field notes, comes from six such workshops. Data from two additional workshops consists of field notes and survey results.

Data

Field notes in the aforementioned settings consisted primarily of records of conversations I had with individual teachers during breaks as well as before and after the scheduled sessions. I used these times to probe more specifically about the origins of questions asked, motivations for attending, querying about what they are getting out of the session, and if there is something else they need or want. This sound very formal and intentional, but in reality, this was all part of natural interactions. In all, I collected notes on over 70 such conversations.

More directed than these natural conversations were the interviews. These were much more formal in nature and provided an opportunity for me to probe further about the conversations we had previously had or the things I had observed during our sessions together. Each interview lasted between 30 and 60 minutes. In all, 36 interviews were conducted over the course of the two years, resulting in 26 hours of audio recordings. These recording were listened to as soon as possible after the interviews and relevant aspects of the recording were flagged for transcription.

The survey used with the Induction Group, The District Learning Teams, and two of the Workshops consisted of an online survey instrument that was sent to the teachers prior to professional learning session. The survey contained five questions, the last two of these were of obvious relevance to the study.

4. *What do you hope to get out of our next session together? You can ask for understanding of mathematical concepts, teaching strategies, resources, lesson ideas, ideas about classroom management, networking opportunities, specific lesson plans, etc. In essence, you can ask for anything that will help you in your teaching or future teaching. List as many as you want but please be specific.*
5. *Please list something from a past session that you found particularly useful.*

The field notes, interview transcripts, and survey data were coded and analysed using the principles of analytic induction (Patton, 2002). "[A]nalytic induction, in contrast to grounded theory, begins with an analyst's deduced propositions or theory-derived hypotheses and is a procedure for verifying theories and propositions based on qualitative data" (Taylor and Bogdan, 1984, p. 127 cited in Patton, 2002, p. 454). In this case, the a priori proposition was that teachers come to professional learning settings with their own goals in mind and that these goals are accessible through the methods described above. With a focus on teachers' goals the data was coded using a constant comparative method. One of the things that emerged out of this analysis was a taxonomy of five types of goals that teachers come to professional learning settings with. To these I add a sixth theme which also emerged out of the analysis. Although

not a goal per se this sixth theme deals with the resistance with which some teachers engaged in some of the professional developing opportunities.

RESULTS

In what follows I present each of these categories in turn, beginning with resistance and following it up with each of the five categories of goals.

Resistance

In the course of the two years of the study I collected data on a number of teachers who were flatly opposed to being part of the professional development setting I was working in. All of this data consisted of observation and conversations and came solely from the workshops and learning team settings. To a person, these teachers were participating in these settings at the request of an administrator or a department head. Left up to them, these teachers would choose to not attend.

First, these resistant teachers were present and they did participate in the sessions. They engaged in the activities, they asked questions, and they collaborated with others in the room. But this participation was guided by their reluctance at being there. As such, their contribution to the group was often negative, pessimistic, defensive, or challenging in nature. They would say things like "that will never work" and "I already do that". This is not to say that these teachers were the only ones to utter these types of statement, but rather that they only uttered these types of statements. Their questions to me were always challenging in nature with greater demands for evidence, justification, and pragmatism. These challenges were welcomed as they often provided others with an opportunity to engage in the content more critically. The call for pragmatism, in particular, was not unique to resistant teachers, but the goals for making that call were clearly different. When they challenged ideas based on their infeasibility the goal seemed to be to detract from the value of what was being offered; to invalidate it. When non-resistant teachers made the same call it seemed to be motivated by a goal to try to navigate the space between the ideal and the feasible; to find a way to make it happen.

The second reason I include this theme is that these teachers did not always remain resistant. There were several cases in my data where teachers who initially approached the setting with resistance softened their stance over time. In the workshop settings this was marked by a shift in the types and ways in which they asked questions, the ways in which they engaged in activities and interacted with their peers, and in the parting comments and conversations I recorded. In the learning team settings this was marked by the fact that between meetings, these initially resistant teachers, reported back at subsequent sessions about efforts made, and results seen, in their own classrooms.

The third reason for including this theme here is because I want to differentiate between the resistance a teacher may have to an idea in a professional learning

setting and the a priori resistance a teacher may approach that setting with. In the former case I am talking about a healthy form of scepticism that, as mentioned, allows teachers to negotiate the space between the ideal and the real, between the theoretical and the practical. The later, however, is a stance that can prevent the uptake of good ideas and helpful suggestions. It can act as a barrier to learning and professional growth.

In all, out of the 70 conversations that I made notes on, 10 were with teachers who were, at least originally, resistant to being in the setting. Of these, four changed their stance over the course of the setting. However, my field notes record observations of many more such a priori resistant teachers as well as observed changes in some of them.

Do Not Disturb

This category of goals characterizes those instances where a teacher engages in professional learning because they want to improve their practice, but is reluctant to adopt anything that will require too much change. Ideally, what they want are small self-contained strategies, lessons, activities, or resources that they can either use as a replacement of something they already cleanly insert into their teaching without affecting other aspects of their practice. Such goals were rarely stated outright. Instead, they manifest themselves as overly specific statements of what it is they seek.

"I was hoping to learn a new way to introduce integers".

"I want something to do for the first 10 minutes of class."

"A different way to do review."

All of these are indicative of situations where the teacher is looking to improve one thing about their teaching. The "don't let it affect anything else around it" is implicit in the specificity of the statement. In conversations or in interviews, however, this can sometimes come out more explicitly.

"I'm happy with the rest of my fractions unit. It's just division of fractions that messes me up. I was hoping that you could show me a better way to explain it."

Delving deeper it became clear that in many of the instances where concern over disturbance and tight control over impact was important there was an underlying anxiety, most often around the deconstructing what they have worked hard to build up.

"I've been teaching for seven years now, and I'm really happy with the way things are going. After the last curriculum revision and with us getting a new textbook I have worked really hard to organize all of my lessons and worksheets in math. I don't want to mess with that. So, please don't tell me anything that is going to mess me up. I really just want to know if there is a lesson that I can do using computers that will be fun and that I can just sort of insert into my area unit."

Less often this anxiety is around what they have worked hard to understand.

"When I started teaching I was fine with math. But when I was given a grade seven class this year I sort of panicked about math. Especially the unit on integers. I had never understood it when I was in school and it took me a long time to teach it to myself. So, I don't really want to learn anything new that will rock the boat for me."

In other instances there didn't seem to be an underlying anxiety, but just a pragmatic disposition that small change is good "less is more".

Willing to Reorganize

A slight nuance on the previous theme is when teachers want very specific improvements and they are willing to significantly reorganize their teaching and resources to accommodate the necessary changes. Although specific in nature, these goals do not come with limitations. They are stated with an implicit openness to the consequences that the desired improvements may necessitate.

"So, yeah. I'm looking for an improved way to have my students learn how to do problem solving. Right now I do it as a unit in February, but it's not working. I've heard that other teachers do it throughout the whole year and I'm hoping to get some ideas around that."

Further probing of this teacher, as well as the others who made similar statements, revealed that they are not hampered by anxiety around invalidating existing resources or undoing things learned.

Willing to Rethink

Unlike the previous two categories, the goals that fit into this are much broader in scope and often welcome a complete rethinking of significant portions of a teaching practice.

"I'm pretty open to anything. I mean with respect to differentiated learning."

From the interviews it became clear that for this teacher, as well as for those who expressed similar goals, there exists something in their practice that they want to bolster. In many cases these teachers want collections of resources that they could then organize and integrate into their teaching.

"Anything to do with numeracy is good for me."

"I'm looking for new ideas about assessment for differentiated learners."

In some cases, however, these teachers are branching out into new territories and are looking for a comprehensive package of what to do.

"I'm hoping to introduce the use of rubrics into my teaching and want to get the rubrics I should use as well as instruction how to do it."

Either way, these teachers have a rough idea of what it is they want and are willing to rethink their teaching in order to accommodate new ideas. They do not have the

anxieties of disrupting already held knowledge or resources that the teachers in the first category did and their goals are broader in scope than the second.

Out With the Old

The goals in the previous category were characterized by a willingness to rethink significant aspects of teaching practice. In the Out With the Old category, the goals are characterized by a rejection of a significant aspects of teaching practice. Teachers with these goals come to professional learning settings unhappy with something in their practice. This unhappiness goes well beyond the awareness that something needs to be improved that was seen in the previous three categories. For these teachers there is nothing to be integrated, there isn't a replacement of some aspect of their teaching to be made. They have already rejected the current paradigm and are now looking for something to fill the void that is left behind.

"My kids can't think for themselves in problem solving. I don't know what I'm doing wrong, but it doesn't matter. I just need to start over with a new plan."

"I can't stand the way group work has been working in my classroom. Or not working is a better description. I have given up with what I've been doing and am looking to learn something completely different."

This is not to say that these goals are coupled with blind acceptance of anything that fits the bill. The teachers who express these goals are often hypercritical of new ideas, usually as a result of their dissatisfaction with something that they have previously changed in their practice.

"I spent a whole year trying to teach and assess each of the processes [communication, connections, mental mathematics and estimation, problem solving, reasoning, technology, and visualization] that are in the curriculum. In the end my students are no better at estimating or communicating, for example, than they were at the beginning of the year. My approach didn't work. I need a new way to think about this."

This is not to say that they are closed minded, but rather that they exert a greater demand on me, as the facilitator, to bridge the theoretical with the pragmatic.

Inquiry

The final category consists of those goals which align with the ideas and ideals of inquiry (Kazemi, 2008). As such, these goals consist, most often, of a general desire to acquire new knowledge and ideas about teaching. The teachers who express these goals are open to any new ideas and often come to professional learning settings without an agenda.

"I'm not really looking for anything in particular. But, I'm eager to hear about some new ideas on assessment."

This is not to say that these goals are flighty and unrefined. The teachers whose goals fall into this category are often methodical in their change, pausing to ask exactly

"what is it I am doing" and "if it's working". And if it is working they question "what is it that is telling me it is working". They want evidence of success, but they want it to come from their own classroom.

CONCLUSIONS

Much can be taken from the results presented above. The most obvious is that teachers who willingly come to professional learning settings do so with one of five possible goals. Further analysis reveals that these goals have some pseudo-hierarchical properties and that they reveal a discordance with the long held belief that single workshops are an ineffective means of creating professional growth (Ball, 2002). Finally, the results indicate that, in essence, teachers treat professional learning settings, and the people that facilitate such settings, as resources for the furtherment of their own professional learning goals.

USING CONTENT ANALYSIS TO INVESTIGATE STUDENT TEACHERS' BELIEFS ABOUT PUPILS

Reidar Mosvold, Janne Fauskanger, Raymond Bjuland & Arne Jakobsen

University of Stavanger

Student teachers' beliefs about teaching are arguably important to their learning and development as teachers. One aspect of these beliefs is that of a focus on the learners. In the study presented in this paper, we use two approaches to content analysis in order to learn more about student teachers' beliefs from transcripts of focus-group discussions. The analyses reveal that the student teachers focus less on the mathematical content and more on characteristics of pupils in their discussions. These characteristics were mainly related to the pupils' behaviour, their cultural background or their certain needs.

Keywords: student teachers' beliefs, learner orientation, content analysis

INTRODUCTION

Teacher education is important in many respects, among others to equip all teachers for effective teaching in the 21st century (OECD, 2011). Throughout their development—from student teachers to experienced teachers—they are faced with different challenges. Richardson and Placier (2001) conclude that novice teachers focus more on surviving in the classroom than on pupils' learning, and additional research is needed in order to learn more about how teacher education can contribute to a shift in focus in this respect.

There are several interesting issues to focus on in a study of student teachers' development—e.g. their beliefs about teaching (Fives & Buehl, 2010). Many consider student teachers' beliefs important, and there are different reasons for this. One reason is that student teachers bring with them strong beliefs about teaching into their teacher education, and these beliefs are important in relation to what the student teachers learn (Richardson, 2003). One conclusion from the Teacher Education and Development Study – Mathematics (TEDS-M) is that: “significant change is unlikely to occur unless teacher-preparation programmes explicitly address beliefs” (Tatto et al., 2012, p. 172).

Previous research has identified learner orientation as one of the main attributes of a high-quality learning environment (Bransford, Brown, & Cocking, 2000). The demands on teachers are increasing, and cultural awareness and regard for individual differences and needs are crucial aspects of a teacher's skills (ibid.). It is important to develop a focus on learners' attitudes, skills and understanding, and not least to use this actively when designing and implementing teaching.

Beliefs have been studied in mathematics education research for decades, and there has been a development of theories, focus and methods in relation to this area of research (see e.g., Philipp, 2007; Fives & Buehl, 2012). There are still, however, unanswered questions regarding beliefs and other aspects of the affective domain (see e.g. Hannula, 2011). In the following, we take a brief look at some of the main issues regarding concepts and categories that have been discussed in beliefs research.

In his handbook chapter, Philipp (2007) provides an overview of some of the more commonly used terms related to beliefs: affect (including emotions, attitudes and beliefs), beliefs systems, conceptions, identity, knowledge and values. All of these concepts have been used with various meanings by different researchers, and, according to Fives and Buehl (2012, p. 471), “the lack of cohesion and clear definitions has limited the explanatory and predictive potential of teachers’ beliefs”. A clarification of terminology is therefore important for determining research focus. Beswick (2012) provides a categorization of mathematics teachers’ beliefs into beliefs about the nature of mathematics, mathematics teaching and mathematics learning (Table 1).

Beliefs about the nature of mathematics (Ernest, 1989)	Beliefs about mathematics teaching (Van Zoest, Jones, & Thornton, 1994)	Beliefs about mathematics learning (Ernest, 1989)
Instrumentalist	Content focused with an emphasis on performance	Skill, mastery, passive reception of knowledge
Platonist	Content focused with an emphasis on understanding	Active construction of understanding
Problem solving	Learner focused	Autonomous exploration of own interests

Table 1: Categories of teachers’ beliefs (Beswick, 2012, p. 130)

The choice of methodology when studying beliefs is strongly connected with the researchers’ view about the nature of these beliefs. For the purpose of this study, we consider beliefs as being held by individuals (Philipp, 2007), and all the aspects from the table above are relevant to consider in studies of teachers’ beliefs. We analyse data from two semi-structured focus-group interviews with student teachers in order to answer the following research question:

What can be learned about student teachers’ beliefs about pupils from content analysis of their focused discussions prior to field practice?

The data material that we analyse and discuss in our attempts to answer this question is part of a larger, cross-disciplinary project entitled Teachers as Students (TasS).

METHODS

The TasS project—which is funded by the Research Council of Norway (project number: 212276/H20)—has a main focus on the field practice, which is part of the teacher education programme. It includes two data collection periods and two groups of participants: a control group (referred to in the project as the “business as usual condition”) and an intervention group (referred to as the “lesson study approach condition”). Data collection in the control group was carried out in the spring of 2012, whereas the data collection for the intervention group is scheduled for the spring of 2013. For the purpose of this paper, we focus on the control group only.

Norwegian student teachers have 20 weeks of field practice during their four-year teacher education programme. For this research project, students in their second year participated. These students were just about to start their fourth three weeks long field practice. Two groups of student teachers from each of the subject areas: mathematics, science, English as a foreign language, and physical education were selected for participation in the control group condition. The intention was to have four student teachers in each group, but some of the groups ended up with only three student teachers in them. A focus-group interview (FGI) was carried out before (pre-FGI) and after (post-FGI) the field practice period in each of the eight groups. A main purpose with the FGIs was to investigate the student teachers’ reflections about the mathematical content (or one of the other content areas involved in the study). Data collection also included video observations from student teachers’ planning lessons with their practice teacher (pre-tutoring sessions), from carrying out lessons (two lessons in each group) and from evaluating lessons (post-tutoring sessions). In this paper, we analyse transcripts from the pre-FGIs conducted with the two groups of student teachers in mathematics (3 + 4 student teachers in these two groups).

Instrument

All pre-FGIs were carried out in a similar manner, and they were scheduled to last for approximately an hour and a half. Each interview consisted of the same four parts. The first part (5-10 minutes) contained introductory questions related to why they chose to enter into teacher education, why they decided to study mathematics, and what they anticipated as being the most interesting and/or challenging parts of being a teacher.

The second part of the FGIs (10-15 minutes) had a focus on the field practice they were about to start, and what reflections they had about their preparation for this period. The student teachers were asked to reflect on issues related to pupils, their own background knowledge and skills in the subject area and practical information given from the university.

Next followed a part of the interview where they were presented with the following case from a classroom situation (this part lasted for about half an hour):

Lise is teaching a class of sixth graders in mathematics. One issue she is very concerned about is getting feedback on ways that she can plan and teach which will enable her pupils' learning.

