

CERME 6

Proceedings of the Sixth Congress of the European Society for Research in Mathematics Education

January 28th-February 1st 2009
Lyon (France)

Viviane Durand-Guerrier, Sophie Soury-Lavergne
& Ferdinando Arzarello (eds.)

INSTITUT NATIONAL
DE RECHERCHE
PÉDAGOGIQUE

Editorial board

Maha Abboud-Blanchard	Marei Fetzer	Alain Mercier
Janet Ainley	Fulvia Furinghetti	John Monaghan
Paul Andrews	Patrick Gibel	Candia Morgan
Ferdinando Arzarello	Juan Godino	Maria Gabriella Ottaviani
Giorgio T. Bagni	Núria Gorgorió	Marilena Panziara
Patti Barber	Ghislaine Gueudet	Birgit Pepin
Christer Bergsten	Markku S. Hannula	Dave Pratt
Morten Blomhøj	Matthias Hattermann	Susanne Prediger
Marianna Bosch	Lisa Hefendehl–Hebeker	Kristina Reiss
Rosa Maria Bottino	Stephen Hegedus	Tim Rowland
Leonor Camargo	Alena Hospesova	Filip Roubicek
Susana Carreira	Elia Iliada	Leonor Santos
José Carrillo	Eva Jablonka	Wolfgang Schloeglmann
Claire Cazes	Uffe Jankvist	Gérard Sensevy
Margarida Alexandra Cesar	Ivy Kidron	Nada Stehlikova
Giampaolo Chiappini	Alain Kuzniak	Constantinos Tzanakis
Sarah Crafter	Jean–Baptiste Lagrange	Paul Vanderlind
Guida de Abreu	Roza Leikin	Jan van Maanen
Jean-Luc Dorier	Florence Ligozat	Kjersti Wæge
Paul Drijvers	Katja Maass	Geoff Wake
Andreas Eichler	Joanna Mamona-Dawns	Hans-Georg Weigand
Marie-Thérèse Farrugi	Maria Alessandra Mariotti	Floriane Wozniak

CERME 6 – TABLE OF CONTENTS

GENERAL INTRODUCTION	XVIII
PLENARY 1	
Signs, gestures, meanings: Algebraic thinking from a cultural semiotic perspective	XXXIII
<i>Luis Radford</i>	
PLENARY 2	
Mathematics education as a network of social practices	LIV
<i>Paola Valero</i>	
SPECIAL PLENARY SESSION	
Ways of working with different theoretical approaches in mathematics education research	1
Introduction	2
<i>Tommy Dreyfus</i>	
Networking of theories: why and how?	6
<i>Angelika Bikner-Ahsbahr</i>	
People and theories	16
<i>John Monaghan</i>	
Discussion	24
WORKING GROUP 1	
Multimethod approaches to the multidimensional affect in mathematics education	26
Introduction	28
<i>Markku S. Hannula, Marilena Pantziara, Kjersti Wæge, Wolfgang Schölglmann</i>	
The effect of achievement, gender and classroom context on upper secondary students' mathematical beliefs	34
<i>Markku S. Hannula</i>	
Changing beliefs as changing perspective	44
<i>Peter Liljedahl</i>	
“Maths and me”: software analysis of narrative data about attitude towards math	54
<i>Pietro Di Martino</i>	
Students' beliefs about the use of representations in the learning of fractions	64
<i>Athanasios Gagatsis, Areti Panaoura, Eleni Deliyianni, Iliada Elia</i>	
Efficacy beliefs and ability to solve volume measurement tasks in different representations	74
<i>Paraskevi Sophocleous, Athanasios Gagatsis</i>	

Students' motivation for learning mathematics in terms of needs and goals.....	84
<i>Kjersti Wæge</i>	
Mathematical modeling, self-representation and self-regulation.....	94
<i>Areti Panaoura, Andreas Demetriou, Athanasios Gagatsis</i>	
Endorsing motivation: identification of instructional practices	104
<i>Marilena Pantziara, George Philippou</i>	
The effects of changes in the perceived classroom social culture on motivation in mathematics across transitions	114
<i>Chryso Athanasiou, George N. Philippou</i>	
“After I do more exercise, I won't feel scared anymore” Examples of personal meaning from Hong-Kong	124
<i>Maike Vollstedt</i>	
Emotional knowledge of mathematics teachers – retrospective perspectives of two case studies	134
<i>Ilana Lavy, Atara Shriki</i>	
Humour as a means to make mathematics enjoyable	144
<i>Pavel Shmakov, Markku S. Hannula</i>	
Beliefs: a theoretically unnecessary construct?	154
<i>Magnus Österholm</i>	
Categories of affect – some remarks.....	164
<i>Wolfgang Schlöglmann</i>	
 WORKING GROUP 2	
Argumentation and proof	174
Introduction.....	176
<i>Maria Alessandra Mariotti, Leanor Camargo, Patrick Gibel, Kristina Reiss</i>	
Understanding, visualizability and mathematical explanation	181
<i>Daniele Molinini</i>	
Argumentation and proof: a discussion about Toulmin's and Duval's models	191
<i>Thomas Barrier, Anne-Cécile Mathé, Viviane Durand-Guerrier</i>	
Why do we need proof.....	201
<i>Kirsti Hemmi, Clas Löfwall</i>	
Proving as a rational behaviour: Habermas' construct of rationality as a comprehensive frame for research on the teaching and learning of proof.....	211
<i>Francesca Morselli, Paolo Boero</i>	
Experimental mathematics and the teaching and learning of proof.....	221
<i>Maria G. Bartolini Bussi</i>	
Conjecturing and proving in dynamic geometry: the elaboration of some research hypotheses.....	231
<i>Anna Baccaglioni-Frank, Maria alessandra Mariotti</i>	
The algebraic manipulator of alnuset: a tool to prove	241
<i>Bettina Pedemonte</i>	
Visual proofs: an experiment	251
<i>Cristina Bardelle</i>	

Teachers' views on the role of visualisation and didactical intentions regarding proof.....	261
<i>Irene Biza, Elena Nardi, Theodossios Zachariades</i>	
Modes of argument representation for proving – the case of general proof.....	271
<i>Ruthi Barkai, Michal Tabach, Dina Tirosh, Pessia Tsamir, Tommy Dreyfus</i>	
Mathematics teachers' reasoning for refuting students' invalid claims.....	281
<i>Despina Potari, Theodossios Zachariades, Orit Zaslavsky</i>	
Student justifications in high school mathematics.....	291
<i>Ralph-Johan Back, Linda Mannila, Solveig Wallin</i>	
“Is that a proof?”: an emerging explanation for why students don't know they (just about) have one	301
<i>Manya Raman, Jim Sandefur, Geoffrey Birky, Connie Campbell, Kay Somers</i>	
“Can a proof and a counterexample coexist?” A study of students' conceptions about proof	311
<i>Andreas J. Stylianides, Thabit Al-Murani</i>	
Abduction and the explanation of anomalies: the case of proof by contradiction.....	322
<i>Samuele Antonini, Maria Alessandra Mariotti</i>	
Approaching proof in school: from guided conjecturing and proving to a story of proof construction.....	332
<i>Nadia Douek</i>	
WORKING GROUP 3	
On “stochastic thinking”	343
<i>Introduction.....</i>	
<i>Andreas Eichler, Maria Gabriella Ottaviani, Floriane Wozniak, Dave Pratt</i>	
Chance models: building blocks for sound statistical reasoning	348
<i>Herman Callaert</i>	
Recommended knowledge of probability for secondary mathematics teachers.....	358
<i>Irini Papaieronymou</i>	
Statistical graphs produced by prospective teachers in comparing two distributions.....	368
<i>Carmen Batanero, Pedro Arteaga, Blanca Ruiz</i>	
The role of context in stochastics instruction.....	378
<i>Andreas Eichler</i>	
Does the nature and amount of posterior information affect preschooler's inferences	388
<i>Zoi Nikiforidou, Jenny Pange</i>	
Student's Causal explanations for distribution	394
<i>Theodosia Prodromou, Dave Pratt</i>	
Greek students' ability in probability problem solving	404
<i>Sofia Anastasiadou</i>	
WORKING GROUP 4	
Algebraic thinking and mathematics education.....	413
<i>Introduction.....</i>	
<i>Janet Ainley, Giorgio T. Bagni, Lisa Hefendehl-Hebeker, Jean-Baptiste Lagrange</i>	

The effects of multiple representations-based instruction on seventh grade students' algebra performance	420
<i>Oylum Akkus, Erdinc Cakiroglu</i>	
Offering proof ideas in an algebra lesson in different classes and by different teachers.....	430
<i>Michal Ayalon, Ruhama Even</i>	
Rafael Bombelli's Algebra (1572) and a new mathematical "object": a semiotic analysis	440
<i>Giorgio T. Bagni</i>	
Cognitive configurations of pre-service teachers when solving an arithmetic-algebraic problem.....	449
<i>Walter F. Castro, Juan D. Godino</i>	
Transformation rules: a cross-domain difficulty.....	459
<i>Marie-Caroline Croset</i>	
Interrelation between anticipating thought and interpretative aspects in the use of algebraic language for the construction of proofs in elementary number theory.....	469
<i>Annalisa Cusi</i>	
Epistemography and algebra.....	479
<i>Jean-Philippe Drouhard</i>	
Sámi culture and algebra in the curriculum	489
<i>Anne Birgitte Fyhn</i>	
Problem solving without numbers – An early approach to algebra.....	499
<i>Sandra Gerhard</i>	
The ambiguity of the sign $\sqrt{\quad}$	509
<i>Bernardo Gómez, Carmen Buhlea</i>	
Behind students' spreadsheet competencies: their achievement in algebra? A study in a French vocational school.....	519
<i>Mariam Haspekian, Eric Bruillard</i>	
Developing Katy's algebraic structure sense	529
<i>Maureen Hoch, Tommy Dreyfus</i>	
Children's understandings of algebra 30 years on: what has changed?.....	539
<i>Jeremy Hodgen, Dietmar Kuchemann, Margaret Brown, Robert Coe</i>	
Presenting equality statements as diagrams	549
<i>Ian Jones</i>	
Approaching functions via multiple representations: a teaching experiment with Casyopee	559
<i>Jean-Baptiste Lagrange, Tran Kiem Minh</i>	
Equality relation and structural properties	569
<i>Carlo Marchini, Anne Cockburn, Paul Parslow-Williams, Paola Vighi</i>	
Structure of algebraic competencies	579
<i>Reinhard Oldenburg</i>	
Generalization and control in algebra	589
<i>Mabel Panizza</i>	
From area to number theory: a case study	599
<i>Maria Iatridou, Ioannis Papadopoulos</i>	
Allegories in the teaching and learning of mathematics	609
<i>Reinert A. Rinvold, Andreas Lorange</i>	

Role of an artefact of dynamic algebra in the conceptualisation of the algebraic equality	619
<i>Giampaolo Chiappini, Elisabetta Robotti, Jana Trgalova</i>	
Communicating a sense of elementary algebra to preservice primary teachers	629
<i>Franziska Siebel, Astrid Fischer</i>	
Conception of variance and invariance as a possible passage from early school mathematics to algebra.....	639
<i>Ilya Sinitsky, Bat-Sheva Ilany</i>	
Growing patterns as examples for developing a new view onto algebra and arithmetic.....	649
<i>Claudia Böttinger, Elke Söbbeke</i>	
Steps towards a structural conception of the notion of variable	659
<i>Annika M. Wille</i>	
WORKING GROUP 5	
Geometrical thinking	669
Introduction.....	
<i>Alain Kuzniak, Iliada Elia, Matthias Hattermann, Filip Roubicek</i>	
The necessity of two different types of applications in elementary geometry.....	676
<i>Boris Girnat</i>	
A French look on the Greek geometrical working space at secondary school level	686
<i>Alain Kuzniak, Laurent Vivier</i>	
A theoretical model of students' geometrical figure understanding	696
<i>Eleni Deliyianni, Iliada Elia, Athanasios Gagatsis, Annita Monoyiou, Areti Panaoura</i>	
Gestalt configurations in geometry learning	706
<i>Claudia Acuña</i>	
Investigating comparison between surfaces.....	716
<i>Paola Vighi</i>	
The effects of the concept of symmetry on learning geometry at French secondary school.....	726
<i>Caroline Bulf</i>	
The role of teaching in the development of basic concepts in geometry: how the concept of similarity and intuitive knowledge affect student's perception of similar shapes.....	736
<i>Mattheou Kallia, Spyrou Panagiotis</i>	
The geometrical reasoning of primary and secondary school students	746
<i>Georgia Panaoura, Athanasios Gagatsis</i>	
Strengthening students' understanding of 'proof' in geometry in lower secondary school	756
<i>Susumu Kunimune, Taro Fujita, Keith Jones</i>	
Written report in learning geometry: explanation and argumentation	766
<i>Silvia Semana, Leonor Santos</i>	
Multiple solutions for a problem: a tool for evaluation of mathematical thinking in geometry.....	776
<i>Anat Levav-Waynberg, Roza Leikin</i>	
The drag-mode in three dimensional dynamic geometry environments – Two studies	786
<i>Mathias Hattermann</i>	
3D geometry and learning of mathematical reasoning	796
<i>Joris Mithalal</i>	

In search of elements for a competence model in solid geometry teaching Establishment of relationships	806
<i>Edna González, Gregoria Guillén</i>	
Students' 3D geometry thinking profiles	816
<i>Marios Pittalis, Nicholas Mousoulides, Constantinos Christou</i>	
WORKING GROUP 6	
Language and mathematics	826
Introduction.....	828
<i>Candia Morgan</i>	
Imparting the language of critical thinking while teaching probability.....	833
<i>Einav Aizikovitsh, Miriam Amit</i>	
Toward an inferential approach analyzing concept formation and language processes	842
<i>Stephan Hußmann, Florian Schacht</i>	
Iconicity, objectification, and the math behind the measuring tape: An example from pipe-trades training	852
<i>Lionel LaCroix</i>	
Mathematical reflection in primary school education: theoretical foundation and empirical analysis of a case study	862
<i>Cordula Schülke, Heinz Steinbring</i>	
Surface signs of reasoning	873
<i>Nathalie Sinclair, David Pimm</i>	
A teacher's use of gesture and discourse as communicative strategies in concluding a mathematical task.....	884
<i>Raymond Bjuland, Maria Luiza Cestari, Hans Erik Borgersen</i>	
A teacher's role in whole class mathematical discussion: facilitator of performance etiquette?	894
<i>Thérèse Dooley</i>	
Use of words – Language-games in mathematics education	904
<i>Michael Meyer</i>	
Speaking of mathematics – Mathematics, every-day life and educational mathematics discourse	914
<i>Eva Riesbeck</i>	
Communicative positionings as identifications in mathematics teacher education.....	924
<i>Hans Jørgen Braathe</i>	
Teachers' collegial reflections of their own mathematics teaching processes Part 1: An analytical tool for interpreting teachers' reflections.....	934
<i>Kerstin Bräuning, Marcus Nührenbörger</i>	
Teachers' reflections of their own mathematics teaching processes Part 2: Examples of an active moderated collegial reflection.....	944
<i>Kerstin Bräuning, Marcus Nührenbörger</i>	
Internet-based dialogue: a basis for reflection in an in-service mathematics teacher education program	954
<i>Mario Sánchez</i>	

The use of algebraic language in mathematical modelling and proving in the perspective of Habermas' theory of rationality.....	964
<i>Paolo Boero, Francesca Morselli</i>	
Objects as participants in classroom interaction	974
<i>Marei Fetzer</i>	
The existence of mathematical objects in the classroom discourse	984
<i>Vicenç Font, Juan D. Godino, Núria Planas, Jorge I. Acevedo</i>	
Mathematical activity in a multi-semiotic environment	993
<i>Candia Morgan, Jehad Alshwaikh</i>	
Engaging everyday language to enhance comprehension of fraction multiplication	1003
<i>Andreas O. Kyriakides</i>	
Tensions between an everyday solution and a school solution to a measuring problem.....	1013
<i>Frode Rønning</i>	
Linguistic accomplishment of the learning-teaching processes in primary mathematics instruction.....	1023
<i>Marcus Schütte</i>	
Mathematical cognitive processes between the poles of mathematical technical terminology and the verbal expressions of pupils	1033
<i>Rose Vogel, Melanie Huth</i>	
WORKING GROUP 7	
Technologies and resources in mathematical education	1043
Introduction.....	1046
<i>Ghislaine Gueudet, Rosa Maria Bottino, Giampaolo Chiappini, Stephen Hegedus, Hans-Georg Weigand</i>	
Realisation of mers (multiple extern representations) and melrs (multiple equivalent linked representations) in elementary mathematics software	1050
<i>Silke Ladel, Ulrich Kortenkamp</i>	
The impact of technological tools in the teaching and learning of integral calculus.....	1060
<i>Alejandro Lois, Liliana Milevicich</i>	
Using technology in the teaching and learning of box plots.....	1070
<i>Ulrich Kortenkamp, Katrin Rolka</i>	
Dynamical exploration of two-variable functions using virtual reality	1081
<i>Thierry Dana-Picard, Yehuda Badihi, David Zeitoun, Oren David Israeli</i>	
Designing a simulator in building trades and using it in vocational education	1091
<i>Annie Bessot, Colette Laborde</i>	
Collaborative design of mathematical activities for learning in an outdoor setting	1101
<i>Per Nilsson, Håkan Sollervall, Marcelo Milrad</i>	
Student development process of designing and implementing exploratory and learning objects	1111
<i>Chantal Buteau, Eric Muller</i>	
How can digital artefacts enhance mathematical analysis teaching and learning.....	1121
<i>Dionysis I. Diakoumopoulos</i>	

A learning environment to support mathematical generalisation in the classroom	1131
<i>Eirini Geraniou, Manolis Mavrikis, Celia Hoyles, Richard Noss</i>	
Establishing a longitudinal efficacy study using SimCalc MathWorlds®	1141
<i>Stephen Hegedus, Luis Moreno, Sara Dalton, Arden Brookstein</i>	
Interoperable Interactive Geometry for Europe – First technological and educational results and future challenges of the Intergeo project.....	1150
<i>Ulrich Kortenkamp, Axel M. Blessing, Christian Dohrmann, Yves Kreis, Paul Libbrecht, Christian Mercat</i>	
Quality process for dynamic geometry resources: the Intergeo project.....	1161
<i>Jana Trgalova, Ana Paula Jahn, Sophie Soury-Lavergne</i>	
New didactical phenomena prompted by TI-Nspire specificities The mathematical component of the instrumentation process.....	1171
<i>Michèle Artigue, Caroline Bardini</i>	
Issues in integrating cas in post-secondary education: a literature review	1181
<i>Chantal Buteau, Zsolt Lavicza, Daniel Jarvis, Neil Marshall</i>	
The long-term project “Integration of symbolic calculator in mathematics lessons” The case of calculus	1191
<i>Hans-Georg Weigand, Ewald Bichler</i>	
Enhancing functional thinking using the computer for representational transfer.....	1201
<i>Andrea Hoffkamp</i>	
The Robot Race: understanding proportionality as a function with robots in mathematics class	1211
<i>Elsa Fernandes, Eduardo Fermé, Rui Oliveira</i>	
Internet and mathematical activity within the frame of “Sub14”	1221
<i>Hélia Jacinto, Nélia Amado, Susana Carreira</i>	
A resource to spread math research problems in the classroom	1231
<i>Gilles Aldon, Viviane Durand-Guerrier</i>	
The synergy of students’ use of paper-and-pencil techniques and dynamic geometry software: a case study	1241
<i>Núria Iranzo, Josep Maria Fortuny</i>	
Students’ utilization schemes of pantographs for geometrical transformations: a first classification	1250
<i>Francesca Martignone, Samuele Antonini</i>	
The utilization of mathematics textbooks as instruments for learning	1260
<i>Sebastian Rezat</i>	
Teachers’ beliefs about the adoption of new technologies in the mathematics curriculum	1270
<i>Marilena Chrysostomou, Nicholas Mousoulides</i>	
Systemic innovations of mathematics education with dynamic worksheets as catalysts	1280
<i>Volker Ulm</i>	
A didactic engineering for teachers education courses in mathematics using ICT	1290
<i>Fabien Emprin</i>	
Geometers’ sketchpad software for non-thesis graduate students: a case study in Turkey	1300
<i>Berna Cantürk-Günhan, Deniz Özen</i>	

Leading teachers to perceive and use technologies as resources for the construction of mathematical meanings	1310
<i>Eleonora Faggiano</i>	
The teacher's use of ICT tools in the classroom after a semiotic mediation approach.....	1320
<i>Mirko Maracci, Maria Alessandra Mariotti</i>	
Establishing didactical praxeologies: teachers using digital tools in upper secondary mathematics classrooms	1330
<i>Mary Billington</i>	
Dynamic geometry software: the teacher's role in facilitating instrumental genesis	1340
<i>Nicola Bretscher</i>	
Instrumental orchestration: theory and practice.....	1349
<i>Paul Drijvers, Michiel Doorman, Peter Boon, Sjef van Gisbergen</i>	
Teaching Resources and teachers' professional development: towards a documental approach of didactics	1359
<i>Ghislaine Gueudet, Luc Trouche</i>	
An investigative lesson with dynamic geometry: a case study of key structuring features of technology integration in classroom practice.....	1369
<i>Kenneth Ruthven</i>	
Methods and tools to face research fragmentation in technology enhanced mathematics education.....	1379
<i>Rosa Maria Bottino, Michele Cerulli</i>	
The design of new digital artefacts as key factor to innovate the teaching and learning of algebra: the case of Alnuset	1389
<i>Giampaolo Chiappini, Bettina Pedemonte</i>	
Casyopée in the classroom: two different theory-driven pedagogical approaches.....	1399
<i>Mirko Maracci, Claire Cazes, Fabrice Vandebrouck, Maria Alessandra Mariotti</i>	
Navigation in geographical space	1409
<i>Christos Markopoulos, Chronis Kynigos, Efi Alexopoulou, Alexandra Koukiou</i>	
Making sense of structural aspects of equations by using algebraic-like formalism.....	1419
<i>Foteini Moustaki, Giorgos Psycharis, Chronis Kynigos</i>	
Relationship between design and usage of educational software: the case of Aplusix	1429
<i>Jana Trgalova, Hamid Chaachoua</i>	
 WORKING GROUP 8	
Questions and thoughts for researching cultural diversity and mathematics education	1439
Introduction.....	
<i>Guida de Abreu, Sarah Crafter, Núria Gorgorió</i>	
A survey of research on the mathematics teaching and learning of immigrant students.....	1443
<i>Marta Civil</i>	
Parental resources for understanding mathematical achievement in multiethnic settings.....	1453
<i>Sarah Crafter</i>	
Discussing a case study of family training in terms of communities of practices and adult education.....	1462
<i>Javier Díez-Palomar, Montserrat Prat Moratona</i>	

Understanding Ethnomathematics from its criticisms and contradictions.....	1473
<i>Maria do Carmo Domite, Alexandre Santos Pais</i>	
Using mathematics as a tool in Rwandan workplace settings: the case of taxi drivers	1484
<i>Marcel Gahamanyi, Ingrid Andersson, Christer Bergsten</i>	
Parents' experiences as mediators of their children's learning: the impact of being a parent-teacher	1494
<i>Rachael McMullen, Guida de Abreu</i>	
Batik: another way of learning mathematics	1506
<i>Lucília Teles, Margarida César</i>	
The role of Ethnomathematics within mathematics education	1517
<i>Karen François</i>	
WORKING GROUP 9	
Different theoretical perspectives and approaches in mathematics education research	1527
Introduction.....	1529
<i>Susanne Prediger, Marianna Bosch, Ivy Kidron, John Monaghan, Gérard Sensevy</i>	
Research problems emerging from a teaching episode: a dialogue between TDS and ATD	1535
<i>Michèle Artigue, Marianna Bosch, Joseph Gascón, Agnès Lenfant</i>	
Complementary networking: enriching understanding.....	1545
<i>Ferdinando Arzarello, Angelika Bikner-Ahsbabs, Cristina Sabena</i>	
Interpreting students' reasoning through the lens of two different languages of description: integration or juxtaposition?	1555
<i>Christer Bergsten, Eva Jablonka</i>	
Coordinating multimodal social semiotics and institutional perspective in studying assessment actions in mathematics classrooms.....	1565
<i>Lisa Björklund-Boistrup, Staffan Selander</i>	
Integrating different perspectives to see the front and the back: The case of explicitness	1575
<i>Uwe Gellert</i>	
The practice of (university) mathematics teaching: mediational inquiry in a community of practice or an activity system.....	1585
<i>Barbara Jaworski</i>	
An interplay of theories in the context of computer-based mathematics teaching: how it works and why	1595
<i>Helga Jungwirth</i>	
On the adoption of a model to interpret teachers' use of technology in mathematics lessons	1605
<i>Jean-Baptiste Lagrange, John Monaghan</i>	
The joint action theory in didactics: why do we need it in the case of teaching and learning mathematics?.....	1615
<i>Florence Ligozat, Maria-Luisa Schubauer-Leoni</i>	
Teacher's didactical variability and its role in mathematics education	1625
<i>Jarmila Novotná, Bernard Sarrazy</i>	
The potential to act for low achieving students as an example of combining use of different theories	1635
<i>Ingolf Schäfer</i>	

Outline of a joint action theory in didactics	1645
<i>Gérard Sensevy</i>	
The transition between mathematics studies at secondary and tertiary levels; individual and social perspectives.....	1655
<i>Erika Stadler</i>	
Combining and Coordinating theoretical perspectives in mathematics education research.....	1665
<i>Tine Wedege</i>	
Comparing theoretical frameworks in didactics of mathematics: the GOA-model.....	1675
<i>Carl Winslow</i>	
WORKING GROUP 10	
Mathematical curriculum and practice	1685
Introduction.....	
<i>Leonor Santos, José Carrillo, Alena Hospesova, Maha Abboud-Blanchard</i>	
Effective ‘blended’ professional development for teachers of mathematics: Design and evaluation of the “UPOLA” Program	1694
<i>Lutz Hellmig</i>	
Teachers’ efficacy beliefs and perceptions regarding the implementation of new primary mathematics curriculum.....	1704
<i>Isil Isler, Erdine Cakiroglu</i>	
Curriculum management in the context of a mathematics subject group.....	1714
<i>Cláudia Canha Nunes, João Pedro da Ponte</i>	
Gestures and styles of communication: are they intertwined?.....	1724
<i>Chiara André</i>	
Teachers’ subject knowledge: the number line representation	1734
<i>Maria Doritou, Eddie Gray</i>	
Communication as social interaction. Primary School Teacher Practices.....	1744
<i>Antonio Guerreiro, Lurdes Serrazina</i>	
Experimental devices in mathematics and physics standards in lower and upper secondary school, and their consequences on teacher’s practices	1751
<i>Fabrice Vandebrouck, Cecile de Hosson, Aline Robert</i>	
Professional development for teachers of mathematics: opportunities and change.....	1761
<i>Marie Joubert, Jenni Back, Els De Geest, Christine Hirst, Rosamund Sutherland</i>	
Teachers’ perception about infinity: a process or an object?.....	1771
<i>Maria Kattou, Michael Thanasia, Katerina Kontoyianni, Constantinos Christou, George Philippou</i>	
Perceptions on teaching the mathematically gifted.....	1781
<i>Katerina Kontoyianni, Maria Kattou, Polina Ioannou, Maria Erodou, Constantinos Christou, Marios Pittalis</i>	

The nature on the numbers in grade 10: A professional problem.....	1791
<i>Mirène Larguier, Alain Bronner</i>	
A European project for professional development of teachers through a research based methodology: The questions arisen at the international level, the Italian contribution, the knot of the teacher-researcher identity	1801
<i>Nicolina A. Malara, Roberto Tortora</i>	
Why is there not enough fuss about affect and meta-affect among mathematics teachers?.....	1811
<i>Manuela Moscucci</i>	
The role of subject knowledge in Primary Student teachers' approaches to teaching the topic of area	1821
<i>Carol Murphy</i>	
Developing of mathematics teachers' community: five groups, five different ways	1831
<i>Regina Reinup</i>	
Foundation knowledge for teaching: contrasting elementary and secondary mathematics.....	1841
<i>Tim Rowland</i>	
Results of a comparative study of future teachers from Australia, Germany and Hong Kong with regard to competences in argumentation and proof	1851
<i>Björn Schwarz, Gabriele Kaiser</i>	
Kate's conceptions of mathematics teaching: Influences in the first three years	1861
<i>Fay Turner</i>	
Pre-service teacher-generated analogies for function concepts	1871
<i>Behiye Ubuz, Ayşegül Eryılmaz, Utkun Aydın, Ibrahim Bayazit</i>	
Technology and mathematics teaching practices: about in-service and pre-service teachers	1880
<i>Maha Abboud-Blanchard</i>	
Teachers and triangles.....	1890
<i>Sylvia Alatorre, Mariana Saíz</i>	
Mathematics teacher education research and practice: researching inside the MICA program	1901
<i>Joyce Mgombelo, Chantal Buteau</i>	
Cognitive transformation in professional development: some case studies	1911
<i>Jorge Soto-Andrade</i>	
What do student teachers attend to?.....	1921
<i>Nad'a Stehlíková</i>	
The mathematical preparation of teachers: A focus on tasks.....	1931
<i>Gabriel J. Stylianides, Andreas J. Stylianides</i>	
Problem posing and development of pedagogical content knowledge in pre-service teacher training	1941
<i>Marie Tichá, Alena Hospesová</i>	
Sustainability of professional development	1951
<i>Stefan Zehetmeier</i>	
A collaborative project as a learning opportunity for mathematics teachers.....	1961
<i>Maria Helena Martinho, João Pedro da Ponte</i>	
Reflection on Practice: content and depth.....	1971
<i>Christina Martins, Leonor Santos</i>	
Developing mathematics teachers' education through personal reflection and collaborative inquiry: which kinds of tasks?.....	1981
<i>Angela Pesci</i>	

The learning of mathematics teachers working in a peer group	1991
<i>Martha Witterholt, Martin Goedhart</i>	
Use of focus groups interviews in mathematics educational research.....	2000
<i>Bodil Kleve</i>	
Analyses of interactions in a collaborative context of professional development.....	2010
<i>Maria Cinta Muñoz-Catalán, José Carrillo, Nuria Climent</i>	
Adapting the knowledge quarter in the Cypriot mathematics classroom	2020
<i>Marilena Petrou</i>	
Professional knowledge in an improvisation episode: the importance of a cognitive model.....	2030
<i>C. Miguel Ribeiro, Rute Monteiro, José Carrillo</i>	
WORKING GROUP 11	
Applications and modelling	2040
Introduction.....	2042
<i>Morten Blomhøj</i>	
Mathematical modelling in teacher education – Experiences from a modelling seminar	2046
<i>Rita Borromeo Ferri, Werner Blum</i>	
Designing a teacher questionnaire to evaluate professional development in modelling	2056
<i>Katja Maaß, Johannes Gurlitt</i>	
Modeling in the classroom – Motives and obstacles from the teacher’s perspective.....	2066
<i>Barbara Schmidt</i>	
Modelling in mathematics teachers’ professional development.....	2076
<i>Jeroen Spandaw, Bert Zwaneveld</i>	
Modelling and formative assessment pedagogies mediating change in actions of teachers and learners in mathematics classrooms	2086
<i>Geoff Wake</i>	
Towards understanding teachers’ beliefs and affects about mathematical modelling.....	2096
<i>Jonas Bergman Ärlebäck</i>	
The use of motion sensor can lead the students to understanding the cartesian graph.....	2106
<i>Maria Lucia Lo Cicero, Filippo Spagnolo</i>	
Interacing populations in a restricted habitat – Modelling, simulation and mathematical analysis in class.....	2116
<i>Christina Roeckerath</i>	
Aspects of visualization during the exploration of “quadratic world” via the ICT Problem “fireworks”	2126
<i>Mária Lalinská, Janka Majherová</i>

CERME 6 – GENERAL INTRODUCTION

INTRODUCTION TO CERME 6

BY BARBARA JAWORSKI PRESIDENT OF ERME EUROPEAN SOCIETY FOR RESEARCH IN MATHEMATICS EDUCATION

CERME is the two-yearly congress of ERME, the European Society for Research in Mathematics Education. CERME 6 marks more than a decade of ERME and it is important to recognise the achievements of the society over this time.

In May 1997, a group of 16 scholars from different European countries met in Osnabrück, Germany, for three days to discuss the formation of a European society in mathematics education. In true European spirit, we decided that we wanted a society which would bring together researchers from across Europe, particularly including colleagues from Eastern Europe, fostering *communication*, *cooperation* and *collaboration*. We wanted a conference that would explicitly provide such opportunity. We wanted especially to encourage and contribute to the education of young researchers. Thus ERME was born and began to take shape.

We decided on a two-yearly conference, or *congress* as it later became known, and the name CERME emerged – Congress of the European Society for Research in Mathematics Education. CERME should have a group structure in which researchers would have sufficient time to really get to know each other, share and discuss their research and engage in deep scholarly debate. The first CERME was planned for February 1999, at Osnabrück. The Program Committee took very seriously the aims for the conference expressed at the 1997 meeting. Seven working groups were planned and 12 hours were provided for work in a group. To avoid most of the conference time being taken up by paper presentation, it was decided there would be no oral presentations at the conference. Papers would be presented in written form before the conference with sufficient time for group participants to read the papers. The 12 hours would be spent discussing the papers and working on themes and issues suggested by the papers and the group leaders. Over the succeeding years, a group led by Konrad Krainer (Austria) and Paolo Boero (Italy) developed a plan and style for a YERME summer school (YESS). The first summer school was held in Klagenfurt, Austria in August 2002. Like CERME, the summer school was based around groups, working on papers submitted by the young researchers, each with an international “expert” as leader.

The pattern of CERME and YERME has developed so they take place in alternative years, the group structure being developed and carried forwards from one to the next. We had CERME 2 in Mariánské Lázně, Czech Republic in 2001; CERME 3 in Bellaria, Italy in 2003; and YESS 2 in Pödebrady, Czech Republic in 2004. CERME 4 took place in Saint Feliu, Spain in February, 2005 and YESS 3 in Jyväskylä, Finland in August 2006. CERME 5 was held in Cyprus in February 2007, and YESS

4 in Trabzon, Turkey in August, 2008. CERME 6 will take place in Lyon, France in 2009 and YESS 5 in Palermo, Italy in 2010. People came from these events speaking of *inspirational* experiences. It seemed clear that the events generated something that we came to call *the CERME Spirit*. Based fundamentally on the three Cs, communication, cooperation and collaboration, the CERME Spirit was about the inspiration that derives from serious scholarly tackling of ideas and concepts in key areas and of mathematics education research with colleagues from multiple nations, facilitated by the group design of the events.

However, the group design was not without its critics. Some critics felt constrained by the requirement to spend a conference, largely, in just one group. Some felt that a conference ought to offer a greater variety of opportunity to participants. Participants should be free to choose where to be at any time. However, the group work at CERME or YESS would be seriously disrupted if participants were to hop from group to group, not engaging seriously with the work in any one. Some suggested that perhaps planning could allow participants to take part in two groups, so that engagement in both could be serious. Such ideas have been considered by the ERME Board and Programme Committees but so far we have remained faithful to the initial conception. Many participants have said in evaluation of the events that the opportunity to spend serious time in one group allowed them to really get to know researchers from other countries, and that this contributed significantly to the depth of thinking that was possible.

We want to encourage wider participation to ongoing activity in our Society, with more nations contributing to hosting events and a secure financial platform for continuing our inclusive communication, cooperation and collaboration within Europe. Further details of ERME can be found at the following site: <http://ermeweb.free.fr/>

Barbara Jaworski – President of ERME

PRESENTATION OF CERME 6 BY FERDINANDO ARZARELLO, CHAIR OF THE SCIENTIFIC INTERNATIONAL COMMITTEE

As pointed out in the document written by our President, CERME is a Congress designed to foster a communicative spirit in European mathematics education according to the three Cs of ERME: communication, cooperation and collaboration. It deliberately moves away from research presentations by individuals towards collaborative group work. Its main feature is a number (15) of thematic groups whose members have worked together in a common research area.

In addition to the working group sessions, there was:

- Two plenary lectures and a panel;
- Two parallel 1 hour sessions where the participants had the opportunity of debating with the plenarists;
- A poster session;
- Final parallel sessions (repeated twice), where each group has presented its work to the interested participants;
- Policy and purpose sessions to negotiate the work and directions of ERME.

The philosophy of our Congress is based on the following two issues:

- i. We need to know more about the research which has been done and is ongoing, and the research groups and research interests in different European countries;
- ii. We need to provide opportunities for cooperation in research areas and for inter-European collaboration between researchers in joint research projects.

In organising this Conference we considered both the ERME spirit and the observations from the questionnaires filled by the participants, which mainly concerned the plenary events. Consequently, the following structure was planned:

- Two plenary lectures of 75 minutes; each plenarist had a reactor: they had 60 minutes for their two presentations, and then there was 15 minutes for questions from the floor. Moreover the interested people had the opportunity to meet the plenarists in an informal meeting in another day.
- An other event is the special 2 hour plenary of the last day, which had three participants: the aim was to discuss a topic emerging from previous CERMEs,

analysing it from different standpoints and to give people the possibility of a wide debate.

The structure of the Working Groups was essentially the same: each group had more of 12 hours for discussing its topic. In the final Sunday session each group have presented the results of its work in two consecutive one hour slots, according to the model experienced in CERME 5, which had received the approval of the participants.

I think that all of us had a very exciting week, plenty of interesting scientific and social opportunities. In particular I underline the lecture of Prof. E. Ghys — <http://www.dimensions-math.org> — and the discussion on a Project of a European Journal of Mathematical Education.

I wish to thank the local organisers, and particularly Viviane Durand-Guerrier, for the enormous work they have done to make possible the realisation of this Conference.

Ferdinando Arzarello – Chair of the scientific international committee

QUALITY AND INCLUSION IN CERME 6: A PROPOSED REVIEW

The European Society for Research in Mathematics Education (ERME), and its principal activities CERME (2-yearly Congress of ERME) and YERME (meetings of Young researchers in ERME) are committed to the three Cs: *Communication*, *Cooperation* and *Collaboration* in research in mathematics education. Over the years in which ERME has existed, the community has developed what has become known as “*The CERME Spirit*”. These words capture a practical manifestation of the objectives expressed in the three Cs. The phrase refers to an *inclusivity* of working in which people genuinely work together, in which all are welcome, and in which members work hard to ensure that all can take a full part in activity. A major factor and issue – that of the language of our work – has been addressed seriously; different groups devising their own approaches to their working language.

However, these things are not straightforward and issues arise as soon as we construct practical situations. The main example of this concerns the scientific quality of our work in mathematics education research. Of course we aspire to a high quality of scientific work, just as we aspire to operate in fully inclusive ways. Ideally we should like there to be compatibility between the two. But what does or can this look like in practice?

These issues face group leaders as soon as they set out to construct a programme of work for their group, starting with a call for papers. Responding to this call, we see that many papers are now received for all groups. This suggests that researchers in our field want to be part of CERME and offer their work to colleagues in CERME. From an inclusive point of view, all papers should be welcome and all those wishing to participate should have a place. However, from a scientific point of view, papers should be reviewed according to scientific criteria, those that are of a suitable scientific quality (according to the group leaders) should be accepted and others rejected. In practice this means that authors of rejected papers may not be able to attend the congress since funding depends on an accepted paper. The practice seems to go against principles of inclusion.

The ERME Board, and Programme Committees of CERME conferences have been aware of these issues and have addressed them by creating a two stage review process. For presentation of papers at the congress, a much more open attitude should be taken to the criteria, aiming to include as many participants as possible. At this stage, feedback to prospective participants should detail what is required for a paper to be acceptable for the scientific proceedings following the congress. Papers not meeting these requirements would not be accepted for the proceedings. Of course, it is then up to the group leaders to determine how to make the necessary decisions: what is acceptable for presentation, and what are the more strict criteria for publication? They also have to decide how to conduct the work of the group in an

inclusive way. Similarly those organising YERME events have to decide how to ensure both quality and inclusion in practice.

Our sixth CERME achieved, it therefore feels like a time to review these issues and procedures. For this purpose, a small group of interested members of ERME has agreed to survey participants in CERME 6 and seek views on the processes and issues that are involved. We have included an opportunity to comment in the evaluation questionnaire for CERME 6 and possibility to send us a personal communication (written) to express your views in more detail. We have also asked group leaders, present and past, to tell us how they have made decisions and what difficulties if any there have been.

As a result of analysing the information received we hope to write a paper for a scientific edited book on the topic of inclusion and quality. Such a paper could also act as a basis for future policy in ERME, CERME and YERME.

SCIENTIFIC PROGRAM

CERME 6 PLENARY CONFERENCES

Jan 28, 15:30 - 16:45

Luis Radford, Université Laurentienne, Ontario, Canada.

SIGNS, GESTURES, MEANINGS: ALGEBRAIC THINKING FROM A CULTURAL SEMIOTIC PERSPECTIVE.

Reactor: Heinz Steinbring (Duisburg-Essen University)

Summary. In this presentation I will deal with the ontogenesis of algebraic thinking. Drawing on a cultural semiotic perspective, informed by current anthropological and embodied theories of knowing and learning, in the first part of my talk I will comment on the shortcomings of traditional mental approaches to cognition. In tune with contemporary research in neuroscience, cultural psychology, and semiotics, I will contend that we are better off conceiving of thinking as a sensuous and sign-mediated activity embodied in the corporeality of actions, gestures, and artifacts. In the second part of my talk, I will argue that algebraic thinking can be characterized in accordance with the semiotic means to which the students resort in order to express and deal with algebraic generality. I will draw upon results obtained in the course of a 10-year longitudinal classroom research project to offer examples of students' forms of algebraic thinking. Two of the most elementary forms of algebraic thinking identified in our research are characterized by their contextual and embodied nature; they rely extensively upon rhythm and perceptual and deictic (linguistic and gestural) mechanisms of meaning production. Furthermore, keeping in line with the situated nature of the students' mathematical experience, signs here usually designate their objects in an indexical manner. These elementary forms of algebraic thinking differ from the traditional one—based on the standard alphanumeric symbolism—in that the latter relies on sign distinctions of a morphological kind. Here signs cease to designate objects in the usual indexical sense to give rise to symbolic processes of recognition and manipulation governed by sign shape.

The aforementioned conception of thinking in general and the ensuing distinction of forms of algebraic thinking shed some light on the kind of abstraction that is entailed by the use of standard algebraic symbolism. They intimate some of the conceptual shifts that the students have to make in order to gain fluency in a cultural sophisticated form of mathematical thinking. Voice, gesture, and rhythm fade away. Embodied and contextual ways of signifying are then replaced with a perceptual activity where differences and similarities are a matter of morphology, and where meaning becomes relational.

Jan 29, 9:15 - 10:30

Paola Valero, Aalborg University, Denmark.

ATTENDING TO SOCIAL CHANGES IN EUROPE: CHALLENGES FOR MATHEMATICS EDUCATION RESEARCH IN THE 21ST CENTURY

Reactor: Margarida Alexandra da Piedade Silva Cesar (Lisbon University)

Summary. Based on an analysis of mathematics education research as an academic field and on current social, political and economic transformations in many European countries, I would argue for the need to rethink and enlarge definitions and views of mathematics education as a scientific field of study in order to provide better understandings and alternatives for practice in the teaching and learning of mathematics today. I will explore the notion of the “network of mathematics education practices” as a complex, multi-layered space of social practice where the meanings of the teaching and learning of mathematics are constituted. I will illustrate the potentiality of this notion to envision possible research paths in the field. I will illustrate these with the research that my colleagues and I have been carrying on multicultural classrooms in Denmark; as well as will offer examples of other research studies in Europe and other parts of the world where I see that the discipline is gaining newer insights that could allow attending to the social changes and challenges of the 21st century.

Feb 1st, 11:00 – 13:00

SPECIAL PLENARY: WAYS OF WORKING WITH DIFFERENT THEORETICAL APPROACHES IN MATHEMATICS EDUCATION RESEARCH

Speakers: **Angelika Bikner-Ahsbabs, Bremen University, Germany**

John Monaghan, University of Leeds, United Kingdom

Chair: **Tommy Dreyfus, Tel Aviv University, Israel**

Structure : This plenary activity is planned to last 2 hours and will comprise five parts

Introduction (T. Dreyfus, 5 min)

Networking of theories – why and how? (A. Bikner-Ahsbabs, 25 min + 5 min for clarifications)

Taking the appropriate parts from a variety of theories (J. Monaghan, 25 min + 5 min for clarifications)

Questions to the floor (T. Dreyfus, 10 min)

Questions and contributions from the audience with reactions from the speakers (45 min)

Background. The development and elaboration of theoretical constructs that allow research in mathematics education to progress has long been a focus of mathematics education researchers in Europe. This focus has found its expression in many CERME working groups: some are focused around a specific theoretical approach and others allow researchers from different theoretical traditions and backgrounds to meet and discuss. More specifically, relationships between theories have been made the explicit focus of attention of the theory working group that started at CERME 4 in 2005. The present plenary activity inserts itself in this line of work of CERME, and aims to broaden the discussion about relationships between theories to include members of all CERME working groups.

Abstract by Angelika Bikner-Ahsbals: Networking of theories – why and how? Research in mathematics education addresses teaching and learning of mathematics in a wide sense. For example, theories about learning fractions may tell a lot of different things about learning fractions. Some of them are about mistakes and why some mistakes are stable. Others may tell us about how students can be motivated to learn fractions. There are theories about how fraction concepts can be built best, which students' imaginations accompany learning fractions and what abstraction processes can be observed. In addition, we have to distinguish between theories for gifted students and theories for students with special needs, etc.

These considerations already show that research objects within mathematics education are complex. This complexity has led to a large variety of theoretical approaches. Every successful new theoretical view broadens or deepens insight in a phenomenon, hence, enriches our knowledge about the phenomenon. Therefore, it seems necessary to regard the large diversity of theories as richness. However, the rich diversity of theoretical approaches engenders problems of understanding and communicating. Sometimes we find the same terms meaning different things, for example the different concepts of abstraction, mathematising and constructing. However, we also find different words for the same or similar meanings, for example reification and constructing can both mean building a new knowledge entity.

Hence, a large diversity of theories can be regarded as richness but it also causes difficulties for researchers to understand each other and for teachers and teacher trainers to make use of research results in an adequate way. These problems raise the following questions: How could researchers gainfully frame the use of the diversity of theoretical approaches? What kind of benefit can be gained through such frames? How can theories be made more useful for practitioners?

In the plenary talk, networking of theories is proposed to be a fruitful approach to frame the diversity of theories or theoretical approaches. It has been practiced and reflected on since 2005 (CERME4) within a group of researchers networking their theories. This work has already shown that networking of theories means more than creating a consistent frame to investigate a research question it is a systematic way of theory development. In the plenary talk, an example is used to clarify the meaning

and to describe some benefit of it for the research and the practice of teaching and learning mathematics.

Abstract by John Monaghan: Taking the appropriate parts from a variety of theories.

I will argue the case for ‘taking the appropriate parts from a variety of theories according to needs of the research’ rather than trying to ‘merge theories’. One part of my argument is who I and, if I may extend this, who most CERME participants are – working mathematics education researchers. Mathematics education research is demanding and does not (except for a few gifted individuals) allow researchers to become specialist philosophers, psychologists and /or sociologists; but we may find it useful to use the ideas of philosophers, psychologists and /or sociologists. Another part of my argument will concern theoretical frameworks within mathematics education and I will argue for caution with regard to attempts to merge such theories. These theories have, in general, distinct historical roots, developed in academic communities which have appropriated constructs in specific ways and the ‘grain sizes’ of their analyses often differ. Attempting to merge whole theories, as opposed to appropriating constructs, comes with a real danger of creating an ill-formed hybrid.

So will I argue that mathematics education researchers should ‘pick a little bit from this theory and a little bit from that theory’? Well, yes, I will ... but with caution! I will argue that the ‘bits we pick’ depend on the situation, the specific focus of the research in which we are engaged, and the consistency of ‘bits we pick’.

I have avoided referring to specific theories in this abstract but I will detail theories in my talk and I will also use research studies as cases to exemplify my arguments.

WORKING GROUPS

15 working groups: 7 sessions, 1 or 2 per day, duration 1h30 or 2h

Final group reports: Sunday Feb 1st, 8:30 - 10:30

Poster Session: Thursday Jan. 29 17:15 - 18:30

N.B. The posters remain during the all congress in the hall of the THEMIS. During the poster session, the authors were present.

Group 1: Affect and mathematical thinking - This includes the role of beliefs, emotions, and other affective factors

Markku Hannula, Finland (Chair); Tine Wedege, Norway; Marilena Pantziara, Cyprus.

Group 2: Argumentation and proof - This includes epistemological and historical studies, learning issues and classroom situations

Maria Alessandra Mariotti, Italy (Chair); Patrick Gibel, France; Leonor Camargo, Colombia; Kristina Reiss, Germany.

Group 3: Stochastic thinking - This includes epistemological and educational issues, pupils cognitive processes and difficulties, and curriculum issues

Andreas Eichler, Germany (Chair); Maria Gabriella Ottaviani, Italy; Dave Pratt, United Kingdom; Floriane Wozniak, France.

Group 4: Algebraic thinking - This includes epistemological and educational issues, pupils cognitive processes and difficulties, and curriculum issues

Chair: Giorgio Bagni, Italy (Chair); Janet Ainley, United Kingdom; Lisa Hefendehl-Hebeker, Germany; Jean-Baptiste Lagrange, France.

Group 5: Geometrical thinking - This includes epistemological and educational issues, pupils cognitive processes and difficulties, and curriculum issues

Alain Kuzniak, France (Chair); Iliada Elia, Cyprus; Mathias Hattermann Germany; Filip Roubicek, Czech Republic.

Group 6: Mathematics and language - This includes semiotics and communication in classrooms, social processes in learning and teaching mathematics

Candia Morgan, United Kingdom (Chair); Marie-Thérèse Farrugia (Malta); Marei Fetzer (Germany); Alain Mercier, France.

Group 7: Technologies and resources in mathematical education - This includes teaching and learning environments

Ghislaine Gueudet, France (Chair); Rosa Maria Bottino, Italy; Stephen Hegedus, United States of America; Hans-Georg Weigand, Germany.

Group 8: Cultural diversity and mathematics education - This includes students' diverse backgrounds and identities, social and cultural processes involved, political issues in the educational and school policies.

Chair: Guida de Abreu, United Kingdom (Chair); Nuria Gorgorio, Spain; Sarah Crafter, United Kingdom.

Group 9: Different theoretical perspectives / approaches in research in mathematics education - This includes ways of linking theory and practice and paradigms of research in ME.

Susanne Prediger, Germany (Chair); Marianna Bosch, Spain; Ivy Kidron, Israel; John Monaghan, United Kingdom; Gérard Sensevy, France.

Group 10: From a study of teaching practices to issues in teacher education - This includes teachers' beliefs and the role of the teacher in the classroom, as well as strategies for teacher education and links between: theory and practice, research and teaching and teacher education, collaborative research.

Chair: Leonor Santos (Portugal) José Carrillo, Spain; Alena Hospesova, Czech Republic; Maha Abboud-Blanchard, France.

Group 11: Applications and modelling - This includes theoretical and empirical-based reflections on: the modelling process and necessary competencies, adequate applications and modelling examples, epistemological and curricular aspects, beliefs and attitudes, assessment and the role of technology.

Morten Blomhøj, Denmark (Chair); Susana Carreira, Portugal; Katja Maass, Germany; Geoff Wake, United Kingdom.

Group 12: Advanced mathematical thinking - This includes conceptual attainment, proof techniques, problem-solving, processes of abstraction, at the upper secondary and tertiary educational level.

Roza Leikin, Israel (Chair); Claire Cazes, France; Joanna Mamona-Downs, Greece; Paul Vanderlind, Sweden.

Group 13: Comparative Studies in Mathematics Education - It includes questions surrounding mathematics teaching and learning in the classroom, learners' and teachers' experiences and identities, and policy issues in different cultures and/or countries.

Eva Jablonka, Sweden (Chair); Paul Andrews, United Kingdom; Birgit Pepin, United Kingdom; Pasi Reinikainen, Finland.

Group 14: Early Years Mathematics . This Working Group deals with the research domain of mathematics learning and mathematics education in the early years, age 3 to 7- In the last decades the interest in this topic has increased immensely.

Götz Krummheuer, Germany (Chair); Patti Barber, United Kingdom; Demetra Pitta-Pantazi, Cyprus; Ewa Swoboda, Poland.

Group 15: Theory and research on the role of history in Mathematics Education - The integration of history of mathematics in mathematics education is a subject which has received increasing attention during the last decades.

Chair: Fulvia Furinghetti , Italy (Chair); Jean-Luc Dorier, France; Uffe Thomas Jankvist, Denmark; Costantinos Tzanakis, Greece.

YERME - YOUNG ERME

YERME is an organization aiming at creating collaboration and mutual support among young researchers of different countries in the field of mathematics education. The two main activities of YERME are:

1. YESS – YERME Summer Schools

The aims of the Summer Schools are:

- To let people from different countries meet and establish a friendly and cooperative style of work in mathematics education research;
- To let people compare and integrate their preparation in mathematics education research in a peer discussion climate with the help of highly qualified and differently oriented experts;
- To let people present their research ideas, theoretical difficulties, methodological problems, and preliminary research results, in order to get suggestions (from other participants and experts) about possible developments, different perspectives, etc. and open the way to possible connections with nearby research projects and co-operation with researchers in other countries.

YESS1 took place in Klagenfurt, Austria, 2002; YESS2 at Podebrady, Czech Republic, 2004; YESS3 at Jyväskylä, Finland, 2006 and YESS4 at Trabzon, Turkey, 2008.

YESS5 will take place in Italy (August 2010). Ph.D., Master and post-graduate students and other people entering Mathematics Education research are invited to take part in YESS summer schools.

2. YERME day

The YERME-day takes place the day before CERME. The spirit is the same as YESS. Young European researchers take part in Discussion Groups and Working Groups. The topics of these groups are close to young researchers' interests. This kind of organization allows European students to meet and start to build links between different countries. They also have the opportunity to work with experts in the research education field. The program of the YERME-Day 2009 (January, 27th and 28th) is available on the YERME Website <http://yerme.eu> .

CERME 6 – PLENARY 1

Signs, gestures, meanings: Algebraic thinking from a cultural semiotic perspective

Luis Radford, Université Laurentienne, Ontario, Canada

Reactor: Heinz Steinbring (Duisburg-Essen University)

Summary. In this presentation I will deal with the ontogenesis of algebraic thinking. Drawing on a cultural semiotic perspective, informed by current anthropological and embodied theories of knowing and learning, in the first part of my talk I will comment on the shortcomings of traditional mental approaches to cognition. In tune with contemporary research in neuroscience, cultural psychology, and semiotics, I will contend that we are better off conceiving of thinking as a sensuous and sign-mediated activity embodied in the corporeality of actions, gestures, and artifacts. In the second part of my talk, I will argue that algebraic thinking can be characterized in accordance with the semiotic means to which the students resort in order to express and deal with algebraic generality. I will draw upon results obtained in the course of a 10-year longitudinal classroom research project to offer examples of students' forms of algebraic thinking. Two of the most elementary forms of algebraic thinking identified in our research are characterized by their contextual and embodied nature; they rely extensively upon rhythm and perceptual and deictic (linguistic and gestural) mechanisms of meaning production. Furthermore, keeping in line with the situated nature of the students' mathematical experience, signs here usually designate their objects in an indexical manner. These elementary forms of algebraic thinking differ from the traditional one—based on the standard alphanumeric symbolism—in that the latter relies on sign distinctions of a morphological kind. Here signs cease to designate objects in the usual indexical sense to give rise to symbolic processes of recognition and manipulation governed by sign shape.

The aforementioned conception of thinking in general and the ensuing distinction of forms of algebraic thinking shed some light on the kind of abstraction that is entailed by the use of standard algebraic symbolism. They intimate some of the conceptual shifts that the students have to make in order to gain fluency in a cultural sophisticated form of mathematical thinking. Voice, gesture, and rhythm fade away. Embodied and contextual ways of signifying are then replaced with a perceptual activity where differences and similarities are a matter of morphology, and where meaning becomes relational.

SIGNS, GESTURES, MEANINGS: ALGEBRAIC THINKING FROM A CULTURAL SEMIOTIC PERSPECTIVE

Luis Radford

Université Laurentienne, Ontario, Canada

À la mémoire de Georges Glaeser

INTRODUCTION

To deal with algebraic thinking in a plenary session is a bit risky. Unavoidably, it conveys the feeling of something *déjà vu*—something that has been said again and again. Indeed, since the 1980s algebraic thinking has been one of the most researched areas in mathematics education. And this is so not by chance. Among the branches of mathematics that students have to learn in school, there is none more frightening than algebra. Many students in our teachers' training program at Laurentian University confess that everything was going well until they met algebra in Junior High School. As they admit, suddenly they found themselves in front of an abstract symbolic language, the meaning of which they could not grasp—a kind of hieroglyphic language that, to their dismay, has become like the Esperanto of modern sciences.

And it is the investigation of the students' legendary difficulties in understanding algebra and the search for new ways to teach this subject that has kept many researchers busy for the past three decades. The question, hence, is whether or not there is really something new to say about algebraic thinking. It looks like there is not much left to be said about it. This impression would only be strengthened if you were to do a Google search. We did one at the end of November 2008, in our preparation for this talk, and our “algebraic thinking” search returned almost 176,000 hits. However, as you go through the entries, you realize that the content does not tell you much about algebraic thinking. The content is rather about items usually included in school algebra curricula. The least that can be said is that the term “algebraic thinking” has become a catch-all phrase. This may be a token of the fact that to deal with algebraic thinking is not a simple matter. It supposes that you have some sort of theory about thinking or at least a clear idea of what you mean by thinking in general. Let us pause for a moment: What do you take “thinking” to mean?

As psychologists, philosophers, anthropologists and others are willing to acknowledge, there is no simple and direct answer to this question. As odd as it may seem, thinking is something that we continuously do. Thinking is as ubiquitous as breathing. Yet, we still do not know how we think! Commenting on the elusiveness of thinking, Dan Rappaport said: “The knowledge that thinking has conquered for humanity is vast, yet our knowledge of thinking is scant. It might seem that thinking eludes its own searching eye.” (Rappaport, 1951; quoted in Benson, 1994, p. 13). Western idealist and rationalist epistemologies have conveyed the idea that thinking is something immaterial, something purely mental, bodiless. The influence of Plato's epistemology on our understanding of thinking is perhaps greater than we are usually aware (Radford, Edwards, Arzarello, 2009).

In this article, I introduce a typology of forms of algebraic thinking based on their level of generality. The typology rests on a theoretical approach that capitalizes on the results of the 1990s algebra research agenda and supplements it by incorporating a semiotic theoretical platform. Signs lose the representational and ancillary status with which they are usually endowed in classical cognitive theories in order to become the *material* counterpart of thought. This semiotic platform opens up new possibilities for understanding algebraic signs and formulas in a nonconventional manner. Traditionally, letters and signs for operations (like “+”, “x”, etc.) have been considered *the* algebraic signs of school algebra. Alphanumeric symbolism has indeed been regarded as the semiotic system of algebra *par excellence*. Yet, from a semiotic perspective, signs can also be something very different. Words or gestures, for instance, are signs on their own — semiotically speaking, they could be as genuine algebraic signs as letters. Of course, as I will argue later in more detail, this does not mean that they are equivalent or that we can simply substitute the ones for the others. What makes semiotic systems unique and unsubstitutable is their *mode of signifying*. There are things that we can signify and intend through certain signs, and things that we cannot. Try to put Pablo Neruda’s famous poem “Canción Desesperada” [“Desperate Song”] in an algebraic formula, and you will see how hopeless the task is.

In the first part of this article, I argue that the mathematical situation at hand and the embodied and other semiotic resources that are mobilized to tackle it in *analytic* ways characterize the *form* and *generality* of the algebraic thinking that is thus elicited. My claim is based not only on semiotic considerations but also on new theories of cognition that stress the fundamental role of the context, the body and the senses in the way in which we come to know. In the second part, I present some concrete examples through which the typology of forms of algebraic thinking is illustrated.

THE 1990s ALGEBRA RESEARCH AGENDA

During the discussions held in the 1980s and 1990s, either in the PME Algebra Working Groups or in other similar research meetings (Bednarz, Kieran, & Lee, 1996; Sutherland, Rojano, Bell, & Lins, 2001), it was impossible to agree upon a minimal set of characteristics of algebraic thinking. There was, however, a more or less general consensus concerning two aspects. Algebra deals with objects of an *indeterminate* nature, such as unknowns, variables, and parameters. Furthermore, in algebra, such objects are dealt with in an *analytic manner*. What this means is that in algebra, you calculate with indeterminate quantities (i.e. you add, subtract, divide, etc. unknowns and parameters) as if you knew them, as if they were specific numbers (see, *e.g.*, Kieran 1989; 1990; Filloy & Rojano, 1984a, 1989; Cortes, Vergnaud, & Kavafian, 1990; for some epistemological analysis, see Filloy & Rojano, 1984b; Puig, 2004; Radford & Puig, 2007; Serfati, 1999).

Of course, one way or another, algebraic objects have to be designated. The general tendency in the 1990s was to associate school algebra and algebraic thinking with the use of letters. Even if at the time the idea was not universally shared (Linchevski, 1995; Balacheff, 2001), it nonetheless prevailed and is still very strong in current research on the teaching and learning of algebra. Although I do believe that it is impossible to practice

abstract algebra (e.g., Galois Theory) without some sort of sophisticated notations, I do not think that algebra and algebraic thinking can be reduced to the use of letters. As John Mason pointed out some years ago, “the manipulation of symbols is only a small part of what algebra is really about” (1990, p. 5). Letters indeed have never been either a necessary or a sufficient condition for thinking algebraically. For instance, in his *Elements*, Euclid used letters without thinking algebraically. Conversely, Chinese and Babylonian mathematicians thought algebraically without using letters (Radford, 2006).

What I am suggesting here is hence this: algebra is about dealing with indeterminacy in analytic ways. But instead of giving alphanumeric symbolism the exclusive right to designate and express indeterminacy I am claiming that there is a plurality of semiotic forms to accomplish it. This is true of the practices of elementary algebra and of advanced algebra as well—even if in the latter, alphanumeric symbolism becomes more salient.

But before I go further, let me reassure you that my idea is not to challenge the power of symbolic algebra. Rather, I am trying to convince you that it is worthwhile to entertain the idea that there are many semiotic ways (other than, and *along with*, the symbolic one) in which to express the algebraic idea of unknown, variable, parameter, etc. I deem this point important for mathematics education for the following reason. Ontogenetically speaking, there is room for a large conceptual zone where students can start thinking algebraically even if they are not yet resorting (or at least not to a great extent) to alphanumeric signs. This zone, which we may term the *zone of emergence of algebraic thinking*, has remained largely ignored, as a result of our obsession with recognizing the algebraic in the symbolic only.

SENSUOUS COGNITION

My claim about a diversity of semiotic forms for dealing with algebraic indeterminacy rests on a perspective on thinking that is squarely at odds with the mental conception of thinking that informed most of the 1990s research on mathematics education. Within this mental conception of thinking signs were often considered “symptoms” of mental activity—hence the distinction between internal and external representations. Drawing on Vygotskian psychology, from the semiotic-cultural perspective advocated here, the question of the relationship between signs and thought is thematized in a different way. First, signs are considered in a broad sense, as something encompassing written as well as oral linguistic terms, mathematical symbols, gestures, etc. (Arzarello, 2006; Ernest, 2008; Radford, 2002a). Second, signs are not considered as mere indicators of mental activity. In contrast, signs are considered as *constitutive* parts of thinking. In more precise terms, within this semiotic-cultural perspective, thinking is considered a *sensuous and sign-mediated reflective activity embodied in the corporeality of actions, gestures, and artifacts*.

The adjective *sensuous* refers to a conception of thinking that is inextricably related to the role that the human senses play in it. Thinking is a versatile and sophisticated form of sensuous action where the various senses *collaborate* in the course of a multi-sensorial experience of the world (Radford, 2009a). This multi-sensory characteristic of cognition

has been emphasized by philosophers like Arnold Gehlen (1988) and Maurice Merleau-Ponty (1945) and at its heart is the idea of the important role that the body plays in the way we come to conceptualize things. As Gallese and Lakoff recently contended,

the sensory-motor system not only provides structure to conceptual content, but also characterizes the semantic content of concepts in terms of the way that we function with our bodies in the world (Gallese and Lakoff, 2005, pp. 455–456).

In tune with such views, some researchers in our field are paying attention to the embodied nature of mathematical cognition. This is the case with Ferdinando Arzarello and the Torino Team in Italy, Rafael Núñez and Laurie Edwards in the USA, Michael Roth and the CHAT group in Canada, the Uniban research team in Brazil, etc. To mention a brief example, the Uniban research team in Brazil is investigating the role of gestures in blind children. Here gestures and tactility come to play a crucial role in understanding mathematical concepts (Figure 1).

Of course, tactility and other sensorial mediated processes are also important in non-impaired children. Ricardo Nemirovsky has suggested that instead of being mere mental processes, understanding and imagination of mathematical concepts are literally embedded in perceptuo-motor action: the “understanding of a mathematical concept spans diverse perceptuo-motor activities” (Nemirovsky, 2003, I -108), so that in this regard, “understanding is ... interwoven with motor action” (Nemirovsky, 2003, I-107).

Figure 1. Exploring area, from research conducted by Solange Ali Fernandes and Lulu Healy with blind children (Ali Fernandes, 2008).

However, thinking encompasses still much more than that. Thinking is an activity that, although performed by an “I” and the “I’s body”, is ubiquitously drawing on culture’s kit of patterns of meaning-making as well as on historically constituted concepts of an ethical, political, scientific, and aesthetic nature. Thinking is bound to the context and the culture in which it takes place. This is why it is more accurate to say that thinking in general, and algebraic thinking in particular, is a body-sign-tool mediated cognitive historical *praxis*.

LEARNING AS OBJECTIFICATION

From an educational perspective, the main question is: How do the students acquire fluency in such cognitive cultural historical *praxes*? How do they become acquainted with

the historically constituted forms of action, reflection and reasoning that those *praxes* convey? Since mathematical forms of reasoning have been forged and refined through centuries of cognitive activity, they are far from trivial for the students. It is the historical density of such *praxes*, sedimented now in compact, systemic, and highly abstract formulations, that is the basis of what Vygotsky intended with his famous distinction between “quotidian” and “scientific” concepts —regardless of how unfortunate Vygotsky’s choice of terms was.

Reflective acquaintance with cognitive historical *praxes* and their concomitant forms of action and reasoning is what learning consists of. And, as I submitted elsewhere (Radford, 2008a), it can be theorized as *processes of objectification*, that is, those social processes through which the students grasp the cultural logic with which the objects of knowledge have been endowed and become conversant with the historically constituted forms of action and thinking.

Working within this theoretical framework, where semiotics, culture and history are driving principles, in recent years my collaborators and I have been busy in implementing classroom holistic activities that can offer the students a possibility to reflect algebraically and to get acquainted with some basic ideas of algebra in different contexts —equations, pattern generalization and, recently, graph interpretation (Radford, 2000, 2002b, 2003, 2009a; 2009b; Radford, Bardini & Sabena, 2007). Our goal has been to try to understand what I previously referred to as the *zone of emergence of algebraic thinking* and forms of algebraic thinking elicited by our activities.

Let me pause this theoretical discussion here and turn now to some short examples that come from our first longitudinal research project—a project that we conducted from 1998 to 2003 and during which we accompanied four classes of students as they went from Grade 8 to Grade 12, i.e., until the completion of high school. The examples will, I hope, give an idea of our approach and the kind of analysis we conducted.

SOME CLASSROOM RESULTS

The students’ first contact with algebraic symbolism occurred when they were in Grade 8. In Grade 9 we decided to start with an activity that was intended as a means to revisit the concepts learned in the previous year. In the introductory part of the activity, the students, working in groups of three, had to draw Figure 4 and Figure 5 of the sequence shown in Figure I and to find out the number of circles in Figures 10 and 100¹. In the second part of the activity, the students were asked to write a message to a student of another Grade 9 class indicating how to find out the number of circles in any figure (“*figure quelconque*”, in the original French), and then to write an algebraic formula for the number of circles in Figure n.

¹Figures identified with Roman numbers (e.g., Figure II) refer to objects in the article, whereas figures identified with Indo-Arabic numbers (e.g., Figure 2) refer to elements of a pattern in the classroom activity given to the students.

Figure I. The sequence of the introductory pattern generalization activity in Grade 9.

Factual Algebraic Thinking

Usually, the students start counting the number of circles in Figures 1, 2, and 3, and realize that, in sequences like the one shown in Figure I, the number of circles increases by the same number each time. However, as the students quickly notice, this recursive relationship between consecutive figures is not really a practical way to answer the question about “big” figures, like Figure 100.

In one of the groups (formed by Jimmy, Dan, and Frank), working on the sequence shown in Figure I, the students imagined the figures as divided into two rows:

1. Dan: (*Referring to Figure I*) Well... (*pointing to the top row*) 2 on top; there, there is 3 on the bottom...
2. Jimmy: [Figure] 2, there are 3; [Figure] 3, there are 4.
3. Dan: wait a minute. Ok (*he makes a series of gestures as he speaks; see four of the six gestures in Figure II*), Figure 1, 2 on top. Figure 2, 3 on top. Figure 3, 4. Figure 4, 5.
4. Jimmy: Figure 10, it will be 11...
5. Dan: ... 11 on top, and 12 on the bottom.
6. Jimmy: All the time it will be one more in the air.
7. Frank: [Figure] 100? 101, 102...
8. Dan: 203.

“Figure 1	2 on top”
“Figure 2	3 on top”
<p>Figure II. Dan makes a sequence of pointing gestures coordinated with words in a first process of objectification (reconstruction from the video data).</p>	

As the students’ dialogue suggests, the generalization was accomplished in two steps.

In the first step (lines 1-3), the students conceived of the figures as divided into two lines, and, drawing on perceptual observations made on the first three given figures, they were able to objectify a *regularity*: a relationship between the number of the figure and the number of circles in its rows.

The grasping of the regularity is not enough, however, to ensure the generalization. The regularity has to be generalized. And this is what the students accomplished in the following lines where they came up with a formula to find the number of circles in Figures 10 and 100. Indeed:

- In lines 4 and 5 the observed regularity of perceptually available figures was *generalized* to Figure 10, a figure that is not in the students' perceptual *field*.
- Line 6 contains a partial linguistic formulation of the general structure of the figures, as perceived by the students: "All the time there will be one in the air", i.e., for all figures of the sequence, there is always one unmatched circle on the bottom row.
- In line 7, Frank resorted to the objectified pattern structure in order to calculate the number of circles in Figure 100.

The students are equipped now with a formula to answer questions about Figure 1000, Figure 1 000 000, or whatever particular figure you may have in mind.

Now, I am talking about a formula, yet there are no letters! That's true. The algebraic formula consists, rather, in a piece of embodied action. We can call it—borrowing an expression from Vergnaud (1996) and changing it slightly—an *in-action-formula*.

A "formula" of this concrete form of algebraic thinking can better be understood as an embodied predicate with a tacit variable: indeterminacy does not reach the level of discourse. It is present through the appearance of some of its instances ("1", "2", "3", "4", "5", "10", "100"). It remains an empty space to be filled up by the eventual uttering of particular terms. We call this type of situated and concrete form of algebraic thinking that operates at the level of particular number or facts *factual*².

Despite its apparently concrete nature, factual algebraic thinking is not a simple form of mathematical reflection. On the contrary, it rests on highly evolved mechanisms of perception and a sophisticated rhythmic coordination of gestures, words, and symbols. The grasping of the regularity and the imagining of the figures in the course of the generalization results from, and remains anchored in, a profound sensuous mediated process—showing thereby the multi-modal nature of factual algebraic thinking³.

Let us turn now to the second part of the Grade 9 activity.

Contextual Algebraic Thinking

In the introduction I suggested that the mathematical task at hand and the social sign-mediated processes of perception and generalization can inform us of the form and generality of the algebraic thinking that is thus elicited. What kind of algebraic thinking will now be generated? The task requires that the students go beyond particular figures and

² The adjective *factual* stresses the idea that this generalization occurs within an elementary layer of generality—one in which the universe of discourse does not go beyond particular figures, like Figure 1000, Figure 3245, and so on.

³ In our current research with Grade 2 students these mechanisms of rhythmic coordination are also present, but they do not reach the subtle sensorial synchrony that we observe in older students as those reported here.

deal with a new object: a *general* figure. Indeterminacy must now become part of explicit discourse. Our question is: How will the students build the formula? In the absence of gestures and rhythm, to which linguistic mechanisms will the students resort?

In fact, in being asked to write a message, the students were invited to enter into a deeper level of objectification than the one of action and perception characteristic of factual algebraic thinking. Writing makes one render explicit things that may have remained on what neuropsychologists call the area of proto-attention, or what Husserl used to call the horizon of intentions (Husserl, 1954).

In Grade 8, writing a message that involves this new object “general figure” proved to be very difficult. As we reported in previous work (see, *e.g.*, Radford, 2000), the students often used particular figures (like Figure 12) as examples to convey a *generic* idea or used particular figures in a *metaphorical* sense to talk about the still unutterable generality (Radford, 2002a). Sometimes the message was not complete. Here is an example: “You add 1 [circle] on the top and 1 on the bottom.”

In Grade 9, the students felt much more comfortable with this level of generality. The following message is paradigmatic of what the students wrote: “You have to add one more circle than the number of the figure in the top row, and add one more circle than the top row to the one on the bottom.”

Of course, this procedural sentence can be seen as a *formula*. But it is very different from the one discussed in the previous section. Here, rhythm and gestures have been replaced by key descriptive terms—“top,” “bottom.” These terms are what linguists call spatial *deictics*, that is to say, words with which we describe, in a contextual way, objects in space. The indeterminate object variable is now explicitly mentioned through the term “number of the figure.” However, although different from factual algebraic thinking both in terms of the way indeterminacy is handled and the semiotic means which the students think, the new form of algebraic thinking is still contextual and “perspectival” in that it is based on a particular way of regarding something⁴. The algebraic formula is indeed a *description* of the general term, as it was to be drawn or imagined. This is why we term this form of algebraic thinking *contextual*. Here is another Grade 9 example: “# of the figure + 1 for the top row and the # of the figure + 2 for the bottom. Add the two for the total.”

Let us turn now to the last part of the Grade 9 activity.

Standard algebraic thinking

Expressing the formula in algebraic standard symbolism was much more difficult than expressing it in words, both in Grades 8 and 9, although, of course, there was some progress from one year to the next. The results mentioned in the previous section shed some light on the nature of these difficulties: previously, the students could resort to a range of semiotic resources, like pointing and iconic gestures, deictics, adverbs, etc. Those

⁴ It still supposes a spatially situated relationship between the individual and the object of knowledge that gives sense to expressions like “top” and “bottom”.

rich semiotic resources do not have a place in the alphanumeric based algebraic formulas. In short, there is a drastic change in the mode of designation of the objects of discourse.

How then to designate the number of circles in a figure, in the highly condensed semiotic system of alphanumeric signs? From an ontogenetic viewpoint, direct “translation” is not something on which we can count, as we cannot count on direct translation from our native language to a new one we are just starting to learn. Direct translation presupposes that you already know the target language. In the case of the standard alphanumeric algebraic language, the situation is even worse, as this language is not even “natural.” Our standard algebraic language is *artificial*. Historical analysis shows that its construction was preceded by a good deal of efforts that ended up in dead ends and failures (Høystrup, 2008; Serfati, 2006).

In Grade 8, the students often resorted to particular examples. Thus, dealing with the sequence shown in Figure III, Dan and his group (in Grade 8, the group was formed by Dan, Frank and Sara), illustrated the formula through the case of Figure 100:

1. Dan: You add 3 on top, and 1 at the bottom.
2. Sara: That’s true if you go by the [form of the] figure.
3. Dan: You add 3 on top, and 1 at the bottom. Let’s say that n equals 100. It would be 100... you add 1, it would be 101 [on the bottom row]...
4. Frank: (Interrupting) and 103 [on the top row].

In other cases, the students often resorted to formulas that, superficially, look to be algebraic, in particular because they contain letters. Thus, in the sequence shown in Figure III, several students in Grade 8 produced the formula $n \times 2 + 4$. However, despite its appearance, the formula is *not* algebraic. It was instead obtained by trial and error. Dan and his group first tried $n \times 2 + 1$, then $n \times 2 + 2$, etc. until they obtained $n \times 2 + 4$, which seemed to work in the few cases in which they tested it. This procedure is not based on an *analytic* way of thinking about indeterminate quantities — the chief characteristic of algebraic thinking. This procedure does not even reach the sophistication of pre-algebraic arithmetic methods such as “false position.” It is rather a kind of arithmetic naïve induction⁵.

To counter these inductive arithmetic procedures, in the designing of the classroom activity, we added a question in which the students were asked to provide a formula for the

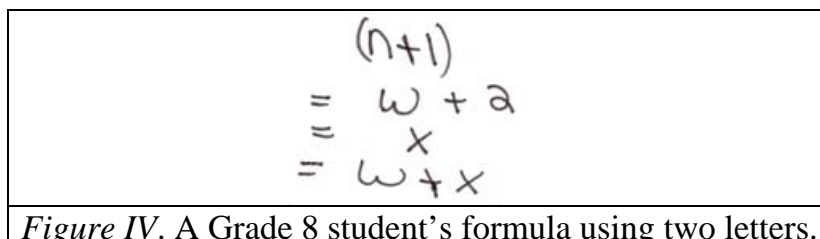

⁵ I do not have the space here to go into the details of the delicate distinction between algebraic and arithmetic formulas. For a detailed discussion, see (Radford, 2006, 2008).

number of circles on the top row of Figure n , followed by the question of finding a formula for the total of circles in Figure n . Establishing a functional relationship between the number of the figure and the number of circles on top of the figure proved very difficult. Dan and his group suggested using two letters:

Dan: (*Noticing that each figure has two more circles than the previous one*) It's plus 2 [to obtain the number of circles in the next figure], plus 2 [to obtain the number of circles in the next figure], plus 2... Unless we put 2 letters... What we would do is ... the top row would be n , and the top row would be like b . After that, you do $n + b + 2$.

In this case, the letters n and b do not designate the number of circles in the top and bottom rows of Figure n . Actually, the number of the figure is not even taken into account. The formula, rather, expresses a vague recursive relationship.

Another Grade 8 group suggested the “cascading formula” shown in Figure IV.

$$\begin{array}{l} (n+1) \\ = w + 2 \\ = x \\ = w + x \end{array}$$

Figure IV. A Grade 8 student's formula using two letters.

The first line corresponds to the number of circles on the bottom row. The result is called “ w ”. This is expressed in the second line, where it is also said that you still have to add 2 to get the number of circles on the top row. This last number is called “ x ”, as indicated in the third line of the formula. Finally, in the last line, the students are saying that you still have to add the numbers represented by “ w ” and “ x ” to obtain the total of circles in Figure n . Not bad, although still a bit far away from the standard way to write formulas within the alphanumeric semiotic system of algebra. Not bad, even if the use of several letters and their inter-connected meanings is not fully clear for the students. As one of the students from this group said to the other two members, “You mix me up with all your letters!”

The first example (Dan's) is interesting in that it shows that, although these students were able to produce an inductive formula that looked like an algebraic one (i.e., “ nx^2+4 ”), they did not produce the expected algebraic formula “ $n+3$ ” for the top row of Figure n —even if the formula “ nx^2+4 ” seems much more complex. The complexity of the formulas cannot be judged by the number of involved terms only; the complexity of the formula should also be judged in terms of the mode of designation of the objects of discourse.

The second example is interesting in that it unveils some of the tremendous difficulties that the students have to face when using letters to intend to say what they perfectly know how to express in natural language. This problem is much more complex than a simple translation. As Glaeser remarked, the need to give an immediate meaning to every intermediate result has to be refrained (1999, p. 154). Meaning, indeed, has to be put in abeyance.

In Grade 9 we still found some formulas that resembled the formulas produced in Grade 8. But more typical of Grade 9 were the formulas shown in Figure V (these formulas correspond to the sequence shown in Figure I).

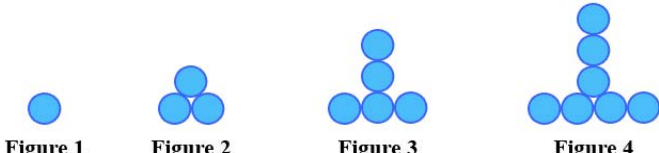

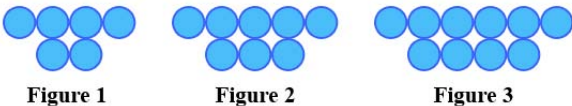

$(n+1)+(n+2)$	$(n+2)(n+1)$
<i>Figure V.</i> Left, the formula produced by Dan's group in Grade 9. Right, a variant of it produced by another Grade 9 group.	

Although much better than the formulas found in Grade 8, the signs in these formulas still keep the embodied and perspectival experience of the objectification process. We easily recognize in the term “ $n+1$ ” the reference to the top row, as we recognize in the term “ $n+2$ ” the reference to the bottom row. In Dan's group, for instance, this embodied manner of symbolizing was made very clear:

1. Dan: No, no, well, it's that... $n + 1$ is the top row...
2. Frank: (*Interrupting*) Yes, I know.
3. Dan : $n + 2$ is the bottom row.

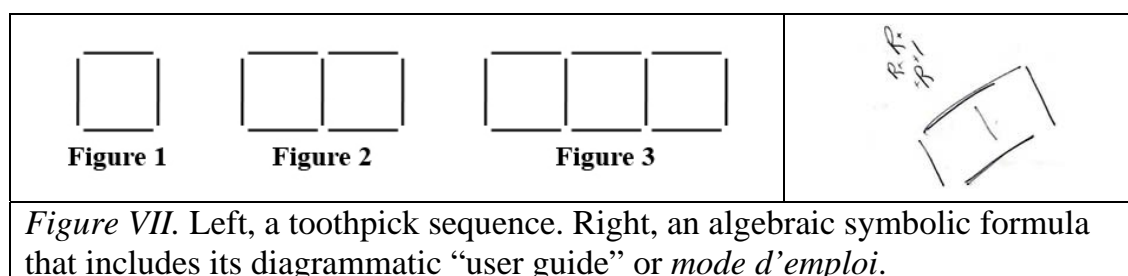

As is clear from Figure V, the students add brackets to carefully distinguish between the rows. This is why, I want to suggest, the formula is an *icon*, a kind of *geometric description* of the figure. In other terms, the formula is not an abstract symbolic calculating artifact but rather a *story* that narrates, in a highly condensed manner, the students' mathematical experience. In other words, the formula is a *narrative*. And it is the narrative dimension of the students' iconic formulas that very often makes it possible to infer from the formula the sequence to which it corresponds (see figure VI).

That which previously was distinguished through pointing gestures and linguistic deictics is now distinguished through the effect of signs and brackets. It is precisely this “perspectival” nature of the formula that leads many students to argue that brackets cannot be removed. Otherwise, they argue, it would be impossible to know what the terms of the formula mean. Yet, this is precisely what constitutes the force of algebra—the detachment from the context in order to signify things in an abstract way. The mode of designation has to move to a different layer where signs borrow their meaning not from the things they denote but from the *relational* way they mean within the context of other signs.

$n+(n-1)$	 Figure 1 Figure 2 Figure 3 Figure 4
$(n+1)+(n+2)$	 Figure 1 Figure 2 Figure 3

The narrative meaning of iconic symbolic formulas became even clearer when a fifth class was added to our project. As our project progressed, other teachers became interested in it and, to the extent that we could, we included new classes. The fifth class regrouped Grade 8 students who were recognized as having difficulties in following the rhythm of “regular” math classes. Dealing with the pattern shown in Figure VII (left) one group of students produced the formula shown in Figure VII (right).

The formula does not have the usual linear organization of standard algebraic formulas. Rather, signs signify in a spatial manner: as the students explained to us, the top “R” means that there are as many toothpicks on the top of the figure as the number of the figure. The “R” placed on the bottom of the formula means that there are as many toothpicks on the bottom of the figure as the number of the figure. The lateral “R” means that there are as many vertical toothpicks on the top of the figure as the number of the figure, but not really. There is an extra toothpick to be accounted for, placed at the right end, signified by the lateral sign “1.” The “+” signs mean that you have to add all of those things.

FROM ICONIC FORMULAS TO SYMBOLIC ONES

One of the important didactic problems is to implement classroom activities that will allow the students to endow their formulas with new abstract meanings. In more precise terms, the problem is to transform the iconic meaning of formulas into something that no longer designates concrete objects. For instance, the formula $(n+1) + (n+2)$ mentioned previously (Figure V), has to be seen in a new light. The narrative dimension of formulas has to collapse (Radford, 2002c). The embodied meaning of the formulas does not disappear. It rather gives rise to a more abstract one. Thus, in addition to signifying the sum of circles in the top and bottom rows, the terms of the formula have to be considered in relation to the signs that they contain. Resemblances and differences—these key aspects of signification in general (Radford, 2008b)— must no longer be exclusively based on spatial and

contextual considerations (such as “top” and “bottom”). In the new form of signifying, there is a shift in focus: attention has to be directed now to morphological differences, i.e., differences in terms of *letters* versus *numbers*. In short, meaning must become *relational*.

The search for the pedagogical actions allowing the students to objectify this abstract form of signifying became one of our goals, both from a theoretical and a practical viewpoint. Our strategy was based on *comparing* and *simplifying* formulas. Here is an example that deals with the sequence of squares shown in Figure VII.

The previous day, the students produced several formulas. At the beginning of the class, the teacher asked for some examples. The students mentioned two, that were written as $r \cdot 3 + 1$ and $(r+1) + r \cdot 2$, where r stands for the rank or number of the figure.

1. Teacher: I would like to compare these formulas and to see where they come from. Brian, do you want to explain the first formula to us?
2. Brian: (*Going to the blackboard*). Ok, yesterday we saw that the first figure only has 1 toothpick at the bottom (*he points to the bottom of Figure 1 on the blackboard*) and the second figure, there were 2, third figure, there were 3. So, we added the bottom and the top, and then we saw that, in the first term, there were 2 [vertical toothpicks] (*points to the vertical toothpicks of Figure 1*) and Figure 2 has 3 (*points to the vertical toothpicks of Figure 2*) therefore, it's always [the rank or number of the figure] plus 1. So we did the bottom plus the top plus the rank plus 1. And then we saw that... Well, we discussed a lot, and we saw that ... it was the rank, rank times 3 (*points towards the first term of the formula*) because it has the bottom, the top and the vertical. There was, there was, plus [one]...
3. Teacher: So you say that this (*pointing to the bottom row of the first square and colouring it with blue chalk; see Figure VIII, pic. 1*) is one r ; this is another r (*pointing to the top row of the first square and colouring it with blue chalk; see pic. 2*); and this is the third r (*pointing to the left vertical side of the first square and colouring it with blue chalk; see pic. 3*) and there remains another one [toothpick] (*pointing to the second vertical line of the first square; pic. 4*). So, (*pointing to the formula*) r times 3... I have three r here (*pointing successively to the coloured sides of the first square*) plus another one in each term (*pointing the uncoloured right vertical side of the first square*). (*Then, the teacher repeated the same set of sequence of pointing gestures on Figure 2, see Figure VIII, pics. 5-8*). This is the explanation of the formula. Now, Ron, would you please explain the second formula?

Figure VIII. Pictures 1-4 (top) show the teacher's effort to relate the terms of the formula $r \cdot 3 + 1$ to the various parts of Figure 1. Pictures 5-8 (bottom) shows the same effort but this time the focus is on Figure 2. The teachers makes apparent for the students the new way of signifying through a subtle coordination of gestures, words, drawings and coloured segments.

Ron went to the blackboard and explained the various elements of $(r+1) + r \cdot 2$. After that, the teacher encouraged a discussion about the formulas. Sandra—a student sitting at the end of the classroom— argued that both equations work but the first one was simpler. The teacher summarized the difference as follows:

1. Teacher: the difference is that here (*pointing to the formula $r \cdot 3 + 1$*) we put together the terms that were the same and we simplified. Since I am calculating the total number of toothpicks, I can put all together (*while talking, she emphasized the words "same", "simplified" and "total"*). It is exactly this that the first formula does. (*Smiling to the class, she says*) I think that you are ready for the next activity.

The previous formula $r \cdot 3 + 1$ looks much like Dan's formula $n \times 2 + 4$ discussed earlier. Yet, the difference is considerable. Brian's formula was not produced by trial and error. It was the result of an algebraic generalizing process where general functional relationships were first identified (*e.g.*, the number of toothpicks on top vis-à-vis the rank or number of the figure), then simplified. As Brian put it, "... it was the rank, rank times 3 *because* it has the bottom, the top and the vertical." The teacher capitalized on Brian's idea and, through a feast of clear and consecutive gestures that echoed Brian's timid gestures, coloured parts of the first two figures to make clear for all the students the relationship between the spatial-geometric parts of the terms and their corresponding rank (Figure VIII, pic. 1-8). After showing each one of the tree r on Figure 1, she linked the first part of the formula ($r \cdot 3$) to the three parts she had just coloured. She said: " r times 3... I have three r here," followed by the crucial remark that there is still "another one in each term" (which corresponds to the constant term of the formula). Her coordinated gestures and words related very well the spatial elements of the figures with the corresponding parts of the formula. The idea of putting *together* the toothpicks on the bottom, the top and the vertical ones, led to *adding* the number of the figure several times.

That day, after the general discussion, the students dealt with a sequence of houses (Figure IX). The students identified the relationship between clue elements of the figures and their rank or number:

1. Raymond: the number of toothpicks in the roof is twice the number of the figure. For the walls [which included the floor], it is twice, and another wall ...
2. Joyce: (*Interrupting*) to close the space...
3. Raymond: So, the formula is rank times 4 plus 1.

Figure IX. Left, a toothpick sequence of houses. Right, one of the students' formulas.

In so doing, the students entered into a new form of algebraic understanding and moved into a deep region of the zone of emergence of algebraic thinking. They moved from a referential understanding of signs (signs as referring to particular objects, like the number of toothpicks in the roof) to a morphological one—the beginning perhaps of what Kieran (1990) Kirshner (2001), Hoch & Dreyfus (2006) and others have called the structural dimension of algebra.

It is clear that the symbolic formula is no longer just iconic. Iconicity is still present, but it has receded to make room for a more concise and abstract form of signification. Naturally, the students have yet to undergo a supplementary lengthy process of objectification to become fluent with the modern form of symbolic algebraic thinking, where symbolic calculations are carried out through formal considerations only. For this to occur, new objects like x^2 and $x^2 + x$ will have to enter the universe of discourse and acquire a detached existence. It is not vain to recall here that this process was not easily achieved in the history of algebra. Thus, to distinguish magnitudes, Vieta—one of the founders of our modern algebraic symbolism—was still in the 16th century talking about “length”, “plane”, “solid”, etc.. Our modern way of referring to the now abstract monomials of algebra still reminds us of their embedded concrete beginnings. Indeed, monomials such as x^2 or x^3 read as “x square”, “x cube”. Our modern language hangs behind the relics of its past revealing thereby the monomials' original geometric-spatial origin.

Synthesis and Concluding Remarks

In this article, drawing on recent conceptions of thinking offered by anthropology, semiotics and neurosciences, I suggested that thinking is a complex form of reflection mediated by the senses, the body, signs and artifacts. In this view, thinking is not a kind of Cartesian mental activity monitored by a homunculus residing somewhere in a black box of ideas and representations. As the Russian philosopher Elvald Ilyekov put it, “Thinking is not the *product* of an action but the *action itself*” (Ilyenkov, 1977, p. 35). To a large extent, thinking is indeed a material process. But thinking is also more than the processes that a sensing body can produce. Thinking is something that is intrinsically *historical* and

cultural, and the proof is that had we happened to live in Babylonian times, we would have found ourselves with body and brain structures and anatomies indistinguishable from the ones we have today. Yet, we would have been thinking mathematically, aesthetically, politically, etc. in a very *different* way. It is this distinctive historical and cultural trait of thinking that I want to convey when I say that thinking in general and algebraic thinking in particular is a body-sign-tool mediated cultural historical *praxis*.

The historical nature of cultural praxes has, as a corollary, the non-transparency of the forms of action, reflection and reasoning they convey. To become fluent in those praxes, we have to undergo lengthy processes of objectification. The creation of the conditions for those processes to occur is an educational problem. In the approach expounded here, the basic premise is that algebraic thinking cannot be confined to activities mediated by the standard alphanumeric semiotic system of algebra. From a semiotic viewpoint, there are several ways in which to analytically reason through, and to reason on, indeterminate quantities. More importantly, the mathematical situation and the semiotic resources that are mobilized to tackle it in analytic ways characterize the *form* and *generality* of the algebraic thinking that is thus elicited. Focusing on the context of pattern generalization, I suggested a classification of three forms of algebraic thinking —factual, contextual, and symbolic. As with most classifications, the borders of those categories are not necessarily well defined. Furthermore, those forms of thinking do not necessarily exclude each other. A student, for instance, can very well combine factual and symbolic forms of thinking. The typology is rather an attempt at understanding the processes that the students undergo in their contact with the forms of action, reflection and reasoning conveyed by the historically constituted praxis of school algebra.

The classroom data presented here offers a glimpse of the ontogenetic journey of our students on their route to algebraic thinking. It stresses some of the challenges that they had to overcome when passing from factual to contextual to symbolic thinking. It stresses in particular the changes to be accomplished in modes of signification. While in factual thinking, indeterminacy remains implicit and gestures, words, and rhythm constitute the semiotic substance of the students' *in-action-formulas*, in contextual algebraic thinking indeterminacy becomes an explicit object of discourse. Gestures and rhythm are replaced by linguistic deictics, adverbs, etc. Formulas are expressed in a perceptual and "perspectival" manner based on key terms like "top", "bottom", etc. Formulas, in short, are based on a particular way of seeing the sequence at hand.