Lise: The pupils in my class are fairly different when it comes to their attitudes to school work, in general, and mathematics, in particular. Some of the pupils are very motivated and hard-working whilst others don't seem to care at all. This is reflected in their educational achievement in mathematics, the effort they put into their school work and their engagement in the learning environment. How can I lift all these pupils to the next level? Some of the pupils are very interested in mathematics and do more homework than they are asked to and in addition they receive a lot of support from home. Other, less motivated pupils don't seem to work at all; neither at school nor at home. And moreover they don't seem to have learned anything from previous classes. In addition I have two pupils with reading difficulties and two minority language pupils who have only lived in Norway for a short time.

Figure 1: Case from the interview guide.

They were then asked to discuss the challenges of the situation presented in the case, and how these challenges were related to the different aspects of teacher knowledge.

In the fourth and final part of the interviews (lasting approximately 30 minutes), the student teachers were asked questions related to the subject area that they were focusing on in their field practice (e.g. mathematics). In this part, they were asked questions about how they would plan a lesson—with a focus on fractions—in the class that was presented in the case from the previous part of the interview. The questions in this part were concerned with important aspects in the planning process, difficulties they believed students would have, ways of organising teaching in such a case, special concerns that they would have to be aware of as teachers, reasonable goals for such a lesson, and how they would assess their students in relation to the set goals.

Data analysis

The transcripts from the FGIs have been analysed by combining two approaches to content analysis. First, the transcripts were analysed by counting words in the text with the purpose of understanding the contextual use of words. This approach is often part of what has been referred to as summative content analysis (Hsieh & Shannon, 2005). Our summative analysis went beyond word count, however, and we tried to discover underlying meanings of the words used by the student teachers. The counting was used to identify patterns in the data and to initiate the process of developing contextualised codes. The word count was also a starting point for identifying the context associated with the word to try to discover the range of meanings the word had in the interviews.

The summative analysis thus provided insight into how particular words were used. This summative approach is, however, “limited by the inattention to the broader

meaning in the data” (Hsieh & Shannon, 2005, p. 1285), and it was followed by a second phase of data analysis. In this phase, we used conventional content analysis to dig deeper into the data. According to Hsieh and Shannon (2005), this analysis is used in studies which aim at describing a phenomenon in order to understand it better—in this case “it” refers to the student teachers’ statements. In conventional content analysis “researchers immerse themselves into the data to allow new insights to emerge” (Hsieh & Shannon, 2005, p. 1279) by reading the data word by word. In our study, we combined the use of these two common approaches to content analysis. The summative content analysis thus served as a way of reducing data, and it was then followed by the conventional content analysis where categories were developed as part of the analysis.

RESULTS AND ANALYSIS

In our attempt to study what can be learned about student teachers’ beliefs from content analysis of their focused discussions prior to field practice, our combination of summative and conventional content analysis seems promising. In this part we will present results from the summative as well as the conventional content analysis, and we will discuss the results in light of previous research in this area.

The summative content analysis

After an initial reading of the interview transcripts, we realised that the student teachers’ reflections had much less focus on the mathematical content than we first anticipated. This impression was strengthened by our initial attempts to analyse the data. As part of our summative content analysis of the transcripts, we generated a concordance in order to learn more about the words that were used in the discussions and the frequencies of those words. We started out with a focus on words related to mathematics.

Frequency	Word/concept
88	mathematics
88	fraction
30	task
26	addition
21	calculate
18	denominator/common denominator

Table 1. The most frequently used words related to mathematics

From this initial summative content analysis, it appeared as if the student teachers were discussing fractions quite a lot, and we started out by focusing our analysis on this. When we moved from a quantitative to a more qualitative analysis of the content, however, it became evident that these words were mainly mentioned briefly with little or no reflection. In one of the interviews, for instance, the interviewer asked about their preparation for the field practice. One of the student teachers followed up by saying that they were well prepared. When the interviewer asked about the mathematical topic they were focusing on, the student teacher replied: “It is algebra”. The reflections did not go deeper than just stating this.

We then decided to make a more open analysis of the content in order to learn more about what the student teachers were actually discussing in the FGIs. When generating a concordance that was sorted after occurrences of words rather than an alphabetically sorted list of the words that occurred, we observed that the most frequently occurring words were general words.

Frequency	Word (in Norwegian)	In English
1702	det	it
963	og	and
784	er	am/is/are
737	de	they/them/those
674	så	so

Table 2. The most frequently occurring words in the transcripts

Most of these words (e.g. like “and”, “is” and “it”) were used in different ways, and it was hard to discover any patterns. When making a more qualitative summative analysis of the most frequently used words, however, we realised that the word “they” was interesting. Throughout the transcripts, the word “they” was used almost exclusively with reference to pupils. It is not surprising that the students used this word to describe the pupils, and this result in itself is probably influenced by the case used. It was, however, through the results of the content analysis that we became aware of this, and we decided to follow up with further analysis to learn more about the student teachers’ beliefs about the pupils—as revealed by their use of the word “they”.

The conventional content analysis

From the summative content analysis, we followed up with conventional content analysis. We started out with analysis of the keyword (“they”) in its immediate

context. In the first step of this analysis, the context was defined as five words before and after the keyword. During the analysis of these context units, the first attempts to categorise the data were made. Then we followed up by increasing the context to entire utterances. The transcripts were read word by word, and categories were developed inductively (Hsieh & Shannon, 2005).

From this analysis, the following categories emerged in relation to how the student teachers' referred to the pupils (as "they"):

- General reference to pupils
- Characteristics of pupils':
 - behaviour (B)
 - cultural background (CB)
 - certain needs (CN)

Below is an utterance from one of the student teachers in the two interviews. It has been chosen for illustration since it contains uses of the keyword "they" that relate to all the three subcategories of "characteristics of pupils". It also contains an example of other uses of the keyword (O).

ST: It is of course possible to provide assistance with homework. It is fair enough that all pupils have a right to receive such assistance. You can, I mean, if you have more than two minority-language [pupils], you have a right to get a teacher assistant. [You] can help them (CB) in this way. By doing that you can split your class. You get those (B) who are diligent, that they (B) might be seated in a group of their own and work with things they (B) are able to [do on their own], so that they (B) are always ahead of the difficult tasks while you still help those (CN) who are struggling. That you have those (O) two assistants who walk around and help, and... Yes. It depends on how much learning difficulties they (CN) have, those (CN) two other pupils, but this is where you have the opportunity to get in some extra help.

As we can see from the first few sentences in this excerpt, the student teacher is talking about the challenges of having pupils with a minority language in the classroom. (S)he points to a regulation concerning the right to receive help with homework (for the minority pupils), and another regulation concerning the right to have a teacher assistant in the classroom if there are more than two pupils with a minority language background in the class. When a teacher assistant is present to take care of the minority-language pupils, the teacher can more easily split the class into groups. This student teacher is obviously in favour of separating the pupils in groups according to level. It is interesting to observe that the best pupils are referred to as diligent rather than smart, clever or high achieving. From this statement, it is

possible to suggest that this particular student teacher holds a belief where high achievement in mathematics is related to effort.

The weaker pupils, on the other hand, are referred to as “struggling”, and the student teacher follows up by talking about them as pupils with a certain level of learning difficulties. So, whereas the best pupils are characterised by their effort, the lower achieving pupils seem to be characterised as pupils with learning difficulties, pupils who have certain needs, and pupils who are entitled to receive extra (external) support.

CONCLUDING DISCUSSION

In their distinction between three important aspects in research on beliefs about teaching, Van Zoest, Jones and Thornton (1994) mentioned learner focused as a third aspect. We have seen in the results from our analyses that the student teachers, when reflecting about teaching, had a strong focus on the pupils. It seems, however, that the student teachers—when talking about the pupils in our FGIs—did not focus much on mathematics, teaching or the pupils as learners; they focused more on characteristics of pupils. In this way, the student teachers’ beliefs—although they were arguably about teaching—somehow did not fit inside of Beswick’s (2012) table (see Table 1). The student teachers did focus on the learners, but they seemed to focus more on the pupils as individuals with different characteristics.

Our aim with applying content analysis to the transcripts of the FGIs was to learn more about student teachers’ beliefs. An underlying assumption then, is that there is a connection between their beliefs and the words they use. After having made some early analyses, it appeared that reflections about the mathematical content were not dominating in the student teachers’ discussions. Mathematical concepts were used, but they were mainly referred to rather briefly. When applying summative content analysis to the data material, we found that the FGIs contained more reflections about pupils than on mathematical content. The word “they”—which was mostly used with reference to pupils—were among the most frequently used words in the FGIs (table 2). This is not surprising as the discussions were obviously influenced by the case that was presented to the student teachers in the interviews. After having made even further analyses of the data material, using conventional content analysis, we learned more about the different aspects of these reflections about pupils.

When analysing their characterisations of the pupils, we could distinguish between reflections concerning the pupils’ behaviour, their cultural background or certain needs that the pupils might have. The student teachers, in their reflections, seemed to believe that the responsibility for pupils’ learning is to be placed outside the teacher. They related the possibilities to help the pupils to other factors than their own competence. One example of this can be found in the excerpt from the transcripts that we have discussed above. In this excerpt, the student teacher suggests that the pupils would learn if there were enough teacher assistants. Their focus here can be

interpreted as being on surviving in the classroom rather than on pupils' learning (Richardson & Placier, 2001). This is, of course, only one example, but we found the same tendency in our analysis of the entire data material. In both interviews, there seemed to be a belief that the pupils represented different kinds of challenges to the teacher, and the student teachers might suggest that a solution to these challenges could be found outside and not inside themselves. Skott (2001) argued that teachers' beliefs about mathematics teaching are often obscured by the more general priorities related to organising the classroom, and this might be part of the explanation for the seeming lack of focus on mathematics and mathematics teaching in our FGIs.

Much can be learned about student teachers' beliefs by analysing their reflections in focused discussions. We decided to use a combination of summative and conventional content analysis in our analyses of data from FGIs with student teachers prior to field practice, but there are other kinds of analyses to make—each with different advantages as well as disadvantages or limitations. One of the advantages of using content analysis in our study was that it helped us discover what the student teachers mainly focused on in their discussions, and we could then use this in further analyses to learn more about their beliefs. The combination of approaches to content analysis also made it possible for us to discover reflections that were made by using a common word like “they”. In order to learn more about student teachers' beliefs, it is also relevant to use the results of these analyses—as well as other analyses—to make a new evaluation of the interview guide. When looking back at the case—which was presented in the FGIs—it can be noticed that it was more focused on students than on mathematics. The case most certainly had an effect on the participants' reflections in the FGIs.

TEACHERS' BELIEFS AND KNOWLEDGE RELATED TO THE CYPRUS MATHEMATICS CURRICULUM REFORM

Marilena Pantziara^{1,3}, Marianna Karamanou² and George Philippou³

¹Cyprus Pedagogical Institute, ²Ministry of Education and Culture,

³Univeristy of Nicosia

This paper presents some results of a larger study that investigates teachers' knowledge, beliefs, practices and enjoyment/confidence related to a mathematics curriculum reform. Data were collected from 100 in-service primary teachers through a questionnaire referring to teachers' background information, their beliefs, their enjoyment/confidence and their knowledge of the new mathematics curriculum. Findings revealed the existence of three factors concerning teachers' enjoyment/confidence, their traditional beliefs, and their inquiry-oriented beliefs. A description for teachers' knowledge of the new curriculum is presented. Correlations existed between their beliefs and their enjoyment/confidence.

Keywords: Teachers, knowledge, beliefs, curriculum reform.

INTRODUCTION

Cyprus launched a curriculum reform in 2008 and started implementing it since September 2011. As far as the new mathematics curriculum is concerned, the target was to move from traditional teaching of mathematics to more progressive approaches. It is, therefore, pertinent investigating the factors that can affect the successful implementation of the mathematics reform.

In mathematics education, a considerable body of research (Ernest, 1989; Stipek, 2001; Tompson, 1992; Wilkins, 2008) underpin the importance of teachers' knowledge, beliefs and attitudes in their effectiveness and their choice of instructional practices, and as a consequence their disposition towards the implementation of innovation. In this respect, we developed a study to investigate teachers' knowledge, beliefs, practices and enjoyment/confidence related to the new mathematics curriculum. In this paper we focus on teachers' beliefs, their enjoyment/confidence about mathematics and its teaching and their knowledge of the new mathematics curriculum.

BACKGROUND AND AIMS

Teachers' knowledge

Prior research refers to several factors that influence teachers' instructional practices and, therefore, the implementation of a new mathematics reform (Charalambous & Philippou, 2010; Handal & Herrington, 2003; Manouchehri & Goodman, 2000). We based our research on the model proposed by Ernest (1989) on teacher knowledge, beliefs and attitudes, as it represents an attempt to understand psychological factors underpinning the impact of curriculum innovation on mathematics teachers. A key

difference in Ernest's model and other related models like Ball's, Thames' and Phelps' (2008) is the inclusion of beliefs and attitudes in the model.

Ernest (1989) suggests that teachers' knowledge of mathematics constitutes of several components: (a) pure subject matter knowledge that the teachers' needs in order to teach mathematics; (b) knowledge of teaching mathematics which involves pedagogical knowledge of the subject, and curriculum knowledge. Pedagogical knowledge of mathematic refers to teacher's knowledge of approaches to school mathematics like awareness of different ways of presenting mathematics and knowledge of students' methods, conceptions and errors. Curriculum knowledge refers to the knowledge of the curricular materials which mathematics instruction is carried out and assessed; (c) knowledge of other subject matter, which provides a knowledge of mathematics uses and applications (d) knowledge of organization for the teaching of mathematics, which refers to the knowledge of organising the mathematics instruction in individual work, co-operative groups, and to the management of practical activities; (e) knowledge of the students and school and (f) knowledge of education. In this paper we present results related to teachers' knowledge of teaching mathematics and particularly their curriculum knowledge.

As Ernest (1989) states, teachers' beliefs of mathematics and mathematics teaching were also found to influence teachers' instructional practices. More specifically, two teachers may have similar knowledge of mathematics but may teach using different methods and procedures due to their different beliefs of mathematics and mathematics teaching. The importance of beliefs and their impact on teaching has also been emphasized by several authors (Hannula, Evans, Philippou, & Zan, 2004; Stipek et al., 2001; Tompson, 1992; Wilkins, 2008).

Teachers' beliefs about mathematics, teaching and learning

There is still a discussion about the definition and characteristics of beliefs. According to Ernest (1989) "beliefs" consist of the teacher's system of beliefs, conceptions, values and ideology. Beliefs develop over time on the basis of related experiences, while the affective dimension of them influences the role and the meaning of each belief in the belief system (Wilkins, 2008). Teacher's beliefs consist of views about the discipline of mathematics, and about the teaching and learning of mathematics. Teachers' beliefs about the discipline of mathematics constitute the "rudiments of a philosophy of mathematics" (Thompson, 1992, p. 132), while their beliefs about the teaching and learning of mathematics may include the role of the teacher and the students in the teaching and learning situation, classroom activities, instructional approaches, mathematical procedures and the acceptable outcomes of instruction (Handal & Herrington, 2003; Thompson, 1992).

Many teachers may have more traditional beliefs about the discipline of mathematics and its teaching. These beliefs include that mathematics is a static body of knowledge which involve a set of rules and procedures that are applied to produce one right answer. Then knowing mathematics means to be skilful in performing procedures

without necessarily understanding what they represent (Stipek et al., 2001; Thompson, 1992). In this traditional standpoint the teacher is in full control of the mathematics learning, providing students with a step by step instruction and allocating problems for practicing the procedure (Stipek et al., 2001; Tompson, 1992). The inquiry based beliefs include a dynamic view of mathematics, a problem centred view, a continually changing field of human creation and invention, open to revision (Stipek et al., 2001; Thompson, 1992). Inquiry-based beliefs refer to students' engagement in activities to construct their own knowledge, to reason, to be creative, to discover the knowledge and to communicate their ideas. The teacher shares the control with students playing a facilitator role, encouraging students to fulfil their own learning aims and construct meaning by themselves.

Teachers with more traditional beliefs were found (Stipek et al., 2001) to be more close to the entity theory of ability, supporting the view that ability is stable and immutable, leaving no room for development and minimizing the importance of effort. On the contrary, teachers with inquiry-based beliefs may be associated with an incremental view of ability in which the ability is amenable to change and increase with learning and effort (Cury, Elliot, Fonseca & Moller, 2006). As far as students' motivation is concerned, several studies (Patrick, Anderman, Ryan, Edelin, & Midgley, 2001; Stipek et al., 2001) showed that teachers with more traditional beliefs value the importance of extrinsic motivation, while teachers' with more inquiry-based beliefs value the importance of intrinsic motivation.

Apart from beliefs, Ernest (1989) includes in the model teachers' attitudes towards mathematics and its teaching, such as liking, enjoyment and interest in mathematics, and also teachers' confidence in their own ability in mathematics and its teaching. In Ernest's model, the interrelationship between knowledge, beliefs and attitudes is not explicitly addressed (Wilkins, 2008). However, studies (Karp 1991 in Wilkins, 2008; Stipek et al., 2001) found that teachers with more traditional beliefs are less confident and enjoy mathematics less than teachers who are related to more inquiry-based beliefs.