Our discussion about symbolic algebraic thinking sheds some light on the meaning with which the students endow their first alphanumeric formulas. Instead of being an abstract calculating device, formulas often appear as vivid narratives. They are icons in that they offer a kind of *spatial description* of the figure and the actions to be carried out. What I called the "collapse of narratives" appears as an important step towards more encompassing ways of algebraic signification. The constitution of meaning after such a collapse deserves more research (see also Barallobres, 2007). While Russell (1976) considered the formal manipulations of signs as empty descriptions of reality, Husserl stressed the fact that such a manipulation of signs requires a shift of intention: the focus

becomes the signs themselves, but not as signs *per se*. And he insisted that the abstract manipulation of signs is supported by new meanings arising from rules resembling the rules of a game (Husserl 1970), which led him to talk about signs having a game signification.

The classroom example discussed in the last section shows how the teacher, through a complex coordination of gestures, alphanumeric formulas, and words, capitalized on the formula of one of the groups to make apparent for the whole class the idea of simplification of formulas. It was a first step, and certainly an important one in the students' ontogenetic journey.

Although I limited my account to the first two years of the 5-year journey, I hope that such an account is enough to get an idea of the students' struggles and progresses towards increasingly more encompassing forms of algebraic thinking.

CERME 6 – PLENARY 2**Mathematics education as a network of social practices**

Paola Valero, Aalborg University, Denmark.

Reactor: Margarida Alexandra da Piedade Silva Cesar (Lisbon University)

Summary. Based on an analysis of mathematics education research as an academic field and on current social, political and economic transformations in many European countries, I would argue for the need to rethink and enlarge definitions and views of mathematics education as a scientific field of study in order to provide better understandings and alternatives for practice in the teaching and learning of mathematics today. I will explore the notion of the “network of mathematics education practices” as a complex, multi-layered space of social practice where the meanings of the teaching and learning of mathematics are constituted. I will illustrate the potentiality of this notion to envision possible research paths in the field. I will illustrate these with the research that my colleagues and I have been carrying on multicultural classrooms in Denmark; as well as will offer examples of other research studies in Europe and other parts of the world where I see that the discipline is gaining newer insights that could allow attending to the social changes and challenges of the 21st century.

MATHEMATICS EDUCATION AS A NETWORK OF SOCIAL PRACTICES

Paola Valero

Aalborg University

As academic fields advance, reflexivity on its own results and processes becomes a centre of attention and of disciplined inquiry. The growing amount of published papers and conference activities considering mathematics education, its theories, methods and results exemplify the need researchers have to make sense of the practice in which they are involved. Such type of reflexivity has always been a central part of my interest, probably due to the fact that my background in the social sciences has led me to constantly formulate questions about the type of insights on educational practices that mathematics education research offers in relation to the realities of schools and mathematics classrooms. Developing awareness on the research perspective that I adopt has, therefore, been as central to me as generating particular understandings and interpretations of the practices of teaching and learning in mathematics classrooms.

In this paper I focus on the issue of how to conceive of mathematics education as a field of research. This implies, on the one hand, examining definitions of the field as they appear in existing literature, and, on the other hand, articulating alternative views and languages to talk about the field. My intention is to provide a ground for discussing the research practices in which we engage and to which we devote a great deal of our effort and commitment. In my examination of this issue, I will contend that in the historical development of what we may identify as the field of mathematics education research, particular dominant definitions about the field of educational practices of mathematics teaching and learning have emerged. Such definitions of the educational practices have defined what the legitimate objects of study of the field of research are, and with that encompassing theories and methodologies to research the field of educational practices. As research advances, however, the definition of the field of research emerging from research practices is being pushed to its limits. I argue that the time has come to open possibilities of defining both research practices and educational practices in a way that allows tackling in serious, rigorous and systematic ways the social, cultural and political complexity of mathematics education in our contemporary societies. Opening the scope of the field does not represent a threat to the identity of the field, but rather an opportunity to engage with the enormous challenges that mathematics education practices pose to all their participants.

I start by a conceptual clarification of the language that I choose to address this issue, which entails a presentation of the underpinning ideas of my theoretical perspective. I clarify the notions of mathematics education as a field of educational practices and as a field of research practices. The distinction is useful in addressing the way in which these realms constitute each other, and of how different meanings have been ascribed

to them particularly from the second half of the 20th century when the international field of mathematics education research has been more visible and identifiable. I then move to argue that dominant definitions of the field of research and its corresponding views of its object of study are insufficient in tackling in a comprehensive manner the impact of larger contextual factors on the teaching and learning of mathematics. While research results continue to point to the influence of the “context” on actual possibilities to an effective improvement of the teaching and learning of mathematics, the field of research misses the development of scientific strategies to deal with both the understanding of those influences and the devising of strategies to deal with them in practice. As a response to this shortcoming, I play with the idea of defining mathematics education as a field of research which studies the complexities of the *network of mathematics education practices*. I define three different types of research moves or strategies that are necessary to deepening the understanding of the practices of teaching and learning of mathematics. I finalize by exemplifying these research moves with projects carried out by a growing number of mathematics educators around the world.

ANALYSING THE FIELD THROUGH ITS DISCOURSES

The increasing attention given to reflexivity in mathematics education research invites to discussions of how and why theories, methods and discourses in research are simultaneously constructed and get reproduced. In his paper during the ICMI study on what is mathematics education and what are its results, Ernest (1998) had identified the need for mathematics education research to address not only the primary objects of the field (the practices of teaching and learning mathematics), but also the secondary objects of the field (i.e., the products and processes of research practices). The growing emphasis on the effects of language and its connection to practices within the social sciences —known as the social turn— has influenced the way mathematics education researchers think about the field. Thus, it appears increasingly important to pay attention to the discourses that mathematics education research constructs about itself and the contributions and limitations of these constructions. By discourses here I understand the ways of naming and phrasing the ideas, values and norms that emerge from the constant and complex interactions among human beings while engaged in social practices. Researchers in academic fields construct particular discourses about their objects of study and their overall activity. Such discourses constitute systems of reason that regulate what is possible to think and do in a given field (Popkewitz, 2004). Thus, discourses generate both a space of possibilities as well as of limitations of what we can imagine as alternatives to existing orders.

Mathematics education as a field of research is not an exception. As researchers engage in studying the field, they not only define what characterizes legitimate practices of mathematics education. They also define the ways in which it is valid and legitimate to research those practices. I have elsewhere engaged in examinations of

the discourses generated in and by the field of mathematics education research, such as the idea of mathematics education being “powerful” (Christensen et al., 2008), the conceptions of students as mathematics learners (Valero, 2004a), and the concept of learners’ identity in mathematics (Stentoft & Valero, in press). In this paper I turn to the discourses of the field about itself. My analysis is based on a study of a variety of texts addressing mathematics education research as a field of study, such as, for example, the work of Jeremy Kilpatrick (e.g., 1992, 2006, 2008; Silver & Kilpatrick, 1994), books addressing the issue (e.g., Menghini, Furinghetti, Giacardi, & Arzarello, 2008; Sierpinska & Kilpatrick, 1998) and recent handbooks (e.g., English, 2008; Lester, 2007). Drawing on elements of critical discourse analysis (Fairclough, 1995), I focus on the dominant ways of talking that emerge from the texts as they address what mathematics education practices and mathematics education research are about. The references in my analysis serve as illustrations of the characteristics of the discourses that I am identifying.

EXAMINING “MATHEMATICS EDUCATION”

The use of the term “mathematics education” in English is ambiguous. Among others, Ernest (1998, p. 72) has argued that the term refers to “both a practice (or rather a set of practices) and a field of knowledge”. The term names the set of practices of mathematical teaching and learning, carried out mainly by practicing teachers and students, in a variety of formal and informal contexts, and where mathematical thinking and communication occurs. The term also refers to the set of practices, carried out mainly by researchers hired at colleges of education and universities, that study teaching and learning practices. A first thing to notice about the two meanings is that each one of them is addressing a field of practice. The former refers to the field of educational practices; the latter refers to the field of research practices. As fields of practice, each one of them has particular embodied, routinized activities, artifacts, ideas, values and forms of communication. They are distinct practices, though with intersections of practitioners (most often than not, researchers are themselves teachers and teachers are also researchers), interests, concerns and discourses. However, the two fields of practice are not identical. It is not my intention to go deeper into the characterization of these two fields of practice here. Suffice to say that their separateness or connection is a matter of concern for many practitioners located in each one of the fields (e.g., Ruthven & Goodchild, 2008; Sfard, 2005).

My intention with distinguishing the two fields here has to do with the relationship between the two, not in terms of how the field of research practice should illuminate and improve the field of educational practice; but rather in terms of how the definitions constructed for each of them are mutually constitutive. Let me explain, starting with a basic assumption. A theoretical perspective and an object of study are mutually constituted. It is not possible to talk about an object of study without a set of assumptions and language that recognizes and phrases a happening or a social event,

and makes it focus of attention. If this is the case, then we can think about the relationship between what is taken to be mathematics education as a field of educational practice and mathematics education as a field of research practice. My contention here is that through the development of the field of research practice, definitions of the field of educational practice have emerged.

Looking back at the history of the field of research practice through a general study of the different trends that have emerged in literature, as well as an examination of texts addressing the history of mathematics education research, there seems to emerge a common narrative about the origins of research. The interest of mathematicians and educators engaged in the teaching of the subject at different levels, particularly in relationship to teacher education, was a seed for paying systematic attention to mathematics in a learning and teaching environment (Kilpatrick, 2006). “The problems of practice” that is, the set of concerns for the predicaments of teachers’ instruction and students’ learning of mathematical topics, as formulated by Silver and Herbst (2007), have become the cornerstone of the research endeavor. The problems of practice have become the natural object of study of the field of research. They have also determined the ultimate goal of research, which is contributing to the improvement of practice. Many people defend these ideas as the essence of mathematics education research; the ideas are a central part of how many researchers define the object and aims of study (e.g., Hart, 1998). These ideas are seen by many in opposition to the idea that mathematics education research is growing as an academic field in itself, with a theoretical and methodological development that not always connects so closely with teaching and learning practices. There are also many scholars who acknowledge and actually try to understand not only the findings, but also the theoretical, methodological constructions of the field (e.g., Silver & Herbst, 2007). Of course, this debate is also fuelled by different agendas outside the field of study and the field of practice of mathematics education, such as the growing political demand for accountability of research funds and the focus on educational research to be the basis for evidence-based practice.

Independently on which side personal intentions and commitments are, two points are evident here. First, there is nothing “natural” in the definitions given to the field of research practice. The discursive construction of the object of study and the aims of research in the field correspond with the practices of researchers both in national and international communities. We actually need to denaturalize what seems to be taken for granted in the way we researchers, collectively and as individuals, talk about the field and engage with the field. Following from this, the second point is that definitions of the field of study entail definitions of the educational practices that research studies. This implies that it is not possible to assume complete independence between the social practices of teaching and learning of mathematics, from the social practices of researching them. The discourses of the field of study construe frameworks for thinking, conceiving and therefore actually engaging in the

educational practices (Popkewitz, 2004). The fields are distinct but discursively related.

Digging deeper into how the educational practices are being defined by the research practices, it is evident that definitions are historical and also situated in particular geographical settings. They are also contingent upon theories adopted to account for the problems of practice. A proper account of the complexity of the definitions exceeds the scope of this paper. Nevertheless, I will point to some salient features of the way research has been defined in general international terms. Although for many researchers the history of mathematics education research is short—in relation to the history of, say, mathematics—it is possible to find shifts in the ways of phrasing the focus of both educational and research practices. Looking at the 100-year long history of the International Commission of Mathematical Instruction (ICMI) as one international organization that has had an important role to play in promoting mathematics education research, the initial focus of the meetings, discussions and concerns of interest in the educational practices was the mathematical content. In what Bass (2008) has named ICMI’s “Klein Era”, at the beginning of the 20th century, attention was paid to issues of content and little distinction existed in fact between the gatherings of ICMI and the general meetings of the International Mathematical Union, except for the fact that the mathematical topics addressed in ICMI were more elemental mathematics. Such observation resonates with Kilpatrick’s assertion that the work of the first mathematics educators at the end of the 18th and beginning of the 19th centuries had a strong focus on the mathematical contents, although few other topics were present as well such as the history of mathematics and teaching experiments (Kilpatrick, 2006). A graphic representation of the field of educational/research practice in this time could look like this:

Figure 1: Mathematics at the centre of the field of practice and research

The linkage to psychology as a support discipline has been important in the construction of an empirical investigative approach towards the problems of practice. With the strengthening of parts of psychology as an experimental science and with mathematics education becoming a field in universities, mathematics education research found theoretical and methodological approaches to the inquiry of teaching and learning problems in mathematics (Lerman, 2000). The influence of the European didactic traditions have also played a major role in defining that the focus

of research is placed in the *didactic triad* constituted by the relationships between mathematics, the teacher and the student. As the 20th century advanced and more research work in the area was produced, explorations of the didactic triad had been focused on each of its elements, on the relationships among them, and on the whole complexity at stake in it. Combined with a variety of theoretical approaches to deal with the specificities of each of the elements, the didactic triad has been a basic but powerful model behind a great deal of research in the field. Saying that the didactic triad has been a model behind research in mathematics education does not intend to oversimplify and dismiss the advances of the field in understanding the complexity of the relations at the interior of the triad. There are numerous examples of particular models that have shown such complexity (e.g., Balacheff & Kaput, 1996, for the case of the role of technology in mathematics learning).

Figure 2: The didactic triad at the centre of the field of practice and research

There are several points to notice in the research and discussions about the field of research adopting this model. A first issue is the issue of the *mathematical specificity*. Mathematics education research is defined as the discipline studying “the practice of mathematics teaching and learning at all levels in (and outside) the educational system in which it is embedded” (Sierpiska & Kilpatrick, 1998, p. 29). In this field, “[...] mathematics and its specificities are inherent in the research questions from the outset. One is looking at mathematics learning and one cannot ask these questions outside of mathematics.” (p. 26). Questions, problems, theories and methods not allowing for mathematical specificity tend to be considered irrelevant, and out of the scope of mathematics education research. Second, there also seems to be an underlying assumption about the *decontextualization* of the triad. The objects of research tend to be presented in terms of students’ learning of concepts (and most often students’ misunderstanding of them), and teachers’ instruction of mathematical concepts. They are text, the content, the centre. The con-text, that surrounding accompanying and constituting the text, does not fall inside the research gaze. Therefore, except for a brief mention to the characteristics of the people involved in a study, no more grounding and information is available about the context of a given phenomenon studied. If some context is mentioned, it is not taken significantly as part of the analysis. The assumption of decontextualization goes also hand in hand with the assumption of *closure* of the didactic triad. This means that research problems are both formulated within and accounted for in the didactic triad. The

practices of teaching and learning are somehow self-contained and self-explanatory. There are plenty of examples to find in research on geometrical thinking, argumentation and proof, etc. A review of, for example, the CERME proceedings on these topics will clearly show this tendency.

As some researchers have started to consider classrooms dynamics, the classroom has appeared as a clear boundary around the triad, a clear, manageable context. One example of research contributing to the strong emergence of the classroom is the work of Cobb and collaborators during the 1990's which lead to the notion of the socio-mathematical norms (e.g., Cobb, Wood, & Yackel, 1992) which explained students' learning possibilities in terms of the continued interactions happening in the instructional practices in classrooms. In the case of Cobb and collaborators, the move from a social constructivist theory of learning to address mathematics education, to a socio-cultural theory of learning was one of the reasons for an enlarged understanding of the role of the social dynamics of the classroom in relation to individual learning. This seems to have been the case for many other researchers who started to focus on the situatedness of teaching and learning practices in classrooms and schools (e.g., Boaler, 1997).

Figure 3: The didactic triad within the boundaries of the classroom

Lerman (2000, 2006) has argued that researchers in mathematics education, influenced by the language turn in the social sciences, have adopted a variety of sociological and cultural-anthropological theories for the study of the teaching and learning of mathematics. The strong social turn in the field has meant the recognition of the embeddedness of mathematical thinking, learning and teaching in larger social, cultural, economic and political structures. Research with a concern for equitable access to mathematics is an example of how such recognition has been fundamental in the generation of new research areas. In many cases, there is an attempt to stick to the formulation of problems within the didactic triad, though, from a different theoretical position. For example, part¹ of the work of Radford concerning semiotic,

¹ In few of his papers, Radford shows a broader analysis of the relation of mathematics and culture. For example, Radford and Empey (2007) present a study of social and mathematical practices outside the didactic triad. They show that “within a certain historical time period, mathematics –in its amplest sense [...] accounts for the formation of new social sensibilities –both in terms of

embodied interpretations of students' mathematical thinking give a cultural dimension to the issues of the didactic triad and show a connectedness of children's thinking and school practices with other forms of practices outside schools and classrooms (Radford, 2008). In general, it is interesting to notice that, despite the adoption of theoretical frameworks that have an understanding of the social and cultural that goes beyond the limited understanding of "social" in terms of interaction among people present in interactionist theories associated with constructivism, the focus of attention of research remains being the classroom and, within it, the didactic triad.

Some other types of research have also challenged the idea that the privileged site for research is the classroom. If mathematical thinking is a social and cultural activity it happens in other social spaces different from classrooms. The classical example of this broadening is the research by Nunes and collaborators (Nunes, Carraher, & Schliemann, 1993) which opened the space for investigations of the relationships between mathematics in school and out of school. The extensive research belonging to the ethnomathematical program has also explored mathematical practices in working and everyday life settings. Already at the beginning of the 1990's Gómez, Perry and collaborators (e.g., Gómez & Perry, 1996; Perry, Valero, Castro, Gómez, & Agudelo, 1998) had studied mathematics teachers' change and professional development within the complexity of the school organization. Such trend has also been explored by Cobb and collaborators (e.g., Cobb, McClain, Silva Lamberg, & Dean, 2003) in an attempt to connect classroom communities with their immediate organizational contexts. More recently attention has been paid to the school mathematical experiences of parents in relation to the school mathematics practices of students when coming to new countries and cultures (Civil, 2007). In general, there has been a growth in research that documents the relationship between factors outside of the classroom (in the context) and the state of affairs inside the classroom, in the didactic triad.

Figure 4: The didactic triad in a context

capacities to create new forms of understanding and novel forms of subjectivity" (p. 232).

In other words, the welcoming of socio-cultural theories to deal with the problems of practice has helped considering the context of those problems as a significant part of them. With such move the interpretations and understandings of the terms “mathematics” “teaching”, “learning”, and “thinking” are broadened and new phenomena, interactions and practices where mathematical elements are present start being included as legitimate objects of study. As an evidence of this we could look at different studies classifying the research published in different international journals and conference proceedings. All these studies assume that certain international journals actually represent the production in the field at any given time. Gómez (2000) argues that “mathematics education research production is centred mainly on cognitive problems and phenomena; that it has other minor areas of interest; and that it shows very little production on those themes related to the practices that influence somehow the teaching and learning of mathematics from the institutional or national point of view” (p. 2-3). In a review of literature focusing on how research addresses the significance of students’ social class for the learning of mathematics, Chassapis (2002) also argues that little and almost insignificant attention has been paid in 30 years of research production to the issue of who are the mathematics learners and how the learners’ background influences mathematical learning. This lack of attention contributes to a lack of comprehension about the social, political and cultural complexity of mathematics education and the factors involved in it. Lerman, Tsatsaroni and Xu (2006; 2002) have also produced an overview of the theories used in mathematics education research in the period 1990-2001. Their data shows that although socio-cultural theories of different types had been more used in the field, the majority of theories used in published papers are traditional psychological and mathematical theories focusing on the learners, the mathematics and the teachers. Skovsmose and Valero (2008) have also classified publications with the purpose of showing how the field gives different meanings to the term “democratic access to powerful mathematical ideas”. The concentration of research on mathematical and psychological interpretations, focusing on the study of classroom practices led them to conclude that “it is highly problematic that dominant research trends in mathematics education operate within a limited scope of the space of investigating democratic access to powerful mathematical ideas. Such a paradigmatic limitation effectively obstructs the possibilities for mathematics education to face the paradoxes of the informational society”. Time has passed and, as Lerman and collaborators show, the adoption of socio-cultural theories enlarges and thereby a sensitivity to define research objects outside the didactic triad emerges. However, the majority of research published defines problems that deal with the central elements of the didactic triad, and from theoretical perspectives focused on mathematical cognition. A recent overview for the papers published in ESM, JRME, MERJ, FLM, ZDM and PME proceedings during the year of 2007² confirms the previous findings: 25% of

² I thank Alexandre Pais for his support doing this overview.

papers choose as a focus a mathematical notion in learning or teaching; 29% of the papers address issues of teachers' dealing with mathematical contents and 31% choose the learners' understanding or thinking of mathematical notions. The issue remaining is how does the field of research practice address the complexity of the field of educational practice beyond the didactic triad?

OPENING UP THE CONTEXT OF THE DIDACTIC TRIAD

Although the research gaze of the field of research practices seems to be enlarged, still many researchers express a concern with the issue of dealing with the “context”. Let us see at this in a more detailed way. In the first place it is important to discuss the notion of context and how the field of research defines and addresses it. In the section above I shortly defined context as the surroundings of an object –the “con” accompanying a “text”. As I argued before, research approaches focusing on the didactic triad tend to ignore context, since the focus of research is the “text”. In the type of research focusing on learning and thinking mathematically within the didactic triad, some understandings of “context” are present, although in the form of the context of the mathematical contents, problems or ideas that students and/or teachers deal with. This is what Wedege (1999, p. 206) calls the *task-context*.

I also argued that socio-cultural theories in mathematics education have opened for considerations of the factors that affect a classroom situation. A *situation-context*, following Wedege's formulations above has been evident in research literature, i.e., in research addressing the immediate context of teaching and learning in the classroom. But I also argued that context can be much more than the walls of the classroom. Concerning the conceptualizations of the notion of context in socio-cultural theories, Abreu (2000) has discussed how different socio-cultural theoretical trends conceptualize context, and which implications such conceptualizations have for the study of mathematical thinking and learning. On the one hand, one can consider the *micro-social and cultural contexts* of mathematics teaching and learning by focusing on “the immediate interactional setting where face-to-face interactions take place” (p. 2). On the other hand, one could focus on the *macro-social and cultural contexts* which are the “non-immediate interactional settings loosely defined by other authors as ‘the broader socio-cultural systems’ [...] or ‘broader sociocultural milieu’” (p. 2), which frame mathematical activity in any particular interactional setting. The interesting research endeavor, however, is how theories connect micro and macro contexts in a search for relationships between how individuals make sense of mathematical ideas in the complex field of activity within larger symbolic systems. For Abreu, the issue of the micro-macro relationship is not only a matter of how particular interactions with certain cultural tools mediate thinking, but also of how social valorizations of knowledge mediate individual positioning towards that

knowledge in the creation of personal identities³. From these perspectives, context is not just like the “the bowl that contains the soup” or the “surroundings of a text”, but rather a constitutive element of the text itself. Text and context are dynamic; and they are dialectically constituted (McDermott, 1996).

In the discussion by Abreu (2000), the distinction between micro and macro context opens up for a reflection on where, on the continuum between agent and structure, mathematics education research tends to focus its research gaze. If mathematics education research is seen as a social/human field of study, it cannot escape this reflection. The classical micro-macro debate in sociology addresses the issue of whether the social world is to be understood by studying individual and their interactions or by studying social structures. Each social discipline delimits the scope of the “social” in its objects of study in particular ways. Some types of areas refer to the “social” as a broad, all-embracing functioning of human action in whole cultures and civilizations (e.g., Beck, Giddens, & Lesh, 1994). Other kinds of sociological viewpoints related to disciplines such as psychology or economics, have defined the “social” as the realm of interaction among individuals. Mathematics education researchers, in the study of the social and human phenomena of mathematical thinking, learning, teaching and education, have taken a stance in this discussion implicitly (more often than not). Mathematics education research, as characterized previously with a focus on the didactic triad, has tended to focus so much in individual *mathematical* thinking, reasoning and cognition that the “social” dimension was almost non-existing. One example of this could be mathematics education as seen from a radical constructivist perspective centered on individual reorganizations of mathematical ideas. Social constructivism and related views of learning opened for a social dimension in terms of inter-personal interactions. It is only with certain recontextualizations of socio-cultural theories that the understandings of the social move beyond the individual and inter-individual level and, as Abreu says, push for the need of establishing a connection between micro and macro levels of the social. Nevertheless, studies in mathematics education from socio-cultural perspectives have also tended to focus on micro-contexts, probably because the dominance of discourses of the field of study with a centre on the didactic triad, and with a closeness to the “problems of practice” define the legitimate problem field in terms of micro-interactions and micro-contexts. The interesting question that emerges here is whether focusing on objects and problems in a micro-sociological level is the only possibility for mathematics education research. I will return to this point.

³ The research of Guida d’Abreu offers an interesting example of the different notions of context put in operation in research on mathematical practices. From her earlier research on Brazilian sugar cane farmers to her recent work on the valorizations of mathematics among immigrant children and parents in England (Abreu, 2007), it is possible to identify the differences in theoretical perspectives concerning how to deal with the significance of context in relation to mathematical practices.

Addressing context—and with it the many factors, actors, meanings and discourses that are difficult to grasp at a micro-social level but that researchers know have a great influence on the micro settings that we choose to research—is a difficult matter. In systematic readings of literature, researchers point to the need of research that actually deals with both the micro-complexity and the macro-complexity of mathematics education. I present here a selection of studies from different types of research and theoretical orientations that illustrate this concern.

In the USA and dealing with the concern of how to expand massively the constructivist-inspired vision of school mathematics of the NCTM, Confrey (2000a, 2000b) argued that it was necessary to expand constructivism from the level of a learning theory operating at individual or classroom level, to the level of a system. She urged for a view of research that could go beyond the micro-findings of research:

[...R]esearch never anticipated all of the leaks in the bucket, nor did it bring strongly enough into relief the fact that the bucket is only a small part of a large system. It is undeniable that researchers identified critical issues [...] Despite the importance of these results, changing any one of them alone was proving insufficient to fix the problems of mathematics and science. [...] All of these changes require one to look more broadly, beyond the restricted focus of a research study. All of them require us to move beyond the level of the classroom, a move that occurs only rarely in educational research. (Confrey, 2000a, pp. 88-89)

An examination of research and development initiatives in the USA to bring democratic access of students to the goods associated with high achievement in mathematics, Rousseau and Tate (2008, p. 315) conclude:

The factors influencing democratic access in mathematics education are complex. If we look strictly at events as they occur in the classroom, without consideration of the complex forces that helped to shape those learning conditions, our understanding is only partial [and] the solutions to the problem [are] ineffectual. We must seek to reach a fuller understanding of the complex issues that shape access and opportunity to learn in mathematics so that, in turn, we can develop more effective strategies to ensure access and opportunity for all students.

In the area of teacher education, studies on the professional development of mathematics teachers and on their learning have argued and shown the importance of broadening the understanding of what is at stake when professional teachers do their work and learn. Krainer has pointed to this systematically since the end of the 1990's. More recently (2007, p. 2), he writes:

It is important to take into account that teachers' learning is a complex process and is to a large extent influenced by personal, social, organisational, cultural and political factors.

Acknowledging the multiple influences in teachers' learning, the third volume of the *International Handbook of Mathematics Teacher Education* (Krainer & Wood, 2007) is organized around chapter addressing teachers' professional learning at individual,

team, community and network levels. The book as a whole illustrates research that moves beyond individual teachers and classrooms.

The examples above represent few key studies of people who, in different research areas and during the last 10 years, have argued for a need to expand the scope of research of the field. If mathematics education research ought to tackle systematically not only the micro-contexts of mathematical teaching, learning and thinking, but also its macro-contexts and the relationship between the two types of contexts, it is evident that definitions of the field of study centered on the didactic triad and recognizing the existence of a context are not enough. I will now engage in exploring a proposal of what the field of research practices, and therefore, the field of educational practices could be thought of.

MATHEMATICS EDUCATION AS A NETWORK OF SOCIAL PRACTICES

Our understandings of mathematics education as a field of research practices need to be enlarged, and with that our understandings of the practices that are the objects of study of the research field. This idea has always been part of a concern that has emerged from my research experience in Colombia as part of the team of researchers called “una empresa docente” at the Universidad de los Andes in Bogotá, later on as part of my doctoral studies at the Danish University of Education in Denmark, and now as part of the research group in mathematics and science education at Aalborg University in Denmark.

This idea has been developing since 1999 when, in the exploration of the relationship between mathematics education and democracy, I wrote:

First, the justifications to connect mathematics education to democracy are not only found in the mathematical content, but also and mainly in the social and political factors that constitute the learning and teaching relationships in the classroom, in the school and in society. Second, and as a consequence of the latter, it is necessary to study the context of the practices and its components. By doing so, we could gain a better understanding of what mathematics education for democracy means in other instances where the social relationships that constitute and shape mathematics teaching and learning are built. Thus, a definition of the social practices of mathematics education should include not only all the institutionalized relationships among teachers, students and mathematics at the different levels of schooling, inside and outside the educational system, but also the activity of policy makers that at a national level deal with the design of curricular guidelines for the teaching of mathematics [...]; the activity of writing mathematics textbooks [...]; the complex relationships that configure the teaching of mathematics within the organizational structure of educational institutions [...]; the spaces of teacher education both in its initial [...] and further stages [...]; as well as the configuration processes of social conceptions about the role of mathematics education in society [...]. All these practices together should be potential and legitimate objects of study if we aim

at understanding and, at the same time, promoting a mathematical education for democracy. (Valero, 1999, p. 21)

My initial concern for the relationship between mathematics education and democracy within the framework of critical mathematics education proposed, among others, by Skovsmose (Skovsmose, 1994) has evolved to become a general concern for developing a socio-political approach to mathematics education. As I have argued elsewhere (Valero, 2004b, 2007), such an approach views mathematics education as social practices where power relationships among the participants in and the discourses emerging from the practices are an important constitutive dimension. In contrast to a socio-cultural perspective to read mathematics education where the issue of power is not dealt with explicitly or is hidden in the valorization of practices and meanings within semiotic systems, a socio-political approach privileges power.

The concept of the *network mathematics education practices* has been under construction for a while and it has been named slightly different in my different writings (Valero, 2002, 2007, 2009). This paper has been an opportunity more to clarify the views, assumptions and analysis behind such notion. More than a finished concept, I see the concept as being still under construction. But what does this notion refer to?

In the first place, if mathematics education practices are to be defined beyond the didactic triad and in relation to their broad context, it is necessary to define “mathematics education” not only in terms of the agents and phenomena strictly related to mathematical thinking, teaching and learning, but also in terms of the series of social practices that contribute giving meaning to the activity of people when thinking, learning and teaching mathematics, as well as when engaging in situation where mathematical elements are present. Thus, the *meaning* of mathematical thinking, teaching and learning is not exclusively related to the particular meaning of the mathematical content and concepts in learning and/or teaching situations⁴. Meaning is also related to the significance given to the mathematical rationality within a diverse series of social practices constituting educational practices in a given historical time. Behind this idea there is the clear recognition that what we understand by mathematics is far from being a unified body of knowledge determined by the practices of professional mathematicians, but rather a series of “knowledges” and “language games” bounded to a diversity of practices, all of which have a family resemblance. The recent work of Knijnik (2008) in ethnomathematics is useful here to discuss the issue of meaning and diversity of mathematics in relation to social practices. The work of Sfard (2009) in identifying the irresistible pervasiveness of *numberese*, the numerical discourses in our societies, is useful in understanding how

⁴ Skovsmose (2005) has pointed to this idea in relation to the sense that students make of mathematical ideas. For him meaning is constructed in relation to the students’ foregrounds and the role that mathematics plays in how students perceive their future possibilities in life.

numerical discourses associated with the diversity of language games of mathematics in our society constitute ways of seeing the world. If mathematics-related language games are present in many spheres of practice, the meaning of them are also constituted in relation to those practices and their discursive elements.

Second, which is the diversity of social practices where the meanings are constituted? Mathematics education as a field of educational practice can be defined as a series of social practices, carried out by different people in different sites, where the meaning of the teaching and learning of mathematics is constituted, in particular historical conditions. Those social practices are to be found not only in the classroom where teachers and students interact around mathematical content, but also in, for example:

- family practices and parents' demands to school (mathematics)
- local community practices and their educational needs
- international or national educational policymaking practices in mathematics, which structure and regulate the forms of valid knowledge, competences and achievement levels to be attained by students and teachers in mathematics
- teacher education practices
- textbook production practices
- labour market practices and expectations on the mathematical qualifications of workers
- mathematics education research practices
- mathematics research practices
- youth culture practices
- mass media practices and the construction of public views and discourses of mathematics
- practices of international comparisons of (mathematics) achievement

Many other sites of practice could be mentioned and could be identified to be relevant at a given historical time. As an example, we could consider the role of the international comparative studies that, from the time of TIMMS in the middle of the 1990's have had a great influence in national policies, local curricular changes and teachers' work. Particular meanings of what counts as mathematics education have been put forward through the impact that results of these comparisons have had on adjusting mathematics educational policies in many countries. The PISA studies have also brought with them definitions of mathematical competency that have been incorporated in several European countries. These definitions have framed what at this historical time policy makers, teachers and researchers understand by mathematical competence. The work of Jablonka (2009) evidencing this rationality is useful in seeing how the PISA rationality has permeated many other spheres of practice in mathematics education. Whether international comparisons will keep on having such a defining role in the network of mathematics education practices in the future depends on political and economic configurations of the discourses that will rule educational thinking in the years to come. As for mathematics education it is

clear that such an element has impacted in this historical time. The future also remains uncertain.

By using the idea of a network—in contrast with the use of the concept of system—I want to convey the idea that these various sites of practice, their participants, organization, rules and discourses, are sometimes loosely and sometimes tightly coupled depending on particular historical circumstances. It is not possible to assume a particular general dynamic and development of the practices, except from the idea that many of them are implicated in the construction of the multiple meanings ascribed to mathematics education in a given time and location. In this sense, this notion is different from, for example, the vision proposed by Confrey (2000b) of a constructivist learning system.

Figure 5 is an attempt to represent the network of social practices of mathematics education, as far as my two-dimensional expertise for this kind of drawings permits to grasp the idea. The “bubbles” represent a site of practice. Notice that some bubbles are empty. With this I want to convey the idea that many practices may be considered at a given time. The connecting lines may sometimes be weaker and some times be stronger. A better representation would be to imagine a 3-D constellation of bubbles that move, become bigger or smaller, and connecting in distinct ways at different times.

Figure 5: A representation of the “Network of mathematics education practices”

For me, defining mathematics education in terms of the network of mathematics education practices allows to evidence the cultural, social, economic, historical and political complexity of mathematics education. It also opens for envisioning a quite distinct field of research practices that, besides dealing with the objects and relationships that it has addressed until the moment, can engage in other types of research moves, with the double aim of generating deeper understandings and

interpretations of the field and of addressing the problems of practice of the multiple participants in this broader field.

If the field of research deals with the study of the field of educational practices defined in terms of the network, then three issues become evident. Firstly, the field of research and any study within it can be defined in terms of the *mathematical specificity* of it. However, the mathematical specificity of mathematics education research cannot be defined mainly in terms of the particular mathematical content, notions or competencies being addressed in the research. Rather, it has to be defined in terms of the significance of the mathematics-related practices and rationalities for the construction of the meaning of such practice, or other related practices, among its participants. When discussing research the concern of some researchers with the mathematical specificity of a given project is often expressed through questions such as: “But... would it matter if one changed the word ‘mathematics’ for the word ‘geography’ or ‘history’ in this project?” If we understand the mathematical specificity of mathematics education research in the broader terms proposed here, questions such as the one above will become completely irrelevant and would not be anymore a question to judge whether a research is a “proper” mathematics education research. If a research addresses in substantial ways the meaning and importance that different participants give to mathematics-related practices, or how mathematics-related rationalities that have an impact on the way mathematics education discourses are formed, then a research could be part of the field of mathematics education. In other words, the mathematical specificity of the field is related more to the social valorization that mathematics-related practices have in the dominant cultural, social and political order, and not to an explicit mathematical content or knowledge being researched. Such valorization is associated to the status of the field as a power/knowledge, which allows participants in mathematics-related practices to gain a positioning in relation to other people. That we study mathematics-related practices and their relation to the meaning of mathematics education has therefore a social and political significance, even if there is no apparent mathematical content involved.

Second, the study of any of the practices involved in the network has to acknowledge seriously *contextualization*. In contrast to the decontextualization that dominates in views of the field focusing on the didactic triad, researching the network of mathematics education practices invites to search for the intricate relationships between different sites of practice in constituting each other. The contextualization of mathematics education practices point to the contingency of practices and discourses when people engage in the task of giving meaning to mathematics-related ideas and practices in educational spheres or in any other sphere of human action⁵.

⁵ For an example of a study exploring the significance of contingency and complexity when researching mathematics education practices see Stenoft (2009).

Third, the view of mathematics education as a network of social practices implies that research problems do not need to be defined nor addressed within the didactic triad in a closed manner, but rather they can be formulated and tackled in the *openness* of the sites of the network. While a closed view of the field of research and practice will tend to become internalistic and provide problems and explanations within the realm of the elements involved in the didactic triad, the network of mathematics education practices highlights that the problems researchers formulate and their interpretations are always fragmented and cover only one little part of the complexity of practice.

The issue that I will engage with now is: how is it possible to do research in the “hyper-complexity” that the network of mathematics education suggests?

RESEARCH MOVES IN THE NETWORK

Whenever we do research, we perform a “move” or a strategy in the process of constructing knowledge about the objects involved in our study. It is obvious to say that these moves depend on theoretical and methodological frameworks, as well as on the traditions of the field of study. In mathematics education as a field of research practice focused mainly on the didactic triad, the most frequent research moves can be characterized as strategies addressing a very well defined research object, where the complexity of variables or factors considered is limited in order to make research projects manageable and realizable. The research move has been then a move towards an in-depth exploration of few factors and actors. The result of such move has been the production of a considerable amount of knowledge about how factors work in isolation, at the expense of how they interact together. Confrey’s quotation cited above pointed precisely to this characteristic of mathematics education research. Some people call this the “fragmentation” of the field, which could be solved by striving for unification of theories. Whether this unification is possible and desirable, and actually can contribute to address the fragmentation is an issue of debate in the community. I do not think that striving for unification is neither possible nor desirable. I agree with Lerman (2006) in the argument that the apparent “fragmentation” is a very condition of the endeavor of researching social and human processes such as mathematics education, at the historical time we are living now. Rather, I would argue that fragmentation emerging from research moves that try to cover the depth of defined problems needs to be complemented by different research moves that provide needed problematization and better insight into the social and political complexity of the multiple practices of mathematics education. In what follows, I will formulate three research moves —among many others one could think of— for researching the network of mathematics education practices.

If mathematics education practices are seen as the network I proposed, the aim of the research field would be to provide insight into not only how each single node of the network operates constructing the meaning and significance of mathematics education, but also into how different nodes interconnect at particular historical

times. A research move aiming at *covering the breadth of the social practices of mathematics education* would then “slice” and define objects of study in a different manner. It would define problems in terms of the interrelationships of different nodes in the network.

Figure 6: Defining research moves in the “Network of mathematics education practices”

The highlighted areas in the diagram above illustrate possible ways of “slicing” the network in a research move trying to gain breadth in the research. The area highlighted in the right side of the diagram would correspond to a study of, for example, how international comparisons in mathematics have affected national policy making, school leadership and demand for change to mathematics teachers in schools at the level of staff organization. The highlighted area to the right could correspond to a study on teaching and learning cultures in the classroom in relation to youth culture and demands from the labor market. The study of Zevenbergen (2005) on “Millennial” young people’s numeracies at the workplace is close to such a kind of exploration of the network.

Other examples of such a research move for breadth is Martin (2000) who examines how the systematic failure of Afro-American students in the USA is constituted in a multilayered space of individuals, schools, families and communities. He shows how the mathematical identities of the students in his study can only be seen and interpreted in this multiple, interconnected levels. The research of Alrø, Skovmose and Valero (2008) argue and document the need of expanding the lenses for researching learning possibilities and conflicts in multicultural mathematics classrooms by considering the interconnectedness of at least nine different settings of practice: students’ foregrounds, students’ identity, teachers’ perspectives of and

priorities in mathematics teaching, classroom interaction, the mathematical content, friends' priorities for participation in mathematics education, parents' expectations of mathematics education, the tools and resources available and the public discourses on diversity and education.

Another important strategy is *moving back and forth along the continuum of agency and structure* or, in other words, micro-social and macro-social units. One example of this type of move is the work of Gellert (2008), who in examining the issue of comparing and combining different theoretical frameworks, delineates a general methodology that, based on interactionist and structural theories, allows to interpret how the mathematics classroom discourses and practices are implicated in the reconstruction of social in(ex)clusion. Morgan (2009) also presents a study that, within the framework of critical discourse analysis, shows how the differential discourses of mathematical ability in curricular documents and textbooks targeted towards students with different attainment levels generate differential educational possibilities for different types of students. This study illustrates that ideas and discourses of individual mathematical ability are not only produced in the classroom, but are also produced in institutionalized practices at a level of structure that goes beyond the individual participants in mathematics education practices in classrooms. These two studies exemplify research moves, with their corresponding theoretical and methodological tools, that connect the micro and the macro contexts of mathematics education.

Yet another strategy is *moving along time to find the historical constitution of the meanings of mathematics education*. Such a move evidences the contextualization of mathematics education practices in particular social configurations. Inspired on the archaeology and genealogy of practices and discourses suggested by Foucault, Knijnik and her collaborators have been recently exploring how different central ideas in the field of mathematics education have come to be created. One example is the research by Duarte (Duarte, 2008) on how the idea of the necessity and importance of connecting school mathematics and the world out of school—or the “real” world—has emerged in the particular case of Brazilian mathematics education discourses. The study digs in the history of education in Brazil and identifies the historical moment in which the conditions for the introduction of such idea took place at the beginning of the 20th century. At the same time, the process of recontextualization of the idea in relation to mathematics education is shown through an analysis of mathematics education journals and conference proceedings in recent times. Other studies (Knijnik, Wanderer, & Duarte, 2008) examine and problematize how other ideas such as the necessity of using concrete materials have become part of the dominant discourses of mathematics education.

TOWARDS THE FUTURE

Mathematics education research has grown as a field of educational research. It has expanded in terms of the amount of results produced, the diversity of theoretical approaches and the richness of the problems addressed. Mathematics-related practices in schools and in different social spheres of action also become more and more evident to different participants in those practices. Whether mathematics education research has the potentiality for addressing in significant ways those practices and generating interesting insights about them, is a matter of how far researchers—as well as practitioners—want to engage in the exploration of the social, cultural, historical, political and even economic significance of them in the construction of society.

Enlarging the scope of the field in terms of the network of mathematics education practices poses both intellectual and ethical challenges. Researching the network of mathematics education practices through, among others, the three types of research moves I suggested here demands much more collective effort, and much more sustained interdisciplinary collaboration with colleagues with expertise in other research fields. I am well aware that, given the tighter funding possibilities for mathematics education research at this moment and the increasing publication demands from university administration, constructing research agendas in this line is an ambitious task. Nevertheless I still think that more studies in this line will help the field gaining a richer insight and understanding into the functioning of mathematics education in society. Tackling the complexity of mathematical thinking, learning, teaching and rationality in our societies is definitely an intellectually sophisticated and demanding—as well as fascinating—endeavor.

It is also an ethical challenge in that an honest concern with the betterment of practices—and with the many tortuous and disenfranchising school experiences of many children around the world—demands taking political risks that go beyond the known boundaries of established disciplines and fields of research. Moving the boundaries of a research field such as mathematics education is an ethical commitment with what our work as educators and researchers has to offer to our selves, our children and the generations to come.

I hope that the complexity that suggests the network of mathematics education practices can question the very many comfortable, good and predictable research results that pullulate in the field, and open the space for a third epoch of research concerned and committed with the relationship between mathematics, education and society. As suggested by different participants in the ICMI Centenary symposium in Rome in March 2008 (i.e., Artigue, 2008; Blomhøj, 2008, p. 172; da Ponte, 2008, p. 110; Povey & Zevenbergen, 2008, pp. 285-286) as an international community we have gained awareness of the complexity of mathematics education. The European community represented in CERME can certainly contribute in that direction. It is time to do it!

ACKNOWLEDGEMENTS

I would like to thank the members of the Science and Mathematics Research Group (SMERG) at the Department of Education, Learning and Philosophy at Aalborg University, in particular Annica Andersson, Alexandre Pais, and Troels Lange, and Tamsin Meaney from Charles Sturt University, for many conversations and discussions during the preparation of this paper. I would also like to thank Margarida César, University of Lisbon, for her patience as a reactor to my presentation and paper, and for the very good comments and provocations in our preparation of the plenary session for the conference.

CERME 6 – SPECIAL PLENARY SESSION
Ways of working with different theoretical approaches
in mathematics education research

The contributions on the following pages constitute a report about a CERME 6 special plenary session; they include an introduction by Tommy Dreyfus, two papers by Angelika Bikner-Ahsbabs and by John Monaghan, and a report on the discussion that followed the presentations by Angelika and John.

We thank Susanne Prediger for her help with recording the discussion.

WAYS OF WORKING WITH DIFFERENT THEORETICAL APPROACHES IN MATHEMATICS EDUCATION RESEARCH AN INTRODUCTION

Tommy Dreyfus

Tel Aviv University

The development and elaboration of theoretical constructs that allow research in mathematics education to progress has long been a focus of mathematics education researchers in Europe. This focus has found its expression in many CERME working groups: some are focused around a specific theoretical approach and others allow researchers from different theoretical traditions and backgrounds to meet and discuss. For example, the working group on *Argumentation and Proof* at the present (CERME 6) conference has reported on passionate discussions about different theories and their relationships (Mariotti, 2009). More specifically, relationships between theories have been made the explicit focus of attention of the theory working group that started at CERME 4 in 2005. This group has been reconvened at CERME 5 as well as at CERME 6; this year, we discussed fifteen papers, twelve of which make use of at least two theories and deal with how or why they can be connected in some way (see the part on Working Group 9 on *Different Theoretical Perspectives in Research in Mathematics Education* in these proceedings). The plenary activity from which this report emanated inserts itself in this line of work of CERME; one of its aims was to broaden the discussion about relationships between theories to include members of all CERME working groups.

The undertaking of mathematics education is very complex; this complexity is well expressed, for example, in Paola Valero's diagram (Valero, 2009). It is not without reason that the field has developed from having a curricular focus via a cognitive focus in various directions including philosophical, socio-cognitive, anthropological, ethnographic, and other perspectives, all the while producing home-grown theories to deal with all these aspects – and I am not even trying to distinguish between paradigms, theories, theoretical frameworks etc. For example, Realistic Mathematics Education has variously been characterized (including by people from the Freudenthal Institute) as a theory for mathematics education, as an instructional design theory or simply a philosophy for mathematics education.

When one reads a journal like *Educational Studies in Mathematics*, it seems at times that every paper presents a new combination of existing theories, a new theory, or at least a development of an existing theory. This raises the question how to look at and deal with the diversity of existing theories in mathematics education. Does this diversity express richness or does it express lack of focus (Steen, 1999) or even arbitrariness?

The question is made all the more urgent and difficult since theories come in different 'shapes' and 'sizes' and have different functions. Some concern the micro-genetic

analysis of a learning processes in a classroom on a time scale of seconds, others the development of an individual student over months (or even years) and still others the momentary functioning of entire education systems. The ‘mesh sizes’ of theories thus range from the individual student via groups, classes, and schools to entire educational systems; and time scales under consideration range from seconds to years. Nevertheless, in the end they all deal with the same fundamental issue: How can students learn mathematics (better)?

However, even for (roughly) the same type of issue and scale, several theories with possibly different outlooks may exist; take for example the role of the social aspects in learning processes at the scale of a lesson: Is the social unimportant since deep mathematics is learned mainly when individual students are thinking by themselves, is the social the very vehicle of learning, or is it something in between, part of the context of learning (see Kidron, Lenfant, Bikner-Ahsbabs, Artigue, & Dreyfus, 2008)? Such a fundamental difference is likely to express itself in terms of different theoretical notions and hence different means and ways to analyze data.

Quite a lot of work has been done and published over the past ten years by people aware of the issues raised by the existence and use of many different theoretical frameworks, and trying to ‘do something about them’. Approaches have been very diverse. A few group studies have been published, in which researchers have worked on a common set of data, each researcher illuminating these same data from a different perspective such as a recent special issue on Affect in Mathematics Education (Zan, Brown, Evans, & Hannula, 2006). While this constitutes an interesting learning experience for the researchers as well as for the readers, it does not help us make progress toward connecting between the theories. We should be more ambitious. Nobody is probably aiming at a grand unified theory (see, e.g., Grand Unified Theory, 2009) as are theoretical physicists - this may be impossible altogether in the social sciences, and even if it is possible, mathematics education certainly has not reached this stage. We cannot even expect our community to converge to a set of common basic notions because the very idea of common basic notions negates the option of a variety of analytic approaches, and such a variety is needed in order to understand the complex multi-scale phenomena we are dealing with.

But we do need to make efforts to realize to what extent we are doing similar things in different languages and to what extent we use the same language to do different things. And once we realize that, we may want to establish connections, eliminate redundancies and distinguish what can and needs to be distinguished. Even more importantly, we want to find points of contact between theories that are dealing with different but related areas and find a language to talk about such theories together, to link between them in ways that are robust in the sense that they can be used by other researchers. These issues are very complex because theoretical frameworks are culturally situated – we have long known this from the difficulties many of us have to

connect to and deeply appropriate the Theory of Didactic Situation (Brousseau, 1997) that has emanated from the French cultural background and grown in the environment of mathematics education in France. A recent issue of *ZDM - The International Journal on Mathematics Education* (Prediger, Arzarello, Bosch, & Lenfant, 2008) emanating from the CERME meeting at Larnaca offers a number of concrete case studies for how different research teams dealt with the fact that several theories were relevant for their study. There exist also examples from outside CERME, for example an attempt to coordinate argumentation theory and Realistic Mathematics Education to provide a microanalysis of a whole-class discussion (Whitenack & Knipping, 2002).

In the following two papers, two researchers experienced in consciously using, combining, comparing and contrasting several theoretical frameworks in the same study, will present different and possibly complementary approaches to such an undertaking. Angelika Bikner-Ahsbahs has taken the initiative of creating and coordinating a group of researchers who continue the work taking place at the CERME conferences also in-between conferences. She has coined the term networking theories to describe her view of how theories can be linked. John Monaghan presents a point of view formed outside of the CERME theory working group, on the basis of his research; this research has led him, for example, to refine the theory of abstraction in context, which has enabled him to take a step of integrating work on instrumentation with a dialectical, situated view of processes of abstraction; he has also recently connected the purely cognitive ideas of concept image and concept definition with a social view of learning mathematics. In his paper, he stresses the role of the person of the researcher when selecting (parts of) theories to network with; these two papers will be followed by some excerpts of the discussion that followed the presentations.

NETWORKING OF THEORIES: WHY AND HOW?

Angelika Bikner-Ahsbals

Universität Bremen

This contribution presents a short overview of the current discussion about a meta-theoretical standpoint of working with theories: the networking of theories as a practice of research. It explains some principles on which this kind of research practice is based. Based on a methodological frame, an example is worked out showing how the networking of theories can lead to deepening insight into a problem and to methodologically reflecting the process of connecting theories.

During the last four years a new kind of research practice has been investigated: the networking of theories (Bikner-Ahsbals & Prediger, 2006; Prediger, Arzarello, Bosch & Lenfant, 2008; Prediger, Bikner-Ahsbals & Arzarello, 2008). What does this mean? Networking of theories is regarded as a systematic way of linking theories (Bikner-Ahsbals & Prediger, 2009). Linking theories is not a new idea. Within conceptual frameworks (Eisenhart, 1991) different theoretical approaches are used to build a consistent frame for research. In the case of design research, Cobb (2007) argues for connecting theories as a kind of “bricolage” in order to capitalize on different views. In addition, triangulation has developed as a kind of evaluation criterion for qualitative research (Schoenfeld, 2002; Denzin, 1989).

A lot of scholars in the community of mathematics educators have already triangulated different theoretical perspectives in their research projects to enhance insight. However, the networking of theories means more than that, it means going beyond triangulation and developing methodological tools for *systematically* connecting theories, theoretical approaches and theory use. To be a bit more precise, I will describe the networking of theories as a process of

- analyzing the same phenomenon in mathematics education from different theoretical perspectives or within different theories,
- reflecting the use of these different theories,
- respecting the identity of each theory,
- exhausting the possibilities for linking them, and
- linking them

Meanwhile some research has been executed which has led to the development of strategies, methods and techniques for the networking of theories and to some insights about the benefit that can be reached this way (Prediger et al., 2008). An interesting example is shown by Kidron (2008). Based on data she explains in detail why more than one theory is needed to understand limit concepts. She networks three theories analyzing the discrete continuous interplay of limits and shows how these

three theories - the concept of procept, the instrumentation approach, and the theory of abstraction in context - provide complementary insights and, hence, deepens understanding of limit concepts like the definition of the derivative. This way, Kidron is also able to show strengths, weaknesses and the limitations of the three theories.

On a product level, the networking of theories might lead to types of networked theories. However, since only first steps have been made in this direction, e.g. at CERME 4, 5, and 6 and elsewhere (ZDM 40 (2) for an overview), it is not yet clear, how these products might look. As Radford (2008) stated, the kinds of products will depend on the aims of networking, for instance, developing the identity of theories, experiencing the limits of linking theories, developing new methodological tools and new kinds of questions etc. One current result of this effort is a landscape of networking strategies that was worked out on the base of the contributions to the theory working group of CERME 5 (Prediger, Bikner-Ahsbabs & Arzarello, 2008).

Figure 1: Networking strategies (Prediger et al., 2008)

This landscape represents a continuum of strategies for relating theories and theoretical approaches to each other including the extreme poles of non-relation between theories on the one hand and unifying them globally on the other. The term connecting theories means all kinds of building theory relations whereas networking strategies exclude the extreme poles. This landscape is ordered in complementary pairs of strategies according to their potential for integration. An example below will illuminate some of these strategies.

The idea of the networking of theories is based on some principles, the principle of

1. regarding the diversity of theories as a form of scientific richness,
2. acknowledging the specificity of theories,
3. looking for the connectivity of theories and research results,
4. developing theory and theory use to inform practice.

The first two principles acknowledge the diversity of theories in the field of mathematics education and accept diversity as a resource for scientific progress (Bikner-Ahsbabs & Prediger 2009). The third principle assumes that research in mathematics education produces much more connectivity than is visible at first sight. Related to different viewpoints, the networking of theories provides the opportunity to make these implicit aspects more explicit. The different ways of connecting

theories presented at the theory Working Group 9 at CERME 6 illustrate the value and variability of the third principle. The fourth principle does not necessarily need to be shared by all the researchers in our field; however, it helps to keep research about the networking of theories grounded in practical problems producing concepts with an empirical load that is not empty (Jungwirth, 2009).

We are all busy doing research within and about mathematics education. If research demands the use of different theories we should use them being aware that this has to be justified somehow. But why is it necessary to engage in a meta-theoretical discourse about theory use? Why do we need to reflect about linking theories?

1. WHY DO WE NEED THE NETWORKING OF THEORIES?

In order to inform practice, theories facing specific practical problems are needed. Therefore a variety of theories of middle range scope, so-called foreground theories (Mason & Waywood, 1996), have been developed, for instance different theories about abstraction (Mitchelmore & White, 2007). Furthermore, the objects of mathematics education research can be viewed from different theoretical perspectives, e.g. cognitive, semiotic, social, Thus, a variety of research perspectives and various theories have been used leading to theory development in different directions. Researchers normally know what their theory is about but often the theories' limitations remain implicit. Limitations of theories can be experienced through the failure to apply them. A systematic way to provoke these experiences is critique. It can lead to a change of view (Steinbring, 2008) but also to the development of theories in that concepts and their limitations become more precise, additional concepts are constructed or the theories' parts become interconnected more deeply. Therefore, the diversity of theories can be regarded as a resource for and a consequence of critique (see also Lerman, 2006) and is scientifically necessary.

However, the diversity of theories has also caused problems (Prediger, Bikner-Ahsbals & Arzarello, 2008), for instance a language problem and a connectivity problem. The first problem arises whenever researchers from different theoretical traditions try to talk to each other, since different theories might use the same words in different ways (e.g. social interaction in different tradition, see for example Kidron et al., 2006) or different theories use different words for the same or very similar phenomena (for example *interest-dense situation* and *a-didactic situation*, see Kidron et al., 2006). The connectivity problem is related to the question of how research results from different theoretical traditions can be connected to understand and solve practical problems.

So we need scientific ways of dealing with the diversity of theories that encounter these problems. The idea of the networking of theories might be a promising concept for this task which has the potential to induce the development of a common language among different research traditions and to investigate the ways in which theories and research results can be linked.

I will now present an example that shows how these goals can partly be achieved.

2. HOW CAN THEORIES BE NETWORKED?

In order to connect theories, a framework is needed that allows building relations among them. Radford assumes a semiosphere that comprises the collection of the semiotic parts of the different theoretical cultures within mathematics education (Radford, 2008). He explains that a semiosphere is

“an uneven multi-cultural space of meaning-making processes and understandings generated by individuals as they come to know and interact with each other.” (Radford, 2008, p. 318)

Theories within this semiosphere can be described as triplets (P, M, Q) that establish languages and allow the building of relationships between them. In these triplets, P represents the system of principles, M is a sign for a system of methodologies that can be connected to these principles in an appropriate way, and Q represents a set of paradigmatic questions related to P and M. A connection between two theories establishes a specific relation that depends on the theories' structures and the goal of this connection.

Using this frame, I will present an example of the networking of two theories illuminating the benefit of critique for developing insight into a problem. Methodological reflections will uncover five steps through which the process of networking has passed. This example refers to a data set that was used by Arzarello and Sabena (Arzarello, Bikner-Ahsbabs & Sabena, 2009). I will use it to explicitly show benefits and limits of networking practices.

An episode about the growth of the exponential function

Figure 2

Two students of grade 10 are working in a pair on an exploratory activity on the exponential function and its growth. They use Cabri Géomètre to explore the graph's tangents. In this situation the teacher asks the students: What happens to the exponential function for very big x . The transcript shows the dialogue among the students G, C and the teacher.

Now I would like to invite the reader to participate in a short exercise using just a few pictures.

Figure 2 shows the computer screen the students observe.

Figure 3 presents two pairs of pictures. The left pair shows the student's gestures accompanying his utterances: his left hand goes up. The right pair illustrates the teacher's gestures accompanying his utterances: he crosses two fingers going to the right.

Figure 3: The student's gestures (left pair of pictures) and the teacher's gestures (right pair of pictures)

Please imagine for a moment what the teacher and the student are talking about. How does the student answer the question about the growth of the exponential function for very big x and how does the teacher react? – The student describes his perception of the screen meaning that the graph seems to approximate a vertical straight line. The teacher wants to show that this is wrong because every vertical straight line would be passed by the graph.

We now consider the beginning of the discussion.

- 1 G: but always for a very big this straight line (pointing at the screen), when they meet each others, there it is again...that is it approximates the, the function very well, because...
- 2 T: what straight line, sorry?
- 3 G: this ... (pointing at the screen) this, for x very, very big

With broken language the student tells something about the growth of the exponential function for big x . This broken language is an indicator for thinking aloud. Saying “sorry” the teacher interrupts the student's train of thought indicating that this question is important. However, the student does not answer the question. Instead, he defends the choice of the term “vertical straight line”. The student reacts to the so-called illocutionary level (telling something through saying something) of the teacher's question. Illocutionarily, the teacher's disruption is an indicator that there is something wrong with the vertical straight line while on the locutionary level (what is said) the teacher wants to know what vertical straight line G refers to.

During the following dialogue the student and the teacher talk about the function's growth, but, illocutionarily they negotiate about whose train of thought will be followed. The student begins to become involved repeatedly but is disrupted every time. In the end the teacher wins.

We now have a look at the last utterances.

- 14 T: eh, this is what seems to you by looking at; but you have here $x = 100$ billion, is this barrier overcome sooner or later, or not?
- 15 G: yes
- 16 T: in the moment it (the vertical straight line) is overcome, this $x 100$ billion, how many x do you have at your disposal, after 100 billion?
- 17 G: infinite

18 T: infinite... and how much can you go ahead after 100 billion?

19 G: infinite (points)

We see: The teacher is involved in arguing and the student's involvement is reduced to one (or two) word sentences (for a more detailed analysis of this episode see Arzarello, Bikner-Ahsbabs & Sabena, 2009).

A case of networking

Two theories were used to understand the episode above (for a short introduction: Arzarello et al., 2009b); a theory about the emergence of interest-dense situations and a theoretical approach about how a semiotic game between the teacher and the students shape the transition of mathematical knowledge.

The perspective of interest-dense situations

The first analysis is done from the view of the theory of the emergence of interest-dense situations. This theory – regarded as a triplet – is based on the following principles, methodology and questions:

- P1: Mathematical knowledge is socially constructed through interpretations of the others' utterances (see as well: Kidron et al., 2008).
- P2: The object of research is “meaning-making” within the process of social interaction.
- P3: In an interest-dense situation successful learning takes place as learners are deeply involved in the activity of social interactions constructing mathematical meanings in a deepening way. In these situations learning with interest is supported.
- P4: If the teacher focuses on the students' train of thought the emergence of an interest-dense situation is supported, if the teacher pushes the student to follow the teacher's train of thought the emergence of an interest-dense situation is hindered.
- M: Main part of the methodology is speech analysis on three levels. On the locutionary level an interlocutor says something; on the illocutionary level he tells something by saying something; on the perlocutionary level the intentions and the impact are taken into account.

The analysis is executed according to three questions:

- Q1: Did an interest-dense situation emerge?
- Q2: What conditions fostered or hindered it?
- Q3: How was mathematical knowledge constructed?

From the perspective of the emergence of an interest-dense situation the dialogues do not lead to increasing student involvement. Locutionarily (what is said) the student and the teacher negotiated the growth of the exponential function for very big x .

Illocutionarily (telling something through what was said) the student and the teacher struggle whose train of thought is followed. In some instances the teacher starts to focus on the student's thinking process but changes his argumentation immediately according to his own train of thought, namely to work out a "proof of contradiction": Given a vertical straight line –seen as a asymptote- this line would be passed by the graph of the exponential function. The degree of the student's involvement decreases while the teacher follows his own ideas, although the teacher tries to connect them with the student's utterances. Several times, an interest-dense situation is about to emerge, but this process is interrupted by the teacher's behaviour forcing the student to follow the teacher's train of thought. The construction of mathematical knowledge is carried out by the teacher; the contribution of the student is very low.

The semiotic bundle approach (Arzarello, 2006; Arzarello et al., 2009a)

- P1: Mathematics is transferred through a semiotic game with the help of the teacher.
- P2: The object of research is the semiotic game and its semiotic bundle.
- P3: Successful learning is interiorisation of mathematics by the help of the semiotic game.
- M: Analysis of the semiotic game according to the use of the semiotic bundle meaning the interplay of speech, gesture, representations and the transition of sign use.
- Q1: How was the mathematical content transferred through the semiotic game?
- Q2: Did the teacher tune speech and gestures with the student's ones?

From the semiotic bundle approach the semiotic game seems to be successful: The teacher takes over the student's words, using more precise explanations or following the students' ideas for a while. He points to the computer screen showing what is wrong in the way of the student's perception. He underpins his explanation and the proof of contradiction using gestures and tunes his words with those from the student. As far as the teacher is concerned, the semiotic game seems to be fruitful. From the perspective of the teacher's options to engage in the semiotic game he has done a lot of things to successfully transfer the mathematical content to the student. The student seems to be convinced, since, in the end, he correctly answers the teacher's questions.

The networking of the theories

At first glance, these results seem to be contradictory. Each theory serves as a resource for criticizing the other. After the networking process we found that the results are complementary since we could add an aspect that provided the integration of the different results: The teacher tries to tune his words with those from the student; but the gestures show that the epistemological views of the teacher and the student are different and they do not converge. The student uses his perception and

extrapolates the growth of the graph of the exponential function for very big x : the function seems to grow like a vertical straight line. The teacher's view is theoretical requiring potential infinity. Neither the teacher nor the student is able to bridge this gap.

Some methodological reflections

The contradictory results were a reason for us to meet and refresh our analysis. During this process five steps emerged:

1. *Re-analysis*: Analysing the data together again from both perspectives made our theories mutually more understandable.
2. *Comparing and contrasting*: As we contrasted and compared our theories we began to juxtapose some principles and methodologies. For example: our views on theory require different uses of the data.
3. *Establishing a common ground*: From the perspective of interest-dense-situations I could explain how the emergence of an interest-dense situation was hindered, but I could not explain why hindrance occurred. We agreed that the semiotic game was not successful as shown from the other theoretical perspective. The question was: why?
4. *Complementary analysis*: A hypothesis occurred as we looked at the semiotic game, the gestures and the speech complementarily: The student's epistemological resource was his perception of the computer screen: he extrapolated the growth of the exponential function for very big x . The teacher's epistemological resource was theoretical. This caused a gap that could not be bridged.
5. *Establishing an inclusive methodology*: We used the three levels of speech in a complementary way for the analysis of gestures and utterances and re-analysed the data carefully. Again we reconstructed the gap between the epistemological resources that could not be bridged through the semiotic game as it was executed.

Conclusions

Did we move forward? Well – yes, we did. The starting point was the contradiction of our results that served as a resource for critique and a challenge for the networking of our theoretical backgrounds. We developed a common methodology including gesture analysis and the levels of speech into one analysis. We have gained a methodological overlap but we do not know yet whether our views will converge. If we do not dig too deep we can say we followed the same question: How is mathematical knowledge gained? However, this question is still understood a bit differently because our principles and paradigmatic questions remained the same. In the end, we deepened our insights and widened our theoretical perspectives. This was possible because the grain sizes of analysis were similar and the theories' principles

were close enough to include the epistemological resource as a matter for explanation.

PEOPLE AND THEORIES

John Monaghan

University of Leeds

People are an essential consideration in networking theories. The dialectical relationship between people and theories is dynamic with regard to development. It is important to consider why people want to develop theories, their motive(s), and how they apply theories, their interpretation(s). Ascriptions of agency to theories, as ways of producing understandings or actions, need to be tempered by considerations of agency on the part of researchers applying theories. The appropriation of a theory by a person starts (and may end) with constructs from the theory.

I saw my role in this CERME plenary as that of reactor to Angelika's contribution. My first reaction is *I think what Angelika is doing is very interesting*. Indeed, "interesting" may be too weak a word as networking local theories is something that I expect to rise to prominence in mathematics education research in the near future. Angelika, Tommy, Ferdinando and I agreed at the outset that the CERME plenary should generate debate. With "debate" in mind I wanted a theme to my reaction that was honest (I did not want to generate debate by simply saying the converse of what Angelika was saying) but addressed issues that Angelika did not address and I focused on people because people network theories.

This paper follows my talk very closely and is in three parts. In the first part I argue that theories cannot be separated from the people theorising. In the second part I look at researchers' motives for adopting/creating theories and their interpretations of data. In the third part I argue that in practice researchers often appropriate parts of theories. I preface these three parts with some preliminary remarks.

PRELIMINARY REMARKS

I am not sure, in general terms, what a theory is. I am aware of discussions in mathematics education and in the social sciences of discussions of this issue. Prediger, Bikner-Ahsbahs & Arzarello (2008) consider the variety of theories in mathematics education research and conclude that 'We can distinguish theories according to the structure of their concepts and relationships' (ibid., p.168). A recent consideration of this issue in the wider social sciences is Ostrom (2005) who considers the difference between frameworks, theories and models with regard to her research interest, institutional analysis. Acknowledging that these terms 'are all used almost interchangeably by diverse social scientists' (ibid., p.27) she goes on to differentiate them according to their function in analysis: frameworks help to identify elements; theories help to specify relevant components for specific questions; models clarify assumptions regarding variables. These authors provide cogent considerations but I am still not sure what a theory is; but I know one when it is presented to me, e.g.

the Theory of Didactical Situations in Mathematics (TDS; Brousseau, 1997). So I will speak of theories with regard to the theories I am aware of that are referred to in mathematics education research.

Mathematics education researchers employ what might be called “out-of-mathematics-education theories” as well as those created within mathematics education. There are, I feel, problems for mathematics education researchers in both of these kinds of theories. The majority of us in mathematics education research are not experts in out-of-mathematics-education theories; most of us do not have a critical insight into all of their ramifications due to a lack of immersion in the academic literatures of philosophy, psychology, sociology etc. Out-of-mathematics-education theories can also miss fine mathematics detail (people interacting with mathematical relationships) that we are so very interested in. Mathematics education theories, on the other hand, can miss the big picture; the sites (classroom, workplace) of most mathematics education research are but a part of the lives of the participants.

THEORIES CANNOT BE SEPARATED FROM THE PEOPLE THEORISING

I present seven statements under this theme.

1 Theories do not exist without people

A theory without someone to interpret the theory is only words (and maybe symbols). A theory accordingly can be considered as a pair, (theory, person). For any given theory and n people there will be n such pairs. Some pairs will be almost identical, some will differ greatly; any given pair will depend on the interpretation of the theory by the person in the pair.

2 Theories develop and people develop them

(theory, person) pairs are dynamic, they change/develop. It is a bit sad if this does not happen! People develop in their understanding of a theory and through scholarships and research they develop theories. It can also be the case that a person appropriates particular development in the history of a theory, e.g. I am influenced by Davydov's (1990/72) mid 20th century use of activity theory but activity theory has developed in numerous ways since his time.

3 People hold implicit and explicit theories

I have heard it said that people can only see via a theory and that people adopt theories. I think both claims, without further explanation, are rubbish. We “see” via the artefacts (including implicit and explicit theories) available to us in our phylogenic and ontogenic development (Wartofsky, 1973). The word “adopt” is too passive. I think there is, to draw a close analogy with Guin & Trouche's (1999) ‘instrumental genesis’, a theoretical genesis in which people with initial ideas (I_I) interact with a theory (T), the person with I_I and T reviews experiences and, if T is convincing for that person, then (T', P) develops. NB This account is certainly too simple but suffices, for my purposes, as an initial hypothesis.

4 Many people subscribe to more than one theory

Theory_1 informs us on ... and Theory_2 informs us on ... With regard to person-theory pairs we do not just have (T1, P) and (T2, P) but (some combination of T1 and T2, P). Maybe this is where networking theories becomes really important.

5 A continuum with regard to theory expertise

At one extreme there are leading theorists; at the other extreme there are those who do not appear to understand a theory; and there are many intermediate positions. In France there is a maximal element in the pair (TDS, Brousseau) but I believe that it is intellectually dangerous to grant absolute authority to leading theorists.

6 Mathematics education researchers network and partially absorb others' ideas

We (mathematics education researchers) read but we also talk – to people. I was introduced to the anthropological theory of didactics (ATD; Chevallard, 1999) by talking to J-b Lagrange. I did eventually read the paper but my understanding of the theory was through my conversations with J-b Lagrange and his research.

1-7 Theories arise in communities and cultures

As academic we may aspire to objectivity but we cannot escape cultural and community influences in our work. The plenary debate took place in France and I have alluded to ATD and TDS above in homage to mathematics education theories from France. I referred to J-b Lagrange introducing me to ATD above but our relationships with this theory will be distinct simply because J-b Lagrange is a French mathematics educator and his, and not my, identity is partially shaped in relation to this French theory.

A different example is provided by Nkhoma (2002), a black South African mathematics educator. This paper comments on attempts to import learner-centred instruction from the USA into Black SA classrooms:

It is not beneficial to stereotype classrooms practices into, simply, teacher-centred therefore bad, and learner-centred therefore good ... rich experiences can be provided in practices that appear teacher-centred. (p.112)

In reading Nkhoma's paper it is difficult not to feel his anger at the importation of a "foreign" theory.

MOTIVES AND INTERPRETATIONS

I now look deeper into people and theories and examine researchers' motives for adopting/creating theories and their interpretations of data within theoretical frameworks.

To examine motives I consider a paper by Kieran & Drijvers (2006) and a response to this paper by Monaghan & Ozmantar (2007). Kieran & Drijvers worked in a form of ATD with they call "task-technique-theory" (TTT). It is a long and interesting paper

on the interplay between computer algebra systems (CAS) techniques and by-hand techniques. The students were working on factorisations of x^n-1 , and the CAS required specific values for n and did not give the classic factorisation every time. They state:

According to the TTT ... a student's mathematical theorizing is deemed to be intertwined with the techniques ... tasks ... we distinguish the following three theoretical elements.

1. Patterns in the factors of $x^n - 1$: Seeing a general form and expressing it symbolically
2. Complete factorization: Developing awareness of the role played by the exponent in $x^n - 1$...
3. Proving: Theorizing more deeply on the factorization of $x^n - 1$ (pp.242-243)

We viewed this with regard to Hershkowitz, Schwarz & Dreyfus's (2001) abstraction in context (AiC) recognising and building-with actions. Students' prior work had involved factorising binomial expressions with regard to the difference of squares and sums and differences of cubes. They *recognise* that expressions of the form x^5-1 can be factored and *build-with* this knowledge artefact to produce factorisations $x^5 - 1 = (x - 1)(x^4 + x^3 + x^2 + x + 1)$.

We also viewed it via Davydov's ascent to the concrete (an inspiration for AiC) whereby an abstraction progresses from an initial entity to a consistent final form. This progression depends on the

disclosure of *contradictions* between the aspects of a relationship that is established in an initial abstraction ... It is of theoretical importance to find and designate these contradictions. (p.291)

One student says, with regard to $x^{135} - 1$, 'how are we supposed to know if it's valid or not?' – the initial abstraction is fragile and limited to specific whole number exponents. The teacher introduced $x^n - 1$ and this required a *vertical* reorganisation of their knowledge. Student work shortly after includes *recognising* and *building-with* but on a higher vertical level than when the exponents were specific whole numbers.

Later in the Kieran & Drijvers paper we see students grappling with contradictions created from attempts to reconcile paper-and-pencil and CAS techniques and how this attempt at reconciliation led to synthesis and further insights.

The difference-of-squares 'proof', for example, with its accompanying treatment of the case $x^{n/2} + 1$, for odd values of $n/2$, helped to extend even further the thinking of students in the class. The $x^n - 1$ conjecture, which had issued from the earlier work of some students with the factoring of $x^{10} - 1$, helped others to integrate their ideas about odd, even, and prime exponents - theoretical ideas that had been generated in interaction with various CAS and paper-and-pencil techniques ... (p.253)

We also viewed Noss & Hoyles' (1996) situated abstraction and webbing as closely related to Davydov's ascent to the concrete

learning as the construction of a *web* of connections – between classes of problems, mathematical objects and relationships, 'real' entities and personal-specific experiences. (p. 105)

We are certainly networking theories (though in a different sense to how Angelika networks theories) but we also attend to differences arising from our ascribed personal motives of the theorist to theorise. Minimal ascriptions of motive are:

- Kieran & Drijvers – to understand the interplay of machine and by-hand techniques;
- Davydov – to develop theory to aid instructional design;
- Noss & Hoyles – to account for mathematical meaning making and the structuring of mathematical activities;
- Hershkowitz et al. - dissatisfaction with empirical theories of abstraction re students' actual development.

I now briefly consider interpretation. Angelika talks about a case where two theories are successfully networked. In CERME 6 Working Group 9 "Different theoretical perspectives and approaches in research: Strategies and difficulties when connecting theories" some papers focused on difficulties in networking theories. This is not new, six years ago Even & Schwarz (2003, p.283) commented 'We exemplify how analyses of a lesson by using two different theoretical perspectives lead to different interpretations ...' I have no problem with this but question whether different interpretations are only the result of different theoretical perspectives. Research is often a team effort. Have you ever disagreed with a colleague during data analysis? I have and the outcome is usually compromise or an impasse. I think this tends not to get reported in papers. This is a further refinement to my point 1 'any given pair will depend on the interpretation of the theory by the person in the pair' but with regard to the interpretation of data via the theoretical perspective. Is at least one interpretation wrong?

ISSUES, CONSTRUCTS AND CONSISTENCY

In this final section I consider the extent to which theories lead research, theories and constructs and consistency issues. This section expands on my "motive" considerations above in that people often turn to/develop theories in order to address issues that they regard as important. But often it is parts of theories that they appropriate and this can lead to potential consistency problems.

Radford (2008, p.320) states that 'a theory can be seen as a way of producing understandings and ways of actions based on' a system of basic principles, a methodology and a set of paradigmatic research questions. I take partial issue with this, as a generality. I consider issues and specific research projects.

In my experience there are fundamental issues that mathematics education researchers return many times over their working lives. In my case one of these is the link between school mathematics and out-of-school mathematics. I have grappled with this over many decades. Research questions, methodologies and principles have come and gone but the issue remains. The construct “transfer” often arises in discussions of this issue for something akin to transfer is central in linking school to out-of-school maths. Personally I hate the term and largely agree with the old Lave (1988) critique but the issue haunts me and I am prepared to consider any theory that will further my understanding of this issue.

I now consider research projects with regard to theories. These generally have a shorter time scale than “issues”. I, like most CERME delegates, write formal proposals with a theoretical framework, research questions and methodology. Almost every time, however, I develop in the process. I encounter unexpected phenomena (and revise the research questions) or experience problems in data analysis (and revise the methodology) or develop the theoretical framework. My point is that sometimes theories lead research, sometimes they do not; and, whatever the case, researcher development is in the dialectic mix. I now consider constructs.

A construct may be regarded as a proper part of a theory, e.g. *didactical contract* in TDS. I think people often appropriate a construct of a theory without appropriating the whole theory. I further think that if a person appropriates a theory, then they appropriate constructs of that theory prior to appropriating the theory. I included ‘I think’ in the previous two sentences because I base these remarks on my reflections of my own development; with regard to my point on “theoretical genesis” in (3) above I am not aware of research that traces the genesis of theory acquisition amongst academics but such research would be relevant to my reflections.

As an instance of construct appropriation in my own development I return to my comments above that J-b Lagrange introduced me to ATD. This is true, he did introduce me to ATD, but what I initially appropriated was the ‘task-technique’ part of ATD (and this focus as the only part of ATD I made sense of lasted several years). This focus was, I am sure, due to my prior experience. I had long experience of working with students and with teachers on using ICT-mathematics tools and the term “technique” in my country’s everyday mathematics-education-speech refers to value-free manipulation. To view, as Lagrange’s exposition of ATD does, techniques as not only being not value-free but techniques having both epistemic and pragmatic values and being viewed with respect to tasks was, quite frankly, a huge revelation and very relevant to my ICT work. Monaghan (2000) provides published evidence of this narrow focus. Perhaps it was due to the big impact this construct had on my thinking that appropriating other aspects of ATD took me a longer period of time.

I do not think the above (ATD, me) is an isolated example. I think the theory-person development is similar to that which I outline in (3) above: a person with a theoretical approach (T, P) interact with a construct C, the person with theoretical approach and

construct reviews experiences and, if C is convincing for that person, then (T+C, P) develops. As with my comments in (3) this is almost certainly simplistic.

As I prepared for the CERME plenary I kept returning to T and C, in (T+C, P), with the thought that T and C must, in some sense, be consistent. I tried to formulate consistency criteria but failed, my attempts to frame consistency criteria ended with grand but empty phrases. This failure may be a personal failure but it may be that there is not a suitable meta-language in which to couch consistency criteria for non-specific theories and if this is the case, then perhaps we just need to resolve consistency tensions in our own research in case and theory specific ways.

DISCUSSION

The discussion was opened and guided by the following questions:

- How can we link our theories to the mathematical background? Is this necessary?
- Why should we care about theories as an object of research? Working with theories and constructing theories within mathematics education is our job. It is not our job to investigate the epistemological processes within ME themselves. We have enough problems to work on if we restrict ourselves to the teaching and learning of mathematics.
- What does consistency mean? Taking bits and pieces from different theories includes the danger to merge inconsistent parts. Does consistency depend on the grain size? How can we link different grain sizes?

The following comments, relating to the above questions, were made by members of the audience and the presenters:

Concerning the link to mathematics, on the one hand, the experience of participants in the *Advanced Mathematical Thinking* group of CERME is that linking the theories to mathematical content domains is crucial, especially crucial when trying to network with mathematicians. On the other hand, most mathematicians hesitate to go into didactical theories, and those who do sometimes point out difficulties of communication (Quinn, 2008).

Concerning the importance of reflecting at the meta-level how we work with more than one theory, other working groups than those mentioned above also reported that they were coming up against this issue; specifically, the working groups on *Affect*, on *Mathematics and Language*, on *Early Years Mathematics*, and on *Comparative Studies* were mentioned. In addition, two comments were made, namely that networking will never end since theories are dynamic entities, and that the important aspect of John Monaghan's presentation is the human one, never mind whether individual or social. However, the characteristic trait of this part of the discussion was that contributors tended to ask questions rather than make comments; these questions included:

- Isn't our research necessarily linked to what happens outside of the discipline since the research needs are defined by politicians, funding agencies, and teachers?
- How do we deal with theories that we adopt from other disciplines such as psychology, epistemology, or even medical science? In particular, how do we integrate mathematics (or at least a mathematical view) into these theories? How do we integrate theories from other disciplines into the area of mathematics education?

- To what extent do home-grown theories integrate, adopt or adapt elements from general (outside) theories?
- How would one distinguish local from global combining of theories?
- Shouldn't networking efforts also include cases where the researchers attempting to connect do not start from a specific phenomenon?
- Why not using the useful (but relative) distinction between background and foreground theories?
- Would it promote networking to start by comparing metaphors?

Concerning the issue of consistency, participants commented that criteria for consistency might better be found outside our community, that it might be preferable to use the term 'compatibility' rather than 'consistency', that the distinction between 'theories of' and 'theories for' could be useful, that looking at complementary phenomena could be a starting point for networking theories – a point already made by Steiner (1985), and that the main reason for connecting theories might be the complementarity of their aims, which is important by itself and might make their convergence rather less important.

While it is far from clear whether our community has already made substantial progress in its attempts to find ways of working with different theories in mathematics education research, this plenary session has made it amply clear that the issue of how to work with different theories is deep, that it occupies a central position for a large number of researchers and plays an important role in the discussions of a majority of the CERME working groups. It is therefore recommended that CERME continue its support of efforts to make progress on this issue and to discuss scientific ways of dealing with the diversity of theories in a manner that is comprehensive and includes researchers from different areas and backgrounds within mathematics education.

INTRODUCTION

MULTIMETHOD APPROACHES TO THE MULTIDIMENSIONAL AFFECT IN MATHEMATICS EDUCATION

Markku S. Hannula, (chair), *University of Turku, Finland*

Marilena Pantziara, *University of Cyprus*

Kjersti Wæge, *Norwegian University of Science and Technology, Norway*

Wolfgang Schläglmann, *Universität Linz, Austria*

The first working group on affect was organized in CERME 3 in 2003. This was the fourth affect working group and like the previous three, it was an energizing and inspiring event. We had 18 participants and 17 papers were submitted to our working group. One of the papers was cancelled, and the peer review process led to rejection of one paper before the conference. Several papers were revised and all except one of these were accepted for publication in the proceedings, leading to 14 published papers.

Early in the conference, Di Martino reminded us of why this field of study is important. He made reference to several mathematics education researchers who have emphasized the role of affect in our efforts to understand human behaviour in mathematical thinking and learning. One of the quotes he shared with us was the following:

“...researchers who are interested in human performance need to go beyond the purely cognitive if their theories and investigations are to be important for problem solving in classrooms” McLeod (1992).

Numerous research studies carried out more recently in mathematics education emphasize in similar fashion the importance, hence relevance of affective factors in interpreting students mathematics performance, behaviour and difficulties in mathematics (e.g. Philippou & Christou, 2002, Young, 1997). In the papers accepted for the proceedings you will find 14 interesting perspectives into the complex world of affect, emotions, motivation and humour in mathematical thinking and learning.

The participants in this Working Group considered it important to report also the way of organized our sessions. The dilemma is to focus discussion in a way that it relates to the papers that each participant is familiar with, but so that it also is able to go beyond presentation of papers. First of all, we were fortunate to have a more or less optimal group size that allowed rich discussions where each participant was able to contribute. The authors of the accepted papers were asked to prepare in advance one or two slides based on their paper on each of the following topics:

- Theoretical framework

- Methodology
- Key findings
- Implications for teaching
- Implications for further research

Slides were collected and organised according to themes at the beginning of the conference. In the sessions each slide was briefly presented by the respective author, which (usually) initiated a discussion. When the momentum of the discussion was used out, the next presenter took the stage.

This way of organizing allowed each participant to have his or her main ideas in the focus of attention. Moreover, this allowed discussion to focus on topics and supported referring to ideas from previous presentations.

THEORETICAL FRAMEWORKS

The group had very intensive discussion on the topic of theoretical frameworks. A helpful framework to structure discussion was the figure from CERME5 summary presentation (Figure 1).

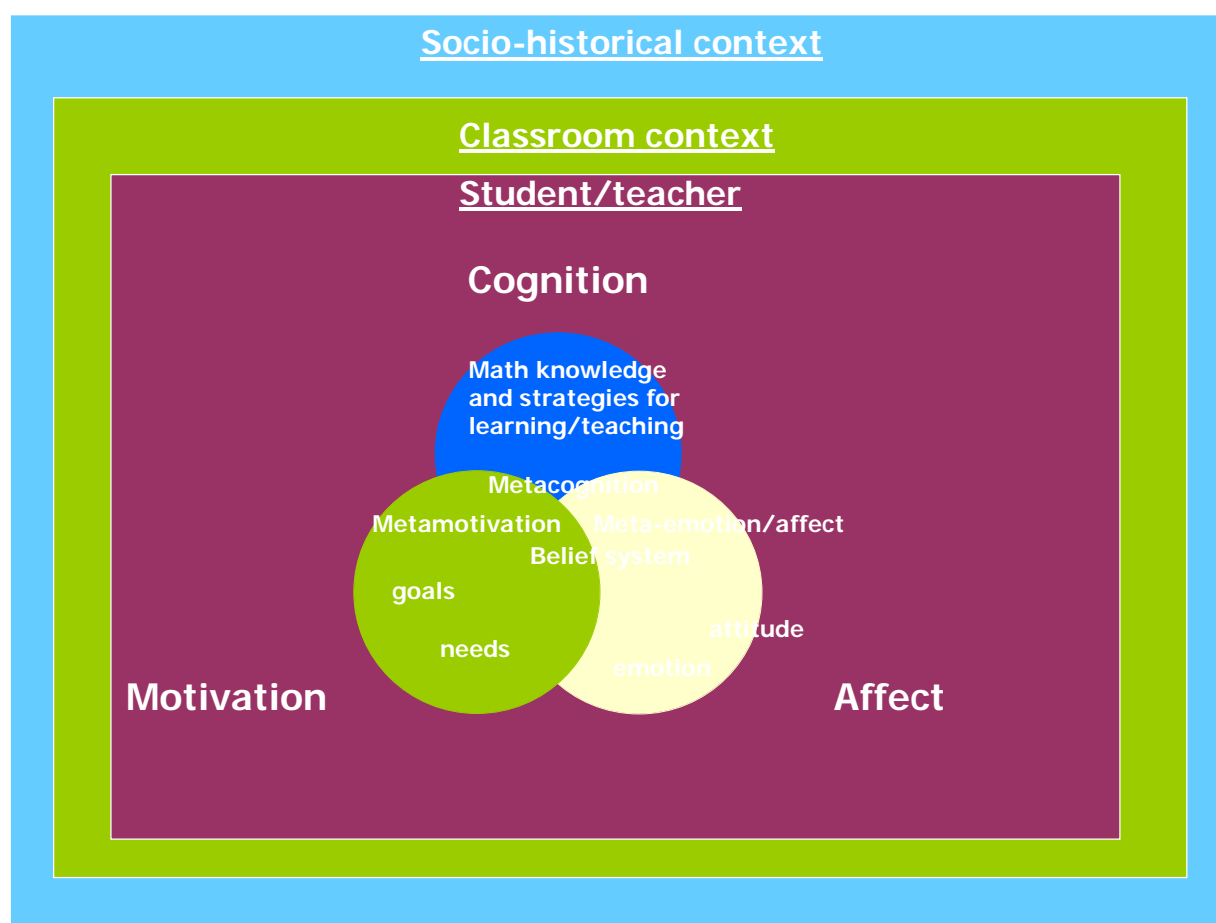

Figure 1. An overall framework for affective constructs within mathematics education research (Hannula, Op 't Eynde, Schlöglmann & Wedege, 2007, p. 204)

The proposed model is based on the socio-constructivist perspective on learning and it is characterized both by its focus on the situatedness of learning (classroom and socio-historical context) and by the recognition of the close interactions between (meta)cognitive, motivational and affective factors in students' learning (Op 't Eynde et al., 2006).

One of the issues that has been discussed in previous CERME-meetings and that was revisited again was the definition of beliefs (Di Martino; Liljedahl; Osterholm). This is an issue, where Furinghetti & Pehkonen (2002) concluded that there can not be a single definition for beliefs that is appropriate for all purposes.

We revisited the characterization by McLeod (1992), where affective domain is divided into emotions, attitudes and beliefs. There was an agreement that beliefs are different from the other concepts in that it is possible to consider their truth value, whereas emotions and attitudes are subjective by their nature. The paper by Österholm led us to discuss the distinction between beliefs and knowledge. Our preliminary conclusion at the conference was that the difference lies in knowledge being determined socially and beliefs being the individual aspect of knowledge (cf. Furinghetti & Pehkonen, 2002).

Self-efficacy issues were also presented in the group (Sofokleous and Gagatsis). We discussed Bandura's framework of self-efficacy, which has not been integrated into belief systems framework. Instead, self-efficacy beliefs seem to have remained a relatively independent framework with some connections to both belief theories and motivation theories.

Epistemological beliefs of mathematics was another framework of interest (Liljedahl). The differentiation between system, toolbox and process view of mathematics has long history from Dionne (1984); Ernest (1991); and Törner and Grigutsch (1994). Moreover, there was lively discussions about the generation of mathematical beliefs (Hannula).

Another concept which we discussed thoroughly was motivation. We recognized that motivation has two dimensions that require attention, namely the quality and the intensity of motivation. The different approaches used in the conference papers (Athanasidou, Pantziara, Wæge) include theory, personal Investment theory, Achievement goal theory and Self Determination Theory of needs and goals. Regarding the generation of motivation, needs, competence based variables, social, demographic and neurophysiological predispositions were recognized (Schlöglmann).

As new theoretical approaches to affect we were introduced to the concepts *personal meaning* (Vollstedt), *humor* (Shmakov & Hannula) and teachers' *emotional knowledge* (Lavy & Shiriki). In the discussion it was argued that it might be more appropriate to call the last of these *emotional skills*. It was reminded that one issue in earlier CERME affect groups had been the need to develop a more coherent language

and/or conceptual system for research on affect. Therefore the group concluded that these new concepts must be related to the existing ones in the domain.

RESEARCH QUESTIONS

The variety of the research questions presented in our group made the use of various research methods (qualitative and quantitative) necessary.

In particular three main themes of research questions were presented, with the first one referring to beliefs:

- ▶ The origin of the beliefs. Are all beliefs constructed in the same way or are some beliefs socially constructed while some others are mainly individual? (Hannula)
- ▶ Changing beliefs as changing perspective. (Liljedahl)
- ▶ “Maths and me”: software analysis of narrative data about attitude towards math. (Di Martino)
- ▶ Students’ beliefs about the use of representations in the learning of fractions. (Gagatsis, Panaoura, Deliyanni & Elia)
- ▶ The relation between self-efficacy beliefs and students’ achievement. (Sophocleous & Gagatsis)

The second theme referred to motivation aspects:

- ▶ Students’ motivation for learning mathematics in terms of needs and goals. (Wæge)
- ▶ Identification of students’ inner characteristics that may develop students’ motivation. (Panaoura, Demetriou & Gagatsis)
- ▶ Social variables (teachers’ practices) that may develop students’ motivation. (Panziara & Philippou)
- ▶ The effects of changes in the perceived classroom social culture on motivation in mathematics across transitions. (Athanasiou & Philippou)

A third theme covered the new approaches to affect:

- ▶ The kind of personal meaning that students relate with mathematics education. Comparison between German and Hong Kong. (Vollstedt)
- ▶ Emotional knowledge of mathematics teachers. (Lavy & Shiriki)
- ▶ Humour as a means to make mathematics enjoyable. (Shmakov & Hannula)

The discussion on research methods showed several studies to have advanced beyond simple correlation and descriptive studies (Panziara & Philippou). Some use a systemic approach and study several different aspects in connection with each other (e.g. Hannula; Panaoura et al.). There are also studies that use methods that allow examining changes in beliefs and motivation (Athanasiou and Philippou).

DISCUSSION AND CHALLENGES

One apparent main focus for research and practice in this domain has been to develop richer theoretical frameworks using aspects and develop better concepts and instruments, preferably combining qualitative and quantitative methods. The frameworks should recognize the close relation between beliefs, motivation and competence. Another, related focus has been the relations between different constructs in the affective domain and their connection to other areas in the realm of mathematics education. A third focus identified was change in beliefs and motivation; how it can happen and how to initiate change.

One specific issue we discussed was the different understandings of the stability of affective constructs. The first aspect here is to distinguish between affective state and affective trait. The second aspect to notice is affects resistance to change. The third aspect of stability is the robustness of affective constructs. The fourth aspect is the relative stability of affect, which means the tendency of people to keep the same order even if their affect might be changed.

When looking into the future, we recognized some promising approaches. In mathematics education affect has typically been approached through psychology. Looking at affect as biological or social phenomenon might open up new insight.

With regard to research on emotions, there is need to move beyond simplistic positive/negative view of emotions and distinguish different types of negative emotions (fear, dislike, sadness, anger) and positive emotions (joy, serenity). We also realized that most research on affective processes has focused on intensive emotions or non-routine mathematical activities. Therefore, it might be interesting to explore students' affect when they experience routine mathematics. Moreover, the research on affect could be extended to various contexts in mathematics, such as vocational education and mathematics at work.

CLOSING REMARKS

In each CERME the effort is denoted to identify some emerging or significant themes that might reflect the field in general, not restricted to the studies presented in the conference. The enrichment of the theoretical framework by clarifying specific constructs related to affect and by introducing new approaches has continued. Besides the illumination of relations among the various affective constructs (e.g. students' and teachers' beliefs, students' achievement goals, students' motivation) and other variables in the mathematics education domain (e.g. students' competence, teachers' practices, and teachers' knowledge) had been proceeded. The clarification of the terminology used in affect together with the new perspectives of stability of affective constructs develop this research domain. Due to the multidimensional face of the variables involved in the affective domain, the multi-method approach is becoming indispensable in the identification of relations among this area of research.