A considerable amount of studies has led researchers to consider teachers' beliefs as an important mediator in curriculum implementation (Charalambous & Philippou, 2010; Handal & Herrington, 2003; Tompson, 1992). It is assumed that in order for teachers to implement a curriculum reform their beliefs must be somehow aligned to the basic philosophical beliefs underlying the reform (Handal & Herrington, 2003).

Cyprus reform and the new role for the teacher

In September 2011, the new mathematics curriculum started to be implemented in grade one (first year of primary school) and grade seven (first year of secondary school) and it is expected to be in full operation by June 2017. It follows current trends in education, presenting mathematics as a dynamic tool for thought (Cyprus Ministry of Education and Culture, 2010).

The new mathematics curriculum has been designed according to four principles: (a) students should be involved in mathematical investigations, which enhance their curiosity and interest, related to already existing knowledge, based on real life situations and interdisciplinary questions, (b) emphasis should be paid on problem-solving, (c) ICT as an integral part of mathematics education and (d) students' experiences will be enriched through pedagogically rich examples, that arise from the active engagement with meaningful mathematical problems and concepts (Cyprus Ministry of Education and Culture, 2010). These principals are to a great extent congruent with inquiry-based mathematics instruction (NCTM, 2000; Wilkins, 2008).

For the effective implementation of the new curriculum, the role of the teacher in the mathematics classroom shifts from the traditional instruction in which the teacher transmits to students pieces of mathematical information to a more demanding role. While students engage in investigations, the teacher is expected to create “a community of inquiry” in which the students comfortably exchange ideas and justify their views (Manouchehri & Goodman, 2000; Wilkins, 2008).

As far as knowledge is concerned, the new mathematics curriculum expects teachers to have the necessary subject matter knowledge and knowledge of teaching mathematics (Ernest, 1989), to understand the core mathematical ideas of the curriculum material, to recognize the relationships among concepts, to be able to reason mathematically and use multiple representations of new mathematical concepts. The teacher is expected to build on students' thinking around different investigations and to connect their thinking to specific mathematical concepts. As other studies revealed (Manouchehri & Goodman, 2000; Stipek et al., 2001) teachers need confidence in their ability to make sense of mathematics and students' solutions and strategies, while they must encourage and reward students' efforts to solve mathematical problems.

Several studies have stressed that many reforms fail due to teachers' lack of mathematics knowledge and knowledge of teaching mathematics or because their beliefs are not congruent with the beliefs supporting the reform (Manouchehri & Goodman, 2000; Stipek et al., 2001). It is therefore evident that teachers' knowledge and beliefs have a determinant role in the success or failure of the new Cyprus mathematics curriculum. In this respect the aim of this study was:

- To investigate teachers' beliefs about: (a) the nature of mathematics (procedures vs. thinking), (b) mathematics learning (correct answers vs. understanding), (c) control of the classroom (teacher's control vs. students' autonomy), (d) the nature of mathematical ability (fixed vs. developing), (e) motivation (extrinsic vs. intrinsic).
- To investigate teachers' confidence and enjoyment of mathematics and mathematics teaching.
- To examine teachers' knowledge of teaching mathematics and particularly the degree of teachers' level of awareness of the new mathematics curriculum.

METHOD

Data were collected through a questionnaire from 100 in-service teachers from primary schools in rural and urban areas in Cyprus. Part of these subjects had earlier participated in professional development programs focusing on the mathematics reform. The questionnaire administered comprised of five parts: (A) teachers' background information, (B) teachers' beliefs, enjoyment/confidence, (C) teachers' knowledge of teaching and particularly their awareness of the new mathematics curriculum, (D) teachers' instructional practices, and (E) teachers' mathematical knowledge. Parts D and E of the questionnaire are not presented in this study since they are beyond the aims of this paper.

The first part of the questionnaire sought demographic data, including the subjects' educational background, such as the number of maths courses they took during their undergraduate studies and the number of seminars they attended during their careers related to mathematics education as well as the seminars they have attended specifically related to the new mathematics reform. Moreover, their experience in teaching mathematics and the class that they were teaching mathematics during the specific year were reported.

The second part comprised of items selected from the questionnaire by Stipek et al. (2001) that were related to teachers' beliefs and enjoyment/confidence about mathematics and teaching. Specifically there were 30 items measuring teachers' agreement on a 5 point Likert scale (1- strongly disagree, to 5-strongly agree). Each item was related to one of the two ends of bi-polar scale of each of six dimensions of mathematics: (a) the nature of mathematics (procedures vs. thinking), for instance: "The best way to understand math is to do lots of problems", "In every lesson teachers need to discuss how people use the math being taught to solve real-life problems"; (b) mathematics learning (correct answers vs. understanding), for instance: "Students who produce correct answers have a good understanding of mathematical concepts", "Children's reasoning in their mathematical problem solving is more important to assess than whether they solve problems correctly"; (c) control of the classroom (teacher's control vs. students' autonomy), for instance: "It is important for teachers, not students, to direct the flow of a lesson", "Good teachers give students choices in their math tasks"; (d) the nature of mathematical ability (entity vs. incremental), for instance: "Mathematical ability is something that remains relatively fixed throughout a person's life", "Improvement should be a major consideration when grading students"; (e) motivation (extrinsic vs. intrinsic), for instance: "Giving rewards is a good strategy for getting students to complete math assignments", "If children aren't working, it is probably because the task is not very interesting"; (f) teachers' self confidence and enjoyment of mathematic, for instance: "I feel confident that I understand the math material I teach".

The third part of the questionnaire assessed teachers' knowledge of teaching and particularly their awareness of the new mathematics curriculum. The eight items measured teachers' knowledge on, disagree or agree. Two spice items are:

“According to the new mathematics curriculum students should not come across many representations of a mathematical concept to avoid being confused” and “In the new mathematics curriculum an attainment target can be found in more than one class”.

RESULTS

The analyses of the data revealed that teachers had various experience of teaching and educational background (table 1). The great majority of the teachers had more than 10 years of experience, while 66% had postgraduate degrees. At the beginning of the implementation of the mathematics reform, 24% of the teachers reported that they had participated in professional seminars focusing on the mathematics reform. In Cyprus dissemination of information related to the new reform might take place in schools, since informed teachers are expected to inform their colleagues.

Experience	Education		
	Undergraduate studies	Postgraduate	Phd
1-5 years	1	11	0
6-10 years	6	12	0
11-15 years	12	14	1
15-20 years	6	20	1
20 -more	6	9	0
(N=99) 1 missing	31	66	2

Table 1. Teaching experience and mathematical background

Regarding the first and second questions of the study, principal component analysis (PCA) was conducted on the 30 items with orthogonal rotation (varimax). The Kaiser-Meyer-Olkin measure verified the sampling adequacy for the analysis, KMO = .72 (“good” according to Field, 2009), $\chi^2(276) = 795.42$, $p < .001$, indicated that correlations between items were sufficiently large for PCA. After various analyses 6 items were deleted due to their loadings on various factors or to their low loadings. We ended in three factors explaining 46.41% of the variance. Table 2 shows the factor loadings after rotation.

Item	Rotated factor loadings		
	Confidence / Enjoyment	Traditional	Inquiry
I think of myself as being good in mathematics.	.833		
I don't enjoy doing mathematics (reverse).	.822		
Math is my favourite subject to teach.	.801		
I enjoy encountering situations in my everyday life that require me to use math to solve problems.	.752		
I'm not competent enough in math to teach it beyond the elementary grades (reverse).	.647		
When my answer to a math problem doesn't match someone else's, I usually assume that my answer is wrong (reverse).	.631		

When I teach math I often find it difficult to interpret students' wrong answers (reverse).	.617		
The best way to understand math is to do lots of problems.		.807	
Students who aren't getting the right answers need to practice on more problems.		.711	
Students who finish their math work quickly understand the material better than students who take longer.		.681	
It is important for teachers, not students, to direct the flow of a lesson.		.653	
It is important for teachers to maintain complete control over math lessons.		.647	
Students who produce correct answers have a good understanding of the mathematics concepts.		.561	
The more students are concerned about grades and performance the more they learn.		.460	
Students who really understand math will have a solution quickly.		.451	
Giving rewards is a good strategy for getting students to complete math assignments.		.450	
Students will work hard on interesting and challenging math tasks, whether or not their work is graded.			.805
Improvement should be a major consideration when grading students.			.689

Table 2. Summary of exploratory factor analysis results (N=100)

The items that cluster on the same factor suggest that factor 1 represents teachers' enjoyment/confidence, factor 2 represents traditional beliefs of mathematics and its teaching, and factor 3 represents inquiry-oriented beliefs of mathematics and its teaching. As it was assumed, the traditional view of mathematics comprised of dimensions for which high scores were presumed to be associated with traditional theory of mathematics and its teaching. Specifically, mathematics is a set of operations which are used to get correct solution to problems rather than tools of thought, the importance of getting the correct answer, the issue of teacher's control in

the classroom and the development of students' extrinsic motivation. There were no items referring to the entity theory in this factor. The inquiry view of mathematics comprised of dimensions for which high scores were presumed to be associated with inquired-oriented beliefs of mathematics and its teaching. Specifically the view of mathematics as a tool of thought and not as a set of operations, the importance of students' understanding and not just the correct answers, beliefs concerning the incremental ability of students in mathematics and the development of students' intrinsic motivation. There were no items referring to students' autonomy in the classroom.

Teachers in this study appeared to be rather confident and enjoyed mathematics ($M=3.83$), while their traditional views of mathematics were moderate ($M=3.14$), and their inquiry based views were higher ($M=3.78$) than their traditional views but not very high.

As far as it concerns the relation between the three factors, the Pearson's product-moment correlation coefficient indicated a significant positive relationship between teachers' confidence/enjoyment and the inquiry-oriented beliefs of mathematics ($r=.276$, $p<0.5$) and also a significant negative relationship between teachers' confidence/enjoyment and traditional views of mathematics, ($r=-.247$, $p<0.5$). Even though the indices were small, it seems that teachers' scoring high on the inquiry based beliefs were more confident about teaching mathematics and enjoyed it more, while teachers scoring high on the more traditional views were less confident and enjoyed mathematics less.

Regarding the third question of the study concerning teachers' knowledge of teaching and particularly curriculum knowledge, Table 3 presents the percentage of teachers' by the number of questions in which they provided positive answers, out of the 8 items.

Number of positive answers	0	1	2	3	4	5	6	7	8
Percent of subjects	6.9	2.9	1	2	5.9	16.7	34.3	27	2

Table 3. Teachers' level of curriculum awareness (N=98, missing 2)

The results present a rather positive picture of these teachers' curriculum knowledge. A considerable percentage (63.3%) of these teachers seems to be well aware of significant issues and new trends (total of 6-8 positive responses) at the beginning of the implementation of the mathematics reform.

Teachers' positive responses ranged between 73%-88% in 6 of the 8 items. Particularly 88% were informed that an attainment target can be repeated in more than one grades and 82% were aware that the new mathematics curriculum included attainment targets, indicative activities, enrichment activities and assessment tasks; Also, 82% of the teachers were well-versed how the new curriculum deals with students' erroneous answers and 81% were informed that in the new curriculum addition and subtraction are perceived as conceptually connected therefore they must

be taught jointly. Finally 76% of the teachers were aware that students are not expected to reach an attainment target in the same pace and 73% were notified of the importance of multiple representations in mathematics as included in the new mathematics curriculum. Teachers scored lower in two items of the questionnaire that referred to more detailed practices in the classroom. The first item refers to the use of enrichment activities in the mathematics class, which provides for differentiating instruction to cater for students of various mathematical abilities. The second item referred to the investigation stage, which is a stage of the didactical model suggested by the new curriculum. In this stage the students are expected to conjecture, investigate and discover the new mathematical concept.

DISCUSSION

The aim of this study was to examine teachers' beliefs, enjoyment/confidence and their acquaintance with the reformed curriculum at the outset of its implementation. Analysis of the data revealed the existence of three factors concerning traditional beliefs, teaching confidence and inquiry orientation. Similar to Stipek's et al. (2001) findings, the factor concerning traditional beliefs referred to the nature of mathematics, mathematics learning, control of the classroom and motivation. Items referred to the nature of mathematical ability were not included in this factor. Regarding teacher's inquiry-oriented beliefs another set of beliefs existed referred to the nature of mathematics, mathematics learning, the nature of mathematics ability and motivation. Items referred to students' autonomy in the classroom were not included in this factor. In this study teacher' inquiry-oriented beliefs found to be moderate, a result that policy-makers should take into consideration since, flourishing curriculum change will more probably occur when teachers' beliefs and curriculum reform goals are congruent (Handal & Herrington, 2003).

Similar to other studies (Manouchehri & Goodman, 2000; Stipek et al., 2001; Wilkins, 2008) teachers in this study who adopted more inquiry-oriented beliefs were more self-confident and enjoyed mathematics more than teachers who adopted more the traditional beliefs. More confident teachers may adopt beliefs and practices that require more decision-making and judgment.

Regarding teachers' acquaintance with the new curriculum the study reveals that teachers' curriculum knowledge (Ernest, 1989) is relatively high even though a small percentage of them have so far received in-service training. In line with the suggestions of other studies (Charalambous & Philippou, 2010; Manouchehri & Goodman, 2000) teachers should continue to receive systematic and sustained support targeting their knowledge of teaching mathematics (Ernest, 1989) in order to succeed in implementing it.

Curriculum implementation is not a process that translates directly into the mathematics classroom. Teachers are the key players in a successful implementation of a curriculum reform. Therefore their knowledge and beliefs should be identified, analysed and improved in the process of the curriculum implementation.

FACTORS MOTIVATING THE CHOICE OF MATHEMATICS AS A CAREER AMONG MEXICAN FEMALE STUDENTS

Mario Sánchez Aguilar, Avenilde Romo Vázquez, Alejandro Rosas Mendoza, Juan Gabriel Molina Zavaleta & Apolo Castañeda Alonso

National Polytechnic Institute, Mexico

In this paper we present a report of an ongoing research focused on identifying the factors that motivated Mexican female students to choose mathematics as a career. The main body of data for the research was generated through semi-structured interviews. The preliminary results show that three are the main factors that motivated women in the sample to choose mathematics as a career: (1) to be aware of the fact that they are good at mathematics, (2) the influence of their mathematics teachers, and (3) the influence of their relatives. We suggest that these three factors promote the constitution of a mathematical identity, which in turn favors the choice of mathematics as a career.

Keywords: Career choice, female mathematics students, Mexican students, mathematical identity.

INTRODUCTION

There are several reports indicating that few tertiary students around the world are enrolled in science, technology, engineering and mathematics (STEM) related careers (European Commission, 2004, Organisation for Economic Co-operation and Development, 2008; Stine & Matthews, 2009). In particular, the recruitment rate of women in these areas is particularly low (see for example European Commission, 2009). Meeting the demand for scientists and engineers is a widespread concern because of the important role that these careers play in the development of modern society; however, there is also a global interest in producing a diverse and gender balanced scientific workforce. This situation has generated a number of studies that try to identify what factors attract and retain students (particularly women) to STEM careers (see for example Brickhouse, Lowery & Schultz, 2000; Herzig, 2004; Hill & Rogers, 2012; Mendick, 2005).

The situation in Mexico, where this study is being developed, is not different from that described above. The recruitment rate of female students in STEM careers, particularly in mathematics, is very low. The latest figures on the study of mathematics at the tertiary level in Mexico show that: (1) women represent 38% of the people studying a bachelor degree in mathematics; (2) women represent 24% of the people studying a master degree in mathematics; and (3) women also represent 24% of the people studying a PhD degree in mathematics (data taken from Barrera, 2012).

In spite of these problems to attract women to the study of mathematics, there are very few studies in Mexico (and in general in Latin America) focused on identifying the factors that may attract and retain female students to study math-related careers in this region. The latest Mexican study focused on this issue is that of Jiménez (2006), where some female researchers in mathematics were interviewed about the reasons that led them to choose mathematics as a field of work.

In this paper we report an ongoing research project focused on identifying some of the factors that may motivate Mexican female students to choose mathematics as a career. Specifically, we are trying to answer the following research question:

What factors motivates Mexican female students to choose mathematics as a career?

The main contribution of our work is to help to understand what motivates female students from Latin American countries to choose mathematics as a field of study. Our research could help to identify differences and similarities between the motivating factors to study mathematics among women from different regions of the world. We also believe that our research can produce pedagogical recommendations to promote the study of mathematics among young women in our country.

The manuscript is organized as follows: first, we will summarize the literature that we have consulted so far and clarify what is the function that this literature review has had in our research; then, we will explain the approach we have taken to collect and analyze empirical data; next, some preliminary results are presented, this is, some of the factors that seems to motivate Mexican female students to choose mathematics as a career; then, we will refer to the concepts of self and identity as theoretical tools to try to interconnect and make sense of the results obtained; finally we will present some conclusions.

A REVIEW OF RELEVANT LITERATURE AND ITS ROLE IN THE RESEARCH

When we began our review of the literature, we focus initially on mathematics education research journals, trying to locate studies that could explain why few women choose to study mathematics. In a second stage we extended our search to science education journals, trying to locate articles focused on studying what factors attract and retain female students to STEM careers.

The literature review had a dual role in our research. On the one hand, it allowed us to locate some of the methods used in the literature to identify the factors that may motivate women to study STEM careers; we used this information to design our own research method. On the other hand, the literature review was useful to identify hypotheses or possible explanations on why some women are attracted to this type of careers.

Regarding the methods used, we found that in some studies questionnaires are employed in conjunction with other instruments (for example in Holmegaard, Ulriksen & Madsen, 2012; Sjaastad, 2012), but most studies use open interviews to

allow women to produce narratives about their experiences with mathematics (see for example Mendick, 2005; Piatek-Jimenez, 2008; Solomon, 2012). Through these personal narratives researchers try to locate activities and experiences that have led women to study mathematics.

With regard to the hypotheses or possible explanations for why some women choose to study (or not so study) mathematics-related careers, they are very different in nature. To explain why some women choose not to study mathematics, some authors claim that mathematics can be perceived as an unfeminine profession, resulting in a discrepancy between female identity and a mathematical identity (Piatek-Jimenez, 2008; Solomon, 2012). Another explanation for the low number of women in mathematics as a field of study is that there is discrimination against women in math-intensive fields and in the mathematics classroom—sometimes unconsciously—(Ceci, Williams & Barnett, 2009). There are authors who claim that the level of creativity required in some hard sciences, which is not socially favored among women, can be a reason why there is a low presence of women in these sciences (Hill & Rogers, 2012). There are at least two factors that have been identified as motivating and inspiring for women to study mathematics-related careers: (1) the confidence that individuals have in their own intellectual abilities (Eccles, 2007) and (2) the positive influence of significant persons, such as parents, teachers and friends (Sjaastad, 2012).

During our review of the literature, we also noted that some studies associate the process of choosing a career with the construction of an *identity* in young people. For example, Sjaastad (2012) uses as a theoretical tool the concept of *self*; he bases his discussion of the concept of self in the works of Higgins (1987) and Swann & Bosson (2010). The self refers to the attributes that a person believes to possess and the attributes the person would like to possess. One important thing here is that, the self is influenced and shaped by interpersonal relationships; as stated by Swann & Bosson (2010): “We know ourselves [...] by observing how we fit into the fabric of social relationships and how others react to us” (p. 589).

In turn, Holmegaard, Ulriksen & Madsen (2012) relate the choice of a career with the process of defining oneself:

“[T]he decision about which course of study to choose after finishing upper-secondary school is not limited to figuring out what could be interesting or promising; it is also about *defining* oneself, and making a decision about whom one wishes to become” (p. 4).

Similar to the theoretical position of Sjaastad (2012), Holmegaard, Ulriksen & Madsen (2012) conceptualize the constitution of an identity as shaped by interactions with others and the cultural context where the person is immersed.

The concept of *mathematical identity* or *identity as mathematics learner* can also be found in the literature on mathematics education (see for example Anderson, 2007; O’Hara, 2010). The construct of identity refers to “the way we define ourselves and how others define us” (Anderson, 2007, p. 8), and serves to explain what makes a

person to feel like an able mathematics student and as a consequence get involved and engaged in mathematical activities. As we shall see, this construct could be helpful to explain some of the results of our study.

METHOD

After identifying in the literature some of the factors that motivate women to pursue a career related to mathematics, we conducted an exploratory study. A role of this exploratory study was to verify whether the factors located in the literature appeared in Mexican female students; another role was to try to identify other possible motivating factors not reported in the literature.

Description of the exploratory study

For the exploratory study a questionnaire was applied to 32 Mexican girls studying a bachelor degree in mathematics in the University of Veracruz, located in southeast Mexico. The questionnaire was applied during February 2012. The head of the mathematics department administered the questionnaire to randomly selected students. The selected students had different degrees of advance in their studies, and their ages ranged from 18 to 21. The questionnaire consisted of eleven open questions focused on their experiences with mathematics before entering the bachelor program and their reasons why they decided to study mathematics. It included questions like: what motivated you to choose this career? and, at what point in your life you decided to study mathematics and why? These two open questions were particularly helpful in identifying some of the reasons why these students chose to study mathematics. Among the reasons they expressed in the questionnaire are:

- Their mathematics teachers motivated them to study mathematics.
- Their parents influenced their career choice.
- Participation in competitions like math Olympiads motivated them to study mathematics.
- At some point in their lives they realized that they were good at mathematics and decided to study it.
- At some point in their lives they discovered some sort of mathematical applications and as a consequence they found the study of mathematics appealing.

With these explanations in mind, we designed an interview guide for semi-structured interviews. Through semi-structured interviews we generated the main body of data for the research. Next we explain in more detail how these data were produced.

Collecting data through semi-structured interviews

In this second stage of our study we interviewed 37 female students enrolled in the Higher School of Physics and Mathematics at the National Polytechnic Institute of Mexico, in Mexico City. As in the exploratory study, the selected students had

different degrees of advance in their studies, but in this case their ages ranged from 18 to 22. All the authors of this paper participated in conducting the interviews. The interviews took place between August and September 2012, about a month after starting the school year. The student participation was voluntary and the interviews were conducted during downtime between lessons, in the gardens of the Institute. Our purpose was to create a casual and comfortable environment for the students. The interviews were audio recorded and their average length was 12 minutes.

The semi-structured interview guide contained a couple of open questions aimed at triggering students' narratives on the activities and experiences that motivated them to study mathematics. These open questions were: (1) can you name one or more experiences or activities of your past that influenced you to choose this career? and (2) was it difficult to choose your career, did you always know you wanted to study this or was there any particular incident that made you choose this career?

There are several similarities between the two samples we used in this study. On the one hand, both samples consist of Mexican women who are studying a bachelor degree in mathematics in a public school, this means that their socio-economic backgrounds should be similar (most likely belonging to middle class or lower middle class); another similarity is their age ranging from 18 to 22; also, both groups of students are studying in urban areas, although the students from Mexico City belong to a much more developed urban area. These similarities between samples made us consider that the explanations obtained in the exploratory study could be similar to the explanations provided by the second group of students. Thus, we expected that the above-mentioned questions could detonate narratives in which teachers, parents, or mathematical competitions were mentioned as factors influencing their choice. For this reason we prepared additional questions to deepen each of these factors, in case they appeared. For example: What did you like about your math teacher and her teaching?; How would you describe your experience in the mathematical competition (positive or negative) and why?; How your parents and friends reacted when you told them you wanted to study mathematics?

Data analysis

To analyze the interviews the audio recordings were distributed among all members of the research team. When analyzing the audio-recorded interviews, we focused on locating the instances where students mentioned any experience or activity that motivated them to study mathematics. Each of those instances was transcribed. To increase the reliability of the results, two researchers independently analyzed each recording; if there was any discrepancy in the interpretation of the interview, both researchers explicitly discussed how they were interpreting the content of the interview to reach consensus.

At the time of writing this report we had analyzed 10 out of 37 interviews. The results presented below are based on the analysis of those ten interviews.

PRELIMINARY RESULTS

The results presented next are the factors that ten Mexican female students mentioned in their narratives as motivating to study mathematics. Some students mentioned more than one motivating factor during the interview. We have classified these factors into seven categories. Figure 1 shows the frequency for each of those categories.

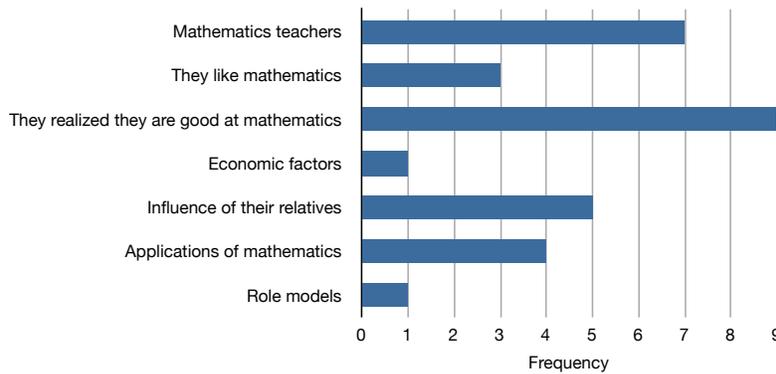

Figure 1: Some factors that motivate the female students in our sample to study mathematics.

Now we will explain in more detail each of the categories listed in figure 1:

Mathematics teachers. Mathematics teachers are the second most mentioned motivating factor among the students. There are several aspects that students highlight about their teachers: Some mentioned that they liked the way they taught, for example, by presenting step by step and detailed explanations of the topics; others mentioned that their teachers were enthusiastic and they transmit them their love for mathematics; other students, as illustrated in the following transcript, mentioned that their teachers assigned them extra activities and even invited them to some math-related extracurricular activities (like math competitions):

Student: The teacher taught me many things because I was interested; then, after finishing the class, she gave me more lessons, she taught me more things. Actually I went with her to several competitions.

They like mathematics. When asked what motivated them to study mathematics, some students simply respond: “because I like them”. When asked why they like mathematics, one student said that she liked mathematics because of its exact nature, and because of the pleasure felt when solving a problem. However, some students find it difficult to clarify their reasons:

Interviewer: Can you explain why do you like mathematics?

Student 1: Well, not really. It’s a delight, as someone who loves music.

Interviewer: Why do you like mathematics?

Student 2: I have no exact idea... I like them because... I don't know how to say it, I feel like it is a science.

They realized that they are good at mathematics. The main motivating factor mentioned by the students was that, at some point in their life, they realized that they were good at math. Different situations allowed them to recognize their mathematical skills: In some cases their teachers explicitly told them that they were good at math; some students noticed their mathematical skills because they did well in mathematical competitions or because they got good grades; some received social recognition when their classmates asked them for help to study or to solve their homework. In some cases there was also a self-recognition of their mathematical skills when noticing that their peers struggled to solve mathematical tasks while they solve them with ease.

Economic factors. There was a student who said that she would have liked to study a bachelor of finance at a private university, but due to financial constraints, she had to choose another math-related career at a public university. It was then when she decided to study a bachelor degree in mathematics.

Influence of their relatives. The family is an important source of motivation for students. There was a student who noted how proud his parents were of her because she was doing well in mathematical competitions; seeing her parents pleased and happy because of her performance motivated her to study mathematics. On the other hand, several students mentioned that someone in their families (their parents, their brothers, uncles) had a math-related job or degree, and that inspired them to study. See for example the next transcription:

Interviewer: What did your parents say when you told them that you wanted to study mathematics?

Student: What happens is that my dad he is a math teacher, then well... then he told me yes, it is a good choice. He encouraged me and asked me to make my best effort.

Applications of mathematics. There were four students who referred to moments in their school life where they found that mathematics could have many applications. The students claimed that this characteristic made them get interested in mathematics. The following is a transcript of one of these accounts:

Student: In high school a teacher played a video about how mathematics is everywhere, ... well it is also used in music and, I don't know, it called my attention to know that there are many applications and that at the end, everything has to do with mathematics.

Role models. When we talk about role models we refer to people who serve as an example and inspiration to students, but who are neither their teachers nor their relatives. One student remembered her encounter with an astrophysicist. Apparently he was a source of inspiration for her:

Student: My dad knows a person who is an astrophysicist, in fact he studied here [in the National Polytechnic Institute], he is now at NASA...I would like to study astrophysics, I really like the outer space, see, I want to see [...]

CONCLUSION AND DISCUSSION

In this project we are trying to answer the following research question:

What factors motivates Mexican female students to choose mathematics as a career?

Based on the previously presented preliminary results, we can say that there are three major factors that influence Mexican female undergraduate students to choose mathematics as a career:

- (1) To be aware of the fact that they are good at mathematics.
- (2) The influence of their mathematics teachers.
- (3) The influence of their relatives.

Our results are similar to those reported in previous research. For example, Eccles (2007) mentions the confidence that individuals have in their own intellectual abilities as a motivating factor for women to study STEM careers; on the other hand, Sjaastad, (2012) recognizes the big influence that parents, teachers and friends can exert on young people for them to choose scientific careers. A result that we found in the study and we have not seen reported in the literature is that mathematical competitions can be a place where students can acknowledge or confirm their mathematical skills.

The three identified factors contain elements that help students to identify and confirm the ownership of attributes (such as the ability to solve mathematical tasks), which in turn could trigger the construction of an identity as mathematics learner (Anderson, 2007). When this identity is constituted, choosing to study mathematics appears as a natural and well-suited option.

For instance, the situation where their classmates asked for help to do their homework, can be interpreted as a process where female students realize that they have certain mathematical abilities; when the teacher assigns extra tasks to the student, in a way is implicitly communicating that the student is special: she possesses qualities that others do not have. In our view, a good performance in mathematical competitions can help students to confirm the ownership of such mathematical skills. These inputs that the female student receives may help to constitute the identity face known as *engagement* (Anderson, 2007), where students identify themselves as capable mathematics learners. On the other hand, noticing that some of your relatives have studied or perform some math-related job can support the creation of a mathematical identity compatible with one of the most important social groups to which you belong: your family. We believe that this type of influences from family members can encourage the student to imagine herself as a person that in

the future could pursue a math-related career. Anderson (2007) refers to this aspect as the *imagination* face of identity.

We believe that it may be productive to continue exploring this theoretical perspective to support the development of our research. The next step in our research will be finishing with the data analysis and categorization of the results. Also, to delve deeper into the theoretical perspectives that connects the self and identity with career choice.

ACKNOWLEDGEMENTS

This paper is a result of the research project SIP-20121127, funded by the Instituto Politécnico Nacional (National Polytechnic Institute) of Mexico.

The authors would like to thank Dr. Adolfo Escamilla Esquivel and M.Sc. Olga Leticia Hernandez Chavez from the National Polytechnic Institute of Mexico, as well as Dr. Raquel Rufino López Martínez from University of Veracruz for their support in conducting this research.

INVESTIGATING TEACHERS' TRIGONOMETRY TEACHING EFFICACY

Ayşe SARAC, Fatma ASLAN-TUTAK

Bogazici University

The purpose of this paper is to share the process of investigating teachers' trigonometry teaching efficacy and determining their efficacy levels for a larger study. Firstly, Teacher Trigonometry Teaching Efficacy Scale (TTTES) was administered to sixteen teachers. Teachers generally scored the highest rank for their efficacy in the scale so they were not differentiated. Then, an interview protocol was designed to decide teachers' levels of efficacy from their experiences of teaching trigonometry. Teachers' answers were studied by using three indicators of self-efficacy: choices, effort, and thought patterns and emotions. Then, the researchers could determine teachers' trigonometry teaching efficacy.

Keywords: Teacher efficacy, trigonometry teaching efficacy.

INTRODUCTION

Teachers' confidence level of their ability to teach, teacher efficacy, has an important role in their teaching practices. Teachers with high teaching efficacy put more effort in teaching and use more diverse teaching strategies in class (Ghaith & Yaghi, 1997). The effective teaching methods may have positive effect on their students' learning and their desire to work on the subjects (Ashton, Webb, & Doda, 1983). So, it is important to study teacher efficacy and its relation to other variables.

Bandura (1982) developed social cognitive theory and suggested the concept of self-efficacy. Tschannen-Moran, Woolfolk-Hoy and Hoy (1998) defined teacher efficacy as the level of belief a teacher has in his or her ability to affect student achievement and they developed a model using Bandura's theory which emphasized the relationship between teacher efficacy and teaching experiences and it was widely used in literature.

The previous studies mainly investigated general teaching efficacy. However, the studies that investigate teaching efficacy for a specific topic such as trigonometry are rare in literature. In our study, we aimed to focus on trigonometry because it is one of the fundamental topics in high school curriculum with its relation to other topics such as complex numbers, derivatives. Also, it includes both algebra and geometry. Since teacher efficacy is related with student achievement and interest (Nelson, 2007); it may also be related with students' self-efficacy. Hence, studying the relationship between teaching efficacy and student self-efficacy in trigonometry would contribute to literature. However, administering a survey to study teachers' content-specific teacher efficacy was challenging because teachers would choose high self-efficacy options. For a larger study, the researchers needed to differentiate and group teachers

according to their teacher efficacy levels. So, another approach was necessary to determine teachers' efficacy levels in order to study the relation between teaching efficacy and student achievement and self-efficacy. The focus of this paper is to share the process of development and the use of an interview protocol with a coding frame in order to determine teachers' levels of trigonometry teaching efficacy. Furthermore, the authors will also propose that the protocol and the coding frame may be used for identifying teaching efficacy levels for other topics.

TEACHER EFFICACY

Teacher efficacy has been defined as how competent a teacher feels in his or her ability to affect the performance of all students (Tschannen-Moran et al., 1998). In fact, a number of studies have concluded that teachers with high levels of efficacy differed significantly in their teaching practice from teachers with low levels of efficacy. Teachers with high efficacy tend to have greater levels of planning and organization as well as being more enthusiastic to teach (Allinder, 1994). Teachers spend more time teaching in subject areas where their sense of efficacy was higher (Riggs & Enochs, 1990); whereas teachers tend to avoid subjects when their efficacy was lower (Riggs, 1995). Specifically, high efficacy teachers demonstrated more effective teacher behaviors that led to higher student achievement (Ashton et. al., 1983). So, teacher efficacy is an important construct with its relation to teachers' teaching methods and it is necessary to understand and study it effectively.