There is still much to be clarified and revealed in the realm of Affect in Mathematics Education. Therefore we go on and look ahead to the next affect working group at CERME 7.

THE EFFECT OF ACHIEVEMENT, GENDER AND CLASSROOM CONTEXT ON UPPER SECONDARY STUDENTS' MATHEMATICAL BELIEFS

Markku S. Hannula

University of Turku, Finland

The influence of achievement, gender and classroom context on students' mathematical beliefs were analysed from survey data from 1436 Finnish upper secondary school students. The results indicate that students of the same class tend to have similar effort, enjoyment of mathematics and evaluation of teacher. Students' mathematical confidence is influenced by gender while their perception of their competence mainly relates to their achievement in mathematics.

Keywords: beliefs, gender, secondary school, multilevel analysis

INTRODUCTION

Mathematical beliefs are on the one hand considered as individual constructs that are generated by individual experiences. On the other hand, beliefs are considered to be constructed socially, in a shared social context of a classroom. Which is more important? Are all beliefs constructed in the same way or are some beliefs socially constructed while some others are purely individual?

In Finnish research on affect in mathematics education the focus has clearly been on the level of human psychology, and only a few studies have explored also the social level (Hannula, 2007). One reason for this is most likely that differences between schools and geographic regions are low and the social variables have generally less pronounced effect on achievement in mathematics in Finland than in most other countries (OECD-PISA, 2004). Finland is also culturally rather homogeneous. Hence, it is not surprising that comparative studies between different groups of students within Finland have not been popular, gender being an exception to the rule. One study on regional effects indicated that students in capital province choose advanced syllabus more often than students in another province (Nevanlinna, 1998). This indicates that geographical differences in mathematics related beliefs may exist.

A general international trend has been that gender differences in mathematics achievement are disappearing. Gender differences in overall achievement of 15-year olds have disappeared also in Finland, but robust gender differences still exist in their affect towards mathematics (Hannula, Juuti & Ahtee, 2007). When attitude towards mathematics has been constructed as a single variable, studies generally have found boys to hold a more positive attitude towards mathematics (e.g. Saranen 1992). However, when different dimensions of attitude have been separated, interesting variations have been found. For example, all studies have not found gender differences in 'liking of mathematics' (Kangasniemi, 1989). Gender difference has

been clearer in how difficult mathematics is seen (Kangasniemi, 1989) and quite robust in students' self-confidence in mathematics (Hannula & Malmivuori, 1997; Kangasniemi, 1989; Hannula, Maijala, Pehkonen & Nurmi, 2005). Class-level factors are seen to influence students' self-confidence, and these seem to be more relevant to girls' than to boys' self-confidence (Hannula & Malmivuori 1997).

Although Finland scored to the top in PISA achievement scores, Finland was also characterised by less favourable results on the affective measures. Finnish students lack interest and enjoyment in mathematics, they have below average self-efficacy, and low level of control strategies. As a more positive result, levels of anxiety were also low. In Finland affect was an important predictor of achievement. Mathematical self-concept was the strongest predictor of mathematics performance, and this correlation was strongest among countries in the study. The study also revealed that gender differences favouring males in affect were larger in Finland than in OECD on average. (OECD-PISA, 2004)

In a study of elementary and secondary teachers' beliefs Pekka Kupari identified two types of mathematics teachers, traditional and innovative teachers. The traditional teacher emphasises basic teaching techniques and extensive drill, while the innovative teacher emphasises student thinking and deeper learning. (Kupari, 1996)

Moreover, Riitta Soro (2002) found out in her study that most mathematics teachers held different beliefs about students based on student's gender. Girls were seen to employ inferior cognitive skills and succeed because of their diligence, while boys were seen to be talented in mathematics but lacking in effort. However, there were also teachers who did not hold such gendered beliefs.

As there are quite different teachers, one would expect this to have an effect on beliefs of their students. If this is the case, then we are likely to find significant amount of variation of students' beliefs to be attributable to the class they study in. Moreover, this variation might be different for male and female students.

In this report we shall explore more deeply which aspects of mathematical beliefs are most affected by shared classroom context or gender, and which seem to be individual constructs, for which gender and class are poor predictors of the belief.

THEORETICAL FRAMEWORK

In the literature, beliefs have been described as a messy construct (Pajares, 1992). There are many variations for characterisations of belief concept (Furinghetti & Pehkonen, 2002). In this article we consider mathematical beliefs as "an individual's understandings and feelings that shape the ways that the individual conceptualizes and engages in mathematical behavior" (Schoenfeld 1992, 358). Op 't Eynde, De Corte and Verschaffel (2002) provide a framework of students' mathematics-related beliefs. Constitutive dimensions are object (mathematics education), self, and context (class), which further lead to several sub-categories:

- 1) Mathematics education (mathematics as subject, mathematical learning and problem solving, mathematics teaching in general),
- 2) Self (self-efficacy, control, task-value, goal-orientation), and
- 3) The social context (social and socio-mathematical norms in the class.). With regard to the social context, Op 't Eynde & DeCorte (2004) found out later that the role and functioning of one's teacher are an important subcategory of it.

In an earlier study (Rösken, Hannula, Pehkonen, Kaasila and Laine, 2007), we have explored the structure of mathematical beliefs among upper secondary school students. Our studies confirmed partially the aspects of mathematical beliefs that Op 't Eynde and his colleagues had suggested.

It is generally assumed that there is a link between teachers' and their students' affect towards mathematics (e.g. Cockroft, 1982). However, few studies seem to confirm this relationship. For example, the review of PME research on affect (Leder & Forgasz, 2006) does not mention any such study. As an example of research relating teacher and student beliefs we can take Crater and Norwood's (1997) study of seven teachers and their 138 students, where they found out that this group of teachers' beliefs influences their practices and what their students believed about mathematics

These different findings can be summarised on a model where there the three levels of gender, classroom context and individual are differentiated in the process of belief development (Figure 1).

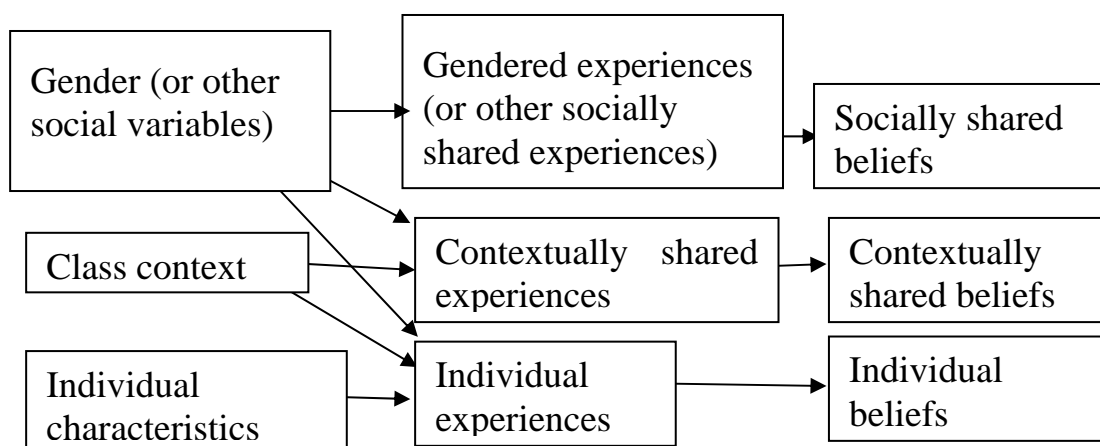

Figure 1. A model for generation of mathematical beliefs.

One origin of different student beliefs are the individual life histories that each student brings into the classroom. These life histories influence the way the students position themselves in the classroom, the way they engage with mathematics, teacher and peers and the way they interpret their experiences in the classroom. On the other hand, there are contextual factors that students of the same class share with each other. These are, for example, the personality of the teacher, the physical classroom and the implemented curriculum. These influence all students in a class and are the origin of shared experiences. Moreover, also students' individual experiences are

partly shaped by the shared events in the classroom. This is illustrated with an arrow from classroom context to individual experiences.

On the most general level there are experiences that people of the same social background (e.g. ethnicity, social class, hobbies, and social subcultures) share. One of such subsets is generated by students' gender. Gender is seen to play a significant part in the experiences in the classroom and in the beliefs that students develop (e.g. Hannula et. al, 2008). Also most teachers' have different beliefs about boys and girls as mathematics learners (Soro, 2002). Therefore it is reasonable to make the claim that individual experiences in mathematics classrooms are not the same for male and female students. Moreover, as teachers and classes are different, these gendered experiences may vary from one class context to another. Therefore, there are arrows from gender to both contextual and individual experiences.

METHODS

Instrument and Participants

The view of mathematics indicator has been developed in 2003 as part of the research project "Elementary teachers' mathematics" financed by the Academy of Finland (project #8201695). It has been applied to and tested on a sample of student teachers and was slightly modified for the present sample. That is, items addressing specifically aspects of teaching mathematics like View of oneself as mathematics teacher (D1-D6) and Experiences as teacher of mathematics (E1-E7) were removed. More information about the development of the instrument can be found e.g. in (Hannula Kaasila, Laine & Pehkonen, 2006).

The participants in our study came from fifty randomly chosen Finnish-speaking upper secondary schools from overall Finland, including classes for both, advanced and general mathematics. The respondents were in their second year course for mathematics in grade 11. Altogether 1436 students from 65 classes (26 general and 39 advanced) filled in the questionnaire and gave it back. The response rate was higher among advanced mathematics courses.

Through an exploratory factor analysis we obtained a seven-factor solution that counts for 59 % of variance and provides factors with excellent internal consistency reliability (Table 1). We related three factors to personal beliefs since a clear self-relation aspect regarding competence (F1), effort (F2) and confidence (F7) can be found. Two factors were related primarily to social context variables, namely teacher quality (F3) and family encouragement (F4), one to more emotional expressions concerning enjoyment of mathematics (F5) and one to mathematics as a subject; that is, difficulty of mathematics (F6). A description of factor analysis as well as all components and their loadings can be found in another report. (Rösken et. al, 2007)

A GLM univariate analysis was performed on SPSS. The seven belief factors were the dependent variables, gender was a fixed factor, and class a random factor.

Mathematics grade was a covariant. Students of advanced and general mathematics courses were analysed separately, and partial η^2 is used as a measure of effect size. It should be noted that although partial η^2 is a reliable estimate within a sample, it does not provide reliable estimate for the whole population. Because all variables did not confirm with the assumptions of normality, we made also a nonparametric Kruskal Wallis test to test the statistical significance of the grouping effect.

Name of the component	Sample item	Number of items	Cronbach's alpha
Competence	Math is hard for me	5	0.91
Effort	I am hard-working by nature	6	0.83
Teacher Quality	I would have needed a better teacher	8	0.81
Family Encouragement	My family has encouraged me to study mathematics	3	0.80
Enjoyment of Mathematics	Doing exercises has been pleasant	7	0.91
Difficulty of Mathematics	Mathematics is difficult	3	0.82
Confidence	I can get good grades in math	5	0.87

Table 1. The 7 principal components of students' view of mathematics.

RESULTS

The GLM univariate analysis indicated several statistically significant effects (Table 2 and Table 3). However, the assumption of equal variance did not hold true in all cases and nonparametric tests were necessary to confirm results (see below).

	General mathematics											
	Grade			Gender			Group			Gender x Group		
	F	Sig.	η^2	F	Sig.	η^2	F	Sig.	η^2	F	Sig.	η^2
Competence*	326,16	,000	,35	,12	,729	,00	1,58	,111	,61	,97	,507	,04
Effort	172,22	,000	,27	3,10	,087	,09	2,03	,041	,67	1,15	,278	,06
Teacher Quality	41,86	,000	,08	10,37	,003	,22	2,95	,004	,75	,92	,577	,05
Family Encouragement	,75	,388	,00	2,20	,147	,06	1,05	,456	,51	1,08	,359	,06
Enjoyment of Mathematics	196,65	,000	,30	2,94	,096	,08	1,65	,107	,62	1,00	,470	,05
Difficulty of Math*	194,80	,000	,30	4,73	,036	,12	1,90	,057	,65	,94	,550	,05
Confidence*	86,40	,000	,16	23,29	,000	,41	1,06	,444	,51	1,02	,433	,05

Table 2. GLM univariate analysis for general mathematics students (gender*group, grade as covariate). η^2 is partial η^2 . *) variance in groups was not equal (Levene's Test of Equality of Error Variance)

Most of the mathematical beliefs were related to the mathematics grade the student had. A simple correlation was calculated to determine the direction of the correlation

(correlation table is not reprinted here). All correlations were positive, except of correlation between grade and perceived difficulty of mathematics.

Regarding gender differences, the GLM Univariate analysis indicated that for both advanced and general syllabus female students were less confident and they perceived teacher quality lower and mathematics more difficult than male students. The effect was strongest in self-confidence.

The analysis indicated a strong group effect for teacher quality. In groups of general mathematics there was also a strong group effect on effort and in groups of advanced mathematics a strong group effect on enjoyment. Moreover, there was a gender and group interaction effect for enjoyment among advanced mathematics courses, indicating stronger group effect for female students.

	Advanced mathematics											
	Grade			Gender			Group			Gender x Group		
	F	Sig.	η^2	F	Sig.	η^2	F	Sig.	η^2	F	Sig.	η^2
Competence*	332,61	,000	,30	1,09	,301	,02	1,63	,077	,63	1,08	,355	,05
Effort*	254,72	,000	,25	,13	,717	,00	1,02	,479	,51	1,13	,278	,05
Teacher Quality*	53,34	,000	,07	5,83	,019	,10	7,26	,000	,88	1,14	,274	,05
Family Encouragement	1,20	,274	,00	,34	,561	,01	1,50	,116	,61	,73	,877	,03
Enjoyment of Mathematics	175,78	,000	,18	,30	,591	,01	2,41	,005	,71	1,49	,036	,06
Difficulty of Mathematics	254,08	,000	,24	34,27	,000	,40	1,67	,066	,63	1,24	,160	,05
Confidence	115,86	,000	,13	75,07	,000	,60	1,29	,228	,57	1,28	,132	,05

Table 3. GLM univariate analysis for advanced mathematics students (gender*group, grade as covariate). η^2 is partial η^2 . *) variance in groups was not equal (Levene's Test of Equality of Error Variance)

Because all variables did not confirm with the assumptions of normality, we made separate analysis to confirm some of the disputable results above (Table 4). Unfortunately this analysis did not allow a simple means to control for effect of achievement. The results confirmed the group effects partially. For students of general mathematics the statistically significant group effects were different for male and female students. For male students, groups had an effect on competence and effort, whereas for female students the group effect was found on teacher quality and confidence. This confirms the group effect on effort for male students and teacher quality for female students. The observed group effects on competence and confidence may actually be effects of grade.

For advanced mathematics a statistically significant group effect was found for teacher quality, effort, and enjoyment. This confirms the results of GLM Univariate analysis. Moreover, for female students only, a group effect on confidence was found.

Kruskal Wallis Test Statistics for group differences

Table 4. Kruskal Wallis Nonparametric Test for the group effect on mathematical beliefs among male and female students in general and advanced mathematics courses. TQ = Teacher quality, FE = Family encouragement

CONCLUSIONS

The results of these analysis confirmed that there is a certain level of agreement in certain mathematical beliefs among students of same class. Most pronounced this was for perceived teacher quality. In our earlier studies on teacher education students (e.g. Hannula et. al, 2006) we were not sure whether the variation in respondents' beliefs about their teacher's quality was an effect of their own mathematical achievement or if it reflected actual differences in the teaching they had received. This study confirms that students' belief of their teacher's quality is shared among students of the same class and therefore it is likely to be generated by shared experiences in the classroom context. Yet, also student's gender and achievement had an effect on this evaluation of the teacher. This provides evidence for the suggested interaction between levels in the model (Figure 1).

Shared classroom context seemed to have an effect also in students' effort (general mathematics) and enjoyment (advanced mathematics). This is indicating that through choices in instruction, it is possible to create a 'culture' in the classroom that is

motivating or enjoyable. However, we can not rule out the possibility that these differences between classes be effect of geography or some other variable that differentiates these groups.

An interesting finding was that there was a gender and group interaction effect for enjoyment among advanced mathematics courses, indicating stronger group effect for female students. This might relate to the anecdotes that students still occasionally tell about chauvinistic mathematics teachers they have had. The small effect size (6%) indicates that this is not a major problem on the level of educational system. However, for those female students who have to suffer through these classes it may be a big problem. Alternatively, this might indicate that there are such teachers in Finnish upper secondary schools that are able to create lessons that female students find especially enjoyable.

It is worth to note that gender had a stronger influence on confidence in mathematics than mathematics grade. The same is true also for and perceiving mathematics difficult in advanced course. In this sense these beliefs are truly gendered beliefs.

The findings provide support for the presented model and give indication to the origin of the measured beliefs (Figure 2). The effects of context and gender were surprisingly strong and the results support the hypothesis of social origin of beliefs.

Figure 2. Empirically confirmed gendered, contextual and individual beliefs.

Enjoyment of mathematics, self-confidence in mathematics and self-efficacy beliefs are often considered as closely related aspects of attitude towards mathematics. This study highlights the different origin of these three aspects of attitude towards mathematics. Hence, it seems worthwhile to separate these different aspects also in future studies.

CHANGING BELIEFS AS CHANGING PERSPECTIVE

Peter Liljedahl

Simon Fraser University, Canada

There is a phenomenon that has been observed in my work with inservice teachers. This phenomenon can be seen as embodying profound and drastic changes in the beliefs of the teachers participating in various projects. In this article I first describe this phenomenon and then more closely examine it using a framework of perspective. This framework allows for the articulation of the changes of beliefs as a foregrounding (or a reprioritization) of already existing beliefs. In doing so, I put forth a theory that allows for beliefs to be seen as both stable and dynamic – but always contextual.

INTRODUCTION

I work with inservice teachers. My reason for doing this is to affect change in these teachers' classroom practices, and ultimately, to affect change in the mathematical experiences of their students. In general, I try to accomplish this change through a focus on teachers' beliefs – beliefs about mathematics and beliefs about what it means to learn and teach mathematics. My assumption is that there is a link between teachers' beliefs and their practice (Liljedahl, 2008) and that meaningful¹ changes in practice cannot occur without corresponding changes in beliefs.

Recently, my main method of operating in this regard is to work with groups of teachers to co-construct some artefact of teaching – a definition, a task, an assessment rubric, a lesson, etc. This has proven to be a very effective method of reifying² the fleeting, and sometimes delicate, changes to beliefs that teachers experience within these settings (Liljedahl, in press, 2007). Within this context I am both a facilitator and a researcher. However, I am not a facilitator and a researcher in only the obvious sense. Although it is true that I facilitate the various activities that the teachers engage in – from discussions to the crafting of artefacts – it is also true that I facilitate the environment within which this all takes place. The sort of inservice work that I am involved in is more than simply the delivery of workshops, it is the provision and maintenance of a community of practice in which ideas are provisional, contextual, and tentative and are freely exchanged, discussed, and co-constructed. At the same time, while it is true that as a researcher I am interested in the down-stream effects of the work that I am engaged in (changes in teachers' practice in the classroom,

¹ Meaningful change is seen as a shift in teaching towards a more reform oriented practice. This change needs to be pervasive and robust.

² In this paper *reify* and *reification* is used in the tradition of Wenger (1998) rather than in the tradition of Sfard (1994). As such, reification means to make concrete – to turn some ephemeral aspect of teaching into *thingness*.

improvement in students' experiences and performance, etc.), it is equally true that I am interested in researching the inservice setting itself. There is much that happens within these settings. It is this later context which is the subject of this paper.

Working as both the facilitator and the researcher interested in the contextual and situational dynamics of the setting itself I find myself too embroiled in the situation to adopt the removed stance of observer. At the same time, my specific role as facilitator prevents me from adopting a stance of participant observer. As such, I have chosen to adopt a stance of *noticing* (Mason, 2006). This stance allows me to work within the inservice setting to achieve my inservice goals while at the same time being attuned to the experiences of the persons involved. I notice, first and foremost, myself. I attend to my choices of activities to engage in and the questions I choose to pose. I attend to my reactions to certain situations as well as my reflections on those reactions, both in the moment and after the session. More importantly, however, I attend to the actions and reactions of the teacher participants both as individuals and as members of a community. I observe intra-personal conflicts, interpersonal interactions, the dynamics of the group, as well as the interactions between individuals and the group. And in so doing, from time to time I notice phenomena that warrant further observation and/or investigation. Often these are phenomena that occur in more than one setting and speak to invariance in individual or group behaviour in certain contexts. Once identified these phenomena can be investigated using methodologies of practitioner inquiry that combine the role of educator with researcher – in this case teacher educator with researcher (Cochrane-Smyth & Lytle, 2004)³. Using a methodology of noticing I have observed rapid and profound changes in beliefs among individual teachers within a context of reification (Liljedahl, in press, 2007) and, more recently, among groups of teachers within this same context. It is this later phenomenon that I report on in this paper.

THEORETICAL BACKGROUND

Green (1971) classifies beliefs according to three dichotomies. He distinguishes between beliefs that are primary and derived. "Primary beliefs are so basic to a person's way of operating that she cannot give a reason for holding those beliefs: they are essentially self-evident to that person" (Mewborn, 2000). Derived beliefs, on the other hand, are identifiably related to other beliefs. Green (1971) also partitions beliefs according to the psychological conviction with which an individual adheres to them. Core beliefs are passionately held and are central to a person's personality, while less strongly held beliefs are referred to as peripheral. Finally, Green distinguishes between those beliefs held on the basis of evidence and those held non-evidentially. Evidence-based beliefs can change upon presentation of new evidence.

³ It should be noted that the main distinction between a methodology of noticing and a methodology of practitioner inquiry is that noticing doesn't presuppose a research question. It is a methodology of attending to the unfolding of the situation while being attuned to the occurrence of phenomena of interest.

Non-evidentiary beliefs are much harder to change being grounded neither in evidence nor logic. Instead they reside at a deeper and tacit level.

A person's belief system can, subsequently, be seen as a collection of beliefs competing for dominance in different contexts. Metaphorically, it is like a scene that is photographed from different perspective, with each perspective allowing something else to be foregrounded. Changes to learners' belief systems can then be seen as changes in perspectives⁴. Green argues that changing learners' belief systems is the main purpose of teaching. I argue that changing teachers' beliefs is the main purpose of inservice education.

METHODOLOGY

The data for the results presented here comes from three different, but similar, contexts in which I worked with groups of teachers in different schools and school districts. The first context (c1) involved a group of grade 5-8 mathematics teachers (n=10) working to design a task that could be used as district wide assessment of grade 8 numeracy skills in a school district in western Canada. This inservice project was comprised of 6 sessions (3 hours long, 3 weeks apart) during which we were to co-construct a working definition of numeracy (later adopted as the district definition) and design and pilot test a number of tasks that would reflect the qualities of our definition. The second context (c2) involved a group of grade 8 mathematics teachers (n=6) from a different district engaged in a very similar project. This time we were attempting to design a task that could measure the numeracy skills of their own students only. This project was comprised of 3 full day meetings 6 weeks apart. The third context (c3) involved all the mathematics teachers (n=18) in a middle school (grades 6-8). In this context we were working to design an assessment rubric that could capture some of the mathematical processes necessary for effective mathematical thinking. This involved a series of 12 one hour meeting held every two or three weeks.

As already mentioned, my method of operating within these inservice environments is through *noticing*. What this means from a more methodological perspective is that there is a great reliance on field notes taken both during the inservice sessions and more prolifically immediately after the inservice sessions. These field notes serve as a record of the things that I have noticed during individual sessions. Of course, they are limited in that they are only a record of that which has been attended to. However, these notes (or *noticings*) then form the basis of what is attended to in future sessions thereby creating an iterative process of refinement of attention. As this process continues phenomena that are deemed to be interesting receive more and more attention. This may simply mean a heightened awareness or anticipation of certain occurrences. Other times this means an adjustment in the facilitation practices in

⁴ This is not to say that changes in beliefs cannot also be seen as changes in beliefs, but for the purposes of this paper I stay with the metaphor of changing perspective.

order to more aggressively pursue the phenomenon. And sometimes it may mean stepping outside my role as a facilitator to investigate the phenomenon more directly as a researcher through methods such as interviews or questionnaires.

As such, the data for this study comes from a number of different sources. First and foremost, are the field notes from each of the aforementioned contexts. These notes increased in detail with each occurrence of the phenomenon. From c2 and c3 there are also transcriptions from interviews with different participants conducted at opportune times during or after certain sessions. These interviews were aimed at uncovering the participants own thoughts about the changes I was observing. The questions were of a semi-structured nature meant to preserve the conversational atmosphere that I had established with all of the participants while at the same time helping to illuminate the phenomenon itself.

THE PHENOMENON

The *exo/endo-spection* phenomenon, as I have come to call it, is comprised of a series of either three or four distinct phases, always in the same sequence, each having its own associated name. The names are an amalgamation – the prefix *exo-* and *endo-* comes from Greek meaning outer, outside, external and inner, inside, internal respectively; while *-spection* comes from the Latin *specere* which means 'to look at'.

Phase 1: *exo-spection* (x)

The teachers work on an activity which, at the time, occupies their focus. This could be a problem solving exercise or the designing of a lesson, task, or assessment rubric. Whether or not the activity is relevant to their own teaching practice is immaterial as the teachers' focus is on the completion of the task, rather than on the potential for the task to inform their own practice. That is, the teachers are looking at the activity as lying outside of themselves.

Phase 2: *eXo-spection* (X)

The teachers realize that the problem they have solved, or the lesson or task they have built, is not commensurate with their own classroom context. They see this as a large scale problem bemoaning the poor state of affairs of all students and the educational system in general. They look at the source of the problem as lying far outside of themselves – societal expectations, the curriculum, the evils of external examinations, deterioration of standards, etc. – and speak of systemic reform as the only solution. As such, they are not only pushing the problem further outside of themselves, but also broadening its scope.

Phase 3: *eNdo-spection* (N)

Suddenly there is a change in the teachers' disposition – the problem, regardless of where it lies, must be solved within their own practice in the scope of the classroom. Now the conversations are about what they can do

within their teaching in order to enable their students to be successful in solving a specific problem, completing a specified task, or performing well on a given assessment. The teachers' are no longer pushing the problem, and any subsequent solutions, away from themselves, but are rather bringing it back to their locus of control.

Phase 4: endo-spection (n)

For some teachers there is a final shift of attention to the plight of individual students. The conversations shift from the classroom to a particular student or subset of students, and with it comes a narrowing of focus on their influence as teachers. This final shift is also marked by a subtle shift in discourse from *teaching* to *learning*.

It should be noted that I have deliberately avoided using the term *introspection* which means to examine one's own thoughts and feelings. This is not what I am trying to capture here. *Endo-spection* is not about looking inside oneself, but about looking at something as lying inside of oneself or one's locus of control. Conversely, *exo-spection* is about looking at something as lying outside of oneself or one's locus of control.

In c1, x occurred in the first two sessions, X during the third session, N during the fourth session, and for two participants, n occurred in the last two sessions. In c2, x and X occurred in the first session, N in the second, and for one participant there was evidence of n in the third session. Finally, in c3, x occurred in the first 3 sessions, X in the fourth and fifth session, N in the sixth session, and for some of the participants, n occurred at various times during the last four sessions.

In general, the adoption of an exo-spection stance was uniformly a group position. That is, without prompting, every member of the group adopts an exo-spection stance and the group as a whole adopts an exo-spection stance. The discourse of the group did not deviate from this stance and there was a general sense that there was no need to do so – until there was a sudden transition to the eXo-spection stance. This transition, as well as the transition to eNdo-spection, was initiated by one or two members of the group, but then uniformly taken up by the group as a whole. It is almost as though the initiators were merely articulating what was already in the minds of the other members of the group, or the initiators merely precipitated an inevitable position. Conversely, the shift to an endo-spection stance, although articulated within the group context, was not taken up in the same way.

ANALYSIS

Because, for this paper, I am most concerned with changes in beliefs I will constrain my analysis to those points of greatest change – that is, the transitions between phases (x → X, X → N, and N → n). Further, I will look at these changes through a lens of changing perspectives.

exo-spection to eXo-spection ($x \rightarrow X$)

As already mentioned in the description of the exo-spection (x) phase, the teachers are initially contentedly working at completing the task at hand. In c1 and c2 this involved designing a numeracy task that conforms to a taken-as-shared definition of numeracy. In this case the teachers made extensive references to the published curriculum learning outcomes, the rationale that forms the underpinnings of the curriculum, as well as some ministry documents pertaining to the positioning of numeracy vis-a-vis the curriculum. In c3 the tasks that occupied the teachers in the first few sessions were increasingly challenging⁵ problem solving activities. Here the teachers were caught up in the excitement of doing mathematics that does not explicitly rely on mastery of specific learning outcomes. This can be seen in Barry's comments during one of the early sessions.

I love these problems. I mean, it's been a long time since I worked on problems myself, and I really like it. That card trick problem had me scratching my head all weekend. (Barry, c3, session II, field notes)

In either case, the teachers were focused on their own completion of these tasks, without much consideration for how they applied to their own practice.

The transition to X occurred in all three contexts when there was a sudden awakening to the fact that what the teachers were working on was not commensurate to their own classrooms contexts. This is nicely captured in the sudden change of tone in Barry's comments.

These problems are all fine and good. I mean, I enjoy doing them, but I don't have time for this with my kids. I have WAY too much stuff to get through to play around with these kinds of problems. Besides, my kids don't have enough patience for this kind of work. (Barry, c3, session V, interview transcripts)

It is also seen in the comments of Heidi and Charlotte working in c1.

I think we're getting it. The task is really starting to look like a numeracy task rather than just a word problem. It's not easy fitting all this stuff about communication, ambiguity, and multiple solutions into a task. But we're getting there. (Heidi, c1, session II, field notes)

I think these tasks are great, we've done a good job, but parents [of my students] are never going to go for this. The first time I send something like this home the phone will be ringing off the hook. We constantly have to work on drills to get the kids ready for the FSA's [Foundational Skills Assessment – an external high stakes exam, the results of which fold back onto the teacher]. And if we're not we're hearing about it from the parents and not because of the FSA's. They don't care about that, but these parents, a lot

⁵ This does not mean an increase in the mathematical complexity of the tasks. What is increasing is the demands on particular problem solving skills required (ability to organize work, communicate thinking, group work, deal with ambiguity, etc.).

of them are from Asia, and to them drills are important. (Charlotte, c1, session III, field notes)

The beliefs that these teachers are expressing (drills are important, learning outcome is curriculum, what parents want is important, kids are not capable) are not beliefs that have suddenly manifested themselves in latter sessions of the project. These are deep-seated beliefs (primary, core, evidential, tacit, or otherwise) that have been in the background during the teachers' initial encounters with their respective tasks. Working alone, or in a group, on something away from the multifaceted demands and expectations of their job less dominant beliefs (mathematics can be fun, numeracy is important, etc.) were able to come to the fore and inform their work in the initial sessions. But as the reality of their job rushed in on them the more dominant beliefs once again moved to the forefront, eventually paralysing their ability to see their initial work as being relevant to their own practice. However, there is still a wish that relevance could be found, but it is overwhelmed by the deep-seated belief that the problem is systemic AND can only be solved systemically. This can be seen in Adam's remarks.

Look, I agree that this is all very important. But there is just no way that we can make this work. There just isn't enough time, the kids aren't strong enough, we don't have administrative support, and, at the end of the day, the Ministry of Education just doesn't care. If they did, this is the kind of stuff we would see on the provincial exams. Until we can get them to change everything from the top down it just isn't going to work. I wish it were different, but it isn't. (Adam, c2, session I, interview transcripts)

eXo-spection to eNdo-spection ($X \rightarrow N$)

Initially, this transition is what drew my attention to the xXNn phenomenon. After commiserating about the negativity and hopelessness experienced in prior session of c1 there was a sudden rebirth of professional growth. This can be seen in Charlotte's comments in the fourth session of c1.

We have to keep pushing on in the direction we are going. If we don't design a task that shows what the kids can't do we're not ever going to be able to make any changes. We won't have anywhere to start. (Charlotte, c1, session IV, field notes)

Adam expressed a similar sentiment in the second session of c2.

In my opinion, these tasks aren't telling me enough. I'd like a task that really showed that these kids don't have a clue how to work together, for example. (Adam, c2, session II, field notes)

He adds details to these comments in a post-session interview.

I started to think about what we were doing here, with this whole project, and what it is we are trying to accomplish. I then started to think about how little I took away from my own math learning and what it is that is really important. We have an opportunity here to develop some really useful skills, stuff that these kids can use in grade 9, in grade 10, in

university, in life. They need to learn how to work together, how to deal with problems, how to tough it out, and stuff like that. But in order to do that we need to first show them that we are serious about this stuff. We can't just talk about it, we have to do it, and we have to mark them on it, and we have to start somewhere. (Adam, c2, session II, interview transcripts)

Tracey, also from c2, has a slightly different perspective.

They loved it. They asked me yesterday when we are going to do another numeracy task. I couldn't believe it. But you know what, they don't have a clue how to work together. So, now I'm working on that in my classroom. (Tracey, c2, session II, field notes)

As did Mary, who brought in samples of students' work.

As you can see there isn't much here – especially the boys. Like, you have to have a secret decoder ring to figure out what they are doing here. BUT, you know what, they did it. They worked on it and they got answers. Now we have to go forward with it. (Mary, c3, session VI, field notes)

The belief that assessments can be used formatively to inform both the teacher and the students is, again, not new. It has now moved into the forefront, however, buoyed by the realization of what it is that it is important, what the students can (or cannot) do, and what it is that the students enjoy doing. Whereas the transition from x to X can be seen as a regression to the norm (a return to a lower energy level, if you will) that is achieved almost subconsciously, the transition to N is almost wilful in nature. This re-prioritizing of beliefs is taxing and will require much effort and energy to sustain. It requires effort and motivation, and that motivation is found both in the successes of the students and the recapitulation of what is important. Or it can be found in the realization that what has come before isn't working, as is articulated by Phil.

I'm not sure if this is going to work. But I know for sure that what I've been doing before isn't working and I can continue to blame the system for all its faults or I can decide to do something about it. All I know is that I'm tired of both teaching my students AND learning for my students. Something has to change. (Phil, c3, session VI, interview transcripts)

eNdo-spection to endo-spection ($N \rightarrow n$)

As already mentioned, only some of the teachers moved to the final phase of the $xXNn$ phenomenon. Those who did, however, did so for seemingly the same reason – they were focusing on the learning of particular students or subsets of students. This was seen in their discourse about particular cases. Whereas some teachers spoke about cases as being exemplifications of the norm or the outliers within their classroom, these teachers spoke about the individual cases as standing for themselves. This can be seen in both Tracey's and Mary's comments.

So, I still have this one girl who is just toxic to anyone I put her with. No matter what I do she just will not work cooperatively. I've talked to the councillor and we think it has to do with self-esteem issues. So, I'm starting to think that this is where I should be putting my focus when it comes to her. (Tracey, c2, session 3, field notes)

In general, the students are doing much better. My work using graphic organizers has really helped. But, I still have a set of boys who just can't figure out which graphic organizer to use, or even that they have to use one. I'm not sure what to do about it, probably just keep working on it. But for now I'm still telling them which ones to use so that they can get through the task. (Mary, c3, session 11, interview transcript)

The belief that students are individuals and, thus, require differentiated instruction is likely not a new belief. However, with the use of formative assessment as an information gathering tool the teachers were giving this belief more and more prevalence.

CONCLUSION

Beliefs are stable patterns of thought, conscious or otherwise (Green, 1971). It is, therefore, unlikely that the teachers in this study changed their beliefs as drastically as the data may indicate. An alternative explanation is that the profound changes in beliefs are not a change at all, but rather a reprioritization of already existing beliefs - an affording of prevalence to less dominant beliefs. Such an explanation allows for both the robustness of beliefs and the possibility of profound change. This idea of reprioritization, or perspective, also allows for a more useful application of Green's organization of beliefs along three dimensions. A person's beliefs are hidden from us. Indeed, they may even be hidden from the person themselves. As such, knowing that beliefs may be central or peripheral, core or derived, evidential or tacit does us no good. Instead, recognizing that in different contexts different beliefs will be foregrounded, wilfully or otherwise, will allow us to think more holistically about belief systems as dynamic and contextual.

The xXNn phenomenon is such a context. Using a methodology of noticing and a framework of perspective I have described and analysed this phenomenon and concluded that the profound changes that are occurring within this context might just be due to a reprioritization of already existing beliefs. Further research into the phenomenon is necessary. There is great potential in analysing it using frameworks of psychology, group dynamics, as well as Gestalt. But it is early days, and this research is still in its exploratory phase. Now that the phenomenon has been identified, articulated, and even anticipated⁶, however, more detailed data can be gathered and more thorough analyses can be performed.

⁶ In fact, since gathering the data for the work presented here I have already identified the phenomenon, or subsets of it, within a master's course, a single session of a lesson study cycle, and a 90 minute workshop.

**“MATHS AND ME”:
SOFTWARE ANALYSIS OF NARRATIVE DATA ABOUT
ATTITUDE TOWARDS MATH**

P. Di Martino

Dept. of Mathematics – University of Pisa - Italy

Some years ago we undertook a research study aimed to obtain a ‘grounded’ characterization of attitude toward maths through the use of a narrative tool: we assigned to a large sample of Italian students the essay “Maths and me”, collecting more than 1600 texts. In this contribution we present some preliminary results, obtained using a piece of software for text analysis, regarding the way students of different grades describe their relationship with mathematics. In particular, we discuss the results from a comparative analysis between students of different school levels in order to find analogies and differences in the description of their own relationship with maths.

INTRODUCTION

Many research studies carried out in the last two decades in mathematics education highlight the relevance of affective factors to analyze and interpret students’ maths-related difficulties, and a specific field of research developed in recent years (for an overview see Zan R., Brown L., Evans J., Hannula M. 2006).

Among the affective factors, attitude toward mathematics is one of the most quoted constructs (by researchers in the field, teachers and educational institutions), but this “object” does not seem to have a well-defined and shared meaning. Among studies that explicitly give a definition, we can recognize three main different characterizations of attitude towards mathematics:

- a) a “*simple*” definition, that describes attitude as the positive or negative degree of affect associated with mathematics (Haladyna, Shaughnessy J. & Shaughnessy M., 1983; McLeod, 1992);
- b) a “*tridimensional*” definition, that recognizes three components in attitude: the degree of affect associated with mathematics, the beliefs regarding mathematics and the behaviour related to mathematics (Hart, 1989);
- c) a “*bidimensional*” definition, that includes only emotions and beliefs and does not consider behaviour (Daskalogianni & Simpson, 2000).

Some critical issues are linked to the choice of a definition for attitude (Di Martino & Zan, 2001), in particular: the consistency between the chosen definition of attitude and the instruments to observe/measure it, the definition of *positive/negative* attitude in the case of multidimensional characterizations. To characterize students’ attitude toward mathematics *from the bottom*, we carried out a narrative study investigating which dimensions students use to describe their relationship with mathematics. After

the characterization with the same data we could compare attitude of students belonging in different school levels.

In the field of mathematics education, narratives are more and more often used, especially in research about teachers' beliefs and teachers' practice (f.e. Da Ponte, 2001). Outside the field of teacher education, less numerous studies about *affect* make use of narratives: some have adults as their object (Karsenty & Vinner, 2000), others used narrative to report their own research (Hannula, 2003), others have students as their object (Ruffell et al., 1998). In this last case the studies are often carried out to criticize traditional instruments used to observe attitude rather than to characterize from the bottom the construct itself.

We used students' narratives (autobiographic essay), confident that in this way students could have the possibility to talk about the aspects *they* considered relevant in their own experience with mathematics. The chosen instrument is consistent with an interpretive approach and allows many typologies of data analysis.

From a qualitative analysis of students' description of their relationship with mathematics (Di Martino & Zan, submitted), a multidimensional model for attitude toward mathematics emerges, characterized by three strictly interconnected dimensions: the emotional disposition toward mathematics, the view of mathematics, the perceived competence in mathematics. That suggests the need to overcome the dichotomy between positive/negative attitude, and move to the identification of different profiles of negative attitude.

In this contribution, we present a quantitative analysis of the same data carried out with the help of T-Lab [1], a powerful software for text analysis, giving some preliminary interpretations of these results: in particular comparing the attitude of students from different educational levels.

METHODOLOGY

We proposed the essay "Me and mathematics: my relationship with maths up to now" to students from different school levels. For the administration of the essays we gave the following guidelines: essays had to be anonymous, assigned and collected in the class not by the mathematics teacher. At the end, we collected 1662 essays [2] ranging from grade 1 to grade 13: 874 from 51 classes of 14 primary schools (grade 1-5); 368 from 24 classes of 8 middle schools (grade 6-8); 420 from 29 classes of 10 high schools (grade 9- 13).

In order to perform the statistical analysis with T-Lab we typed all data in a unique Corpus, respecting some specific guidelines, and we classified all essays with three control variables: identification number, grade and school level.

After this phase of data coding, we started to set the customized settings: selection of the lexical units to be included in the analysis, management of the lemmatization's phase, that is the reduction of the Corpus to their respective headwords called *lemmas* (for example general rules of lemmatization are: verbs' forms are taken back to the

infinite tense, nouns to the singular form, and so on).

RESULTS AND DISCUSSION

Our attention will be focused on two typologies of analysis: co-occurrence and comparative analysis. The first one is finalized to find lexical units that more frequently are in co-occurrence [3] with some specific lemma, the latter is finalized to identify differences between texts from different subsets of the Corpus identified by some variables (in our case we selected the variable *school level*).

Co-occurrence analysis

Starting from the choice of the key-term '*maths*', the software calculates, in the whole Corpus, the lemmas with more co-occurrence with it through the association index of cosine [4]. This is a way to have a preliminary idea about the lexical units that students, in their autobiographical essays, more frequently associated with maths. Graph 1 is one of the outputs of the analysis: the nearness of each lemma to the central lemma '*maths*' is proportional to its degree of association.

Graph 1: Lemmas associated with *maths*

This representation strikingly shows that the emotional disposition (concisely expressed by “*I like/do not like maths*”) is very often in co-occurrence with maths: this is an indication that students tend to express their emotional disposition toward mathematics when they tell their relationship with mathematics itself. Moreover, the nearness of '*teacher*' can be interpreted in light of the fact that students recognize the teacher as a protagonist of their story with maths. For what concerns '*T*', it is obvious that, in an autobiographical essay regarding the writer's relationship with maths, the

lemmas *I* and *maths* are in co-occurrence.

Another analysis enables us to find the lemmas that are more correlated to both terms: *I* and *maths*. In graph 2 the co-occurrence with the two terms is shown in decreasing order with respect to the chi square test [5].

Graph 2: co-occurrences with *I* and *maths*

The relevance of the *teacher* in students' building of their own relationship with maths seems to be confirmed. But other two dimensions emerge heavily: an affective one (linked to lemmas as *to_like*, *to_adore*, *to_cry* and also *friend*) and one correlated with the idea of success in maths (associated to lemmas as *to_understand*, *clever*, *gifted*).

Comparative analysis

As we said earlier, with this typology of analysis we try to underline the differences between the three groups of students, as identified by the variable '*school level*'.

The first analysis regards the specificities of each group: T-Lab compares the subset A of the Corpus with the rest of the Corpus, individualizing which lexical units are typical (by the Chi-square test) or exclusive of the subset A. In table 1, for each group (Primary, Middle, High) the ten lemmas with the biggest chi-square value are reported.

Table 1: Specificities of three school levels

Primary school

Middle school

High School

WORD	CHI ²	SUB	TOT	WORD	CHI ²	SUB	TOT	WORD	CHI ²	SUB	TOT
to_like	459,7	1560	2488	expression	63,7	114	282	to_succeed	254,5	645	1078
operation	222,2	397	539	rule	38,3	50	111	school	185,8	399	638
to_learn	166,0	535	837	to_study	31,2	211	714	to_study	87,9	382	714
nice	149,8	302	423	algebra	27,2	48	118	exam	72,2	66	80
amusing	141,9	284	397	complex	25,9	39	91	time	69,1	156	252
examination	135,4	179	222	arithmetic	21,6	56	154	task	65,9	201	349
number	111,3	410	658	complicated	20,1	56	157	method	60,3	64	82
geometry	89,0	376	619	Easy	17,9	119	401	teacher	52,8	955	2168
calculation	67,6	250	401	important	17,3	84	267	to_apply	52,2	56	72
error	63,5	151	220	maths	14,0	1288	5603	insufficient	49,9	49	61

Sub = number of word's occurrences in subset, Tot = number of word's occurrences in Corpus

One interesting remark is about the strong characterization of the two extreme groups (Primary and High), testified by very high chi-square values. Moreover, looking at the first lemmas for each group, we can observe a shift from a *mastery-oriented* view (*to_learn*) of the relationship to a *performance-oriented* view (*to_succeed*, *exam*) and it is also interesting that the two first lemmas of the Middle group are related to an instrumental view of mathematics. According to our qualitative findings (Di Martino & Zan, submitted), this instrumental view is often combined with negative emotions towards mathematics and low perceived competence. This can be a possible explanation of the fact that in Italy the relationship with mathematics often becomes problematic just at middle school level. A factorial analysis allows us to characterize more precisely the specificity of the three groups: we can visualize their position in the factorial plane.

Graph 3: variables' position in factorial plane

So we can observe that Primary and High groups are opposite poles in the X axis, while Middle group is characterized by its negative Y-component. In graph 4 all

lemmas that define the factorial plane are reported: this allows us to interpret the meaning of the distance between the three groups:

Graph 4: lemmas in factorial plane

This analysis confirms the interpretations following the analysis of specificities. In particular, the Primary group seems to be characterized by descriptive – illustrative lemmas regarding mathematics (*geometry, number, calculation, measure, problem*) and by an often positive judgement of one's mathematical experience (*wonderful, nice*). The Middle group, strongly positioned at the negative pole of the Y-axis with respect to the other two groups, has many lemmas referring to an instrumental view of mathematics (*procedure, memory, rule*). Moreover, this group is in the 0 of the X-axis that is also characterized by emotional responses. Finally, the High group is characterized by very strong emotions (*to_love, to_hate*) and also by a particular attention to succeed (*to_succeed*). To summarize these results, it seems that at the beginning of the school experience with mathematics, curiosity prevails over other aspects and *novelty* is often appreciated. Besides, there is little stress related to assessment. After the move to the middle school level, students' attention seems to shift toward some procedural aspects of mathematics, so an instrumental view of mathematics emerges. This view rarely arouses a strong passion (negative or positive). In High school we find opposite lemmas for what concerns emotions (*love, hate*) but also perception of success; perhaps, this means that the relationship toward mathematics of these students becomes more radical than the relationship reported by

their youngest colleagues. These interpretations are also reinforced by the cluster analysis that we performed with a partitioning method. We fixed to 5 the cluster numbers because with a smaller one we hadn't a clear distinction between groups identified by variables. We briefly report a table with the lemmas characterizing each cluster and the relationship between clusters and variables.

Graph 5: clusters and variables

Graph 6: Percentage groups subdivision in clusters

The percentages of cluster 1 are very small but it is present for any subdivision in clusters more than two. From an evolutionary point of view, we can observe that cluster 2 becomes less representative passing from 35% at Primary level to 11% at High level and cluster 5 is more or less stable from Primary to Middle level but becomes less representative at High level. While clusters 3 and 4 increase the number of their representatives. So it is very interesting to give a look to lemmas that characterize these four clusters in the following table (lemmas are in decreasing order

of relevance):

Table 2: description of clusters 2, 3, 4 and 5

Cluster 2

to_like, to_learn, number, geometry, operation, nice, calculation, amusing, error, examination, multiplication_table, to_write, to_make_a_mistake, fear, figure, logic, to_calculate, measure, drawing, correct, to_discover, wonderful, get_angry, question, to_play, to_draw, ability, exercise_book, brain, to_read, happy, to_worry, to_measure, anxiety, to_reproach, tidy, heart, to_sweat_blood, to_cry, gaiety, punishment, to_bore, mysterious, angry, test

Cluster 3

to_study, school, to_explain, mark, task, engagement, time, to_hate, to_hope, to_improve, to_carry_out, algebra, to_comprehend, rule, explanation, complex, oral_test, course_book, luck, best, future, to_love, worsening, resolution, cause, gifted, sincere, memory, reasoning, patience, to_overcome, positive, passion, to_forget, fundamental, serious, set_theory, possible, negative, genius, unpleasant, to_attract, to_fascinate, to_repeat_year, competition, to_give_up, theory, able, procedure, nightmare, frightened, torment, unlucky, serene, unbearable, tension, surprise, to_persecute, suffering

Cluster 4

teacher, to_understand, to_succeed, to_find, to_think, difficulty, interesting, to_know, to_believe, to_talk, formula, to_try, attention, will, ugly, to_memorize, immediately, friend, truth, effort, blackboard, sure, alone, strange, to_appreciate, idea, quiet, pleasant, clear, to_reflect, confuse, to_upset, experience, impossible, to_imagine, sense, thought, reality, stupid, to_resign, terrible, dream, terror, to_make_curious, hateful, slow, pride, success, disgusting, sadness, horrible, shame

Cluster 5

maths, I, problem, difficult, clever, to_teach, easy, boring, exercise, to_be_useful, certainty, expression, important, to_solve, simple, liking, arithmetic, useful, complicated, to_reason, game, quickly, severe, exciting, happiness, school_report, mathematician, to_implement, fascinating, tiring, to_support, challenging, to_listen, intelligence, shout, dubious, to_confuse, tremble

Cluster 2 is centred on the description of the *objects* of mathematics as well as on related activities (*to_learn, number, geometry, operation, calculation, multiplication_table, to_write, figure, logic, to_calculate, measure, drawing, to_discover, to_play, to_draw, exercise_book, to_read, to_measure*). Cluster 3 centres on theories of success (*to_study, engagement, time, to_comprehend, rule, cause, gifted, memory, reasoning, patience,...*) like cluster 4 (*to_understand, to_succeed, to_find, to_think, to_know, to_believe, formula, to_try, attention, will,*

effort,...), but whereas cluster 3 seems to be projected ahead (*to_hope, to_improve, future, to_overcome*), cluster 4 seems to be more *static* and centred on a definitive evaluation of what happened (*impossible, to_resign,...*), cluster 5 seems to be the cluster of balance between difficulties (*difficult, simple, complicated,...*) and usefulness (*to_be_useful, important,...*). Finally, all four clusters have some emotional components: surely clusters 3 and 4 are characterized by lemmas that evoke stronger emotions (*to_hate, to_love, nightmare, frightened, torment, tension, to_persecute, suffering* for cluster 3 and *terrible, terror, disgusting, hateful, pride, horrible, shame*) than cluster 2, which seems to be the one with the highest number of lemmas linked to *positive* emotions, and cluster 5.

CONCLUSIONS

An important aspect of the described research study is the combination of quantitative analysis with an interpretive approach. All the results we got led us to interpretive hypotheses, that become stronger if compared to, and interconnected with, the qualitative analysis performed on the same material (and partially described in Di Martino & Zan, submitted). We point out that if on the one hand, the obtained results offer extremely interesting stimuli, on the other hand they cannot provide certainties, due to the type of material we analyzed (*open* texts). In this case, we really ought to be cautious: the analysis of open texts based on lexical units only, without an analysis of the contexts within which these lexical units are used, might be problematic. To exemplify, the lemma *to_like* is not always referred to mathematics; the word *problem* might stand for a mathematical problem but also for a real life problem. Therefore, it was really important to compare results of this analysis with those of the qualitative one (described in Di Martino & Zan, *ibidem*): in particular, the results about the three dimensions characterizing attitude towards mathematics are confirmed.

The ‘evolutionary’ results that emerge from cluster analysis seem to be particularly interesting. A general deterioration of students’ relationship with mathematics can be clearly detected but, most of all, as the school level increases, the lemmas used to describe one’s relationship with mathematics suggest that the latter becomes more and more radical. Moreover, there seems to be a move from a phase of interest in the novelty of mathematics -the pleasure of discovery- to a phase in which succeeding prevails over the subject matter itself. One final remark: the fact that in this phase emotional aspects become more radical provides material for further reflection.

NOTES

1. The bibliography related to T-lab is available on-line: <http://www.tlab.it/en/presentazione.asp>
2. The collected essays constitute a convenient sample, obtained through a collaboration with teachers and heads of schools who accepted our requests. The schools are situated in six different area of Italy: from North to South.
3. Co-occurrence is when two or more lemmas are present together in the same text.

4. To calculate the cosine index between lemma X and lemma Y we have to consider $a = \#$ of essays with lemma X and Y, $b = \#$ of essays with lemma X and without lemma Y, $c = \#$ of essays with lemma Y and without lemma X. Cosine (lemma X, lemma Y) = $a / \sqrt{(a + b) \times (a + c)}$.

5. The Chi-square test is a well-known test used to check if the frequency values obtained by a survey are significantly different from the theoretical ones. T-Lab applies this test to 2x2 tables then the threshold values is 3.84 (df=1, p=0.05) or 6.64 (df=1, p=0.01).

STUDENTS' BELIEFS ABOUT THE USE OF REPRESENTATIONS IN THE LEARNING OF FRACTIONS

Athanasios Gagatsis**, Areti Panaoura*, Eleni Deliyianni** and Iliada Elia**

* Frederick University, ** University of Cyprus

Cognitive development of any mathematical concept is related with affective development. The present study investigates students' beliefs about the use of different types of representations in understanding the concept of fractions and their self-efficacy beliefs about their ability to transfer information between different types of representations. The interest is concentrated on differences among students at primary and secondary education. Results indicated that students at secondary education have less positive beliefs for the use of representations at the learning of mathematics than at primary education. As a consequence they have less positive self-efficacy beliefs about their abilities to use them. Unexpected was their lower performance at solving tasks on fractions for which the information is represented in different forms.

Keywords: representations, beliefs, self-efficacy, fractions

Mathematics is a specialized language with its own contexts, metaphors, symbol systems and purposes (Pimm, 1995). From an epistemological point of view there is a basic difference between mathematics and other domains of scientific knowledge as the only way to access mathematical objects and deal with them is by using signs and semiotic representations (Duval, 2006). Cognitive development is related with metacognitive and affective development. One's behavior and choices, when confronted with a task, are determined by her/his beliefs and personal theories, rather than her/his knowledge of the specifics of the task. Thus, students' academic performance somehow depends on what they have come to believe about their capability, rather than on what they can actually accomplish.

The relationship between cognition and affect has the last decades attracted increased interest on the part of mathematics educators, particularly in the search for causal relationship between affect and achievement in mathematics (Young, 1997). This is due to the fact that the mathematical activity is marked out by a strong interaction between cognitive and emotional aspect. The affective domain is a complex structural system consisting of four main dimensions or components: emotions, attitudes, values and beliefs (Goldin, 2001). At the present study we focus on students' beliefs and mainly their self-efficacy beliefs in using different types of representations in mathematics learning and understanding. We concentrated our attention on the notion of fractions.

Fractions are among the most essential (Harrison & Greer, 1993), but complex mathematical concepts that children meet in school mathematics (Charalambous & Pitta-Pantazi, 2007). An important factor that may contribute to students' difficulties in learning fractions is the transition from primary in secondary school with all the changes that this encompasses in mathematical teaching and learning.

THEORETICAL BACKGROUND

Self-efficacy beliefs

Beliefs is a multifaceted construct, which can be described as one's subjective "understandings, premises, or propositions about the world" (Philipp, 2007, p. 259). According to Pehkonen and Pietila (2003) there are several difficulties in defining concepts related to beliefs. Some researchers consider beliefs to be part of knowledge (e.g. Pajares, 1992), some think beliefs are part of attitudes (e.g. Grigutsch, 1998), and some consider they are part of conceptions (e.g. Thompson, 1992).

The construct of self-efficacy beliefs constitutes a key component in Bandura's social cognitive theory; it signifies a person's perceived ability or capability to successfully perform a given task or behavior. Bandura (1997) defines self-efficacy as one's perceived ability to plan and execute tasks to achieve specific goals. He characterized self-efficacy as being both a product of students' interactions with the world and an influence on the nature and quality of those interactions. Self-efficacy beliefs have received increasing attention in educational research, primarily in studies for academic motivation and self-regulation (Pintrich & Schunk, 1995). It was found that self-efficacy is a major determinant of the choices that individuals make, the effort they expend, the perseverance they exert in the face of difficulties, and the thought patterns and emotional reactions they experience (Bandura, 1986). Furthermore, self-efficacy beliefs play an essential role in achievement motivation, interact with self-regulated learning processes, and mediate academic achievement (Pintrich, 1999).

Multiple representations in mathematics teaching and learning

The representational systems are fundamental for conceptual learning and determine, to a significant extent, what is learnt (Cheng, 2000). Learning involves information that is represented in different forms such as text, diagrams, practical demonstrations, abstract mathematical models, simulations etc (Schuyter & Dekeyser, 2007). Recognizing the same concept in multiple systems of representations, the ability to manipulate the concept within these representations as well as the ability to convert flexibly the concept from one system of representation to another are necessary for the acquisition of the concept (Lesh, Post, & Behr, 1987) and allow students to see rich relationships (Even, 1998). Recently the different types of external representations in teaching and learning

mathematics seem to become widely acknowledge by the mathematics education community (NCTM, 2000). The necessity of using a variety of representations or models in supporting and assessing students' constructions of fractions is stressed by a number of studies (Lamon, 2001). The geometric shapes used for introducing the continuous model of fractions are distinguished into two types: the circular model which is based on the use of circles and the linear model which is based on a rectangle divided into a number of equal part (Boulet, 1998).

An issue that has received major attention from the education community over the last years refers to the students' difficulties when moving from elementary to secondary school and to the discontinuities in the curriculum requirements, the use of teaching approaches, aids and methods. According to Schumacher (1998) the transition to secondary school is accompanied by intellectual, moral, social, emotional and physical changes. Pajares and Graham (1999) investigated the extent to which mathematics self-beliefs change during the first year of middle school. By the end of the academic year, students described mathematics as less valuable, and they reported decreased effort and persistence in mathematics. The findings of the Deliyianni, Elia, Panaoura and Gagatsis's (2007) study suggest that there is a noteworthy difference between elementary and secondary education in Cyprus concerning the representations used in mathematics textbooks on fractions. There are also differences in the functions the various representations in the school textbooks fulfil.

The present study investigated Grade 5 to Grade 8 students' beliefs about the use of different representations for the learning of the fractions and their self-efficacy beliefs about the use of those types of representations. That means that it explores the differences of students' beliefs at primary and secondary education concerning the use of different types of representations.

METHOD

The study was conducted among 1701 students of 10 to 14 year of age who were randomly selected from urban and rural schools in Cyprus. Specifically, students belonging to 83 classrooms of primary (Grade 5 and 6) and secondary (Grade 7 and 8) schools (414 in Grade 5, 415 in Grade 6, 406 in Grade 7, 466 in Grade 8) were tested.

A questionnaire was developed for measuring students' beliefs about the use of different types of representations for understanding the concept of fractions. The questionnaire comprised of 27 Likert type items of five points (1=strongly disagree, 5=strongly agree). The reliability of the whole questionnaire was very high (Cronbach's alpha was 0.88). The items of the questionnaire are presented at Table 1.

At the same time a test was developed for measuring students' ability on multiple representation flexibility as far as fraction addition is concerned. The test included 22

fraction addition tasks that examine multiple-representation flexibility and problem-solving ability. There were treatment, recognition, conversion, diagrammatic problem-solving and verbal problem-solving tasks (further details for the tasks can be found at the paper of Deliyanni et al. (2007). Indicative examples of the items are presented at Appendix. Cronbach's alpha for the test was 0.87.

The test and the questionnaire were administered to the students by their teachers at the end of the school year in usual classroom conditions. Right and wrong or no answers were scored as 1 and 0, respectively. Solutions in treatment, recognition and translation tasks were assessed as correct if the appropriate answer, diagram, equation or shading were given respectively, while a solution in the problems was assessed as correct if the right answer was given.

RESULTS

The analysis of students' responses to the items of the questionnaire resulted in six factors (KMO=0.933, $p < 0.001$) with eigenvalues greater than 1 (Table 1). The first factor corresponded to students' self-efficacy beliefs about conversion from one type of representation to another. The second factor was associated with their general self-efficacy beliefs in mathematics. The third factor represented their beliefs about the use of the number line, while the fourth factor represented their beliefs about the use of models, materials or representations. The fifth factor corresponded to students' beliefs about the use of diagrams in problem solving and the sixth factor to their self-efficacy beliefs about the use of verbal representations.

Item	F1	F2	F3	F4	F5	F6
I can easily find the diagram that corresponds to an equation of fractions.	.53					
I can easily solve tasks than ask to convert the part of a diagram into an equation.	.62					
I can easily find the diagram that corresponds to an equation of decimals.	.67					
I can easily find the equation of fraction addition that corresponds to a part of a surface of a rectangle.	.63					
I can easily find the equation of fraction addition which is presented with arrows in number line.	.58					
I am very good in solving tasks with decimals.		.70				
I am very good in problem solving fractions.		.78				
I can easily solve tasks with fractions.		.79				
I can easily solve equations of fraction addition.		.70				
I can easily solve equation of decimal addition.		.56				
Number line helps me in problem solving with fractions.			.68			
Number line helps me in solving equations with fractions.			.68			
My teacher usually uses number line in order to explain us the operations of fractions.			.64			
Number line helps me in solving equations with decimals.			.64			
A good student in mathematics can present the solution of a problem by many different ways.					.55	
For the problem solving the use of equation is necessary.					.65	
In mathematics the use of materials (fraction circles, dienes cubes etc) is						

useful mainly for students at primary education	.59
The diagrams (number line, rectangle etc) are useful for executing operations.	.42
If I have to explain how I have solved a problem with decimals, I prefer to use an equation.	.57
If I have to explain how I have solved a problem with fractions, I prefer to use a diagram.	.65
When I solve a problem with fractions, I use the number line for executing the operations.	.44
When I solve a problem with fractions by using a diagram, I then try to solve it by using an equation, as well.	.49
When I solve a problem with decimals I use a diagram.	.67
I can easily explain how I have solved a problem with decimals by using a diagram.	.47
I prefer solve problems with decimals which present the data verbally.	.79
I can easily explain verbally how I have solved a problem with decimals.	.69

Table 1: Factor loading of the six factors against the items associated with participants' beliefs

Analysis of variance (ANOVA) indicated that there were statistically significant differences in respect to grade for the factors F1, F2, F5 and F6. Specifically in the case of F1 there were differences at the means ($F_{3,1547}=9.09$, $p<0.001$) between students' self-efficacy beliefs to converse flexibly the concept of fraction addition from one representation to any other who were attending the Grade 8 with the students of the Grades 5, 6 and 7. In the case of the F2 the statistically significant differences ($F_{3,1574}=31.615$, $p<0.001$) were between the Grade 5 with Grades 7 and 8, the Grade 6 with the Grade 7 and 8. Students at the Grade 8 seemed to have less positive beliefs for the significance of using different types of representations (F5). There were statistically significant differences between Grade 5 and Grade 8, Grade 6 and Grade 8. In the case of their preference for using verbal explanations the differences were between Grade 5 with Grade 7 and 8 and Grade 6 with Grade 7 and 8. Therefore, most of the differences revealed were between the students at primary education and the students at secondary education. All the means are presented at Table 2.

	F	p	\bar{X}_5	\bar{X}_6	\bar{X}_7	\bar{X}_8
F1	9.09	<0.001	3.63	3.58	3.53	3.37
F2	31.615	<0.001	4.08	3.93	3.70	3.56
F5	6.209	<0.001	3.29	3.24	3.17	3.09
F6	21.036	<0.001	3.46	3.36	3.15	2.96

Table 2: The means for the factors F1,F2, F5 and F6 with the statistically significant differences in respect to grade.

Very impressive and unexpected were the descriptive results of the students' mathematical performance at the test. As it is obvious in Figure 1 students at the Grade 7 have lower performance than the students at the Grade 6.

Figure 1: Students' of different grades performance on the mathematical test.

Students were cluster, by using cluster analysis, according to their performance at the test into three groups (Group1: 426 students with low performance, Group2: 788 students with medium performance, Group3: 487 students with high performance) Analysis of variance (ANOVA) with independent variable the three groups and dependent variables the six factors, which were comprised from the abovementioned factor analysis, indicated statistically significant differences in respect to F1 ($F_{2,1547}=51.819$), F2 ($F_{2,1474}=74.903$), F4 ($F_{2,1609}=12.057$) and F6 ($F_{2,1671}=8.844$). In all cases the first group had the most negative beliefs and self-efficacy beliefs and the third group had the most positive beliefs. That means that students with high mathematical performance had at the same time positive beliefs for the use of representations and high self-efficacy beliefs.

Finally students were clustered into two groups according to their general self-efficacy beliefs in mathematics (F2), by using cluster analysis. The group with higher self-efficacy beliefs consisted of 1047 students ($\bar{X}=4.31$) and the second group consisted of 528 students ($\bar{X}=2.82$). T-test analysis between the two groups in respect to the other five factors indicated that there were in all cases statistically significant ($p<0.01$) differences (Table 3). Students with higher general self-efficacy beliefs in mathematics had at the same time more positive beliefs for the use of different forms of representations and more positive self-efficacy beliefs for the use of those representations and their ability to transfer their knowledge.

	t	df	\bar{X}_1	\bar{X}_2
F1	22.82	1463	3.81	2.97
F3	6.508	1527	3.30	2.99
F4	13.897	1507	4.09	3.57
F5	9.151	1499	3.32	2.96
F6	14.616	1565	3.48	2.73

Table 3: Students' with high and low self-efficacy beliefs differences in respect to their beliefs about the use of representations

DISCUSSION

The main emphasis of the present study was on investigating students' self-efficacy beliefs for mathematics in relation to their beliefs about the use of representations for understanding the concept of fraction. The analysis of the data confirms earlier findings that young students have high self-efficacy beliefs (Bandura, 1986) and that they tend to overestimate their abilities. However those beliefs decreased at the secondary education. It seems that students' sense of efficacy diminishes somehow when they compare their abilities with classmates and even more in relation to their mathematical performance as it is revealed by their final grades at mathematics. The influence of those active experiences is too strong and with immediate results. Accepting that the most important step is getting individuals to become aware of their own processes, strengths and limitations in order to have an accurate self-representation, it seems that the specific result is important for the learning of the concept of fractions. Nevertheless it is not positive generally, because there are too many other concepts at the teaching of mathematics at secondary education for which students have to use flexibly different types of representations. For example the concept of function admits a variety of representations, each of which offers information about particular aspects of the concept without being able to describe it completely (Elia et al., 2008).

Interesting and unexpected was the differences between students' performance in the use of different forms of representations at primary and secondary education and mainly the lower performance at secondary education. A possible explanation for the lack of improvement regarding their mathematical performance observed are the differences regarding the representations and their functions in mathematics textbooks used in primary and secondary education in Cyprus (Deliyianni et al., 2007). Furthermore, the secondary school students may had not created referential connections between corresponding elements and related structures in a way that promotes understanding of this concept during their primary schooling. Their difficulties increased in secondary education since no emphasis is placed on learning with multiple representations.

Results confirmed that students with low performance in mathematics have at the same time negative beliefs for the use of different forms of representations because they cannot use them fluently and flexibly as a tool to overcome obstacles while solving tasks and handling the whole situation. It seems that there is a need for further investigation into the subject with the inclusion of a more extended qualitative and quantitative analysis. Most mathematics textbooks today make use of a variety of representations more extensively than ever before in order to promote understanding (Elia, Gagatsis & Demetriou, 2007). Much more research is needed for the students' beliefs about the role of those representations regarding different mathematical concepts in relation to their self-efficacy beliefs for using them as a tool for the better understanding of the concepts.

Appendix

1. Circle the diagram or the diagrams whose shaded part corresponds to the equation $2/3 + 1/4$.

(recognition)

2. Solve the following equation

$$1/6 + 2/5 = \dots$$

(treatment)

3. Write the fraction equation that corresponds to the shaded part of the following diagram:

EFFICACY BELIEFS AND ABILITY TO SOLVE VOLUME MEASUREMENT TASKS IN DIFFERENT REPRESENTATIONS

Paraskevi Sophocleous & Athanasios Gagatsis

University of Cyprus

The aim of this study was to investigate the relationship between students' efficacy beliefs and their performance in volume measurement tasks which were given in different representations. A group of sixth grade students (N=173) completed a four-part self-report questionnaire and solved six volume measurement tasks in different representations format: text, diagram of 3-D cube array and net diagram. Perceived efficacy to solve volume measurement tasks was found to be a significant predictor of students' general performance. Furthermore, high-ability students had stronger and more accurate efficacy beliefs towards tasks with net diagram which were unfamiliar, whereas low-ability students had more accurate efficacy beliefs towards verbal tasks which were familiar.

Key words: efficacy beliefs, volume, 3-D cube arrays, net.

INTRODUCTION

The affective domain has in recent years attracted much attention from mathematics research community (Philippou & Christou, 2002). A number of researchers who have examined thoroughly the connections and the relationship among affect and mathematical learning found that affect plays a decisive role in the progress of cognitive development (Bandura, 1997; Ma & Kishor, 1997; Philippou & Christou, 2002). One of the components of affective domain are self-efficacy beliefs (Goldin, 2002), which were found to have significant correlations and direct effects on various math-related variables (Pajares, 1996). However, although much work has been done in this area, little attention has been given to the relationship between self-efficacy beliefs and the use multiple representations in mathematics (e.g. Patterson & Norwood, 2004).

In this paper we try to investigate the relationship between efficacy to solve volume measurement tasks and performance in volume measurement of cuboid tasks which are given in different modes of representations.

THEORETICAL BACKGROUND

Self-efficacy beliefs and mathematics performance

Self-beliefs, such as self-esteem, self-concept and self-efficacy, comprise components of the general beliefs system (Philippou & Christou, 2002). Students' perceived self-efficacy for a task, are defined as their judgments about their ability to complete a task successfully (Bandura, 1997).

A number of studies have found a positive relationship between students' self-efficacy beliefs and mathematics performance (Pajares, 1996). More specifically, Pajares and Miller (1994) reported that self-efficacy in solving math problems was more predictive of that performance than sex, math background, math anxiety, math self-concept and perceived usefulness of mathematics. Additionally to this, Pajares and Kranzler (1995) found that self-efficacy made as strong a contribution to the prediction of problem-solving as did general mental ability, an acknowledged powerful predictor and determinant of academic outcomes. In this line, Mayer (1998) stressed that students who improve their self-efficacy will improve their success in learning to solve problems.

Researchers have also indicated that high-ability students have stronger self-efficacy and have more accurate self-perceptions (e.g. Pajares & Kranzler, 1995; Zimmerman, Bandura, & Martinez-Pons, 1992). Schunk and Hanson (1985) found that students who expected to be able to learn how to solve the problems tended to learn more than students who expected to have difficulty.

Self-efficacy beliefs have already been studied in relation to a lot of aspects of mathematics learning, such as arithmetical operations, problem solving and problem posing (e.g. Pajares & Miller, 1994; Pajares, 1996; Nicolaou & Philippou, 2007). However, these beliefs haven't been examined in relation to volume measurement tasks and this study tries to investigate this relationship.

Students' understanding of 3-D rectangular arrays of cubes

A number of researchers investigated students understanding of three dimensional rectangular arrays (3-D) of cubes, using interviews or tests (Ben – Chaim, Lappan & Houang, 1985; Battista & Clements, 1996). In particular, Ben – Chaim et al. (1985) indicated four types of errors that students in grades 5-8 made on the volume measurement tasks with three dimensional cube arrays. The first error was to count only the number of faces of cubes shown in a given diagram, while the second error was doubling that number. The third error was counting the number of cubes shown in the diagram and the fourth error was doubling that number (see for example figure 1). In this study, when researchers asked students to determine how many cubes it would take to build such prisms, they found that only 46% of the students gave the correct answer, while most of them made the errors of type 1 or 2 (Ben-Chaim et al., 1985). These results are in line with those from a recent work by Battista and Clements (1996) where they found that 64% of the third graders and 21% of the fifth graders double-counted cubes. These types of errors made by students are clearly related to some aspects of spatial visualization (Ben-Chaim et al., 1985). In addition to this explanation, Battista and Clements (1996) stressed that many students are unable to correctly enumerate the cubes in such an array, because their own spatial structuring of the array is incorrect. In particular, they found that for some students the root of such errant spatial structuring seemed to be attributed to their inability to coordinate and integrate the views of an array to form a single coherent mental model

of the array. However, Hirstein (1981) believes that these errors are caused by their confused notions of volume and surface area.

How many unit cubes does it take to make this rectangular solid? (Clements & Battista, 1996)

Four types of errors that students make on this problem:

Error type 1: Counting the cube faces shown in the diagram, e.g. $20+12+15=47$

Error type 2: Counting the cube faces shown in the diagram and doubling that number, e.g. $47 \times 2 = 94$

Error type 3: Counting the numbers of cubes showing in the diagram, e.g. $20+8+8=36$

Error type 4: Counting the numbers of cubes showing in the diagram and doubling that number, e.g. $36 \times 2 = 72$

Figure 1: Four types of errors that students make on volume measurement problems.

THE PRESENT STUDY

The purpose of the study

The purpose of this study was to explore the relationship between students' efficacy beliefs to solve volume measurement tasks and their ability to solve volume measurement cuboids tasks; these were given in different modes of representations, namely text, diagram of 3-D cube array and net diagram. More specifically, the present study addresses the following questions: (a) Are students' efficacy beliefs to solve volume measurement tasks strong predictor of their performance in these tasks? (b) What is the relationship between students' efficacy beliefs to solve volume measurement tasks and their errors in dealing with 3-D cube arrays and net diagrams? (c) Are there differences in the efficacy beliefs and the accuracy of these beliefs among students of varied abilities?

Participants and Test

In the present study data were collected from 173 sixth grade students (84 females and 89 males) ranging from 11 to 11.5 years of age. These students were from 10 primary schools in Cyprus from rural and urban areas.

All participants completed a five-part test which was developed on the basis of previous studies (e.g. Ben-Chaim et al., 1985; Battista & Clements, 1996; Nicolaou & Philippou, 2007). For the purpose of this paper, we did not use students' answers from the first part of the test. The first four-parts of the test measured efficacy beliefs towards mathematical problems and volume measurement tasks and the fifth part

measured students' ability to solve volume measurement tasks in different representations. Specifically, in the second part, students were asked to read each of the three volume measurement tasks: verbal task (SEiA), task with 3-D cube array (SEiB) and task with net diagram (SEiC) and state their sense of certainty to solve these tasks, without solving them. Responses were recorded on a 4 point Likert scale with 1 indicating not at all certain and 4 very much certain. In the third part, students were asked to state which one of the tasks from the second part was easy to solve (Es), was difficult to solve (Df), liked to solve (Lk) and did not find interesting to solve (Lint). The fourth part comprised of five cartoon-type pictures and statements explaining the situation presented by each picture; the students were requested to select the picture that best expressed their efficacy beliefs (very high-SEI, high-SEII, medium-SEIII, low-SEIV and very low-SEV) to solve volume measurement tasks. The fifth part of the test had six volume measurement cuboids tasks which were given in different modes of representations: text, diagram of 3-D cube array and net diagram (see figure 2).

Verbal tasks

1. Mary tries to put 28 unit-sided cubes (1 cm edge) in a rectangular box with dimensions 2 cm x 5 cm x 3 cm. Is this possible? Explain your answer. (VPr1)

4. Four friends went to the cinema. They decided to buy some bags of nuts during the movie. The vendor said to them that there were two size bags of nuts, where:

- The price of small bag was €1.
- The large bag's dimensions were two times the small bag's dimensions and its price was €6.

The dimensions of small bag were 20 cm, 10 cm and 5 cm.

One child suggested to his friends that it was better to buy and share one large size bag, instead of buying four small bags. Do you agree? Explain your answer. (VPr4)

Tasks with diagram of three dimensional cube array

Find the volume (the number of cubes) of the following cuboids:

(SPr2a)

(SPr2b)

Which one of these cuboids has the greatest number of cubes? Explain your answer. (SPr2Ans)

Tasks with net diagram

The figures below show the nets of cuboids with one of its sides missing. Find the volume (number of cubes) of this net when folded:

(NPr3a)

(NPr3b)

Which one of these nets when folded can carry the least number of cubes? Explain your answer. (NPr3Ans)

Figure 2: Volume measurement tasks.

The coefficient of reliability Gronbach's Alpha of the five-part of test was very high ($\alpha=0.794$). Specifically, we found that the reliability of answers of students in the first four-part of questionnaire was $\alpha=0.782$ and the reliability of answers in volume measurement tasks was $\alpha=0.810$.

Data Analysis

Students correct responses in volume measurement tasks were marked with 1 and incorrect response with 0. However, the marks to responses of the questions: "Which one of these cuboids has the greatest number of cubes? Explain your answer." and "Which one of these nets when folded can carry the least number of cubes? Explain your answer." were: 1 for fully correct response, 0.5 for partly correct response (wrong explanation) and 0 for incorrect answer. We used the classification of errors made in previous studies (Ben Chaim et al., 1985; Battista & Clements, 1996) to code the students' errors while solving the volume tasks with 3-D cube array diagram and net diagram.

To answer the research questions of this study, four different analyses were conducted: a Regression Analysis, an Implicative Statistical Analysis with the use of the computer software CHIC (Bodin, Coutourier, & Gras, 2000), an Analysis of Variance one way and a Crosstabs Analysis. The implicative statistical analysis is a method of analysis that determines the similarity connections and the implicative relations of factors.

RESULTS

We used regression analysis with independent variable students' efficacy beliefs to solve volume measurement tasks (answers of students in forth part of test) and dependent variable their general volume measurement performance in the test. We found that students' efficacy beliefs to solve volume measurement tasks can be a statistically significant predictor of their performance in the test (10,1%). Furthermore, we examined the predictive role of students' efficacy to solve verbal

volume measurement tasks to their performance in these tasks and regression analysis confirmed that (6%). Additionally, students' efficacy to solve volume measurement tasks with 3-D diagram can be a statistically significant predictor of their performance in one of these tasks (3%). We also found that students' efficacy to solve volume measurement tasks in net diagram predicted only 4% of their performance in these tasks.

To examine the relationships between students' efficacy beliefs to solve volume measurement tasks, their performance in these tasks which were given in different representations and their errors in dealing with 3-D cube arrays and net diagrams, we employed the statistical implicative analysis for the data of this study and gave us the similarity diagram (see figure 3), which allowed for the grouping of the tasks and the statements based on the homogeneity by which they were handled by students.

Figure 3: Similarity diagram of students' responses to the four-part of test.

Note: The similarities in bold color are important at level of significance 99%.

In figure 3, three distinct clusters of variables were formed. The first cluster consists of correct responses of students to volume measurement tasks and high efficacy beliefs, while the second and the third cluster consist students' errors and low efficacy beliefs. More specifically, the first cluster involved five similarity groups. The first group included the two statements of high efficacy beliefs to solve all volume measurement tasks and verbal tasks. The second group involved the verbal volume measurement tasks, while volume measurement tasks with 3-D cube array diagram and net diagram formed the third similarity group. These groups provided further support that different cognitive processes were required in order to solve verbal volume measurement tasks and volume measurement tasks with diagram.

However, their similarity connection indicated that equivalent content knowledge was needed to develop volume measurement ability in different representations. The fourth group included the three statements of high efficacy beliefs to solve all volume measurement tasks, tasks with 3-D cube array diagram and tasks with net diagram. Finally, the fifth group of the first cluster involved mainly four statements which referred to students' evaluation for verbal tasks as easy and interesting and for tasks with net diagram as difficult and less interesting. All above groups of similarity of the first cluster show that students with high efficacy beliefs to solve volume measurement tasks in different representations solved these tasks in a similar way. Furthermore, these students assessed the verbal tasks as easy and interesting, while the task with net diagram as difficult and less interesting. It is hypothesised that students solved mainly verbal volume measurement tasks in their textbooks and so they had more experiences to solve these tasks than tasks with net diagram. Therefore, they felt more certain to solve familiar tasks than unfamiliar ones.

The second cluster involved two similarity groups. The first group mainly included four statements which referred to students' evaluation for tasks with net diagram as easy and interesting and for verbal tasks as difficult and less interesting. The second group involved the statement of low efficacy beliefs to solve volume measurement tasks and the wrong strategy: count the number of faces of cubes shown in diagram, which used from students to solve tasks with 3-D cube array diagram. The third cluster involved the statement of lowest efficacy beliefs to solve volume measurement tasks and errors to tasks with diagram. From the second and third cluster indicated that different cognitive processes were required to calculate the number of faces of cubes shown in 3-D cube array diagram and in net diagram. However, in the case of errors: count the number of faces of cubes shown in diagram and double that number, similar cognitive processes were required to apply it in 3-D cube array diagram and in net diagram.

The sample of this study was clustered into three groups according to their volume measurement performance in the tasks of the fifth part of the test. The performance of the three clusters of students was examined in respect to their efficacy beliefs to solve volume measurement tasks. The comparison of the means by one way ANOVA indicated statistically significant differences between these groups ($F_{(2,169)}=6.240$, $p=0.002$) at efficacy beliefs towards volume measurement tasks. Using Bonferroni procedure, we found only statistical significant differences at efficacy beliefs between students with the lowest performance ($\bar{X} = 3.10$) and highest performance ($\bar{X} = 4.18$) in volume measurement tasks. Therefore, high-ability students have stronger efficacy beliefs towards volume measurement tasks than low-ability students.

However, at the same time, according to the results of the crosstabs analysis, students who solved the tasks of test correctly or wrongly indicated both very high efficacy beliefs and very low efficacy beliefs. We found that students who solved the tasks of the test correctly had more accurate self-efficacy than students who solved the tasks

of the test wrongly. More specifically, high-ability students were more accurate in their efficacy beliefs towards tasks with net diagram in relation to their performance in these tasks (73% of students who solved the tasks with net diagram correctly indicated very high and high efficacy beliefs and only 7.5% of them indicated very low and low efficacy beliefs). The tasks with net diagram considered as an unfamiliar form of the volume measurement tasks for the students, because they did not solve any similar tasks in their mathematics textbooks. Also, crosstabs analysis showed that low ability students were more accurate in their efficacy beliefs towards verbal tasks in relation to their performance in these tasks (37% of students who solved verbal tasks wrongly indicated very high and high efficacy beliefs and 35% of them indicated very low and low efficacy beliefs). The verbal tasks are more familiar to the students, since their mathematics textbooks have a number of these tasks.

Additionally, the sample of this study was clustered into five groups according to their efficacy beliefs towards volume measurement tasks. The efficacy beliefs to solve volume measurement tasks of the five clusters of students were examined in respect to their general volume measurement performance. The comparison of the means by one way ANOVA indicated statistically significant differences between these groups ($F_{(5,166)}=3.697$, $p=0.003$) on volume measurement performance. Using Bonferroni procedure, students with very high efficacy beliefs ($\bar{X}=2.43$) and students with very low efficacy beliefs ($\bar{X}=0.55$) differed significantly in their general volume measurement performance.

DISCUSSION

The purpose of the present study was to investigate the relationship between students' efficacy beliefs to solve volume measurement tasks in different representations and their performance in these tasks. We found that students' efficacy beliefs to solve volume measurement tasks was a statistically significant predictor of the general volume measurement performance of students. The predictive role of efficacy beliefs was indicated from various studies in different concepts of mathematics (Pajares & Miller, 1994; Pajares & Kranzler, 1995; Nicolaou & Philippou, 2007).

In the similarity diagram three distinct clusters of variables were formed. The first cluster included students who solved correctly the tasks of the test and indicated very high and high efficacy beliefs towards volume measurement tasks, whereas the second and the third group involved students who used wrong strategies to solve volume measurement tasks with 3-D cube array diagram and net diagram and indicated very low and low efficacy beliefs towards volume measurement tasks. Specifically, these different similarity groups which were formed show that the confidence with which students approached volume measurement problems connected and had direct effects on their volume measurement performance.

We found, also, that high-ability students had stronger and more accurate efficacy beliefs towards volume measurement tasks in comparison to low-ability students.

These findings confirm the earlier results by Pajares and Kranzler (1995) and Zimmerman et al. (1992). Furthermore, high ability students had more accurate efficacy beliefs towards volume measurement tasks with net diagram which were unfamiliar, whereas low-ability students had more accurate efficacy beliefs towards verbal volume measurement tasks which are more familiar to them.

Moreover, students who had high efficacy understand the volume measurement tasks better than the students who have low efficacy beliefs. This finding confirms the results of the study of Schunk and Hanson (1985). Also, students with high efficacy beliefs tend to assess the verbal tasks as easy and interesting, whereas the tasks with net diagram as difficult and less interesting. Therefore, these students' perceptions probably play an important role to their volume measurement performance and/or the development of their efficacy beliefs. This finding needs to be further explored.

In conclusion, the above findings about the predictive role of efficacy beliefs towards volume measurement tasks in different representations are very important in mathematics teaching and learning. Efficacy beliefs is an important component of motivation and behaviour (Pajares, 1996) and thus teachers need to develop ways to enhance efficacy beliefs of students of varied abilities. More specifically, high ability students need to solve "new" and creative tasks in which they will give the necessary attention and low ability students need to solve more easy and familiar tasks in which they can succeed.

MOTIVATION FOR LEARNING MATHEMATICS IN TERMS OF NEEDS AND GOALS

Kjersti Wæge

Programme for Teacher Education, Norwegian University of Science and Technology, Trondheim

This article suggests a framework for analysing students' motivation for learning mathematics. In the present paper, motivation is defined as a potential to direct behaviour. This potential is structured through needs and goals. The author examines students' motivation in terms of needs and goals, and the emphasis is on the psychological needs for competence and autonomy. The proposed theoretical framework as an analytical tool is useful in describing the students' goals and changes in goals in details. It could also contribute to increased insight into relations between different aspects of instructional designs and the students' motivation for learning mathematics. The usefulness of the theoretical framework will be illustrated with some findings from the study.

INTRODUCTION

In mathematics education there has not been done much work on people's motivation to date (Evans & Wedege, 2004; Hannula, 2006). Only a few researchers have distinguished between intrinsic and extrinsic motivation in mathematics (Goodchild, 2001; Holden, 2003; Middleton & Spanias, 1999), or between task orientation and ego orientation (Nicholls, Cobb, Wood, Yackel, & Patashnick, 1990; Yates, 2000). Some mathematics educators have discussed students' motivation under the terms of motivational beliefs (Kloosterman, 1996; Op't Eynde, De Corte, & Verschaffel, 2002) and interest (Köller, Baumert, & Schnabel, 2001; Schiefele & Csikszentmihalyi, 1995). Evans and Wedege (2004; , 2006) consider people's motivation and resistance to learn mathematics as interrelated phenomena.

Hannula (2006) points out that many of the above approaches fail to describe the quality of the individual's motivation for learning mathematics in sufficient detail. He suggests that the reason for this is that the authors' approaches aim to measure predefined aspects of motivation, not to describe it (p. 166). Hannula developed a theoretical foundation of motivation as a structure of needs and goals, and his study shows that the students' goals vary a lot from person to person. The aim of this article is to present (develop) a theoretical framework for analysing the students' motivation for learning mathematics, in terms of needs and goals. The article reports on a particular aspect of a study where the focus is the development of Norwegian upper secondary school students' motivation for learning mathematics when they experience an inquiry mathematics teaching approach. The study followed a design-research approach in that it involved both instructional design and classroom based

research (Cobb, 2001). I collected a large and varied pool of data (participant observation, semi-structured interviews, videotapes of students working, conversations with the teacher, students' diaries, collection of material, assessment) on seven of the students. The focus of this article is the development of theory. Some findings from the study will be presented, mainly to illustrate the usefulness of the theoretical framework. Due to space constraint, the original data and analyses cannot be included. The interested reader should return to original papers.

MOTIVATION

Motivation is defined in different ways in the literature of (achievement) motivation, and I have chosen to use the following definition:

Motivation is a potential to direct behaviour that is built into the system that controls emotion. This potential may be manifested in cognition, emotion and/or behaviour. (Hannula, 2004, p. 3)

Motivation is considered as a potential to direct behaviour, and therefore, my focus is on the orientation of motivation. According to the definition, students' motivation may be manifested in cognition, emotion and/or behaviour. For example, a student's motivation to get a good grade in mathematics may be manifested in happiness (emotion) if he or she scores high on a test. It may also be manifested in studying for a test (behaviour) and in new conceptual learning (cognition) when studying for the test. Needs are specified instances of the potential to direct behaviour (Hannula, 2004). Psychological needs that are often emphasised in educational settings are competence, relatedness (or social belonging) and autonomy (e.g. Boekaerts, 1999; Ryan & Deci, 2000). I have chosen to define motivation as a potential to direct behaviour and therefore the orientation of motivation becomes central. Thus it is necessary to add a more fine grained conceptualization of motivation focusing on needs and goals.

Self Determination Theory and needs

Self Determination Theory (SDT) is a general theory of motivation that focuses on psychological needs, and I have chosen to use Ryan and Deci's (2002) definition of needs. Before presenting the definition, I will give a short presentation of the theory. Most contemporary theories of motivation assume that people engage in activities to the extent that they believe the behaviours will lead to desired goals or outcomes (Deci & Ryan, 2000). Within Self determination theory one is concerned about the goals of the behaviour and what energizes this behaviour. SDT is founded on three assumptions. The first assumption is that human beings have an innate tendency to integrate. *Integrating* means to forge interconnections among aspects of one own psyches as well as with other individuals and groups in his or her social world:

...all individuals have natural, innate and constructive tendencies to develop an even more elaborated and unified sense of self. (Ryan & Deci, 2002, p. 5)

This assumption of active, integrative tendencies in development is not unique to SDT. However, specific to this theory is that this evolved integrative tendency cannot be taken for granted. The second assumption in SDT is that social-contextual factors may facilitate and enable the integration tendency, or they may undermine this fundamental process of the human nature:

...SDT posits that there are clear and specifiable social-contextual factors that support this innate tendency, and that there are other specifiable factors that thwart or hinder this fundamental process of human nature. (Ryan & Deci, 2002, p. 5)

In other words, there is a dialectic between an active organism and a dynamic environment (social context) such that the environment act on the individual, and is shaped by the individual. To describe and organize the environment as supporting versus thwarting the integrative process, the concepts of needs are used. *Needs* are defined through optimal functioning (growth and well-being), and I have chosen to use the following definition:

There are necessary conditions for the growth and well-being of people's personalities and cognitive structures, just as there are for their physical development and functioning. These nutriments are referred to within SDT as basic psychological needs. (Ryan & Deci, 2002, p. 7)

Looking back at Hannula's definition, psychological needs are specified instances of the general potential to direct behaviour. The third assumption in SDT is that human beings have three basic psychological needs, the needs for competence, relatedness and autonomy (Deci & Ryan, 2000; Ryan & Deci, 2002). Within SDT, competence, relatedness and autonomy are defined in the following way:

Competence refers to feeling effective in one's ongoing interactions with the social environment and experiencing opportunities to exercise and express one's capacities (Ryan & Deci, 2002, p. 7). *Relatedness* refers to feeling connected to others, to caring for and being cared for by others, to having a sense of belongingness both with other individuals and with one's community (Ryan & Deci, 2002, p. 7). *Autonomy* refers to being the perceived origin or source of one's own behaviour (Ryan & Deci, 2002, p. 8). (My italics in the three quotations)

According to the definition, competence is not an attained skill or capacity, but it is a felt sense of confidence and effectiveness in action. The individual feels and experiences competence in the specific situation, it is not a product that shall be used (Wæge, 2007). In that case it is different from the way it is used by Hannula (2002). Hannula defines competence as the individual's functional understanding and skills. He considers competence to be a product, something the individual could use. Relatedness, in the definition above, refers to the psychological feeling of being together with other persons in a secure community or unity. In a similar way as for the construct of competence, Hannula considers social belonging (or relatedness) to be a target to attain. It also includes a goal of social status in the group. Within SDT

relatedness refers to the students' feelings of belongingness with others. When individuals are autonomous they experience themselves as volitional initiators of their own actions. Cobb and colleagues (Cobb, 2000; Cobb, Gravemeijer, Yackel, McClain, & Whitenack, 1997; diSessa & Cobb, 2004) use the concept of intellectual autonomy as a characteristic of a student's way of participating in the practices of a classroom community. They speak of the students' awareness and willingness to draw on their own intellectually capabilities when making mathematical decisions and judgments as they participate in mathematics activities. Hannula define autonomy as "the need to have control over own actions and to feel self-determining" (Hannula, 2002, p. 74). His definition differs from Ryan and Deci's definition in that it adds an aspect of having control over own actions.

The concept of needs is useful because it allows the specification of the social-contextual conditions that will facilitate motivation. According to SDT, students' motivation will be maximized within social contexts that provide them with the opportunity to satisfy their basic psychological needs for competence, autonomy and relatedness. I have chosen to use Ryan and Deci's definitions of the three psychological needs [1]. The data in the study did not give a basis for detailed analyses of the student's needs for relatedness and the goals the students' have in relation to this need. Therefore, the need for relatedness was not a focus in my study. In my study I focused on the students' needs for competence and autonomy. In his study, Hannula focuses on the three psychological needs for competence, relatedness and autonomy, but as I pointed out above, his definitions of the constructs differ from Ryan and Deci's definitions, which are the ones I have chosen to use.

Needs and goals structures

Hannula's definition of motivation (above) purports the potential to direct behaviour is structured through needs and goals. Needs and goals are specified instances of the potential to direct behaviour. According to Hannula, goals are derived from needs, and the difference between needs and goals is their different level of specificity. A need may be directed toward a relatively large category of objects, while a goal is directed toward a specific object (Hannula, 2004). For example, in my study, Berit realised her need for competence as a more specific goal of gaining a good grade. She translated her need for autonomy into the more specific goal of developing her own ideas, independently of the teacher. Another student, David, realised his need for relatedness as a goal to gain the mathematics teacher's confidence and respect.