Many teacher efficacy instruments have been developed in the last three decades. In 1984, Gibson and Dembo developed the Teacher Efficacy Scale (TES), and the scale included items related with general teaching efficacy- teachers' beliefs about their ability to affect students' achievement. The measure uses a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree). With the recognition that efficacy belief is context specific (Bandura, 1982), researchers began to develop scales that focused on specific content areas, such as Science Teaching Efficacy Belief Instrument (STEBI, Riggs & Enoch, 1990). Riggs and Enoch changed the items on TES from more general teaching perspective to science specific items and they focused on the teachers' confidence level in teaching science. Similarly, Betz and Hackett (1981) developed Mathematics Self-Efficacy Scale (MSES). In addition, the authors were investigating teaching efficacy for a specific topic, trigonometry. Therefore, the authors adapted the Mathematics Self-Efficacy Scale (MSES) to trigonometry by changing items being specific to trigonometry teaching.

It is aimed to study trigonometry because of its importance in high school curriculum. It is a product of algebraic techniques, geometrical realities and trigonometric relationships. For most of the students in higher education, it is necessary to study trigonometry with its relation to other topics such as integral, derivative. Understanding of its basic concepts and application to the geometry and algebra is important for students to learn other mathematics topics effectively. However, studies have indicated that students had difficulty in understanding trigonometry (Akkoc, 2008) and they were not motivated to do it (Durmus, 2004). As teacher efficacy is

one element that is related with student achievement and motivation, it should also be studied for such an important topic. However, there is limited research related to teachers' trigonometry teaching efficacy.

METHOD

As a part of a larger study we intended to differentiate 16 teachers according to their trigonometry teaching efficacy. For this purpose, Teacher Trigonometry Teaching Efficacy Scale (TTTES) which was adapted from MSES was used, but the results show that all 16 participants had high efficacy. With this result the researchers could not determine teachers' trigonometry teaching efficacy; in turn its relation with the student variables (achievement and efficacy) could not be studied. Therefore, the researchers developed an interview protocol with a coding frame to differentiate teachers as low and high trigonometry teaching efficacy. Among the sixteen teachers of the larger study, 13 of them voluntarily agreed to participate in individual interviews.

Sample

The sample of the larger study consisted of mathematics teachers ($n=16$) from various high schools in Istanbul, Turkey. In Turkish education system, the four-year secondary education is provided in two different types of schools, non-vocational and vocational. Non-vocational secondary education institutions consist of General High School and Anatolian High School. Anatolian High Schools admit students according to their high-stake test scores whereas General High Schools admit students with low scores or without any scores. These two types of institutions demonstrate some differences with respect to the number of students in classrooms, selection of teachers, conditions for admission, etc. All schools are required to apply the national curriculum. Therefore, teachers of different types of schools teach the same objectives as stated in the curriculum.

In this study, in order to control the effect of school, same type of schools (general high school) were chosen from similar districts of Istanbul with similar student profiles (such as low social economic status). Number of students who involved in the larger study was 571. Furthermore, among the 16 participating teachers, four of them were male and 12 of them were female. Ten of them graduated from mathematics department, three of them graduated from mathematics education, two graduated from physics and one from chemistry department. Teachers with non-educational degrees were certified to teach after a short period of pedagogy training. Teachers' years of experiences in teaching mathematics was high, as majority of them have been teaching more than ten years. Four of them had more than 15 years, three of them had 10-15 years, six of them had 5-10 years and three of them had less than 3 years of experience.

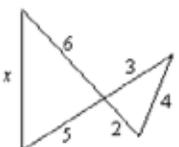

Teachers Trigonometry Teaching Efficacy Scale (TTTES)

This scale was adapted by the researchers in order to measure the efficacy level of teachers in teaching trigonometry. Mathematics Self-Efficacy Scale (MSES) which was developed by Betz and Hackett (1981) was used as the primary model. Betz and Hackett (1981) developed the MSES to measure college students' mathematics self-efficacy with greater specificity than previous instruments. This instrument has been used widely in research (e.g. Zimmerman, 2000). The MSES has 52 items which address some college mathematics topics such as algebra, calculus, economics, and statistics. Each item has a rating scale with 5 levels to show the confidence level of participants to solve the given problems for an item.

Since the purpose of the present study was to measure efficacy on trigonometry teaching, the teachers were asked about their confidence of teaching trigonometry problems. This adaptation of the items was supported by the suggestions of Bandura (1997) to assess self-efficacy. According to Bandura, the items should be aligned with the task being assessed and the domain which is analyzed.

For the adaptation, we needed to consider the Turkish curriculum for trigonometry. In order to determine the questions of the instrument, the objectives of national curriculum were used. In the curriculum, the trigonometry unit consists of six main sub topics: Trigonometric Functions, Graphs of Trigonometric Functions, Inverse Trigonometric Functions, Trigonometric Relations in a Triangle, Addition Formulas, and Trigonometric Equations. In other words, the mathematics problems for the instrument items were developed to cover all the sub-topics. There were 18 items in the instrument. The items were adopted from problems in several resources (MEB, 2005; Altuntas, 2007). Some examples from the TTTES are presented in Figure 1.

- Graph the function $f(x) = 3 \sin(2x)$.
-

Find the x value in the above figure.

- $\tan\left(\arctan \frac{1}{2} + \operatorname{arccot} \frac{2}{3}\right) = ?$

Figure 1. Items from TTTES

As in MSES of Betz and Hackett (1981), teachers were not asked to solve the problems but they only rated their perception of confidence to teach given problems. Each item has a rating scale with 5 levels ranging from 1 (I am not at all confident) to 5 (I am totally confident). The whole test can be seen in Sarac (2012). In our study, for this instrument, teachers generally marked the highest rank as their self-efficacy.

There were 16 participants and 12 of them got 90 and the remaining four got more than 80 out of 90. In the previous study (Betz & Hackett, 1981), when MSES was used with college students, the researchers did not report a similar situation. On the other hand, in our study teachers were asked about their confidence level to teach those problems rather than their confidence level to solve problems. It might also be possible that teachers thought to be tested about their profession and their knowledge of trigonometry. Hence, in our study TTTES was not effective in determining teachers' trigonometry teaching efficacy.

Individual Interviews

When we did not reach our purpose with TTTES, we searched for another way to get detailed information about teachers' efficacy. Instead of asking teachers about their confidence of teaching a given mathematics problem, we decided to conduct interviews with them about their teaching trigonometry experiences. Among the sixteen teachers, thirteen of them accepted to participate in an interview. Without asking direct questions about their confidence in teaching trigonometry, the interview was designed to talk with teachers about their experiences because ones' experience related to a task is one of the major indicators of self-efficacy (Bandura, 1997). Furthermore, as Philippou and Christou (1998) pointed out, "teachers' formative experiences in mathematics emerge as key players in the process of teaching since what they do in the classroom reflects their own thoughts and beliefs" (p. 191). Therefore, the researchers developed a semi-structured interview protocol with three questions:

- 1) Could you give information about your teaching methods for trigonometry?
- 2) Could you share your experiences related with teaching trigonometry in this year?
- 3) Could you share your experiences related with teaching trigonometry in previous years?

During the interview, teachers articulated their teaching trigonometry experiences and their teaching methods. They also shared the challenges they encountered and their methods of overcoming those.

Interviews lasted 40- 45 minutes. They were conducted and analyzed in Turkish but the researchers translated them into English for this paper. The interviews were audio-taped and transcribed. To be able to determine teachers' efficacy in teaching trigonometry as low and high, three indicators, *choices*, *effort thought patterns and emotions*, of teacher efficacy were utilized. These indicators were based on two sources: Bandura's self-efficacy theory and previous studies related with the features of high and low self-efficacy people (Pajares, 1996). The indicators and their use for the determination of teaching efficacy are explained in detail as follows:

Choices: People who have high self-efficacy engage in the activities more willingly and they tend to set higher goals to achieve. On the other hand, people with low self-

efficacy tend to set incomplete goals and they feel incompetent (Bandura, 1997). In this study, some teachers reported that they really liked teaching trigonometry and wanted to teach trigonometry (they were coded as 1 for this indicator as willingly engage in the activity) while some stated teaching trigonometry to students was more difficult than other subjects (they were coded as 0 for this indicator as they were not willingly engage in the activity).

Teacher A: I really like to teach trigonometry. It is a wonderful subject, since I teach it by forming connections with analytic geometry. I teach it by helping students to connect it to the triangles and unit circle. (Engage willingly and set high goals. Choices indicator is present)

Teacher B: It is difficult to teach trigonometry because students do not have the necessary pre knowledge. It is so long that students get easily bored and once they get lost, they cannot continue. I am not able to help all of them. (Do not set high goals and do not wish to involve in teaching trigonometry. Choices indicator is not present.)

Effort: People with high self-efficacy put more effort on the job and they work harder. They show more self-regulated behaviours and use more effective strategies (Bong, 1997). They believe in themselves whatever the situation is. They attribute the success or failure to themselves while low self-efficacy people blame other factors such as crowded classrooms, intense curriculum (Rotter, 1966). Some teachers in the interview stated that they tried hard to teach trigonometry and strived to overcome the difficulty of students' lack of previous knowledge (they were coded as 1 for this indicator as they put more effort) while some stated that they could not do anything to teach the students who were not good at mathematics and unmotivated (they were coded as 0 for this indicator as they did not try to get over difficulties).

Teacher C: I strived hard to teach trigonometry since it is a very important subject. Firstly, I tried to teach the necessary prerequisite knowledge. Also, I gave homework to students to help them learn all the parts of it well. I talked individually with the students who are not so good at the subject and recommended them some extra work to close the gap with other students. (Putting more effort and striving hard to teach. Effort indicator is present.)

Teacher D: It is a difficult subject. Students' levels were low. It was necessary to complete their missing previous knowledge and to teach it at low level. However, it was not possible to teach all the previous knowledge because when I went back, the subject was messed up and I could not build it up. (Not striving hard for the students who do not have the previous knowledge. Effort indicator is not present.)

Thought Patterns and Emotions: People with high self-efficacy are more comfortable and they are less anxious (Pintrich & De Groot, 1990). While they talk about their experiences they use less negative words (Bandura, 1997) whereas people who have low self-efficacy concentrate on difficulties and use more negative words about their

experiences. In this study, some teachers talked more on difficulties of teaching and blame students (they were coded as 0 for this indicator) while some concentrated on their efforts in teaching trigonometry (they were coded as 1 for this indicator).

Teacher E: This year it was good for me to observe that I could teach students some necessary knowledge in trigonometry. Also, I feel successful in that I helped them to study in 80 per cent. If I can help them to change their negative emotions about trigonometry, the remaining part becomes nice to teach. (Not concentrating on difficulties and not using negative words. She says that it is good to observe students learn. Thought Patterns and Emotions indicator is present.)

Teacher F: Teaching those [low achieving] students was very frustrated for me since I could not get any sign of learning from them. (Concentrating on difficulties, using negative words. Thought Patterns and Emotions indicator is not present.)

Teachers' answers to interview questions were evaluated by giving code for each indicator (0 or 1). The teachers who showed the features of the indicator were coded as 1 and the ones who did not show the features were coded as 0. With the summation of the codes for three indicators, the final score for each teacher was calculated. Teachers with 2 or 3 were categorized as having high trigonometry teaching efficacy and the ones with 0 or 1 were categorized as having low trigonometry teaching efficacy. The categorization of the teachers according to their interviews was checked by a mathematics education expert.

Among the 13 teachers, six teachers got 0 or 1 and were categorized as having low trigonometry teaching efficacy whereas 7 teachers get 2 or 3 and they were categorized as having high trigonometry teaching efficacy. Table 1 presents the scores according to teachers. Pseudonyms were used for each teacher.

Teacher	Choices	Effort	Thought Patterns and Emotions	Total
Oyku	1	1	1	3
Dilan	1	1	1	3
Cigdem	1	1	0	2
Hulya	0	1	1	2
Fahri	1	1	0	2
Kerem	1	0	1	2
Ozge	0	1	1	2
Hasan	1	0	0	1
Gaye	0	1	0	1
Ayca	0	0	0	0
Nermin	0	0	0	0
Hale	0	0	0	0
Melisa	0	0	0	0

Table1. Trigonometry Teaching Scores for the Indicators

Furthermore, as it was stated before, the differentiation of the teachers was used in a larger study (Sarac & Aslan-Tutak, 2012) to investigate the relation between teachers' trigonometry teaching efficacy and their students' self-efficacy. The students were grouped according to their teachers' efficacy level and the groups' self-efficacy levels were compared. Significant difference was found between two groups of students in terms of their trigonometry self-efficacy.

DISCUSSION

In this paper, we suggested a method of determining teachers' trigonometry teaching efficacy. Firstly, trigonometry teaching efficacy was attempted to be studied using TTTES in which teachers were asked about their confidence level to teach trigonometry for a given problem. However, we could not differentiate the teachers since teachers ranked the highest score for their trigonometry teaching efficacy for almost all questions. So, we decided to get further information about their teaching efficacy by developing an interview protocol.

In these interviews, teachers were not asked directly about their confidence level to teach trigonometry, instead they were asked to share their teaching methods and teaching process, assuming that teaching experiences were the major indicators for one's teaching efficacy. From their answers, we were able to determine teachers' trigonometry teaching efficacy. For instance, some teachers concentrated on the

difficulties expressing negative feelings such as frustration of not being able to teach all students while some were on the more positive side expressing the enjoyment to teach all students. Therefore, teacher efficacy can be studied using the mentioned indicators- *choices, effort, and thought patterns and emotions*. So, this paper proposes a method for studying teacher efficacy for specific topics.

Teacher efficacy and student attitudes toward a subject found to be related (Nelson, 2007). By means of the interview protocol we could differentiate teachers according to their teaching efficacy and compare the students' of high and low efficacy teachers. In the larger study, teacher efficacy and student self-efficacy found to be related. The results of the larger study also support the effectiveness of the protocol to determine teachers' levels of efficacy.

Furthermore, the interview protocol and the coding frame may also be applied for other content-specific topics. These types of studies will also provide information about the effectiveness of the method. On the other hand, by using the findings of these interviews, TTES can be improved by adding items targeting the indicators. In this study, we used binary scale for the indicators since our purpose was categorizing teachers in two groups. However, differentiated scales can be used for the efficacy levels for other studies. These efforts might yield into developing a new survey to measure teacher efficacy.

UNCERTAINTY ORIENTATION, PREFERENCE FOR SOLVING TASK WITH MULTIPLE SOLUTIONS AND MODELLING

Stanislaw Schukajlow and André Krug

University of Paderborn

In this study 235 ninth graders from ten German middle track classes were asked about their preference for solving tasks with multiple solutions, uncertainty orientation and treating tasks with multiple solutions in their everyday mathematical classes. Preference for solving tasks with multiple solutions and uncertainty orientation were assessed before and after a five-lesson teaching unit promoting modelling competency with either one solution or multiple ones as well as in the control group. The findings show that (1) preference for solving tasks with multiple solutions is connected with students' uncertainty orientation and treating these tasks in the classroom, (2) after the teaching unit, a group where multiple solutions were treated indicated the stronger preference for solving tasks with multiple solutions.

Key words: multiple solutions, affect, modelling, word problems, teaching methods

INTRODUCTION

The principles of high quality teaching mathematics include the use of cognitively demanding tasks, development of multiple solutions, reflecting on, comparing and discussing different solution methods (Silver, Ghouseini, Gosen, Charalambous, & Font Strawhun, 2005). For the recent 10 years, there have been first evidences that the comparison of different solution methods can improve students' mathematical competency, if students have a sufficient prior knowledge in the target domain (Rittle-Johnson, Star, & Durkin, 2009). This finding is in line with the outcomes of studies that compared teaching methods in different countries. Teachers in high-performing countries such as Japan demand from students to find more than only one solution and to discuss solution methods in the classroom. Teachers in the other countries often think that students will be lost in the variety of solutions and therefore do not practice them (Leikin & Levav-Waynberg, 2007).

There is still a lack of studies, which investigate emotions, attitudes and beliefs regarding to the use of multiple solutions. As students' improvement in the affect domain is an important goal of mathematics education, we focus in this study on students' uncertainty orientation, preference for solving problems with multiple solutions, and treatment of (or dealing with) these problems in the classroom. Further, we have investigated the possibilities to influence students' uncertainty orientation and their preference for solving problems with multiple solutions positively. A five-lesson teaching unit promoting multiple solutions while modelling was conducted and evaluated using a 3x1 experimental-control-group design.

This study was carried out in the framework of MultiMa-project (*Multiple solutions for mathematics teaching oriented towards students' self-regulation*) that has been funded by the German Research Foundation since 2011 (SCHU 2629/1-1). MultiMa aims to investigate students' dealing with multiple solutions while modelling, students' affect as well as the development of mathematical competency in learning environments oriented towards self-regulation (Schukajlow & Krug, in press).

THEORETICAL BACKGROUND AND RESEARCH QUESTIONS

Multiple solutions and modelling problems

The analysis of solving problems showed that there are three types of multiple solutions (see a similar approach by Tsamir, Tirosh, Tabach, & Levenson, 2010). The first type of multiple solutions can be conducted due to the variation in *mathematical* solution methods. The second type of multiple solutions can be developed if students solve problems with missing data. For solving these problems, they have to take assumptions about the missing data and thus, get different outcomes. The third type of multiple solutions includes the variation in mathematical solution methods as well as in different outcomes.

The missing data is one of typical features of modelling problems. The core of modelling activities are demanding transfer processes between reality and mathematics (Blum, Galbraith, Henn, & Niss, 2007). We illustrate different types of multiple solutions using the task "Parachuting". For calculation of hypotenuses while solving this problem, students can use as mathematical procedure either Pythagoras' Theorem or scale drawing. Further, in order to solve the problem, they have to take assumptions about some data such as wind power and can get different results using the same mathematical method.

Parachuting

When "parachuting", a plane takes jumpers to the altitude of about 4000 metres. From there they jump off the plane. Before a jumper opens his parachute, he free falls about 3000 metres. At an altitude of about 1000 metres the parachute opens and the sportsman glides to the landing place. While falling, the jumper is carried off target by the wind. Deviations at different stages are shown in the table below.

Wind speed	Side deviation per thousand metres during free fall	Side deviation per thousand metres while gliding
Light	60 metres	540 metres
Middle	160 metres	1440 metres
Strong	340 metres	3060 metres

What distance does the parachutist cover during the entire jump?

Affect and modelling

Stability (state vs. trait) and functionality (truths, feelings and preferences) are important characteristics of affective domain (Hannula, 2012). In this study, we focus on the personal trait “uncertainty orientation” and students’ preference for solving tasks with multiple solutions.

The uncertainty orientation (Sorrentino & Roney, 1999) describes a person’s typical ways of dealing with complexity, uncertainty, and abundant information (Hänze & Berger, 2007). Uncertainty-oriented persons are interested in complex situations and use these situations to gain the new knowledge. Persons with strong certainty orientation look for situations, which are already familiar. Huber, Sorrentino, Davidson, Eppler, and Roth (1992) found that students with uncertainty orientation learn more, if cooperative teaching methods were applied in the classroom. However, this result could not be confirmed in further studies (Hänze & Berger, 2007). One possible explanation of this inconsistency is that the level of structuring the learning material such as the type of tasks, influences the learning processes. The treatment of problems, in which all data are given, meets the needs of certainty-oriented students. The treatment of problems with missing data, whereas the development of multiple solutions is demanded, meets the needs of uncertainty-oriented ones. As the uncertainty orientation is a personal trait regarded to the dealing with uncertainty in different situations, we do not expect that solving the tasks with multiple solutions in the classroom can change this trait.

Preferences are closely connected with motivational constructs (Hannula, 2012). They can regard to the global objects such as learning, or to the specific situations, such as dealing with different kinds of tasks. The assessment of task-specific measures allows to collect information about students’ affective dimensions and can help to answer questions that are specific for mathematics educations. Task-specific measures are more sensitive than traditional instruments and can be used for evaluation of short-term interventional studies, where significant changes in motivational traits using traditional scales could not be expected. In the study by Schukajlow et al. (2012), there was found that student-centred teaching method for fostering modelling competency improved students’ *task-specific* enjoyment, interest and self-efficacy expectations. The nearby average relationship of $r=0.27$ between treating tasks with multiple solutions and students’ preference for solving these tasks (Krug & Schukajlow, 2012) indicates that treating tasks with multiple solutions can influence students’ preference in a positive way. One goal of this study is to replicate this result. Another goal is to investigate, whether treating multiple solutions while solving modelling problems influences students’ preference for solving problems with multiple solutions positively. “Treating tasks with multiple solutions” means in this context that students work on problems, which demanded the development of more than one solution.

Research questions

The research questions of the study are:

1. How strong is a relationship between students' uncertainty orientation, preference for solving tasks with multiple solutions and dealing with this kind of tasks in the everyday classroom?
2. Does treating multiple solutions while solving modelling problems influence students' uncertainty orientation?
3. What is the impact of treating multiple solutions while solving modelling problems on students' preference for solving tasks with multiple solutions?

METHOD

Design and sample

235 German ninth graders (46% females; mean age=15.4 years, SD=0.62) were asked about their preference for solving tasks with multiple solutions and their uncertainty orientation before and after five-lesson teaching unit. Further, before the teaching unit the students were asked, how frequently they solved tasks with multiple solutions in their regular classes. In some German federal states, students, who completed the fourth grade, are assigned to the low, middle or high track classes depended on their performance level. The middle track classes were chosen for this study because in these classes the students of all three performance levels are to be found. Ten middle track classes (Realschule) from ten comprehensive schools (German Gesamtschule) and 8 teachers with at least two years' experience of teaching mathematics participated in the study. We assume that experienced teachers could better implement the instructions of the study.

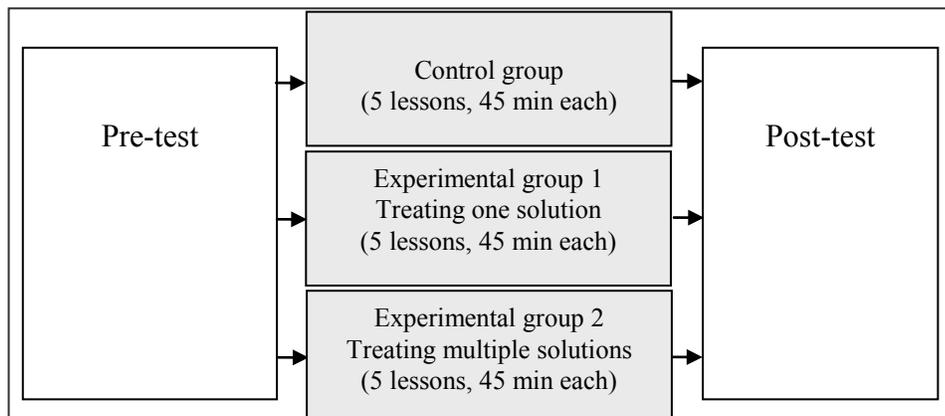

Figure 1: Overview of the study design

The sample consists of one control group and two experimental groups. The experimental groups needed a strong support by the research team, so six classes from three schools near the university were assigned to experimental groups. The remaining four classes were assigned to the control group. During the five-lesson period 105 students of the control group were not allowed to solve modelling

problems – solving of which may lead to comparison of different solutions – as well as to the problems to the “Pythagoras’ theorem”. To control, whether teachers really used only these types of problems, all the tasks solved by the students of control group were collected and analysed. The task analysis showed that no problems that required multiple solutions were treated.

Three schools with two middle track classes each were assigned to the experimental groups. Each of six classes was divided into two parts with the same number of students in such a way that the average achievements in both parts did not differ and there was the approximately same ratio of males and females in each part. In one part of each class one solution of modelling problems (experimental group 1: “one solution”) and in the other part multiple solution of modelling problems (experimental group 2: “multiple solutions”) were treated. During the teaching unit, students of both experimental groups were taught using modelling problems about “Pythagoras’ theorem”. The topic “Pythagoras’ theorem” had already been treated using mathematical tasks without connection to reality before the MultiMa teaching unit, in order to foster the use of this powerful mathematical procedure and to prevent applying different solution methods.

To implement the treating of modelling tasks with and without multiple solutions, two teaching scripts were developed. Four teachers, who had to give lessons in experimental groups, received these scripts with all tasks to be treated and a detailed plan of the teaching unit. Further, they were instructed about the specific ways to promote multiple solutions vs. one solution. Each teacher taught the same number of student groups in the experimental group “one solution”, as well as in the experimental group “multiple solutions”, so the influence of a teacher personality on students’ learning did not differ between both groups. In each lesson that was provided in the experimental groups, one member of the research team was present to videotape and to observe the implementation of the instructions.

In both experimental groups the same methodical order was committed. Students solve a modelling task according to a special kind of group work (alone, together and alone again) (Schukajlow et al., 2012). A solution (or different solutions) of the first modelling task is presented in the first lesson by the teacher and in the following ones by the students. The teacher summarizes and reflects on the key points of each group. In the group “multiple solutions” the teacher emphasises the development of different outcomes by estimating the missing data.

In order to stimulate the development of multiple solutions in the group “multiple solutions” and to prevent the development of more than one solution in the other experimental group, two similar versions of each treated task were developed. In the group “one solution” students solved among other tasks the task “Parachuting”, where the data, needed to solve the task, were given. These data were the wind velocity and the altitude, in which the parachute opens. The question posed in the task was: “What distance does the parachutist cover during the whole fall, if the wind

speed is middle?” The similar task in the group “multiple solutions” demanded the development of two solutions. The question posed in the task was: “What distance does the parachutist cover during the entire jump? Find *two* possible solutions” (see sample tasks by Schukajlow & Krug, 2012b).

Measures

The main difference between experimental groups was the demand to develop one solution or multiple solutions. We proved this key using students’ questionnaires. After every lesson the students were asked about the number of solutions they developed for each modelling problem in this lesson. For example: “While solving the problem “Parachuting” I developed today (0: no solution; 1: one solution; 2: two or even more solutions)”.

Students’ self-perceptions were measured using a 5-point Likert scale (1=not at all true, 5=completely true) before and after a five-lesson teaching unit. A sample item was for uncertainty orientation (5 items) “I like unexpected surprises”. The scale uncertainty orientation was adapted from the studies by Dalbert (1996) and Hänze & Berger (2007). Students’ preference for tasks with multiple solutions (6 items) was developed using the theoretical background to multiple solutions. This scale consists of questions about three issues: (1) multiple mathematical solution methods (“While working on mathematical problems, I like different calculations leading to success.”), (2) multiple outcomes (“While working on mathematical problems, I like to get different results”) and (3) multiple solutions in general (e.g. “While working on mathematical problems, I like to use different solution methods.”) Treating multiple solutions in the everyday mathematics classroom was measured using 6 items that are similar to the scale “preference for tasks with multiple solutions” (e.g. “In mathematics, we often work on problems that offer different solution methods”). Using of 6 items for measurement of each scale is one limitation of this study. The reliability values (Cronbach’s Alpha) for uncertainty orientation were 0.86 and 0.87, those for the preference for tasks with multiple solutions 0.77 and 0.85 in the pre- and the post-test respectively, and the reliability value for treating multiple solutions in mathematics classroom was 0.81 in the pre-test. More information about the validity of the measures should be collected in the future studies. All measures were a part of the longer questionnaires. Pre- and post-tests took 30 minutes each.

RESULTS

Preliminary analysis

First, we compared the number of solutions developed by both groups, “multiple solutions” and “one solution” (Schukajlow & Krug, 2012a). We analysed students’ answers using the t-test. The analysis shows that there are significant differences between the numbers of solutions that were developed in the respective groups ($T(138)=6.7$; $p<0.001$; effect size Cohen’s $d=1.16$). Whereas the majority of the students in the group “multiple solutions” developed two and more solutions

(mean=1.55, standard deviation SD=0.39), students in the group “one solution” reported on the development of one solution only (mean=1.14, SD=0.33). The analysis of the number of students’ solutions in the experimental groups and that of the tasks treated in the control group indicates that it was possible to realise the instruction conditions as it was intended in the study.

Uncertainty orientation, preference for solving tasks with multiple solutions and treating multiple solutions in the everyday mathematics classes

To answer the first research question, we analysed the relationship between students’ perceptions in the pre-test. There are low to middle statistically significant correlations between respective measures (cf. Tab. 1). Uncertainty-oriented students more frequently report on treating problems with multiple solutions in the classroom and on their preference to solve these problems than students without uncertainty orientation. The middle correlation of 0.46 was measured between students’ preference for solving tasks with multiple solutions and the treatment of the tasks with multiple solutions in the classroom. As a correlation between treating multiple solutions in the classroom and uncertainty orientation is weak, it is possible that the treatment of such problems foster students’ uncertainty orientation, but not significantly.

	UncO	PrMS	MSC
UncO	1	0.26*	0.17*
PrMS		1	0.46*
MSC			1

* The correlations are at least significant at the 5% level

Table 1: Pearson correlations between uncertainty orientation (UncO), preference for problems with multiple solutions (PrMS) and treating multiple solutions in the classroom (MSC)

The second research question pertains to the effect of treating modelling problems with multiple solutions on students’ uncertainty orientation. Is it possible to change students’ uncertainty orientation after the five-lesson teaching period and are there any differences between control and experimental groups? In order to test, whether the factor “type of intervention” influences students’ uncertainty orientation in post-test, ANCOVA (covariate: uncertainty orientation in pre-test) was conducted. The ANCOVA revealed a significant effect of the pre-test score ($F(1, 213)=84.60$, $p<0.05$), but no effect of “type of intervention” on the uncertainty orientation ($F(2, 213)=1.53$, $p=0.22$). This result shows that treating multiple solutions while solving modelling problems does not influence students’ uncertainty orientation.

The effect of the “type of intervention” on students’ preference for problems with multiple solutions (research question 3) was also computed using ANCOVA (covariate: PrMS in pre-test). The ANCOVA showed effects of PrMS in pre-test on

the PrMS in post-test ($F(1, 215)=56.43, p<0.05$) and a significant impact of the factor “type of intervention” on students’ preference for problems with multiple solutions in post-test ($F(1, 215)=6.87, p<0.05$). Students in the group “multiple solutions” report in post-test with respect to pre-test on stronger preference for problems with multiple solutions compared with the students in the group “one solution” or in the control group. No differences in this scale were found between the group “one solution” and the control group.

		Control group	One solution	Multiple solutions
		M(SD)	M(SD)	M(SD)
UncO	pre	3.66(0.89)	3.61(0.94)	3.50(0.92)
	post	3.32(0.99)	3.49(1.03)	3.41(1.03)
PrMS	pre	3.22(0.85)	3.29(0.90)	3.35(0.73)
	post	2.98(0.92)	3.03(1.02)	3.56(0.87)
MSC	pre	2.96(0.78)	3.05(0.78)	3.04(0.77)

Table 2: Students’ uncertainty orientation (UncO), preference for problems with multiple solutions (PrMS) and treating multiple solutions in the classroom (MSC) in the control and experimental groups

DISCUSSION

In the study reported here, students’ uncertainty orientation, preference for solving tasks with multiple solutions and dealing with this kind of tasks in the everyday classroom were assessed. Between uncertainty orientation and students’ preference for solving tasks with multiple solutions, a small statistically significant relationship was found. This relationship shows that students who were looking for unfamiliar situations like to solve the tasks that demand taking assumptions, allow choosing different mathematical methods and having different mathematical results. So, the results of the study support the assumption by Hänze & Berger (2007) that the level of structuring the material can influence students’ learning. However, we did not gain any results, whether uncertainty-oriented students prefer solving well-defined tasks more than certainty-oriented students. It is possible that uncertainty-oriented students have more positive perceptions of solving any kind of mathematic tasks than certainty-oriented students. One important future research field is therefore to compare students’ preference for tasks with multiple solutions with students’ preference for clear-structured, well-defined tasks that have one right solution only, taking in account students’ personal traits such as uncertainty orientation. Another important question concerns the connection between uncertainty orientation and the construct of identity. Uncertainty orientation may be a part of identity which influences our actions in learning situations.

The average correlation between the dealing with tasks required multiple solutions and preference for solving these tasks means that students who frequently report on solving the tasks with multiple solutions like to solve this kind of tasks more than students that solve them rarely. This finding confirms our previous results (Krug & Schukajlow, 2012) and indicates that treatment of tasks with multiple solutions can improve students' preference for solving this type of problems.

In order to prove the direction of the assumed connection between both measures, an experimental study was conducted. In the experimental groups modelling problems with and without multiple solutions were treated five lessons long. The analysis of the data showed that students of the group, where multiple solutions were treated, liked the tasks with multiple solutions more than the students who solved modelling tasks with one solution only, or than the students of the control group with respect to their pre-test. As no differences between the group "one solution" and the control group were found, the changes in the students' preference could not be attributed to the special kind of student-centred teaching method applied in the experimental groups. Also, we showed that a students' task-specific motivational construct regarding to multiple solutions can be changed positively. The positive changes in students' preference for tasks with multiple solutions can promote students' involvement in the content activities and, as a result, improve their performance. Investigation of relationships between students' preferences, emotions, beliefs and performance concerning different type of problems is an important future research field. Finally, we showed that the personal trait uncertainty orientation did not differ between the experimental groups and the control group. For changing this stable trait, a special long-term training program regarding different domains is needed.