According to Boekaerts, the students' goal structures are complex, and they tend to pursue multiple goals. The goals are related to each other, and pursuing one goal might be necessary to attain another goal or different goals may be seen as contradictory (Boekaerts, 1999; Shah & Kruglanski, 2000). Learning goals and performance goals are usually considered as contradictory to each other (Lemos, 1999; Linnenbrink & Pintrich, 2000), but Hannula's (2004) and my own findings (Wæge, 2007) indicate that these goals should not be seen as mutually exclusive

goals in mathematics education. To exemplify this I present an utterance of a student [2]:

Berit: [...] I think it has been pretty enjoyable. In the beginning I thought it was a bit difficult (Interviewer: Mm) because I was not used to this kind of teaching approach. [...] I think this mathematical approach is much better. The full-day test [3] was pretty special this time, because usually I didn't quite understand what I was doing {inaudible}. Do this, follow rules and things like that. This time I thought that I understood everything and I thought the test went very well. And then I get a 4[4] and when I didn't understand it I used to get a 5. But I almost think it's better to try to understand a little more and nevertheless get a lower grade. Anyhow, I think it is possible to increase the grade. It's only a new way of thinking. It's quite interesting, I think {laughing} strange, yes.

My analysis of Berit shows that she has a specific goal of relational understanding in mathematics (Skemp, 1976). Her sense of mastery and her feeling of succeeding in mathematics are higher when she experiences that she understands the mathematics problems, than when she uses rules without understanding. Another important goal for Berit is to get good grades on the mathematics tests. Her goals of relational understanding in mathematics and good grades in mathematics support each other mutually. Getting good grades are important to Berit, but relational understanding in mathematics is the most important goal for her.

FIVE MOTIVATION VARIABLES

There is a serious methodological problem with research on a mental construct like motivation. Students' motivation cannot directly be observed, and thus measured, and it needs to be reconstructed through interpretation of the observable. I have developed an instrument to assess students' motivation for learning mathematics in terms of cognition, emotion and behaviour. In doing this I focus on the five sets of motivational variables that Stipek, Salmon, Givvin & Kazemi (1998) used in their study entitled: "The value (and convergence) of practices suggested by motivation research and promoted by mathematics education reformers" [2]. These are the students'

1. focus on learning and understanding mathematics concepts as well as on getting right answers;
2. enjoyment in engaging in mathematics activities;
3. related positive (or negative) feelings about mathematics.
4. willingness to take risks and to approach challenging tasks;

5. self-confidence as mathematics learners;

All these motivation variables figure prominently in the achievement motivation literature and in the mathematics reform literature. The five motivation variables are closely related to the needs for competence and autonomy. The first and the fourth variable, students' focus on learning and their willingness to take risks and approach challenging tasks, are closely related to the students' need for competence. Deci and Ryan (2002) claim that the students' need for competence leads them to seek adequately challenging mathematics tasks and to attempt to maintain and develop their mathematical understanding and skills. In my analysis I distinguish between students' learning orientation and performance orientation (Nicholls, Cobb, Wood, Yackel, & Patashnick, 1990). In addition, I also make a distinction between relational understanding and instrumental understanding (Skemp, 1976). The fifth variable, students' self-confidence, is related to students' willingness to approach tasks (Stipek, Salmon, Givvin, & Kazemi, 1998). The second and the third variable, students' enjoyment and their feelings about mathematics, are related to the students' intrinsic motivation in mathematics. According to Deci and Ryan (2002), intrinsic motivation represents a prototype of self-determined activity. They suggest that there is a strong connection between people's intrinsic motivation and their need for autonomy and competence. Mathematics classrooms that support the students' needs for autonomy and competence will enhance their intrinsic motivation in mathematics. Contextual events that students experience as thwarting satisfaction of these needs will undermine their intrinsic motivation.

In analysing the data, I assess these five motivation variables and I analyse the needs and goals of the students in relation to these specific motivational orientations. More specifically, the analysis is divided into two parts. First I analyse the data according to the five motivation variables. Although the variables can be seen as interrelated they are analysed separately in order to provide detailed insight into the students' motivation for learning mathematics. In the second part, I analyse the student's needs and goals in relation to these five specific motivational orientations. Furthermore, my emphasis is on the students' need for autonomy and competence.

TEACHING APPROACH

The teaching approach in the study was intended to give more space for the students to satisfy their needs for competence and autonomy, than teacher-centred and teacher-controlled teaching approaches. In the study attention was given to the development of students' mathematical thinking and reasoning. Our (the teacher and I) task was to create instructional activities that supported the development of both collective mathematical meanings evolving in the classroom community and the mathematical understanding of the individual student. We tried to support

...the collective learning of the classroom community, during which taken-as-shared mathematical meanings emerge as the teacher and students negotiate interpretations and solutions (Gravemeijer, Cobb, Bowers, & Whitenack, 2000, p. 226).

The teacher always asked the students “What did you think when you solved this problem? What strategies did you use?” In the written tasks we developed, the students were frequently asked to explain their solutions and strategies, and the students were invited to find several solution strategies to a problem. The teacher tried to promote a classroom microculture (Cobb, Boufi, McClain, & Whitenack, 1997) where active participation and encouragement to understand were emphasised. In some of the instructional activities the students had to develop their own ideas, apply the mathematics in realistic situations and draw their own conclusions. Collaboration was important in our teaching approach. When the student’s were given problems they were not familiar with, we wanted the students to collaborate. The students had an opportunity to experience themselves and their peers as active participants in creating mathematical insight. Every student brought a personal contribution at his or her level. These elements of our design study were suitable for meeting the students need for competence, autonomy and relatedness.

THE THEORETICAL FRAMEWORK – SOME KEY POINTS

The proposed theoretical framework for analysing students’ motivation is useful in describing students’ goals and changes in goals in detail. The framework is useful in clarifying students’ notion of what it might mean to understand in mathematics. For example, the analysis of Berit shows that for her, to understand means to know what to do and why. We may also understand the relations between different goals through the use of such a framework. The complete analysis of Berit shows that there was a strong connection between her goal of relational understanding and her goal of finding her own solutions. She believes that finding own strategies for solving problems helps her in learning and understanding mathematics. As I described above, her goal of getting a good grades in mathematics and mastery goal, in this case a goal of relational understanding in mathematics, mutually supported each other.

The study shows that students’ motivation for learning mathematics, although it is considered relatively stable, can be influenced by changes in the teaching approach. The case of Berit shows that students’ motivation for learning mathematics might change in a relatively short time. Within the first semester of the school year, Berit changed her goal of instrumental understanding (Skemp, 1976) to a goal of relational understanding in mathematics.

We may also understand the relations between different aspects of the instructional designs developed in the study and the students’ motivation for learning mathematics in terms of needs and goals through this framework. The analysis of Berit indicate that a combination of working with mathematics problems and routine tasks from the textbook, and the fact that the students were given opportunities to find their own

solutions and rules for solving the problems, in collaboration with peer students and with guidance from the teacher, contributed to a sense of understanding and mastery with Berit.

I perceive that the theoretical framework as an analytical tool captured the complexity and the richness of the students' motivation in detail, and the tool made it possible for me to present detailed descriptions of the students' motivation for learning mathematics.

NOTES

1. See Wæge (2007) for a detailed description of my interpretation of the definitions.
 2. Key to transcripts: [...] extracts edited out of transcript for sake of clarity; {inaudible} unclear words; {text} comments about context or emotional behaviour like laughing; {.} 1 sec pause, {...} 2 sec pause, and so on.
- The interviews took place in Norwegian. I have tried to translate from colloquial Norwegian to colloquial English, but it does not give an exact word for word translation. My analysis took place without any translation, that is, I analysed the transcripts in the original language.
3. At the end of each semester, the students have an all-day test in mathematics.
 4. 1 is the lowest grade and 6 is the highest.

MATHEMATICAL MODELING, SELF-REPRESENTATION AND SELF-REGULATION

Areti Panaoura*, Andreas Demetriou, Athanasios Gagatsis****

** Frederick University, ** University of Cyprus*

The aim of the present study was to investigate the improvement of students' self-representation about their self-regulatory performance in mathematics by using mathematical modeling. Three materials were developed and administered at 255 11th years old students, for mathematical performance, self-representation and the use of self-regulatory strategies for problem solving. A web page with the proposed model (the model of Verschffel, Greer & De Corte, 2000) was constructed and used individually by students. Results indicated that the program created a powerful learning environment in which students were inspired in their own experiences. Although the program improved their cognitive and self-regulatory performance, it reproduced the differences among students in respect to their cognitive and metacognitive performance.

Keywords: self-regulation, self-representation, mathematical modeling

In the last decades, children's early understanding of their own as well as others mental states has been intensively investigated, reflecting growing interest for the concept of metacognition (Bartsch & Estes, 1996). In psychological literature, the term metacognition refers to two distinct areas of research: knowledge about cognition and self-regulation (Boekaerts, 1997). Self-regulation refers to the processes that coordinate cognition. It reflects the ability to use metacognitive knowledge strategically to achieve cognitive goals, especially in cases where someone has to overcome cognitive obstacles.

As regards the relationship between academic self-concept and academic achievement, extant literature supports both direct and indirect relationships between them; however, the range of correlations reported is a function of several factors (Guay, Marsh & Boivin, 2003). Age is a factor that affects this relationship since young students, academic self-concept is usually very positive and not highly correlated with external indicators, such as skills and achievement (Guay et al., 2003). Veenman and Spaans (2005) assumed that metacognitive skills initially develop on separate islands of tasks and domains. Beyond the age of 12, these skills will gradually merge into a more general repertoire that is applicable and transferable across tasks and domains. The present work is concentrated on the improvement of metacognitive performance on the domain of mathematics and more specifically on the improvement of self-regulatory behavior.

Learning mathematics, as an active and constructive process, implies that the learner assumes control and agency over his/her own learning and problem solving activities (De Corte, Verschaffel & Op't Eynde, 2000). Knowing when and how to use cognitive strategies is an important factor to successful word problem solving (Teong, 2002). Metacognitive behavior can be applied in every stage of the problem solving activity (Lerch, 2004). For example before starting solving a particular problem, students can ask themselves questions like what prior knowledge can help them develop a solution plan for the particular task; during the application of the solution plan the students monitor their cognitive activities and compare progress against expected goals. Finally, after reaching a solution, the students may need to look back, to check for the reasonableness of outcomes and integrate newly acquired knowledge to existing.

Problem solving procedure and the use of mathematical modeling

Studies on solving mathematical word problems refer to various conditions that cause transfer to occur, for example, providing solved examples (e.g. Bassok & Holyoak, 1989), having a scheme (Nesher & HersHKovitz, 1994), and providing feedback (Hoch & Loewenstein, 1992). The first step in solving a problem is to encode the given elements (Davidson & Sternberg, 1998). Encoding involves identifying the most informative features of a problem, storing them in working memory and retrieving from long-term memory the information that is relevant to these features. Incomplete or inaccurate metacognitive knowledge about problems often leads to inaccurate encoding and could generate learning obstacles.

A specific strategy frequently taught in math classes in order to enhance problem solving ability, is to use analogy in order to create a mental model of similar problems. In this regard, the students are expected to extract the relevant facts from the statement of the problem, compare it to their knowledge base, relevant to the problem domain, and recognize similarities between the new problem and problems they have previously encountered, and abstract the proper entities and principles. Empirical findings show that students fail to see the underlying principles unless they are explicitly pointed out (Panaoura & Philippou, 2005).

The modeling of open-ended problems have been of interest to mathematics educators for decades. Mathematical modeling of problem solving is a complicated procedure which is divided into different stages (Mason, 2001). When a mathematical modeling task is offered in a school the goal generally is not that students learn to tackle only that particular task. Rather, students are expected to recognize classes of situations that can be modeled by means of a certain mathematical concept, relation or formula, and to develop some degree of routine and fluency in mapping problem data to the underlying mathematical model and in working through this model to obtain a solution (Van Dooren, Verschaffel, Greer & De Bock, 2006).

A characteristic is that the modeling process is not a straightforwardly sequential activity consisting of several clearly distinguishable phases. Modellers do not move sequentially through the different phases of the modeling process, but rather run through several modeling cycles wherein they gradually refine, revise or even reject the original model. The present paper discusses the impact of the use of the mathematical model proposed by Verschaffel et al. (2000) on the development of students' self-representation about their self-regulatory behavior in mathematics. The main stages of the model are: 1) Understanding the phenomenon under investigation, leading to a model of the relevant elements, relations and conditions that are embedded in the situation (situation model), 2) Constructing a mathematical model of the relevant elements, relations and conditions available in the situation model, 3) Working through the mathematical model using disciplinary methods in order to derive some mathematical results, 4) Interpreting the outcome of the computational work to arrive at a solution to the real – word problem situation that gave rise to the mathematical model, 5) Evaluating the model by checking if the interpreted mathematical outcome is appropriate and reasonable for the original problem situation, and 6) Communicating the solution of the original real – word problem.

At the first phase of the problem solving procedure by the use of the mathematical model students have to consider and decide what elements are essential and what elements are less important to include in the situation model. In the next phase, the situation model needs to be mathematised i.e. translated into mathematical form by expressing mathematical equations involving the key quantities and relations. Students need to rely on another part of their knowledge base, namely mathematical concepts, formulas, techniques and heuristics. After the mathematical model is constructed and results are obtained by manipulating the model, numerical result needs to be interpreted in relation to the situation model. At this point, the results also need to be evaluated against the situation model to check for reasonableness. As a final step, the interpreted and validated result needs to be communicated in a way that is consistent with the goal or the circumstances in which the problem arose.

Nowadays problem solving skills have become a prominent instructional objective, but teachers often experience difficulties in teaching students how to approach problems and how to make use of proper mathematical tools. Many teachers of mathematics teach students to solve mathematical problems by having them copy standard solution methods. It comes as no surprise, therefore, that many students find it difficult to solve new problems, especially problems within a context (Harskamp & Suhre, 2006). Attempts to improve problem solving should focus on episodes students neglect when solving problems. The aim of the present study was to develop students' (5th grade) problem solving ability and to enhance their ability to self-regulate their cognitive performance in order to overcome cognitive obstacles when they encounter difficulties

while trying to solve mathematical problems. One of the main emphases was to oblige students reflect on their cognitive processes while trying to solve the problems and encounter difficulties in order to self-regulate their behavior. We hypothesized that the development of self-representation in order to be more accurate regarding the students' strengths and limitations would improve their self-regulatory behavior in mathematics. Especially for the problem solving procedure we hypothesized that the better distinction of problems and the clustering of those problems according to their similarities and differences would have as a consequence the better transfer of knowledge and strategies from the one domain to the others and from general situation to the specific ones.

METHODOLOGY

Participants: Data were collected from 255 children (107 experimental group and 148 control group), in Grade 5 (11 years old) from five different urban elementary schools. The participation at the program were voluntary because we had used the extra time students stayed at school for the program of the Ministry of Education, called "day-long school".

Procedure: The main emphasis was on the development of the program for the use of the proposed mathematical model, the training of students on the model and the evaluation of its results. At the first phase of the study three materials were constructed for pre and post test. The first one was about students' self-representation, the second for mathematical performance and the third one for their behavior while trying to solve mathematical problems. The first one comprised of 40 Likert type items of five points (1 = never, 2 = seldom, 3 = sometimes, 4 = often, 5 = always), reflecting students' self-representation about mathematical learning (e.g. "I can better explain my solution for a problem when I use a diagram", "I can easily compare two pictures in order to find their similarities"). The reliability was very high (Cronbach's alpha was .87).

The second questionnaire comprised of 20 mathematical tasks on counting, geometry, statistics and problem solving (e.g. "How the area of a square, side 4cm, will be changed if the side is doubled", "Construct the bigger four digit number with the digits 9 and 3", "In our neighborhood every year since 2000 we organize a celebration, For the three following years, after the first one it did not organize. At what date (chronology) did it start again?") All items in the mathematical performance questionnaire were scored on a pass-fail basis (0 and 1). The reliability was high (Cronbach's alpha was 0.85).

The third questionnaire comprised of ten couples of sentences and students had to choose which one expressed better their cognitive behavior while they were encountering a difficulty in problem solving (a. When I explain to my friend how to solve a problem, I prefer to use a diagram, b. When I explain to my friend how to solve a problem I prefer to do it verbally). All the questionnaires were first used at a pilot study in order to examine their construct validity.

Then an intervention program was developed in order to propose the use of the mathematical model (Figure 1) for problem solving, proposed by Verschaffel et al. (2000). The emphasis was on the understanding that different stages of problem solving would have as a consequence the use of different cognitive procedures and that the cognitive obstacles could be encountered by realizing the cognitive interruptions at one or more of those stages and mainly by self-regulating the cognitive performance. For example a self-regulatory strategy is the ability to recognize the “inner” mathematical similarities and differences of mathematical problems in order to transfer cognitive and metacognitive strategies among different domains. For the purpose of the project we had constructed a web page which was visited individually by each student of the experimental group (107 students) during 20 “meetings”. One of the main emphases was to oblige students rethink their cognitive processes while trying to solve the problems and encounter difficulties in order to monitor their performance.

Figure 1: The mathematical model proposed by Verschaffel et al. (2000)

We had organized twenty “individual meetings” of the students with the webpage in order to work with the model (almost 20 minutes each meeting). Using the model used the first four “meetings” for the familiarization with the environment of the computer and for understanding the whole idea of the webpage for the problem solving procedure. The ten following “meetings” concentrated on different stages of the proposed mathematical model. For example at the stage of “understanding the problem” students had to solve problems with not enough data, or with more than the necessary data, they had to answer specific questions about the data of the problem, they had to explain in their own words the problem, to summarize it etc. At the stage of “modeling” they had to work on the classification of mathematical problems by explaining the criteria they used in order to classify the problems. There were problems with the same situational characteristics or the same context in order to oblige students to be concentrated on the structural mathematical characteristics. At the last six “meetings” students should solve mathematical problems by using all the stages of the mathematical model. In each stage the “cartoon” that was the hero of the web page asked questions such as “How did you get that? This isn’t a better solution? (for a proposed solution). Do you have any better

solution?”, in order to force students to self-regulate their cognitive performance. We wanted to have a reflection at all the stages of their work. The students’ responses were recorded automatically at a database with details such as when they had worked on the specific task and for how long. The whole procedure is presented at Figure 2.

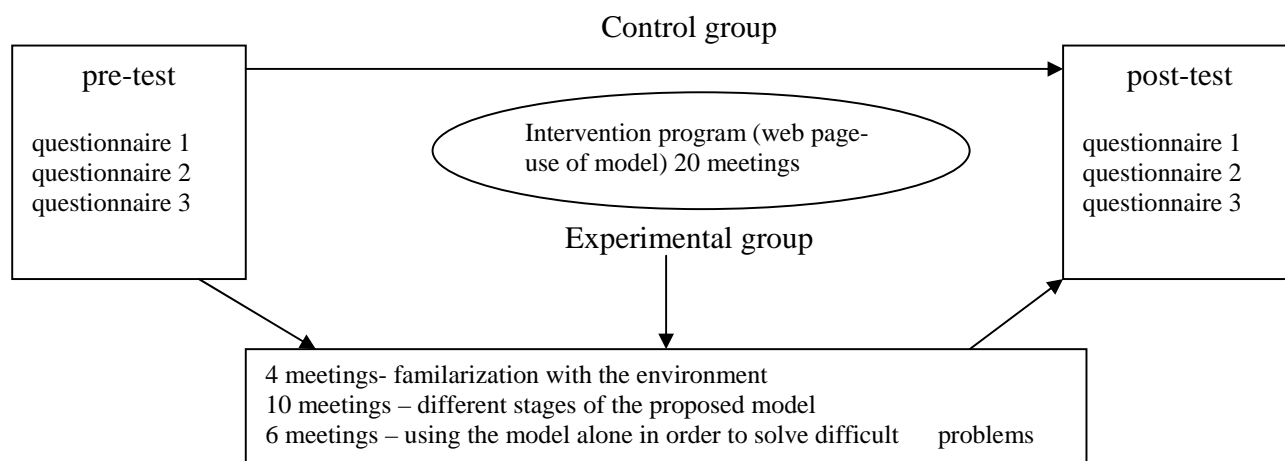

Figure 2: The development of the intervention program

RESULTS

The data about self-representation (1st questionnaire) were first subjected to exploratory factor analysis in order to examine whether the presupposed factors that guided the construction of the items of the first questionnaire were presented in the participants’ responses. This analysis resulted in 6 factors with eigenvalues greater than 1, explaining 65.56% of the total variance. After the content analysis, according to the results of the exploratory factor analysis items were classified in the following factors: F1: general self-image about mathematics, F2: self-representation about problem solving abilities, F3: self-representation about the strategies used in order to self-regulate the cognitive performance, F4: self-representation about students’ spatial abilities in mathematics, F5: self-representation about the degree of concentration on problem solving procedure, F6: the preference for different types of representations

We concentrated on the three factors which were related with self representation in respect to problem solving and self-regulation (F1, F2 and F3). The comparison of the means of the three factors between the pre and post tests for the experimental and the control group were statistically significant in all cases ($p < 0.001$). Nevertheless the improvement was highest for the experimental group in the case of the second and the third factors (Table 1). It is obvious the increase of the control group as well as a consequence of the age development and the impact of teaching and learning (those were factors that could not be controlled). However the improvement was in all cases higher in the case of the experimental group.

	pre - test		post - test	
	experimental	control	experimental	control
F1	3.92	4.00	4.00	4.07
F2	3.22	3.25	3.69	3.57
F3	2.76	2.78	3.35	3.20

Table 1: The means of the experimental and the control group for the three factors at the pre and post test.

At the same time for the experimental group the improvement was highest in the case of the general mathematical performance ($\bar{X}_{1\text{exp}}=0.27$, $\bar{X}_{2\text{exp}}=0.63$, $\bar{X}_{1\text{control}}=0.27$, $\bar{X}_{2\text{control}}=0.52$) and the problem solving performance ($\bar{X}_{1\text{exp}}=0.20$, $\bar{X}_{2\text{exp}}=0.47$, $\bar{X}_{1\text{control}}=0.20$, $\bar{X}_{2\text{control}}=0.39$). Specifically the highest differences were found in the domain of geometry ($\bar{X}_{1\text{exp}}=0.28$, $\bar{X}_{2\text{exp}}=0.47$, $\bar{X}_{1\text{control}}=0.29$, $\bar{X}_{2\text{control}}=0.44$) and statistics ($\bar{X}_{1\text{exp}}=0.38$, $\bar{X}_{2\text{exp}}=0.69$, $\bar{X}_{1\text{control}}=0.38$, $\bar{X}_{2\text{control}}=0.64$). This result reveals the positive impact of the use of the specific mathematical model on the mathematical performance.

The most important in the case of self-representation is the accuracy of this feature in relation to the real mathematical performance. We have clustered, depended on cluster analysis, the participants in respect to their general self-image about their mathematical performance into three groups. The first group was consisted of 42 students with low self-image ($\bar{X}=2.55$), the second one of 82 students with medium self-image ($\bar{X}=3.26$) and the third one of 99 students with high self image ($\bar{X}=3.94$). There were statistically significant differences between the first and the third group at the initial phase (pre – test) in respect to their real mathematical performance ($F=4.716$, $df=2$, $p=0.01$, $\bar{X}_1=0.466$, $\bar{X}_2=0.543$, $\bar{X}_3=0.605$). After the program the difference of the groups regarding their general self-image in relation to their mathematical performance (post test) was significant only in the case of the experimental group ($F=4.447$, $df=2$, $p=0.01$, $\bar{X}_1=0.557$, $\bar{X}_2=0.6059$, $\bar{X}_3=0.699$). Those results indicated that most students had accurate self-image in respect to their real mathematical performance and they did not seem to overestimate their abilities. At the same time students' means at the classification of similar mathematical problems according to the mathematical structure of the problems were highest at the post test. The development was statistically higher in the case of the experimental group ($\bar{X}_1=0.29$, $\bar{X}_2=0.49$, $t=12.79$, $p<0.001$) than the control group ($\bar{X}_1=0.29$, $\bar{X}_2=0.41$, $t=11.69$, $p<0.001$). The difference between the two groups was statistically significant ($t=3.32$, $df=228$, $p<0.01$).

A part of the couples of sentences at the third questionnaire were about the self-regulatory strategies they use in order to encounter difficulties and cognitive obstacles at the problem solving procedure. For the self-regulatory strategies the difference of the

means between the two measurements was statistically significant ($t=2.93$, $df=98$, $p<0.01$, $\bar{X}_1=0.65$, $\bar{X}_2=0.69$) only in the case of the experimental group. That means that students tended to develop more self-regulatory strategies or tended to believe that they have to develop those strategies. Even the second learning situation is an important step for the change of cognitive and metacognitive behavior, as well.

Students of the experimental group were clustered according to their self-representation about problem solving ability and their general mathematical ability into three groups (low self-representation: 24 students, medium: 36 students, and high self-representation: 34 students). Analysis of variance (ANOVA) indicated that there was a statistically significant difference concerning their self-representation about the use of self-regulatory strategies in mathematics ($F_{2,93}=6.094$, $p=0.003$). As it was expected the mean of the group with the high self-representation was higher (0.80) than the other two groups (medium: 0.63 and low: 0.58). The most interesting result was that the students' with medium and low mathematical performance was increased after the program (low: $\bar{X}_1=0.83$, $\bar{X}_2=0.87$, medium: $\bar{X}_1=0.90$, $\bar{X}_2=0.94$, high: $\bar{X}_1=0.94$, $\bar{X}_2=0.94$). In the case of the improvement on the self-representation about the use of self-regulatory strategies for the three groups the changes were similar (low self-representation: $\bar{X}_1=0.50$, $\bar{X}_2=0.53$, medium self-representation: $\bar{X}_1=0.64$, $\bar{X}_2=0.67$, high self-representation: $\bar{X}_1=0.80$, $\bar{X}_2=0.84$). This stability or low increase may indicate that students realized their difficulties and limitations and did not tend to overestimate their abilities in using strategies.

DISCUSSION

Results confirmed that providing students with the opportunity to self-monitor their learning behavior in the case of encountering obstacles in problem solving through the use of modeling is one possible way to enhance students' self-representation about the self-regulatory strategies they use in mathematics and consequently their mathematical performance. It seems that the program with the use of the model created a powerful learning environment in which students were inspired in their own experiences. Nevertheless it is obvious that students with high self-representation about their mathematical abilities in the initial phase were at the same time students with the most self-regulatory strategies after the impact of the intervention program, as well. That means that although the program improved the metacognitive performance and the mathematical performance of the experimental group, further research is needed in order to find ways to change the initial differences among students.

For the development of a more accurate self-representation about mathematical performance and self-regulation in problem solving teachers must create a powerful learning environment, in which children are allowed and inspired to, their own learning experiences. According to the self-regulated learning approach students are self-regulating when they are aware of their capabilities of the strategies and resources

required for effectively performing a task (Paris & Paris, 2001). Learners, who decide to ask a more competent person for assistance when faced with a task, indicate that they realize their difficulties and try to find out ways to overcome them. The accurate self-representation about the strengths and limitations is a presupposition for the development of self-regulation. Instruction should mainly lead students to self-questioning as a systematic strategy in helping them control their own learning and organize by themselves the different occasions they may encounter. In the area of mathematics, a number of important questions about metacognition remain unanswered. Much more research is needed to study the different aspects of metacognition in a more systematic and detailed way. We suggest specifically that further research could focus on interactive computer programs that may be designed to provide feedback and hints to assist students in becoming more aware of their cognitive and metacognitive processes. It would be optimistic and naïve to claim that such types of intervention programs would develop the self-regulatory strategies of all students. Possibly different models and programs are suitable for different groups of students.

ENDORISING MOTIVATION: IDENTIFICATION OF INSTRUCTIONAL PRACTICES

Marilena Pantziara and George Philippou

Department of Education –University of Cyprus

This paper presents some results of a larger study that investigates the relationship between instructional practices in the mathematics classroom and students' motivation and their achievement in mathematics. Data were collected from 321 sixth grade students through a questionnaire comprised of three Likert-type scales measuring motivational constructs, a test measuring students' understanding of the fraction concept and an observation protocol for teachers' instructional practices in the classroom. Findings revealed the importance of multi-level modelling in the analysis of instructional practices suggested by achievement goal theory and mathematics education research that promote both students' motivation and achievement in mathematics.

INTRODUCTION

Research on achievement motivation provides substantial evidences of instructional practices that foster students' motivation (Anderman et al., 2002; Turner et al., 2002). These instructional practices are alike the ones developed by mathematics educators to achieve both learning and motivational outcomes (Stipek et al., 1998). Motivation is treated in mathematics education as a desirable outcome and a means to enhance understanding (Stipek et al., 1998). In broad, the socio-constructivist perspective on learning (Op't Eyndne et al., 2006) underlines the interplay between cognitive, motivational and affective factors but also it highlights the influence of the specific classroom context in the whole process.

In this respect, the present study investigates variations in instructional practices and their impact on students' achievement motivation and outcome. Understanding the interplay between the characteristics of a particular instructional setting, and students' achievement-related goals and outcomes is an important direction for both motivational and mathematics education research (Anderman et al., 2002; Stipek et al., 1998). In the next section we consider the basic concepts and define the research questions.

THEORETICAL BACKGROUND AND AIMS

Motivation

Motivation cannot directly be observed but it can be noticeable only by its interaction with affect, cognition and behaviour. Hannula (2006) defines motivation as the preference to do certain things and to avoid doing some others. In regards to students' motivation four basic theories of social-cognitive constructs have so far been identified: achievement goal orientation, efficacy beliefs, personal interest in the task, and task value beliefs (Pintrich, 2003). In this study we conceptualise motivation

according to achievement goal theory because it has been developed within a social-cognitive framework and it has studied in depth many variables which are considered as antecedents of students' motivation constructs. Some of these variables are students' competence based variables, such as need of achievement or fear of failure, self-based variables, such as self efficacy beliefs, and demographic variables, e.g. gender (Elliot, 1999). In addition, one of the strengths of goal orientation theory in understanding students' motivation is that it explicitly considers the role of teachers and instructional contexts in shaping students' goal orientations. Thus a major tenet of goal theory is that students' adoption of personal goals is influenced even in part, by the goal structures promoted by the classroom and boarder school environments (Anderman et al., 2002).

Achievement goal theory is concerned with the purposes-goals students perceive for engaging in an achievement-related behaviour and the meaning they ascribe to that behaviour. A mastery goal orientation refers to one's will to gain understanding, or skill, whereby learning is valued as an end in itself. In contrast, a performance goal orientation refers to wanting to be seen as being able, whereby ability is demonstrated by outperforming others or by achieving success with little effort (Elliot & Church, 1997). Recently, there has been a theoretical and empirical differentiation between performance-approach goals, where students focus on how to outperform others, and performance-avoidance goals, where students aim to avoid looking inferior or incompetent in relation to others (Cury et al., 2006).

These goals have been related consistently to different patterns of achievement-related affect, cognition and behaviour. Being mastery focused has been related to adaptive perceptions including feelings of efficacy, achievement, and interest (Anderman et al., 2002; Elliot & Church, 1997; Cury et al., 2006). Although the research on performance goals is less consistent, this orientation has been associated with maladaptive achievements beliefs and behaviours like low achievement, fear of failure and superficial cognitive commitment, i.e. the use of 'surface' learning strategies such as copying, repeating and memorizing (e.g. Cury et al. 2006). Efficacy beliefs encountered as an antecedent variable in the achievement goal theory, refers to the beliefs in one's capabilities to organize and execute the courses of action required to manage prospective situations (Bandura, 1997).

Instructional practices

Environmental factors are presumed to play an important role in the goal adoption process and eventually in students' achievement (Anderman et al., 2002). Elliot & Church (1997) underline that if the achievement setting is strong enough it alone can establish situation-specific concerns that lead to goal preferences for the individual, either in the absence of a priori propensities or by overwhelming such propensities.

Earlier studies on achievement goals specify various classroom instructional practices as contributing to the development of different types of goals and consequently, eliciting different patterns of motivation and achievement outcomes (e.g. Ames,

1992). Goal orientation theorists relying on a large literature on classroom motivational environments focus on six categories that contribute to the classroom motivational environment. The categories, represented by the acronym TARGET refer to task, authority, recognition, grouping, evaluation and time. *Task* refers to specific activities, such as problem solving or routine algorithm, open or closed questions in which students are engaged in; *Authority* refers to students' level of autonomy in the classroom; *Recognition* refers to whether the teacher values the progress or the final outcome of students' performance and how the teacher treats students' mistakes (as a part of the learning process or as cause for punishment); *Grouping* refers to whether students work with different or similar ability peers; *Evaluation* refers to how the teacher treats assessment, giving publicly grades and test scores, or focusing on feedback as a means for improvement and mastery; *Time* refers to whether the schedule of the activities is rigid or flexible.

This framework has been adapted and developed by goal theory researchers working within classroom context (Anderman et al., 2002; Turner et al., 2002). Using classroom observations and qualitative analysis, they found that instructional practices in classrooms in where students adopted mastery goals differed from instructional practices in classroom characterized by students' low mastery goals or high performance goals. Specifically, according to the task variable, in mastery oriented classrooms teachers used an active instructional approach, ensuring that all students participated in classroom talk and adapted instruction to the developmental levels and personal interests of their students, while in low mastery oriented classrooms, learning was processed by students listening to information and following directions (Anderman et al., 2002; Turner et al., 2002). Regarding authority, in high mastery oriented classrooms teachers engaged the class in generating the rules, while in low mastery oriented classrooms the teachers presented their rules to the students (Anderman et al., 2002). In high mastery classrooms teachers emphasized the intrinsic value of learning, while recognition practices were characterized by warm praise, which was also task oriented, clear, consistent and credible (recognition). High levels of genuine enthusiasm, positive affect and enjoyment by these teachers with respect to engaging in academic tasks was also observed. In low mastery oriented classrooms teachers used punishment and threats with students who did not do what they were told (Anderman et al., 2002). In high mastery orientation classrooms students had considerable freedom within the classroom-e.g. talking to classmates (autonomy) and peer collaboration (grouping) (Anderman et al., 2002). Reversely, in high mastery classrooms teachers emphasized students' performance, relative performance and differential prestige (evaluation) while in low mastery classrooms teachers emphasized test scores and grades or students' differential performance on tasks (evaluation). Moreover teachers in high mastery classrooms valued the time during the lesson referring to time allocation for different activities (time) while students in the low mastery oriented classrooms were allowed to work on their paces (Anderman et al., 2002).

In mathematics education domain, Stipek et al. (1998) in a relevant study referring to instructional practices and their effect on learning and motivation found that affective climate was a powerful predictor of students' motivation and mastery orientation. Students in classrooms in which teachers emphasized effort, pressed students for understanding, treating students' misconception and in which autonomy was encouraged reported more positive emotions while doing math work and enjoying mathematics more than other students while they also scored higher in a fraction test. Teachers' provision of substantive feedback to students rather than scores on assignments was also associated with mastery orientation.

Despite the apparent utility of the list concerning the classroom practices both by achievement goal researchers and mathematics educators, very few studies have examined these practices in relation to students' perceptions of achievement goals and outcomes in the ecology of regular classroom. To the best of our knowledge none of these studies had employed multilevel statistical tools for the identification of teachers' practices that influence students' specific goals and vis-à-vis students' achievement. In this respect the purpose of this study was:

- To test the validity of the measures for the six factors: fear of failure, self-efficacy, interest, mastery goals, performance-approach goals and performance-avoidance goals, in a specific social context.
- To construct and test the validity of an observational protocol that includes convergent variables referring to instructional practices in the classroom from the mathematics education domain and the achievement motivation one.
- To identify instructional practices suggested by achievement motivation theory and mathematics education theory that affect students' motivation (mastery and performance goals) in the mathematics classroom applying multilevel analysis.

METHOD

Participants were 321 sixth grade students, 136 males and 185 females from 15 intact classes and their 15 teachers. All students-participants completed a questionnaire concerning their motivation in mathematics and a test for achievement in the mid of the second semester of the school year.

The motivation questionnaire comprised of six sub-scales measuring: a) mastery goals, b) performance goals, c) performance avoidance goals, d) self-efficacy, e) fear of failure, and f) interest. Specifically, the questionnaire comprised of 35 Likert-type 5-point items (1- strongly disagree, and 5 strongly agree). The five-item subscale measuring mastery goals, the five-item subscale measuring performance goals, the four-item subscale measuring performance-avoidance goals, as well as the five item subscale measuring efficacy beliefs were adopted from the Patterns of Adaptive Learning Scales (PALS) (Midgley et al., 2000); respective specimen items in each of these four subscales were, "one of my goals in mathematics is to learn as much as I can"

(Mastery goal), “one of my goals is to show other students that I’m good at mathematics” (Performance goal), “It’s important to me that I don’t look stupid in mathematics class” (Performance-avoidance goal), and “I’m certain I can master the skills taught in mathematics this year” (efficacy beliefs). Students’ fear of failure was assessed using nine items adopted from the Herman’s fear of failure scale (Elliot & Church, 1997); a specimen item was “I often avoid a task because I am afraid that I will make mistakes”. Finally, we used Elliot and Church (1997) seven-item scale to measure students’ interest in achievement tasks; a specimen item was, “I found mathematics interesting”. These 35 items were randomly spread through out the questionnaire, to avoid the formation of possible reaction patterns.

For students’ achievement we developed a test measuring students’ understanding of fractions. The tasks comprising the test were adopted from published research and specifically concerned students’ understanding of fraction as part of a whole, as measurement, equivalent fractions, fraction comparison and addition of fractions with common and non common denominators (Lamon, 1999).

For the analysis of teachers’ instructional practices we developed an observational protocol for the observation of teachers’ mathematics instruction in the 15 classes during two 40-minutes periods. The observational protocol was based on the convergence between instructional practices described by Achievement Goal Theory and the Mathematics education reform literature. Specifically, we developed a list of codes around six structures, based on previous literature (Ames, 1992; Anderman et al., 2002; Stipek et al., 1998), which were found to influence students’ motivation and achievement. These structures were: task, instructional aids, practices towards the task, affective sensitivity, messages to students, and recognition.

The structure *task* included algorithms, problem solving, teaching self-regulation strategies, open-ended questions, closed questions, constructing the new concept on an acquired one, generalizing and conjecturing. We checked whether teachers made use of instructional aids during their lesson. *Practices towards the task* included the teacher giving direct instructions to students, asking for justification, asking multiple ways for the solution of problems, pressing for understanding by asking questions, dealing with students’ misconceptions, or seeking only for the correct response, helping students and rewording the question posed. Behaviour referred to *affective sensitivity* included teachers’ possible anger, using sarcasm, being sensible to students, having high expectations for the students, teachers’ interest towards mathematics or fear for mathematics. *Messages to students* included learning as students’ active engagement, reference to the interest and value of the mathematics tasks, students’ mistakes being part of the learning process or being forbidden, and learning being receiving information and following directions. Finally, *recognition* referred to the reward for students’ achievement, effort, behavior and the use of external rewards by the teachers.

During the two classroom observations lasted for 40 minutes for each teacher, we identified the occurrence of each code in each structure.

RESULTS

Fig 1: The factor model of students' motivation with factor parameter estimates.

With respect to the first aim of the study, confirmatory factor analysis was conducted using EQS (Hu & Bentler, 1999) in order to examine whether the factor structure yields the six motivational constructs expected by the theory.

In the analysis for the identification of the six factors, we followed a process including the reduction of raw scores to a limited number of representative scores, an approach suggested by proponents of Structural Equation Modelling (Hu & Bentler, 1999). Particularly, some items were deleted because their loadings on factors were very low (e.g. for the factor interest the item i.3.18. and for the factor fear of failure the item f.5.28) and some other items were grouped together because they had high correlation with each other (e.g. for the factor fear of failure the items f.1.5 and f.3.17). From the

analysis the factor performance-avoidance goals failed to be confirmed.

Then in line with the motivation theory,

a five-factor model was tested (fig. 1). To assess the overall fit of the model we used maximum likelihood estimation method and three types of fit indices: the chi-square index, the comparative fit index (CFI), and the root mean square error of approximation (RMSEA). The chi square index provides an asymptotically valid significance test of model fit. The CFI estimates the relative fit of the target model in comparison to a baseline model where all of the variable in the model are uncorrelated (Hu & Bentler, 1999). The values of the CFI range from 0 to 1, with values greater than .95 indicating an acceptable model fit. Finally, the RMSEA is an index that takes the model complexity into account; an RMSEA of .05 or less is considered to be as acceptable fit (Hu & Bentler, 1999).

Items from each scale are hypothesized to load only on their respective latent variables. The fit of this model was ($\chi^2 = 691.104$, $df = 208$, $p < 0.000$; $CFI = 0.770$ and $RMSEA = 0.086$). After the addition of correlations among the five factors the measuring model has been improved ($\chi^2 = 343.487$, $df = 198$, $p < 0.000$; $CFI = 0.931$ and $RMSEA = 0.049$).

Concerning the second aim of the study, analysis of the observations involved estimating the mean score of each code for the two 40 minutes observations using the SPSS and creating a matrix display of all the frequencies of the coded data from each classroom. Each cell of data corresponded to a coding structure. From a first glance, the observational protocol succeeded in detecting differences in teachers' practises during the mathematics lessons. Notably, teachers 4, 9, 13, 15 used more algorithmic tasks than the others, while teachers 2, 4, 7 used more problem solving activities than their other colleagues. Open-ended questions were used more by teachers 3, 5 while teachers 8 and 14 used more the closed type of questions. Very few teachers made use of the visual aids (4, 7, and 8). From the category practices towards the task justification of students' answers were asked from almost all teachers except from teachers 2, 3, 10, 13. Press for understanding characterized teachers' 6 and 13 practices, while asking for multiple problem solutions was not popular to this sample of teachers. Teacher 5 was characterized by her willingness to help students. Regarding teachers' affective sensitivity, teacher 1 expressed anger while teacher 7 showed great sensitivity to students. Concerning the structure messages all teachers apart from teachers 1 and 15 treated students' erroneous responses as part of the learning process, while the other codes regarding this category were met rarely during these lessons. Regarding recognition, teachers 1 and 7 rewarded students for their performance.

According to the third aim of the study, the identification of instructional practices suggested by achievement motivation theory and mathematics education that affect students' mastery and performance goals, we applied Multilevel analysis using the program MLwin (Opdenakker & Van Damme, 2006). Multilevel analysis is a methodology for the analysis of data with complex patterns of variability, with a focus on nested sources of variability: e.g. students in classes, classes in schools, etc. The main statistical model of multilevel analysis is the hierarchical linear model, an extension of the multiple linear regression model to a model that includes nested random effects. Multilevel statistical models are always needed if a multi-stage sampling design has been employed (a sample of pupils and a sample of teachers) because the clustering of the data should be taken into consideration avoiding the drawing of wrong conclusions (Opdenakker & Van Damme, 2006). The simplest case of this model is the random effects analysis model (null model). The null model exhibits only random variation between groups and random variation within groups. (e.g. students and teachers). Estimating the variance at the distinguished level (e.g. students and teachers) it is possible to see which level is important for the estimation of the variance. For example if the estimation variance at student level (level one) is much higher than the estimation of the variance at the teacher level, then this means that differences between students with respect to the characteristics under study are largely related to individual students and not to the teachers. The null model can be expanded by the inclusion of explanatory variables. With the explanatory variables, we try to explain part of the variability of the dependent variable. It is possible to

explain variability at level one as well as in a next-step at level two (Opdenakker & Van Damme, 2006).

In our case a two level model was employed with students' performance or mastery goals as the depended variable and students' motivational constructs and teachers' practices as the exploratory variables. The first test in the analysis regarding variables that influence the development of mastery goals was to determine the variance at the student level and teachers' level without explanatory variables (null model 0). The variance at each level reached statistical significance ($p < 0.05$) and this implied that MLwiN could be used to identify the variables which were associated with achievement in each subject. Regarding mastery goals, student effect was much higher than teachers effect (91% and 9% respectively). Following the procedure we added in model 1 student demographic variables. Model 1 explained 2% of the total variance. From the three variables (education mother-father and gender) only gender had statistically significant effect on students' mastery goals. The variance was explained solely to student level (2%). Explicitly, female students demonstrated higher mastery goals than male students. In model 2 all affective variables according to achievement goals theory were added to the model. Specifically the antecedent variables fear of failure and efficacy beliefs were added to the model and also performance goals. Model 2 explained 26% of the total variance. The antecedent variables had a statistically significant effect to the model, with fear of failure to have negative effect, while performance goals did not have any effect. From the 26% of the total variance 23% was at the student level and 3% at the teacher level. In Model 3 we added teachers' educational background but it turned out not to have any statistical significant effect on students' mastery goals. Then we added to the model teachers' practices concerning the structure Task and again they did not have any statistical significant effect to the model. We continue adding the other categories of teachers' practices. The only one that had negative statistical significant effect on students' mastery goals was the absence of visual aids. Model 3 explained 2% of the total variance and this variance was explained exclusively to teacher level.

We followed the same process to identify variables that had significant effect on students' performance goals. We ended that from student level, fear of failure and self efficacy had statistically significant effect on students' performance goals while from teacher level the practice, "teacher rewords the question asked" had statistically significant effect to students' performance goals.

Next, we followed Stipek et al. (1998) process grouping instructional practices in each of the six categories regarding the observational protocol together with the ratio of open-ended questions to closed questions. The ratio related to the questions had statistically significant negative effect on students' performance goals.

Figure 2 presents the results of the multilevel analysis in identifying exploratory variables that affect students' mastery and performance goals in mathematics. Dotted arrows represent negative effect.

* $p < 0.05$, ** $p < 0.001$

Fig 2: Results of the Multilevel analysis on mastery and performance goals.

CONCLUSION

Regarding the first aim of the study, data revealed that factors referred to the five of the six motivational constructs were confirmed in the Cypriot environment. The factor regarding performance-avoidance goals failed to be confirmed in contrast to the results of other studies (Cury et al., 2006). This may be due to students' age-usually this factor is confirmed in elderly students or to the different cultural context.

Regarding the second aim of the study, the data revealed important differences in the instructional practices used in the mathematics classrooms in line with other studies (Anderman et al., 2002; Pantziara & Philippou, 2007; Stipek et al., 1998). However the need for in-depth analysis of these practices born due to the study's evidence that while in some classrooms teachers applied the practices suggested by motivation and mathematics education to foster students' motivation, students' motivation was high while their mathematics performance was poor.

As far as the third aim is concerned, taking into consideration the clustering of the data in the multi-stage sampling (sample of pupils and sample of teachers) we applied the multilevel analysis to identify variables that have statistically significant effect on students' achievement goals. The results revealed that more effect on students' motivation had students' variables (gender, fear of failure, efficacy beliefs) while only few of the numerous instructional practices suggested by other studies (Anderman et al., 2002; Stipek et al., 1998) found to have statistically significant effect on students' motivation. This may be due to the new analytical tools used considering the variance between the different level of the depended variables or to the small number of teachers involved in the study. Whatever the case is, further research is needed using multilevel analysis in domains regarding achievement goals and mathematics education for the identification of instructional practices that endorse motivation and achievement in mathematics.

THE EFFECTS OF CHANGES IN THE PERCEIVED CLASSROOM SOCIAL CULTURE ON MOTIVATION IN MATHEMATICS ACROSS TRANSITIONS

Athanasidou C. and Philippou G. N.