As in this study we used new scales with a limited number of items, and as there are only few studies in the domain of mathematics that investigated students' preferences regarding to multiple solutions or their uncertainty orientation, a replication of our results in future research is essential.

STUDENTS' MOTIVATION AND TEACHERS' PRACTICES IN THE MATHEMATICS CLASSROOM

Kjersti Wæge¹ and Marilena Pantziara²

¹Norwegian University of Science and Technology

²Cyprus Pedagogical Institute

This paper presents five different families of social cognitive motivational constructs: efficacy, control, interest, values and goals. Two motivation theories will be developed further, namely achievement goal theory and self-determination theory. Research on the relationship between teachers' practice in the mathematics classroom and students' motivation, in terms of intrinsic motivation and goal orientation, will be reviewed. It seems like some aspects of mathematics teachers' instructional practices have a positive influence on both students' intrinsic motivation and goal orientation.

Keywords: Motivation, goal orientation, intrinsic motivation, teachers' practice

INTRODUCTION

The importance of motivation in mathematics education has been well documented (Hannula, 2006b; Pantziara & Philippou, 2007). It is believed that motivation is one of the energizing forces to learning and adaptive behaviour in school settings (Pintrich, 2003; Zhu & Leung, 2010). As Hannula (2006b) points out "To understand students' behaviour we need to know their motives" (p. 165). Theorists believe that motivation has a determinative role in students' success and failure in school (Cury, Elliot, Fonseca, & Moller, 2006; Pintrich, 2003).

Motivation is characterized by its complex nature due to its different definitions, different theoretical perspectives and the various ways that has been measured (Hulleman, Schweigert, & Harackiewicz, 2008; Pintrich, 2003). Motivation cannot be observed directly, but it can be manifested in cognition, emotion (affect) and/or behaviour. In this paper motivation is defined as "the preference to do certain things and to avoid doing some others (Hannula, 2006b). A vast number of theoretical perspectives have been developed in the realm of Educational psychology in order to better describe motivation. These theoretical perspectives can be seen as complementary to one another as each of them accounts for different aspects of motivation. Pintrich (2003) identifies five different social cognitive constructs that have dominated recent research on motivation in school settings. In this paper we will present these five basic families of motivational constructs. Two motivation theories will be developed further, namely achievement goal theory and self-determination theory, which integrates multiple social cognitive constructs. We will discuss research studies on how different aspects of teachers' instructional practices influence students' motivation, in terms of intrinsic motivation and goal orientation in mathematics.

MOTIVATIONAL CONSTRUCTS

One family of motivational constructs refers to self-efficacy beliefs and competence perceptions. Many different constructs are related with this theoretical family like self-efficacy, expectancy, perceptions of competence, self-worth, and self-determination (Bandura, 1994; Bouffard & Couture, 2003). Even though these constructs are defined differently they all focus on the same idea. Students who believe they are capable, and that they will do well, are more expected to be motivated, to have persistence and a more adaptive behaviour than students who believe that they cannot do well and therefore they will not succeed (Kaplan & Midgey, 1997; Pajares & Graham, 1999; Pantziara & Philippou, 2007). Research (Pintrich, 1999, 2003) also revealed that these self-assured students are more engaged in learning and thinking than students who mistrust their abilities.

A second family of motivational constructs are adaptive attributions and control beliefs (Pintrich, 2003). Basically these theoretical perspectives argue that students who believe that they have control on their learning and behaviour are expected to perform well and have higher achievement than those students who do not believe that they have the control of their learning. Similar to these notions are also entity and incremental theory of ability. Entity theory describes ability as steady and unalterable, whereas incremental theory characterizes ability as open to change (Cury, et al., 2006). Entity theory is posited to predict a poor set of outcomes, like low levels of persistence, performance and interest while incremental theory is posited to predict beneficial outcomes like high levels of persistence, performance and interest (Dweck & Leggett, 1998). In this family of research also belongs self-determination theory, which together with the fifth family of motivational constructs, which is achievement goal theory, will be developed further.

Self-determination theory is a model that integrates psychological needs and social-cognitive constructs (Ryan & Deci, 2000a). This model is built on the assumption that human beings have three basic psychological needs: the needs for competence, relatedness, and autonomy. Competence refers to the feeling of mastery and effectiveness in interactions with the environment. Relatedness reflects the feeling of being together with other persons in a secure community. Autonomy refers to being in control or being the perceived origin of one's own behaviour. When individuals are autonomous they experience themselves as volitional initiators of their own actions (Ryan & Deci, 2002). Cobb, Gravemeijer, Yackel, McClain and Whitenack (1997) use the concept of intellectual autonomy as a characteristic of a student's way of participating in the practices of a classroom community. They speak of students' awareness and willingness to draw on their own intellectual capabilities when making mathematical decisions and judgments as they participate in mathematics activities. The concept of need is useful because it allows the specification of the social-contextual conditions that will facilitate motivation. According to self-determination theory, students' motivation will be maximized within social contexts that provide them with the opportunity to satisfy their basic needs for competence, autonomy and

relatedness (Ryan & Deci, 2000a, 2002). Self-determination theory makes a distinction between intrinsic motivation and extrinsic motivation. Intrinsic motivation refers to doing of an activity for its own sake and enjoyment. In contrast, extrinsic motivation reflects a behaviour that is undertaken in order to attain some separable outcome (Ryan & Deci, 2000a). Research from self-determination theory has demonstrated the importance of perceptions of autonomy and competence in adaptive behaviour, and the theory highlights the importance of providing some autonomy, choice, and control for students, in order to facilitate students' intrinsic motivation (Ryan & Deci, 2002). Research has shown that there is a positive correlation between students' feeling of autonomy and more positive feelings, better learning and performance in school (Deci & Ryan, 2000).

A third family of constructs related to motivation is interest and intrinsic motivation. Interest can be defined as a psychological state in which someone is engaged, and entirely absorbed by an activity (Hulleman, et al., 2008). A distinction in this area is made between personal and situational interest (Pintrich, 2003). Personal interest is a more stable and lasting disposition of an individual who is attracted, enjoys or likes to be involved in an activity for its own sake (Hulleman, et al., 2008; Pintrich, 2003). Situational interest refers to the psychological state of interest that develops through the interactions with a task's characteristics, like pictures, humor etc. (Hulleman, et al., 2008). Research on personal and situational interest has revealed that high levels of both types of interest are related with more cognitive engagement, learning and achievement (e.g. Pintrich & Schunk, 2002). Interest is one of the central features of intrinsic motivation in self-determination theory (Deci & Ryan, 1985). Students who are intrinsically motivated work with an activity for the enjoyment or challenge entailed. They experience high levels of interest. Research found that intrinsic motivation is positively related to a number of desired cognitive and motivational outcomes such as students' academic performance and self-esteem (Gottfried, 1985; Ryan & Deci, 2000b).

Another family of constructs refers to students' thoughts about the importance of a task. This family of constructs is reflected in expectancy-value theory. Theorist argue that individuals' choice, persistence and performance can be explained by their beliefs about how well they can do a task and how they value this task (Wigfield & Eccles, 2000). Expectancy beliefs refer to children's beliefs about how well they can do on forthcoming tasks in the immediate or longer future (Wigfield & Eccles, 2002). Task value beliefs are defined by four components: intrinsic interest; utility, importance and cost (Pintrich, 2003). Research has found that task value beliefs predict choice behaviour, such as the intentions to enrol in future math courses. Expectancy beliefs like efficacy or competence perceptions found to predict achievement as students are enrolled in the course (Pintrich, 2003; Wigfield & Eccles, 2000).

The fifth family of constructs is goals and goal orientation, and within this family there have been two main directions of research on student motivation. One direction

focuses on goal content and the students' goal structures. These approaches assume that the students' goal structures are complex, and that the students tend to pursue multiple goals in the classroom. The goals are related to one another, and pursuing one goal might be necessary to attain another goal or different goals may be seen as contradictory (Boekaerts, 1999). Research shows that students' pursuit of social goals such as making friends and being responsible are related to effort and achievement (Pintrich, 2003). The second direction has focused on the nature of achievement goals or goal orientations. This has been one of the most active areas of motivation research on students' motivation. Achievement goal theory is concerned with the purposes of students' behaviour. Students with mastery goal are oriented toward learning and understanding as an end in itself. In contrast, a performance goal orientation refers to seeking to demonstrate that one has ability by outperforming others (Elliot, 2005). Recently, there has been a theoretical distinction between performance-approach goals, where the student is focused on outperforming others, and performance-avoidance goals, where the student is concerned with avoiding the demonstration of low ability or appearing incompetent in relation to others (Cury, et al., 2006). These goals have been related consistently to different patterns of achievement-related affect, cognition and behaviour. Mastery goals have been related to adaptive perceptions including feelings of efficacy, achievement, and interest (Anderman, Patrick, Hruda, & Linnenbrink, 2002; Cury, et al., 2006; Elliot & Church, 1997). Research on performance goals is less consistent, but students' performance orientation has been associated with maladaptive achievement beliefs and behaviour like low achievement, fear of failure and superficial cognitive commitment, i.e. copying, repeating and memorizing (Cury, et al., 2006).

HOW DOES TEACHERS' INSTRUCTIONAL PRACTICES INFLUENCE STUDENTS' MOTIVATION?

Most social-cognitive models of motivation assume that students' motivation is influenced by classrooms interactions, activities, practices and culture (Pintrich, 2003). Therefore the teacher's instructional practice has a crucial role in facilitating students' motivation. Within mathematics education there has been some research on the relation between different aspects of teachers' instructional practices and students' motivation in mathematics. In this paper we focus on two motivation frameworks, namely self-determination theory and achievement goal theory, and we will discuss research studies that have made use of these theories in order to understand or interpret how students' motivation in mathematics is influenced by teachers' instructional practices.

Students' needs and goals

Hannula (2006a, 2006b) claims that there is little room to meet students' need for competence, autonomy and relatedness in teacher-centred mathematics classrooms that tends to focus on the learning of routine procedural skills and individual work. More student-centred or reform-classrooms where the emphasis is on meaning-

making and collaborative work would give students more opportunities to fulfil their needs. Hannula (2004) suggested the need for more research to examine how students' motivation is influenced by the mathematics classroom practice.

Wæge (2008, 2010) examined students' (age 16) motivation in mathematics in terms of needs and goals. The results showed a close relation between the students' feeling of competence, in terms of relational understanding (Skemp, 1976) and learning, and their enjoyment in engaging in mathematical activities. Students who developed a feeling of relational understanding experienced higher levels of enjoyment than students with instrumental understanding. The study also showed that there were particularly three aspects of the teaching approach that conduced toward students' feelings of competence and sense of autonomy during action: 1) instructional activities, such as projects, problem solving activities, and real life problems, 2) students' collaboration with each other, and 3) encouragement and acceptance of students' own strategies for solving problems. The three factors were closely related to each other. The results indicated that the instructional activities positively influenced the students' enjoyment in mathematics, because they fulfilled their needs for competence and autonomy. Further, the study showed that the students' need for competence and autonomy were realised into more specific goals. The students realised their need for competence into a general goal of mastery in mathematics and a more specific goal of developing relational understanding. The students were concerned about knowing what to do and why. The need for autonomy was translated into the more specific goal of using own thoughts and ideas and generating own solutions.

These findings are consistent with previous research on students' motivation in mathematics (Cobb, Wood, Yackel, & Perlwitz, 1992). Boaler (2004) describes how teachers at a high school employed a reform-oriented mathematics teaching approach in order to develop good relationships between the students and to reduce social and academic status differences in the mathematics classrooms. Teachers encouraged students to take responsibility for each others learning and they created multidimensional classes where many dimensions of mathematical work was valued, such as generating multiple solution methods, asking good questions, justifying and explaining their answers. The results show that students learned to treat each other in more respectful ways and they enjoyed mathematics more than students taught in more traditional approaches.

A study by Stipek and her colleagues (Stipek, Salmon, Givvin, & Kazemi, 1998) showed that three aspects of mathematics teachers' practices were positively associated with students' positive feelings as well as their learning: 1) a positive affective climate, which means that the teacher treated students with respect, listened to their ideas and valued all student contributions, 2) teachers' emphasis on learning and understanding and the encouragement of autonomy, and 3) teachers' providing substantive, constructive feedback. The more teachers focused on these aspects, the more students experienced positive emotions and enjoyed learning.

The findings presented here are consistent with self-determination theory and research on students' motivation, indicating that students' feeling of relatedness, autonomy and competence facilitate enjoyment and intrinsic motivation in activities. According to Ryan and Deci (2002), intrinsic motivation represents a prototype of self-determined activity. They suggest that there is a strong relation between intrinsic motivation and the need for autonomy and competence. Mathematics classrooms that support students' needs for autonomy and competence will engender their intrinsic motivation in mathematics. Contextual events that students experience as thwarting satisfactions of these needs will undermine their intrinsic motivation.

Students' learning orientation

One of the strengths of goal orientation theory in understanding students' motivation is that it considers how the role of the teacher and the instructional context might influence students' goal orientations. Thus a major tenet of achievement goal theory is that students' adoption of goals is partly influenced by the goal structures promoted by the classroom environments (Anderman, et al., 2002). Goal orientation theorists often focus on six categories when studying classroom motivational environment. The categories are often described by the acronym TARGET, which refers to task, authority, recognition, grouping, evaluation and time. Task includes activities, such as problem solving or routine algorithm tasks, and open or closed questions or tasks; Authority refers to the level of autonomy in the classroom; Recognition refers to whether the focus is on the learning process or the final outcome of students' performance; Grouping refers to whether the teacher divide the classroom into groups according to their performance or not; Evaluation refers to teachers' assessment of students' learning and whether they focus on grades and test scores or feedback as a means for improving students' learning; Time refers to the flexibility of the schedule.

Studies (Anderman, et al., 2002; Turner, et al., 2002) showed that aspects of mathematics classroom environments in which students adopted mastery goals differed from classrooms in which students adopted performance goals, in terms of avoidance goals. In mastery oriented classroom teachers focused on the process of learning and understanding (recognition), challenging students and learning from mistakes (evaluation). The instruction was adjusted to the developmental level and interest of students (task), and students were encouraged to generate own strategies and solutions (authority) and to collaborate with each other (grouping). Teachers also valued the time during the lesson referring to time allocation for different activities (time).

Pantziara and Philippou's study of 15 mathematics classrooms (2007, 2010) showed similar results. In order to analyse teachers' instructional practice they developed a list of six categories based on achievement goal theory and mathematics education reform literature (Stipek, et al., 1998). These categories were: task, instructional aids, practices towards the task, affective sensitivity, messages to students, and recognition. This list of categories has some commonalities with the categories proposed by Anderman et al. (2002). Both models included the categories Task and

Recognition. Anderman et al. (2002) incorporated also the categories Authority, Grouping, Evaluation and Time. Pantziara and Philippou (2010) included practices towards the task and the use of instructional aids, practices that Anderman et al. (2002) included in the category Task. Moreover, they (2010) refer to affective sensitivity and messages to students. Pantziara and Philippou (2010) found that in the classroom in which sixth grade students demonstrated the highest interest and self efficacy beliefs, the teacher used problem solving activities, visual aids, as well as open questions. New mathematical ideas were connected to students' prior knowledge and the teacher focused on understanding and worked with students' misconceptions. In addition, the teacher developed a warm environment in which the students' effort was recognised and positive comments were declared by the teacher.

These findings are consistent with previous research studies on the relation between teachers' instructional practices and students' goal orientation in mathematics (Nicholls, Cobb, Wood, Yackel, & Patashnick, 1990). Stipek et al. (1998) found that some of the same aspects of teachers' instructional practices that had a positive impact on students' intrinsic motivation also were a powerful predictor of students' goal orientation. Classroom in which teachers created a positive climate and in which they focused on substantive constructive feedback to students rather than test-scores were associated with a mastery orientation. These findings are consistent with a study by Cobb et al. (1992) indicating that students who experience a reform-based teaching approach are more likely to develop a mastery orientation in mathematics than students in more traditional classrooms.

The findings presented here are consistent with more general research on students' goal orientation, and they reveal that design principles and instructional practices suggested by goal orientation theorists (Pintrich, 2003; Stipek, 1996) promote students' mastery orientation in mathematics. These instructional practices are similar to ones promoted by the mathematics reform literature (Stipek, et al., 1998)

CONCLUSION

Pintrich's identification of five different families of social cognitive motivation constructs provides a structured overview of the different perspectives of motivation and research that has been done. Research studies on the relationship between teachers' practice in the mathematics classroom and students' intrinsic motivation and goal orientation indicate that some of the same aspects of teachers' instructional practices that have a positive impact on students' intrinsic motivation also positively influence students' goal orientation, in terms of mastery goals. It seems like a focus on learning and understanding, generating own solution strategies and a good affective climate positively influence both students' intrinsic motivation and learning orientation in mathematics. There is still a great deal of research needed to understand students' motivation for learning mathematics and how teachers' instructional practice influences their motivation.

HANDLING NEGATIVE EMOTIONS IN LEARNING MATHEMATICS

Engin Ader

Emine Erktin

Boğaziçi University

This study is part of a project that aims to investigate students' coping with negative emotions when faced with difficulties in mathematics. Frydenberg and Lewis's (1993) adolescent coping model was adopted to explore coping and The Coping with Mathematics Scale was developed to evaluate students' strategies for coping when faced with difficulties in mathematics (Ader, 2004). The aim of the present study was to determine the prevalent coping strategies of 490 middle school students using the data based on The Coping with Mathematics Scale. The results indicated that students used coping strategies focusing on solving the problem most frequently and significant correlations between use of various coping strategies and math anxiety were found.

Keywords: coping, mathematics anxiety

THEORETICAL FRAMEWORK

The present study is part of an ongoing project that aims to investigate students' coping with math anxiety and negative emotions when faced with difficulties in mathematics. Mathematics anxiety has been defined as the feeling of pressure that limits the use of numbers and solving mathematical problems in academic settings and everyday life (Richardson & Suinn, 1972). It has been shown to lead to emotional symptoms, such as panic, fear of failure, self doubt, frustration, hopelessness, shame, powerlessness as well as sweating, nausea, stomach disturbance, difficulty in breathing and inability to concentrate. Mathematics anxiety turns mathematics into a source of stress for many people, frequently leading to detrimental cognitive consequences (Ashcraft & Ridley, 2005).

Mathematics anxiety being a source of stress for many students is thought to be overcome by some who can successfully cope with anxiety and negative emotions when faced with mathematical difficulties. The theoretical framework put forward by Frydenberg and Lewis's (1993) adolescent coping model was adopted to investigate this claim. It was assumed that as the prevalent coping strategies for math anxiety were unfolded, the obtained information could be utilized in math education to train math anxious students for more effective coping strategies (Frydenberg, 2004).

METHOD

Initially, The Coping with Mathematics Scale was developed to evaluate students' strategies for coping with difficulties in mathematics (Ader, 2004). The scale was found to be an effective tool to determine students coping strategies to overcome mathematics anxiety. Initially, items were generated by adaptation of items from Frydenberg and Lewis' Adolescent Coping Scale for contexts of dealing with

mathematics. The opening study for the development of the scale was conducted with 751 students preparing to take the university entrance examination in Turkey. The final form of the scale in the first study comprised 36 items in three sub categories: 13 items in *coping focused on solving the problem*, 13 items in *non-productive coping* and 10 items in *coping with reference to others* (Ader, 2004). In the second study for the revised short form of the scale, data were collected from 174 adolescents. The psychometric characteristics of the 18 item short form of the scale were reported (Ader & Erktin, 2012).

The aim of the present study which was the third study of the project was to determine the prevalent coping strategies of students when faced with math anxiety and difficulties in mathematics using the data based on The Coping with Mathematics Scale. 490 adolescents from year 6 to 8 of a public primary school (aged between 11 and 15) took part in the study. Math anxiety levels of 293 of the students were also obtained.

RESULTS

The results indicated that students used coping strategies focusing on solving the problem more frequently than non productive coping strategies and coping strategies with reference to others. Yet use of coping strategies focusing on solving the problem were significantly lower among 8th graders in comparison with 6th graders. When the relationship among use of coping strategies and levels of math anxiety were considered, a strong negative correlation between use of problem focused coping and math anxiety, and a positive correlation between use of non productive coping and math anxiety were found. Building on the findings of this study, a pressing need for further studying coping strategies and the links between anxiety and coping through various other approaches (e.g. longitudinal studies) is highlighted.

Keywords: *Mathematical discourses; conceptual analysis; semiotic representations; mathematical practices; classroom norms; social interaction; group discussion; mediating artefacts; didactical environments; problem solving*

A BRIEF HISTORICAL OVERVIEW

In 1998, at the first Congress of the new-born European Society for Research in Mathematics Education at Osnabrück, Germany, there was a Working Group entitled ‘Social Interactions in Mathematical Learning Situations’ (Krummheuer, 1999). The same group was held in the Czech Republic (Krummheuer, 2002), and in Italy (Price, 2004). Most activities of the Working Group ‘Language and Mathematics’ were then initiated and developed, and have been maintained ever since through meetings in Spain (Duval, Ferrari, Johnsen-Høines, & Morgan, 2006), Cyprus (Morgan et al., 2007), France (Morgan, 2010), Poland (Cestari, Mercier, Ferrari, & Tatsis, 2011), and recently at CERME 8 in Turkey. When tracing the development of our Group by reading the texts in the Proceedings, we have come to see two major issues, the survey of themes, and the variety of methods and tools. For both issues, it becomes clear that language and mathematics research is not unique to our Group. It has important connections to other working groups. This is also reflected in the fact that some researchers at one conference may change to another group, and then perhaps later change back again.

Concerning the survey of themes one will notice that initially the emphasis was on students’ mathematical learning. Fundamental to the first meetings of the predecessor of our Group (Krummheuer, 1999, 2002; Price, 2004) were the topics of classroom interaction and mathematical learning. These two foci have evolved towards the study of more general language and interaction phenomena that coherently draw on the assumption that the teaching and learning of mathematics is mediated by the role and use of language through particular discourses, registers, systems, and/or meanings. Thus, the term ‘language’ is taken as a term covering a whole range of studies. Classroom social interaction still is a strong theme in the Group as an object of study (Cestari et al., 2011; Duval et al., 2006; Morgan, 2010; Morgan et al., 2007). However, the Group has also come to include works where the object of study is language and, if it is the case that the mathematics classroom is the setting for

investigation, social interaction is part of what happens when certain discourses, registers, systems, and meanings are orchestrated. Researchers in the Group want to understand why it is that teaching, thinking and learning happen as they do in contexts of mathematics education (not only schools and classrooms), and how one might expect language issues to have an influence on these processes. As a consequence of having broadened the survey of themes one can find a significant number of reports that do not summarize specific situations of interaction among participants in the mathematics classroom.

The variety of methods and tools has been the basis for very productive controversies, over which are more adequate and for what. Researchers from different theoretical traditions in the field have brought up the issue of how a common theme may be investigated in different ways. However, a characteristic of our Group is the dominance of qualitative approaches to the interpretation of data and findings, primarily from classroom based research (as can be seen below in the synthesis of the works presented at CERME 8). Throughout the meetings of the Group, there have been some studies that combine quantitative and qualitative approaches to their data and discussion of findings, but most of them give priority to the implementation of qualitative methods. The description, application and evaluation of analytical instruments have progressively gained representation. We see this fact as important in that a major effort is put into issues of rigor to unravel methodological complexity. Interesting discussions have been conducted on the choice of methods and the implications in terms of the resulting findings.

Despite all these positive comments concerning the development of the Group, much work is to be done, and it is not totally clear in which directions. In the final section, we will come back to what is reasonable to do next. We do not yet have, and cannot expect to have in the near future, a situation in which the European community of researchers on language and mathematics (education) can tell the rest of the community sufficiently refined solid finding emerging from our activity as a Group.

SYNTHESIS OF THE CURRENT PERSPECTIVE

At CERME 8 a total of 18 papers were presented in the Group. In addition four participants presented posters in the Poster Sessions, and two persons participated in the Group without being involved in a paper or a poster. The papers were grouped into six themes, corresponding to the six groups that were used for presentation and discussion during the Conference. As said before the topic *Language and Mathematics* is very wide and diverse and this is also reflected in the papers of the Group. Many of the papers could easily have fitted in other working groups and vice versa. Similarly, there are no clear borders between the six themes listed above.

Students' mathematical meanings and practices

This group comprise three papers, Barrier, Hache, & Mathé, Fernández-Plaza, Rico, & Ruiz, and Schütte. An important issue in this theme is that language is contextual

and that learning mathematics means entering in specific ways to interpret the world as well as specific language practices. Language is a medium of the social negotiation of the specificity of mathematical practices and of the meaning of terms. Many mathematical terms are taken from everyday language and given a meaning in mathematics that not always coincides with the everyday meaning of the word.

The paper by Barrier et al. is concerned with the meaning of the word *circle*, whereas the paper by Fernández-Plaza et al. discusses the meaning of the word *limit* in calculus. In the paper by Schütte the topic is deictical language with pointing vs. the teacher acting as a model for learning the language of mathematics. Some questions raised in this session were what the role of language in the negotiation of particular meanings in mathematics can be, and which the difficulties are due to conflict between everyday and mathematical meanings of a word.

Semiotic systems and representations

This group comprise four papers, Priolet, Rønning, Swidan, and Nosrati. All four papers deal with issues of working with different semiotic representations and in particular issues to do with changing between semiotic representations. Common topics are mediation by semiotic representations and the use of artefacts. Moreover, the research behind all the papers in this group is based on carefully designed learning environments and can be said to have implications for pedagogical practice.

Prioleto uses a framework based on four principles, one of them being conversion of semiotic representations, to work with small children solving elementary number problems. Rønning also works with small children but in his paper the focus is on different representations of fractions and decimal numbers, Swidan works with university students and how they make sense of the concept *antiderivative*, using a dynamic and multi-semiotic technological environment. Nosrati explores how students construct and choose their own semiotic representations when working with physical artefacts on a topic (group theory) which for them is an unfamiliar topic.

Group discussion, norms and communication

In this group are placed the papers by Morera, Planas, & Fortuny, Tatsis, Planas & Chico, and Iversen, four papers in all. A key issue in this group is how use of language positions students in relation to the learning of mathematics. The first three papers mostly deal with language in the sense of oral communication whereas the last one (Iversen) deals with students' mathematical writing.

In the paper by Morera et al., as well as the paper by Planas and Chico, the interest lies in identifying what the authors refer to as *Mathematical Learning Opportunities*. Both papers are concerned with the social aspects of mathematical learning and study interaction in whole group discussions. Tatsis is concerned with classroom social and sociomathematical norms and he is looking into interactional processes in order to identify factors affecting the establishment of such norms. Iversen is interested in investigating how students' mathematical writing in light of the concept *writer*

identity. In the paper one particular student is chosen as a case to illustrate how he in different types of assignments constructs his identity as a writer of mathematics.

Diverse languages in the teaching and learning of mathematics

The concept *different languages*, used in the heading of this session could mean different things, and indeed this is the case. In the paper by Ni Ríordáin, ‘different languages’ means English and Irish. Ni Ríordáin discusses a potential connection between syntactical and semantic differences between Irish and English, and the learning of mathematics. She suggests that the syntactical structure of the Irish language in terms of sentence length, topical prominence and word order, may lend itself to easier interpretation of mathematical meaning in comparison to English. In the paper by Peters and Graham, the different languages that are studied are the formal mathematical language (mathematical register) and the informal language (natural register). Peters and Graham have studied mechanical engineering students’ expression of their mathematical thinking when explaining a physical experiment involving three balls of different masses being rolled down a ramp. Based on the students’ analysis of the system the tension between the everyday meaning and the precise mathematical definition of the terms involved is being carried out.

Use of tools and interactional strategies by teachers

The papers by Riesbeck, Schreiber, and Ingram, Baldry, & Pitt were all placed in this session. It may be argued that they do not have very much in common, an argument which is also reflected in the title of the session with two different aspects.

Use of tools, and in particular ICT tools, is discussed by both Riesbeck and Schreiber. Riesbeck studies pupils from preschool, year 1 and year 2 in their work with numbers and place value. The pupils work with different kinds of artefacts, from concrete materials to computers and interactive whiteboards, and Riesbeck shows how the pupils’ language develops with the use of the different artefacts. Schreiber has worked with primary school pupils to produce mathematical podcasts. The pupils produce the podcasts, e.g. with the purpose of explaining a mathematical concept, in several versions where a new version is expected to be an improvement of the previous version. In this process it is of interest to investigate the development of mathematical knowledge as well as doing a semiotic analysis of the content. The paper by Ingram et al. is different in many respects. It is not about tools but it is about how teachers interactionally manage mistakes in the students’ work. The structure of sequences of interactions in which a mathematical mistake occurs is described to reveal the conflict between the pedagogical and interactional messages.

Didactical environments, scaffolding and mediation

The two papers in this session, by Dias & Christinat, and Moulin & Deloustal-Jorrand, are based in the French Didactic Tradition. Both papers are concerned with oral language used between teacher and pupils and they both deal with a paradoxical question concerning the didactical contract. It appears that using a story in the

classroom instead of a usual word problem may lead to dividing the problem into small parts, thereby reducing the complexity of the didactical situation. The papers give examples of two different approaches; one starting with a didactical situation which is looked at from a linguistic perspective, and one starting with a linguistic question which leads to a didactical approach.

SOME FUTURE DIRECTIONS

To expand the survey of themes and for our agenda as a Group to move forward, we see at least two directions: research on multilingual teaching and learning classroom practices, and research on the role and use of language in teacher education. The first direction is still weakly represented in the Group, though some papers have addressed multilingualism. The second direction would help to complement the mainstream research on teacher education that, in general, does not focus its attention on the language contexts in which the practices of teacher education take place.

SEEING–ACTING–SPEAKING IN GEOMETRY: A CASE STUDY

Thomas Barrier¹, Christophe Hache², & Anne-Cécile Mathé¹

The purpose of this paper is to describe and analyse the confrontation and changing processes of frequentation modes (seeing – acting – speaking) of 1st grade secondary school students (10-11 years old) during two geometric construction tasks. This work is based on a logic analysis of the mathematical concepts involved: the midpoint of a line segment and the circle.

INTRODUCTION

When we try to better understand how the students' "relationship to knowledge" changes in a learning situation in geometry, language interactions are often considered as preferential indicators of the reference framework underlying the students' geometry activity. In this case, the language remains subordinated to the analysis of the physical activity. As for us, we try to consider language not only as a reflection of the conception of an acting subject but to take into account, in our analysis, both the language and the physical part of geometry activity. For this purpose, Bulf, Mathé, and Mithalal (2011) introduce the notion of *frequentation mode* which aims at accounting for the consistency of physical and language dimensions of activities in geometry. They insist on the fact that, on the one hand, language practices are not different from other practices, they have no hierarchy (in order to avoid language issues being pushed into the background of the action, especially in geometry) and, on the other hand, language practices are constituent parts of subjects' knowledge rather than mere reflections of pre-existent knowledge.

Frequentation modes of a geometrical object should articulate three dimensions at the same time: a way of *seeing* in geometry, which will form most of our theoretical horizon and will allow to make students' appreciation of a geometry activity more clear; the ways of *acting* taken by the subject and the instrument usage rules; the ways of the *speaking* and the subject's discourse on objects and actions. The word *seeing*, that we prefer here to the word *thinking*, even if they have analogous meanings, underlines the importance of visualization in geometry (Duval, 2005; Duval & Godin, 2006). As for the word *acting*, we have decided to focus specifically on the artefacts as a didactical variable which is determining in construction situations (Perrin-Glorian, Mathé, & Leclerc, 2013). At last, as for the word *speaking*, we shall intend to describe the specific *language games* (Wittgenstein, 1953) implemented by students and their changing process (Barrier, 2011; Mathé, 2012). Therefore, defining a frequentation mode consists of describing a geometry activity by a way of thinking and considering modalities of action consistent with a certain discourse characterized by its structure and the meaning given to the terms by the

subject in the context. In this context, learning is described as a changing process of frequentation modes to a relationship in line with knowledge objects.

This approach seems to echo the hypothesis of a "discursive community" (Bernié, 2002; Jaubert, Rebière, & Bernié, 2003), a French approach analogous to the discursive or communicational one (Kieran, Forman, & Sfard, 2001). In a Vygotskian perspective, these authors introduce the notion of a school disciplinary discursive community: knowledge is tightly linked with the community which created it, learning in a school subject area is learning how to act-think-speak somewhat like experts. This means learning how to take position in a social universe characterized by interesting issues, specific objects, material and practices, in particular language practices, learning *Discourse practices* (Moschkovich, 2007).

However, we do not have the feeling to follow a radical *communicational* way of thinking (Sfard, 2001). Indeed, we are as interested in the dialogical and social aspects of discourse as in the semantic dimension of language, i.e. its ability to refer to external mathematical objects. The purpose of this paper is to show, from a case study, how a logic analysis of concepts can help to describe frequentation modes and their dynamics. We shall use the language of the first-order logic, i.e. the fundamental logic categories will be those of object, predicate and relation. This work is part of a larger project aiming at creating tools that could account for the geometrical practices both in the physical and language dimensions of these practices.

CORPUS AND METHODOLOGY

The extracts analyzed in the following pages are taken from data collected for another work dedicated to issues relating to the use of history of mathematics in the classroom. Detailed information on the context of data collection and on students' tasks is available in Barrier, de Vittori, and Mathé (2012). In this study, we selected some sequences of a lesson during which 1st grade students (10-11 years old) in a French secondary school had to draw a square on the playground using unusual artefacts: a chalk and a rope. The construction program given to the students and the expected figure are available in annex. The lesson lasts just under one hour and takes place outdoors, in the playground. Students are divided in groups of three or four and the teacher moves from one group to the other. The sequences reported have been filmed.