Department of Education, University of Cyprus

This study investigates the effects of changes in the perceived classroom social environment on students' motivation in mathematics across the transition from primary to secondary school and during the transition from one grade level to the next within the same school (elementary or secondary school). The comparisons of students who perceived an increase, decrease or no change in the classroom social environment across the transition to middle school indicated that students' who reported a decline in their classroom social dimensions also reported a decline in social aspects of motivation and an incline in negative self-esteem. Furthermore, the effect of the changes in the classroom social dimensions on motivation were found to be larger across the transition to middle school than across the transition within elementary school, whereas they were mirrored in the secondary school transition.

BACKGROUND AND AIMS OF STUDY

The period surrounding the transition from primary to secondary school has been found to result in a decline in students' motivation in mathematics (e.g. Athanasidou & Philippou, 2007, MacCallum, 1997). This decline was found to be related to certain dimensions of the school and classroom culture (e.g. Eccles et al., 1993, Urdañ & Midgley, 2003). It has been suggested that the two types of schools are very different organizations with respect to "ethos" as well as to practices and that this discrepancy influences students' motivation and performance. Most children move from a relatively small, more personalized and task-focused elementary school to a larger, more impersonal and performance-oriented middle school where they face differences in grading and teaching practices and expectations (Midgley et al, 1995).

The focus of the above studies has been on the academic aspect of motivation and of the school environment. However, students' social perceptions and goals were found to influence their motivation within a new school setting and thus are a significant part of motivation. The importance of attending to the social aspects of students' transition experiences in order to gain a fuller understanding of young adolescents' motivation in school was reinforced by the study of Anderman & Anderman (1999), in which students' social perceptions made significant, unique contributions to their achievement goal orientations. Furthermore, many longitudinal studies documented that the discontinuity in the social environment students' face across the transition to secondary school has an effect on motivation in mathematics (e.g. Eccles et al., 1993). Social discontinuities include changes in the diversity of the student population, relations with teachers and classmates and sense of school belonging.

In these studies middle school classrooms were characterized by less positive teacher-student relationships than elementary school classrooms (Midgley et al., 1995). The study of Eccles et al. (1993), revealed that the students who moved from the mathematics classroom of a high-support teacher (with respect to fairness and friendliness) to a classroom of a low-support teacher showed a decrease in their ratings of the intrinsic value and the perceived usefulness and importance of mathematics, whereas students who experienced a change from low-to-high-support teacher showed an increase in their ratings of intrinsic value. Furthermore, Anderman & Anderman (1999) found that the feeling of belonging in one's school and the endorsement of social responsibility goals were associated with an increased focus on academic tasks and predicted an increased task goal orientation, whereas endorsement of social goals for forming peer relationships and maintaining social status were associated with an increased focus on the self and predicted an increased ability goal orientation.

All the above longitudinal research shed some light on the nature of motivational change and the influence that social classroom and school environmental factors have on this process during the transition from primary to secondary school. These studies however examined motivational change for students as a whole group assuming and inferring that the transition affects all students the same way. This is not necessarily the case; recent research in the area of students' perceptions of their classroom environments supports the view that students perceive the same environment in variable ways at least on some of its dimensions (Urduan & Midgley, 2003). If there are differences in students' perceptions of their classroom environment across the transition which should really be expected, then it is possible that students perceive the transition differentially.

Despite the above theoretical considerations we are aware of only one study, by Urduan & Midgley (2003), which examined the effect of moving from a classroom perceived to emphasize a mastery goal in elementary school to a performance goal structure in secondary school (i.e. that the purpose of engaging in academic work is to develop competence or to demonstrate competence respectively). These researchers compared students who perceived an increase, decrease and no change in the mastery and performance goal structures of their classrooms during the transition to middle school and across two grades within middle school. The results of their study indicated that changes in the mastery goal structure were more strongly related to changes in cognition, affect and performance than were changes in the performance goal structure, whereas the most negative pattern of change was associated with a perceived decrease in the mastery goal structure of classrooms across the transition to middle school.

The aim of the present research is twofold. Firstly, to examine the effects of changes in the perceived classroom social environment on students' motivation in mathematics across the transition from primary to secondary school (grade 6 to 7). To

this end the classroom social environment was operationalized focusing on three dimensions: (a) teacher fairness and friendliness (**FAI/FRI**), (b) cooperation and interaction (**COOP/INTE**), and (c) competition (**COMPET**), whereas students' motivation was conceptualized involving social cognitive (orientations and goals) and affective dimensions (self-esteem). Secondly, to investigate whether the changes observed in students' perceptions of classroom social environment and the related motivation across the transition to middle school are mirrored across the transition from one grade level to the next within the same school context. More specifically, the research questions are formulated as follows:

- (1) What are the effects of the direction of change in the perceived classroom social environment on students' motivation in mathematics across the transition from primary to secondary school?
- (2) Are the changes observed in students' perceptions of the classroom social environment and the related changes in motivation across the transition from primary to secondary school mirrored across the transition from grade 5 to 6 in elementary school and across grade 7 to 8 in secondary school?

METHOD

Participants in this study were 331 students who were followed over a period of two consecutive school years. The students were divided in three Cohorts. The 220 students in Cohort T (CT) experienced the transition from primary to secondary school (grade 6 to 7); the 42 students in Cohort E (CE) were followed over the last two years of elementary school (grade 5 to 6), and the 69 students in Cohort S (CS) were followed over the first two years in secondary school (grade 7 to 8).

Data were collected through a self-report questionnaire in the spring semester of each school year, since by that time of the year students' motivation and their perceptions of the classroom social environment are well developed and established. The questionnaire was comprised of 42 items measuring four dimensions referring to students': (a) social motivational goals (students' social reasons for engaging in math work with 14 items tapping three specific motivational goals such as competition/social power, social concern and affiliation e.g. for affiliation "In mathematics I try to work with friends as much as possible"); (b) social motivational goal orientation (4 items tapping students' perceptions of how socially oriented they are e.g. "I am most motivated when I am showing concern for others in mathematics"); (c) self-esteem in mathematics (students' perceptions of their competence in doing mathematics with 8 items tapping two dimensions such as positive and negative self-esteem e.g. for negative self-esteem "I often make mistakes in mathematics"); and (d) classroom social dimensions (16 items measuring three dimensions referring to teacher fairness/friendliness, cooperation/interaction and competition e.g. for cooperation/interaction "We get to work with each other in small groups when we do math"). The items referring to the first three dimensions were

adapted from the Inventory of School Motivation Questionnaire (McInerney, Yeung & McInerney, 2000), whereas the items for the latter were adapted from the Student Classroom Environment Measure (Eccles et al., 1993). All statements were presented at a five-point Likert-type format (1=Strongly Disagree, 5=Strongly Agree). The reliability estimates were found to be quite high for all the scales ranging from $\alpha=.69$ to $\alpha=.88$.

Data processing was carried out using the SPSS software. The statistical procedure used in this study was Repeated Measures ANCOVA. Change group (CG-3 levels) was the independent, between-groups factor and time of measurement (TM-2 levels) was the within-groups repeated measures component. For all the analyses, gender was included as a covariate to control for any differences by gender.

In order to provide answers to the two research questions, three groups of students for each of the classroom environment variables were created. To create the three groups, students' classroom environment scores were firstly standardized. Next, the change score was calculated by subtracting students' scores on the first measurement from the respective scores on the second measurement, in each classroom dimension. The change scores for each dimension were then divided into three groups: (i) increase; (ii) no change; and (iii) decrease in classroom environment variable. The groups were created by using .50 standard deviations as the cut-off such that students in the "increase" groups scored at least half a standard deviation above the mean change score, those in the "decrease" groups scored at least half a standard deviation below the average change score, and those in the "no change" groups were within .50 standard deviations either above or below the mean change score. Half standard deviation was selected as the cut-off point to make sure that the groups created would be different from one another and yet maintain a large number of participants in order to allow comparisons across groups.

RESULTS

To answer the first research question, CT students' responses were analysed using Repeated Measures ANCOVAs. Table 1 presents the means, standard deviations and the F ratios for the Change Group x Time of Measurement interactions (CG x TM) for each of the three social dimensions change groups on each of the dependent variables. The alphabetical superscript "a" within each classroom social dimension change group indicates that the means in grades 6 and 7 are significantly different from one another. Similar numeric superscripts indicate non significant differences between group means on variables measured in 7th grade using univariate post hoc tests. The .05 level of significance was adopted for these comparisons.

The analyses indicated that the CG x TM effect was significant for social goal orientation, social concern and affiliation goals and negative self esteem for the **FAI/FRI** and the **COOP/INTE** change groups. Examining the results from the 6th to 7th grade transition, it appears that the most negative pattern of change in motivation

was associated with a perceived decline in **FAI/FRI** and **COOP/INTE** classroom social dimensions. Specifically, the tests of simple effects within groups indicated that students' social goal orientation, social concern and affiliation goals were significantly lower in 7th grade than in 6th grade within the group that perceived a decrease in **FAI/FRI** and in **COOP/INTE** across the transition to middle school. No significant differences were found between the 6th and 7th grade means for either the perceived "no change" or "increase" groups. The opposite pattern was observed for negative self-esteem, i.e., students' mean ratings were significantly higher in 7th grade than in 6th grade within the group that perceived a decrease in **FAI/FRI** and in **COOP/INTE** across the transition. The univariate post hoc tests of 7th grade means revealed that the mean ratings of students in the **FAI/FRI** and in the **COOP/INTE** "decrease" change groups on social goal orientation, social concern and affiliation goals were significantly lower than the mean ratings of students in the "no change" or "increase" groups, whereas their negative self-esteem was significantly higher. Also, the analysis of TM effect revealed a significant decline from 6th to 7th grade in social goal orientation ($F=3.341$, $p<0.05$), social concern ($F=8.656$, $p<0.01$) and affiliation goals ($F=2.946$, $p<0.05$) and a significant incline in negative self-esteem ($F=3.038$, $p<0.05$). Since no statistically significant differences were found between the means of students in the **FAI/FRI** and in the **COOP/INTE** "no change" or "increase" groups from primary to secondary school for social orientation, goals and negative self-esteem, these declines in orientation and goals and the incline in negative self-esteem were not evident for students who perceived no change or an increase in both the above classroom social dimensions.

The ANCOVA analyses for **COMPET** change groups indicated that the CG x TM effect was significant for social goal orientation, competition/social power, social concern and affiliation goals and negative self-esteem. The largest differences were associated with a perceived incline in **COMPET** classroom social dimension. Specifically, the tests of simple effects within groups indicated that students' social goal orientation, social concern and affiliation goals were significantly lower in 7th grade than in 6th grade within the group that perceived an increase in **COMPET** classroom environment across the transition from primary to secondary school. In both the perceived "no change" and "decrease" groups there weren't any significant differences between the 6th and 7th grade means. For competition/social power goal and negative self-esteem the opposite pattern was observed since students' mean ratings were significantly higher in 7th grade than in 6th grade within the group that perceived an incline in **COMPET** environment across the transition. The univariate post hoc analyses of 7th grade means revealed that the mean ratings of students in the **COMPET** "increase" change group on social goal orientation, social concern and affiliation goals were significantly lower than the mean ratings of students in the "no change" or "decrease" groups, whereas their competition/social power goal and negative self-esteem were significantly higher. Also, the analysis of TM effect revealed a significant decline in social goal orientation ($F=3.427$, $p<0.05$), social

concern ($F=9.507$, $p<0.01$) and affiliation goals ($F=3.105$, $p<0.05$) from 6th to 7th grade and a significant incline in competition/social power goal ($F=9.144$, $p<0.01$) and negative self-esteem ($F=3.247$, $p<0.05$). Since there were no statistically significant differences between the means of students in the **COMPET** “no change” or “decrease” groups from primary to secondary school for social orientation, competition/social power, social concern and affiliation goals and negative self-esteem, these declines in orientation and goals and the incline in competition/social power goal and negative self-esteem were not evident for students who perceived no change or a decrease in the **COMPET** classroom social environment.

Table 1: Means, Standard Deviations and Summary of Repeated Measures ANCOVAs on motivational variables by changes in classroom social dimensions

* $p<0.001$ ** $p<0.01$ *** $p<0.05$

To answer the second research question, the same set of analyses were conducted as students moved from 5th to 6th grade in elementary school (CE) and from 7th to 8th grade in secondary school (CS). Table 2 presents the means and the F interaction (CG x TM) for all the classroom social dimension change groups for students in CE and CS. Standard deviations are not presented due to space limits.

Regarding the comparability of results involving the direction of changes in classroom social dimensions between the elementary to secondary school transition (grade 6 to 7) and the elementary school transition (grade 5 to 6), the patterns of results involving all the classroom social dimensions change groups across the

transition from primary to secondary school were not replicated during the elementary school transition. There were no significant interactions for **COMPET** change groups, whereas for **FAI/FRI** and **COOP/INTE** only one significant interaction was observed involving social goal orientation with students' perceptions across the transition within elementary school changing the same way as the perceptions of students across the transition from primary to secondary school.

Table 2: Means and Summary of Repeated Measures ANCOVAs on motivational variables by changes in classroom social dimensions for students in CE and CS

***p<0.001 **p<0.01 ***p<0.05**

On the contrary, the patterns of changes in classroom social dimensions change groups for students across the transition from primary to secondary school were mirrored for students across the transition within secondary school, with some notable exceptions. Firstly, social goal orientation increased significantly from 7th to 8th grade among those students who perceived an increase in **FAI/FRI** and **COOP/INTE** classroom social environment but decreased significantly for those students who perceived a decrease in **FAI/FRI** and **COOP/INTE** social environment over time. A similar pattern was observed for the analysis regarding social concern and affiliation goals as the dependent variable for the **COOP/INTE** social dimension. In addition, the comparison of the differences found across the transition to secondary school (6th to 7th grade) with those found during middle school (7th to 8th grade) among the **COMPET** social dimension change groups revealed similar directions of change for social orientation, social concern and affiliation goals and negative self-esteem. However, a significant difference over time was found for the competition/social power goal. The students who moved from 6th to 7th grade and perceived an increase in the **COMPET** social dimension of their classroom reported endorsing competition/social power goals significantly more, whereas students in the no change or decrease groups did not change significantly in their adoption of competition/social power goal. But when students moved from 7th to 8th grade, the endorsement of competition/social power goal decreased significantly among those students who perceived a decrease in the **COMPET** social environment over time.

DISCUSSION

The results of the study suggest that when students make the transition to middle level schools they are likely to move into classrooms that are characterized by less teacher-student relations, less cooperation and interaction whereas competitiveness is emphasized. Despite those general trends, there are students who perceive no difference in their classroom social environment before and after the transition and other students who perceive an increase in their classroom social orientation. Recent studies have contributed to our understanding of what occurs within classrooms, but nothing is known about the effects of moving from one classroom social environment to another. Thus, while it has been documented that the classroom social environment changes after the transition from primary to secondary school, it remains unclear what effects these differences might have on students' motivation in mathematics. The present study shed some light on these issues.

More specifically, the results of the study revealed that students who reported a decline in their classroom social environment across the transition to middle school also reported a decline in the social aspects of their motivation and an increase in negative self-esteem. Also, it was found that among students who reported an increase in the social environment of their classrooms after the transition, the general negative pattern of change in motivation was not evident. These results suggest that whereas a perceived increase in classroom social dimensions has advantages, the

disadvantages associated with a perceived decrease in the classroom social environment are even stronger. Perhaps social messages in the classroom are more evident to students when they are first removed than when they are perceived to be added. In other words, students may not notice the presence of social dimensions in the classroom as much as they notice their absence. This may be particularly true when students move from what has been described as the more nurturing elementary school environment to the more impersonal middle school classroom environment (Anderman & Anderman, 1999).

The changes in motivation associated with changes in the perceived classroom social dimensions were found to be larger during the transition to middle school than they were during the last two years in primary school. This finding is pretty logical taking into consideration the fact that the classroom environment in elementary school is almost the same across grades. On the contrary, the effect of changes in the perceived classroom social environment and changes in motivation that were found across the transition to middle school were replicated within the first two years of middle school. Therefore, the stress of moving to middle level schools does not enlarge the size of the effects of changes in the perceived classroom social dimensions on motivation, despite the fact that previous research has documented that the transition to middle level school can be a stressful time in students' lives (e.g. Eccles et al., 1993).

Although the size of the changes in motivation associated with changes in the perceived classroom social environment were quite similar across the transition to middle school and within the first two years in middle school, there were some interesting differences in the direction of the changes and in which change groups the largest differences were found. The changes in the means were largest among students in the decrease groups for **FAI/FRI** and **COOP/INTE** dimensions from 6th to 7th grade. For students in the 7th to 8th transition the differences within these groups remained whereas differences in the **FAI/FRI** and **COOP/INTE** increase groups were found since students' who perceived an increase in the above social dimensions reported higher social orientation and goals and lower negative self-esteem. It also appears that the pattern of change among the **COMPET** social dimension change groups differed across the two time periods of the study. For example, the **COMPET** increase group reported a decrease in motivation from 6th to 7th grade, whereas when students made the transition from one grade to the next within middle school the **COMPET** decrease group reported an increase in their motivation.

These shifting patterns of results are evident due to the fact that the transition to middle school influences the salience of the presence or absence of social messages in the classroom (Anderman & Anderman, 1999). When moving from a smaller and perhaps more social oriented elementary school environment to a middle school environment, students may be particularly aware of decreases in the emphasis on social orientations and goals in the classroom, creating stronger effects on motivation among those students who perceive a decrease in the classroom social environment.

Once familiar and comfortable with the middle school environment, however, increases in the classroom social environment become as salient as decreases and the effects of these two types of change become more even.

The findings of the present study highlight the effects of changes in the classroom social environment on students' motivation in mathematics during the transition from one school context to another or from one grade level to the next within the same context. Therefore, longitudinal studies examining these issues can assist in unravelling the complexity of motivational change across transitions. Such studies should examine different aspects of motivation (academic, social and affective) and various dimensions of the classroom or school environment. This multidimensional perspective is very important in order to understand not only the effects of what is more prevalent in classrooms but in determining what the most facilitative environments are, even if they are uncommon, in order to test the effects of these environments on the nature of change in students' motivation in mathematics. Such information will be useful for teachers, educators and policy makers in their planning to make systemic transitions easier so fewer students are lost.

“AFTER I DO MORE EXERCISE, I WON'T FEEL SCARED ANYMORE” – EXAMPLES OF PERSONAL MEANING FROM HONG KONG

Maike Vollstedt

University of Hamburg, Germany

What kind of meaning do students relate with mathematics education? To answer this question, the concept of personal meaning is developed and integrated in an interplay with context and culture. Personal meaning hereby denotes the personal relevance students relate with a certain action or object. Finally, the concept is illustrated with an example of personal meaning constructed by a 15-year-old student from Hong Kong. Along this example, the relation of personal meaning and (learning) culture is disclosed.

INTRODUCTION

The demand for meaning in the context of mathematics education and education in general has been noted for many years. Hurrelmann stated in the early 1980ies that students are in the need of meaning when dealing with learning contents at school (Hurrelmann, 1983). But what exactly is understood by the term *meaning* when thinking about school education? Do educators and students denote the same concept when using the term? To be more precise: What kinds of meaning are there? And which meaning do students see when dealing with mathematics in school context? To shed some light on the obscurity of this realm, this paper starts with briefly presenting different understandings of *meaning* before the focus is put on the perspective of the students. Then, the concept of *personal meaning* is related to the notions of context and culture. The discussion shows in what way personal experiences and perspectives are important for the student to construct meaning. Finally, examples of personal meaning constructed by a 15-year-old Hong Kong student are presented to illustrate the concept and to show its relations to the (learning) culture the student has been socialised in.

FROM MEANING TO PERSONAL MEANING

Meaning: A blurred concept

A review of the relevant literature shows that very different understandings of *meaning* are used. The notion may refer for instance to the act of leading the schema of an unconscious sensori-motor or mental activity to consciousness (Thom, 1973), to the development of a certain mathematical concept over time (Bartolini-Bussi, 2005), or to the collectively shared understanding and application of mathematical concepts (Biehler, 2005). These kinds of meaning deal primarily with mathematical concepts and develop a theory about its referents.

On the other hand, meaning can also be understood as a condition for students to engage in the action of learning (Alrø, Skovsmose & Valero, 2007), i.e. as an integrated aspect of acting (Lange, 2007) and the educational situation (Skovsmose, 2005), or as the personal relevance an object or action has for a certain student (Vollstedt, 2007). These interpretations move the focus from the meaning of concepts to the meaning of action, i.e. the educational process and the perspective of the students. The term *meaning* is therefore used here in a personal sense (Kilpatrick, Hoyles & Skovsmose, 2005).

Quite important differences between the understandings of *meaning* as described in the last two paragraphs can be detected. Howson therefore points out that

one must distinguish between two different aspects of meaning, namely, those relating to relevance and personal significance (e.g., ‘What is the point of this for me?’) and those referring to the objective sense intended (i.e., signification and referents). (Howson, 2005, p. 18)

To sharpen the terminology used, I will use the more specific terms *personal meaning* when denoting the personal relevance of an object or action for a certain person, and *objective* or *collective meaning* when denoting a collectively shared meaning of an object or action (Vollstedt, 2007; Vollstedt & Vorhölter, 2008 [1]).

Characteristics of personal meaning and its construction

As described in Vollstedt (2007), some assumptions can be made concerning personal meaning. It is characterized by the following traits:

- Personal meaning is subjective and individual. This means that every person constructs his/her own meaning with respect to a certain object or action. As the construction of meaning is not collective but individual, different students who attend the same lesson can also construct different meanings relating to the same object or action.
- The construction of personal meaning is also context bound. Here, context denotes on the one hand the subject context as well as the situation in the classroom. On the other hand, it also embraces the personal context of the students (see below).
- Personal meanings can be reflected on but normally do not have to. This means that the process of the construction of personal meaning can in some parts be dominant in the situation so that one is aware of it (e.g. in an Aha-experience); the meaning enters consciousness. On the other hand, meaning may remain latent and can be constructed implicitly.

The student's perspective

Bearing in mind that there are different understandings of meaning in relation with mathematics education, one has to decide which perspective to put the focus on: collective or personal meaning? This means one has to ask whether mathematical concepts or the students are in the centre of attention.

My dissertation project reported on in this paper (see below) evolves from the context of the Graduate Research Group of Educational Experience and Learner Development located at the University of Hamburg. In this research group we investigate processes of learning and *Bildung* from the learner's perspective. Special attention is paid to the individually experienced tensions resulting from societal or institutional demands on the one hand, and the learner's individual responses being rooted in his/her biography on the other hand. On the one hand, special emphasis is put on the way how students acquire knowledge and skills. On the other hand, research is done about how they develop the ability to come to decisions and to act responsibly in an increasingly complex and difficult world (Graduiertenkolleg Bildungsgangforschung, 2006).

Due to the connection to the field of Educational Experience and Learner Development, the focus of my study lies clearly on the learner's perspective. The study seeks to find out what kinds of personal meanings students construct in the context of mathematics education. Like Lange I therefore want to “look *with* children” (Lange, 2007, p. 271) instead of looking at them.

Personal meaning, context, and culture

Personal meaning cannot be constructed in a vacuum but is related to context. Context is here used as a cover term for both, situational context (i.e. context of the learning situation in terms of topic as well as classroom situation) and personal context. The personal context of a student then may consist of his/her personal traits (i.e. aspects which concern the student's self like his/her self-concept, motivation, or beliefs) and his/her personal background (i.e. aspects which concern the world around the student like his/her socio-economic status, migration background, or surrounding (learning) culture) (Vollstedt & Vorhölter, 2008).

Mercer describes context from the student's perspective in the following way:

What counts as context for learners [...] is *whatever they consider relevant*. Pupils accomplish educational activities by using what they know to make sense of what they are asked to do. As best they can, they create a meaningful context for an activity, and the context they create consists of whatever knowledge they invoke to make sense of the task situation. (Mercer, 1993, pp. 31–32, italics in original)

Therefore the student decides which information and experiences are relevant for him/her to deal with the given task. I interpret Mercer's description in a broad way as not only knowledge but also for instance beliefs, goals or other kinds of personal traits or background may be relevant for the student in a learning situation. These are, however, object to cultural influence as culture has a strong impact on the way how learning takes place in any learning situation (Leung et al., 2006).

This understanding goes along with Mercer, who states that learning in the classroom depends both on culture and context as learning is,

(a) culturally saturated in both its content and structure; and (b) accomplished through dialogue which is heavily dependent on an implicit context constructed by participants from current and past shared experience. (Mercer, 1993, p. 43).

When we take for instance the East Asian and the Western traditions, both, culture and context of a learning situation are very different as they are based on Chinese/Confucian and Greek/Latin/Christian traditions respectively (Leung, 2001). In how far culture also has an impact on the construction of personal meaning will be shown in the following section with the help of an example from Hong Kong.

PERSONAL MEANING CONSTRUCTED BY A HONG KONG STUDENT

To illustrate the concept of personal meaning, I will present some findings from a qualitative study which seeks to find out similarities and differences between the personal meanings constructed by students in two different learning cultures, namely Germany and Hong Kong. I will restrict myself here to Hong Kong data and results.

The study

In total, the study is based on 33 interviews with 15- and 16-year-old students in Germany (form 9 and 10) and Hong Kong (Secondary 2 and 3) [2]. In Germany I interviewed 16 students attending a grammar school; the 17 Hong Kong students attended band one EMI-schools (schools with the highest academic standards and English as medium of instruction [3]). The interviews began with a phase of stimulated recall (Gass & Mackey, 2000) based on a video-sequence of five to ten minutes from the last mathematics lesson the interviewee attended. The student was asked to utter and reflect on his/her thoughts he/she had when having attended the lesson. This was followed by a guided interview about various topics like the student's beliefs about and attitudes towards mathematics (lessons), his/her connotations of mathematics (lessons), or the feelings he/she associates with mathematics (lessons), i.e. personal traits. Aspects of personal background were not explicitly asked for [4]. In average, the interviews lasted for about 35 to 45 minutes. In the style of grounded theory (Strauss & Corbin, 1996), the theory of personal meaning was refined and deepened in the process of data evaluation. Data evaluation itself was a coding process following grounded theory with the aim to construct different types of personal meaning evolving from the data. These types are then reflected on from a cultural perspective.

Personal meanings constructed in the context of mathematics education in Hong Kong

Emma, a 15-year-old girl from Hong Kong, attends a highly selective band one school in which the classes are divided into academic achievement. She is a member of class *Secondary 3C*, which is the class of the top 40 students of her year. Although she attends this class, she explains that she has difficulties with mathematics and shows a low mathematical self-concept (Marsh, 1986). This low self-perceived ability in mathematics, being part of her personal traits (i.e. personal context), is an impor-

tant precondition for the personal meaning she constructs in relation with learning of mathematics at school. The following extract from the interview ([5]) may help to illustrate this point:

- 99 Interviewer: First of all, what comes to your mind when you hear the word *mathematics*?
- 100 Emma: First, at the beginning I feel, I'm afraid of mathematics. Because it is difficult for me to think. Think is the main problem for me. When I saw the mathematics sentence questions, I will feel scared. I think I don't understand, whether I understand that question or not, so that I feel scared. But after I do more exercise, I won't feel scared anymore and I feel I am safe.
- 101 Interviewer: So is it because of the language, the problem is given in or is it because it's something unknown, or do you know why you are scared?
- 102 Emma: I think it's not the language problem. I think is my problem because I think very slow. So I'm afraid I can't catch up with the other classmates.
- 103 Interviewer: But you are in C class and C class is the best, isn't it?
- 104 Emma: It is very difficult for me to go into this class because there is many pressure. There are many students are get high marks. So, there will be against students and students. So I need to study hard.

We can see that Emma comes to her low mathematics self-concept by means of internal and external references (Marsh, 1986). On the one hand she negates that her difficulties in mathematics are due to the fact that the mathematical problems and lessons are given in English (101-102), which is not her first language. The internal comparison of her self-perceived verbal ability with her self-perceived mathematics ability (Marsh, 1986) make her come to this conclusion. She also, on the other hand, compares her abilities in mathematics with those of her classmates (102, 104), i.e. significant others in her frame of reference (Marsh, 1986). Due to the selective process, there are lots of very good students in her class so that it is not astonishing that Emma experiences high pressure when she compares her own achievement with the ones of her classmates. Especially as she mentions that there is quite some competition going on between the students (104).

The reason Emma gives for her difficulties with mathematics is that she has problems to think fast enough (100, 102). Therefore she stresses that actively doing mathematics can help “train us our mind and the logic” (66). Also, practice can help her to overcome her difficulties (100) as well as meet the pressure experienced between the students (104). She also refers to this point in another sequence of the interview in which she explains the importance of good grades with relation to the pressure caused by the *Hong Kong Certificate of Education Examination* (HKCEE):

- 198 Interviewer: How important is it for you to achieve the mark you want to achieve in quizzes, or tests, or examinations, or whatever?

- 199 Emma: Do more exercise. And when you see the questions, you should not feel afraid of them. Just like homework or worksheets, not a quiz or exams. So that we can relax and we won't feel more pressure.
- 200 Interviewer: Is it important for you to get good marks?
- 201 Emma: Yes, because we need to study in form four. And when we study in form five, there is Hong Kong CEE. It is very important because if we got a pass in a Hong Kong CEE we can study in form six and form seven. And if we are not pass in a Hong Kong CEE, maybe we can't study in form six, form seven and so that at that time maybe we need to find a job. But it is very difficult to find a job with form five level because many companies needs a person who got a university level. So the competition is very big.

Emma describes how practice can help to overcome anxiety and pressure as quizzes and exams may lose their threatening power when having done enough exercises beforehand (199). Therefore she is of the opinion that “it is not enough for us to do the school work. We should do more, so we find more practice exercise” (230). Her aim is to “remember all the steps” (230) necessary to solve a question. As a consequence she can relax and does not feel more pressure (199). On the other hand, she explains that the results of the HKCEE are so important for Hong Kong students as their future depends on them (201). This means that Emma reflects here on her future opportunities or foreground (Skovsmose, 2005).

To meet this high pressure and competition, the warm and friendly atmosphere that relates her with the teacher is very important for her:

- 203 Interviewer: Which feelings do you relate with mathematics lessons?
- 204 Emma: Happy.
- 205 Interviewer: Why?
- 206 Emma: Because teacher is our friend and a friend teaches us things and it will be easy to remember a friend's words. So that we will more easily to understand mathematics and the explanation. So I think Ms. Wong's teaching method is good for us.

Describing her teacher as “friend” (206) shows Emma's strong need for relatedness (Ryan & Deci, 2004) with the teacher and its importance for her learning (206). This positive relation is the cause that Emma relates a happy feeling with mathematics lessons (204) in spite of great pressure and competition.

Taken together we can describe Emma as a girl with low mathematical self-concept who suffers from the high pressure experienced in her learning environment. Therefore she fears mathematics and examinations, especially the HKCEE. The situational context as well as personal traits are therefore highly influential for the personal meanings Emma constructs. The *positive atmosphere in the classroom* (resulting from the good relation with the teacher) *opposes high pressure*. In addition, *studying hard is soothing preparation for important exams* for Emma and works against her low mathematical self-concept.

Discussion from a cultural perspective

Emma's personal context as described in the last section can be explained with reference to the culture she was socialised in, i.e. the Chinese (a Confucian Heritage Culture (CHC) (Wong, 2004)). Leung shows that the CHC does have influence on how mathematics is taught in schools because “there exist distinctive features of mathematics education in East Asia and [...] those features are expressions of distinctive underlying cultural values” (Leung, 2001, p. 48). He identifies six features of mathematics education in East Asia and contrasts them with features in Western countries. To provoke discussion, he formulates these features in the form of the following six dichotomies (East Asia vs. West): product (content) vs. process; rote learning vs. meaningful learning; studying hard vs. pleasurable learning; extrinsic vs. intrinsic motivations; whole class teaching vs. individualised learning; and concerning the competence of teachers: subject matter vs. pedagogy (Leung, 2001). Leung, however, stresses the point that

[i]t does not mean that all East Asian societies are on one side of the dichotomies and all Western countries are on the other side. Very often, it is a matter of the relative positions of the two cultures on a continuum between two extremes rather than two incompatible standpoints. (Leung, 2001, p. 38)

Emma is certainly not the only student with a low mathematical self-concept who studies hard and practices as much as possible to pass the HKCEE. This behaviour is, as far as I can judge from observation and data evaluation, somehow typical for Hong Kong students. It seems to be culturally determined and can be related to the three features of East Asian mathematics education that refer to students' behaviour, namely rote learning, studying hard, and extrinsic motivation.

Emma's attitude to practice as many tasks as possible can be explained by the Chinese belief that practice makes perfect (Li, 2006). It is closely linked with the feature of rote learning which Leung describes to be rooted in the East Asian view on the nature of mathematics learning. In East Asia, rote learning or memorization are not negatively connoted but, on the contrary, accepted and necessary steps of learning (Leung, 2001). Also, memorization and understanding are not necessarily separated (as a Western view might presume) but may be intertwined to lead to higher quality outcomes (Dahlin & Watkins, 2000).

Closely linked to the belief that practice makes perfect is the belief that studying hard is necessary to gain deep knowledge of the subject. This belief comes from the East Asian view that learning is necessarily accompanied by hard work (Leung, 2001). How deeply rooted this belief is in China can be deduced from the Chinese characters denoting education: 教育. They consist of different parts which mean 'young people' (lower left part of the first character), 'hard burden' (upper part of the first character), and 'development' (second character). So taken together the characters of 'education' confer the idea that “young people grow and develop under the condition in which

they make every endeavor to tackle tough tasks” (Li, 2006, p. 131). Therefore, diligence and effort are needed to come to a deep level of pleasure and satisfaction as the outcome of study.

Finally, Emma studies hard to prepare herself for the HKCEE, which she has to sit in 2.5 years. Although the HKCEE is still fairly far in her future, it has already quite some power over Emma. This power comes, due to the large population, on the one hand from the serious competition between students for university admission. There is, however, also a historical argument of the big importance of exams in China or Hong Kong respectively. Throughout history, education has been a way for social advancement insofar as examinations had to be taken to be selected for important officer positions (Li, 2006). In addition, examinations are a warrantable source of motivation in the East Asian understanding. As Leung points out, “East Asians believe that, being human, we need some 'push' in our learning” (Leung, 2001, p. 43). Therefore, an optimal level of pressure is helpful to direct students' energy and attention to study and to learn.

From this illustration we can see that culture has an impact on the context of the individual in different ways: culture shapes the identity of mathematics education (see Leung (2001)) and with it the learning situation, and cultural beliefs seem to determine the individual's actions and beliefs about learning.

CONCLUSION

The discussion of personal meaning has shown in what way the personal context is important for constructing personal meaning in the context of mathematics education. It is of special importance that personal meaning may be explained with reference to culture (the Confucian Heritage Culture in Emma's case). Her personal meaning (practising mathematics soothes and prepares for important exams) could be related to the CHC on three levels. Some of her personal traits (being diligent) as well as some of the actions she carries out in line with her personal meaning (working hard, practising as much as possible) seem to be rooted in cultural beliefs which are part of the CHC culture. So – as culture seemingly does matter for the construction of personal meaning – it is at near hand to support Leung, Graf & Lopez-Real, who assume that “the impact of cultural tradition is highly relevant to mathematics learning” (Leung et al., 2006).

NOTES

1. The German term for *personal meaning* we use in our research is *Sinnkonstruktion*. *Objective* or *collective meaning* on the other hand are equivalents of *Bedeutung*.
2. In Hong Kong, compulsory schooling starts with primary school, which lasts for 6 years (*Primary 1* to *Primary 6*). Subsequently students attend up to 7 years of secondary school. After *Secondary 5*, the *Hong Kong Certificate of Education Examination* (HKCEE; similar to GCSE in the United Kingdom) has to be sit.

3. Secondary schools in Hong Kong are divided in band one to three. This division is based on the achievement of their students in the HKCEE. After finishing primary school, Hong Kong students are divided into different groups according to their achievement in relation to the standing of their school. Only high-achieving students are allowed to attend a band one school after primary school.
4. All students come from rather privileged and well-educated background. This can be argued by the kind of school they attend (private band one school/grammar school). For other aspects it was assumed that interviewees would give the information voluntarily or could be asked about it.
5. The transcripts of the interviews are simplified in language in the way that stuttering and break-ups are left out; grammatical mistakes are not corrected but left unchanged. As Emma is very fluent in English, it was not necessary to mark hesitation etc. in the quoted sequences.

EMOTIONAL KNOWLEDGE OF MATHEMATICS TEACHERS – RETROSPECTIVE PERSPECTIVES OF TWO CASE STUDIES

Ilana Lavy

Atara Shriki

Emek Yezreel Academic College Oranim Academic College of Education

Abstract

In this paper we provide a partial description of certain facets and experiences that are central to the development of emotional knowledge from the retrospective perspectives of two highly experienced mathematics teachers in middle and high school. One of the study participants refers to the emotional knowledge she developed over the years regarding her interactions with her students, while the second participant also refers to the emotional knowledge she developed regarding her interaction with the school principal. Both indicate the differences in their emotional reactions between the first practice years and the years after. The differences are seen primarily in the type and in the intensity of their emotions. While negative feelings mostly accompanied the first years, later years were accompanied by more positive emotions.

1. Introduction

Teaching and emotions are inseparable. Emotions are dynamic parts of ourselves, and whether they are positive or negative, all organizations, including schools, are full of them (Hargreaves, 1998). In his literature review, Zembylas (2007) asserts that although "teacher knowledge" has become a major area of exploration in educational research, limited attention is given to the emotional aspects of teaching. While Shulman's (1987) work on pedagogical content knowledge (PCK) was further investigated and discussed by many researchers, teachers' understandings of emotional aspects of teaching and learning continued to be ignored. Zembylas argues that "any effort to expand current conceptions of PCK should include the connection between PCK and *emotional knowledge* (EK) in general – that is, a teacher's knowledge about/from his or her emotional experiences with respect to one's self, others (e.g. students, colleagues), and the wider social and political context in which teaching and learning takes place" (p. 356). Furthermore, Zembylas continues, in order to teach well, "teachers must be able to connect their emotional understanding with what they know about subject matter, pedagogy, school discourses, personal histories, and curriculum" (p. 364). In this paper we provide a partial description from a study we conducted that focused on themes identified by teachers as central to their

development of EK. We present two case-studies of mathematics teachers, each of whom has more than 30 years of teaching experience.

2. Theoretical background

In the process of determining mathematics teachers' qualifications, teacher educators focus on various types of knowledge identified as essential for good teaching: content knowledge, didactical knowledge, knowledge about students, and knowledge of class management (Shulman, 1987; Shulman, 2000). Often these types of knowledge are discussed, separately on the assumption that teachers are capable of integrating them into a coherent whole. However, issues concerning emotional aspects of teaching and their interrelations with the above knowledge types, are rarely discussed in mathematics teachers' training programs.

Planes and types of EK. Zembylas (2007) finds a reciprocal relationship between PCK and EK, and argues that the latter "occurs on different *planes* as there are different *types* of EK that are aspects of PCK" (p. 358). These planes are: individual, relational, and socio-political. The individual plane refers to how teachers experience and express their EK on the personal plane; the relational plane refers to how teachers use EK in their relationships with students; and the socio-political plane refers to EK of the institutional and cultural context of schooling and its influence on teachers' curricular decisions and actions. There is no hierarchical order between the three planes. Their boundaries are blurred, and mutual influence and interaction exist between them.

Positive vs. negative emotions. Smeltzer (2004) studied the emotions of beginning teachers, and discerned positive and negative emotions according to their characteristics and forcefulness, as they appeared in the teachers' reactions. The categories of positive emotions include: joy-happiness, fulfillment-reward-satisfaction, competence-confidence-motivation, and surprise-fun. The categories of negative emotions include: frustration-anger, incompetence-anxiety-fear-doubt, exhaustion-stress, and disappointment-discouragement-sadness. Smeltzer also found that the most dominant and intense category of emotion is frustration-anger. It comes as a result of the turmoil beginning teachers, experience as defeat, distress, or displeasure. The incompetence-anxiety-fear-doubt category represents low self-efficacy, expressed by feelings of inadequacy, uneasiness, apprehension, worry, hesitancy, or uncertainty. The exhaustion-stress category characterizes weariness, fatigue, and energy loss. The disappointment-discouragement-sadness category refers to the most desperate and desolate of emotions such as unfulfilled expectations, sorrow, low spirits, disheartenment, and dashed hopes.

The categories of positive emotion were found to be of less frequency and intensity. The joy-happiness category represents the delight, pleasure, and contentment experienced in the early years of teaching. The fulfillment-reward-satisfaction category extends the joy-happiness category, representing a deeper and more intense degree of gratification. The competence-confidence-motivation

category signifies teacher self-efficacy identified by assurance, certainty, and proficiency. The least dominant and intense of all the emotional classifications is the surprise-fun category that refers to unanticipated and spontaneous experiences in teaching. In the present study the research participants recounted various emotions that can be generally grouped into positive and negative headings. Moreover, these emotions can also be further categorized according to Smeltzer's types which were previously mentioned.

3. The study

Our study focuses on experienced mathematics teachers, each of whom who has more than 30 years of teaching experience. The aims of our study are to characterize: (i) facets and experiences that are central to the development of EK from retrospective perspectives; (ii) interrelations between EK and PCK; and (iii) the evolvement of teachers' EK during their years of practice from retrospective perspectives. In this paper we provide a partial description of the results from the first part of our study. We also present certain facets and experiences of the emotional component of teaching that are central to the development of EK, as shown in these two case-studies.

3.1 The study participants

Twelve mathematics teachers with more than 30 years of teaching experience each were interviewed. In this paper we will briefly present the narratives of only two of them: Betty (56) and Rose (55), both who teach mathematics in middle-high school. We chose to make use of their stories because more than the other participants, Betty and Rose were able to identify the "causes and effects" that impacted their emotions and the development of their EK. In section 4 we present excerpts from their actual narratives.

3.2 Method

Data collection. We asked the twelve teachers to tell us their stories, with deliberate attention given to emotional aspects of teaching and EK. The interviews were open. We asked the teachers several general questions (for example – why they chose to become teachers), and following their narratives we asked for further clarification. We were careful not to direct them, or to interfere in their associative train of thought. The interviews were tape-recorded. Each interview lasted between 3 to 4 hours and took place in an informal setting, such as the teacher's home or Cafeteria.

Data analysis. Scanning the transcripts of the recorded interviews, we first picked out all the excerpts which included expressions of emotion. Then we differentiated between various types of emotion according to the addressee of the emotional reaction, namely: emotional reactions towards students, the school principal or other colleagues.

Being aware of the small size of our sample, we cannot say that the data collected represents the general emotional profile of the teachers in our country.

However, it does shed light on some important aspects of the teaching experience that should be considered.

4. Results and discussion

In this section we make use of the narratives of Betty and Rose to characterize some of the important facets and experiences that emerged in relation to EK development. In the scope of this paper we focus merely on EK with respect to students and school principal.

Betty's story

Betty is 56 years old and has more than 29 years of teaching experience. Betty was born and raised in Lebanon. She remembers her classmates "standing tensely and quietly in their places until the teacher entered the class and gave us permission to sit down. All the students behaved politely and respected the teachers, and there were no disciplinary problems...When I came to Israel I knew it was a different country with a different culture but I could not anticipate the extreme differences."

Betty immigrated to Israel when she was 16 years old. When she was 18, she began to study computer science. After graduation she worked as a computer programmer for two years in a large commercial company, and then was offered a position as a mathematics teacher in a middle-high school. She accepted the offer. Betty chose to begin her story as a mathematics teacher with a description of her first lesson in the school:

"Although it happened many years ago I remember it as if it were yesterday. This was my first day at school and I had to teach mathematics in one of the 11th grade classes. I opened the door and I was shocked. All the students were half-sitting, half-lying on the tables and no one even bothered to turn his/her head toward me when I entered the classroom. I felt discouraged. I asked the students to sit properly so that we could start the lesson and they said: "This is how we behave!" I felt hopeless and speechless but after a few seconds I said: "If you do not follow my request, I will leave the classroom." One of the boys went to the door lay down on the floor and said: "Over my dead body!" The rest of the students laughed. I was very close to tears and felt very frustrated and hopeless. But I knew that if I showed any sign of weakness I would not be able to teach this class again. So with my remaining bit of strength I insisted that they follow my instructions which eventually they did. I must admit that from time to time I ask myself what I would have done had they had kept misbehaving..."

Unfortunately, I had to face similar situations several times during my first two years of teaching. I felt like the students were testing me, looking to see how consistent my behavior was...However the second time is never like the first. The first time you confront a certain situation which was not anticipated, the emotional effect is very powerful since it is accompanied by a sense of helplessness. The first time it happens to you, you do not know how to respond,

you feel a lack of proper communication skills, and your self-esteem plunges. However, when you face a similar situation again, knowing that you have already survived such an experience, your emotional reaction (ER) is less intense. You feel like you already know how to handle the situation successfully."

Betty claims that although the first years were difficult she chose not to quit her job: "I had many moments when I asked myself why keep on suffering? However, emotionally, I could not afford to give up. It was actually like admitting that I was not capable of handling a class. I could not bear this thought...It was my pride [smiling] that prevented me from quitting."

Betty's description of her first lesson is full of negative emotional expressions: shock, disrespect, hopelessness, and frustration. These emotions resulted in a sense of "being pushed to the corner," which affected her ER and her decision to use the threat of leaving the classroom against the students. After the students laughed, her emotions intensified to such an extent that Betty was close to tears. The fact that Betty chose to open her story with this lively and unpleasant memory demonstrates how powerful these emotional impressions were. Betty, however, quickly regained her composure and repressed her negative emotions. She chose to use an alternative ER, and then insisted that the students follow her instructions. Although this alternative reaction was successful, the pestering thought of "what would have happened if..." occupied her thoughts for years. It appears as if some sort of "emotional sequence" in Betty's mind remained unsolved.

According to Betty, ERs decrease in their intensity due to the building of EK. The second time she had to face such an episode in the teaching environment, she already knew what to do and how to react. Emotions can either paralyze one's actions or serve as a starting point for learning how to transform them into an actual response. This is the meaning of building EK. In Betty's case, EK that was translated into communication skills with students and knowledge about classroom management. In the ensuing years Betty asserts that she continued to suffer from negative emotional experiences and reactions within the classroom. Building her EK actually sustained her through the inner emotional struggle of whether to give up and thus lose her pride or whether to learn to confront her emotions and regulate and navigate her way through them. Gradually Betty built her self-image as a teacher:

"During the first few years of my teaching I remember that my students kept asking me personal questions. I believe this was their way to get to know me and to adjust their behavior to my expectations. At the beginning I was flattered and I cooperated with them. But then I realized that they interpreted this cooperative behavior of mine to mean I was their friend. When I had to be authoritative they were confused. So I realized that I had to operate differently - to be nice to them not as a friend but as a teacher. In fact, my image as a mathematics teacher was built during that period... I believe that after the first two years at the school my image as a mathematics teacher was solidified and the students conveyed that information about me to new incoming students."

Learning to reflect on her EK also enabled Betty to establish her image as well as her status as an appreciated teacher. Although she was tempted to cooperate with the students and to provide them with personal information, she chose to remain nice to them, but not too friendly. We might say that these were Betty's first steps in developing emotional understanding (Denzin, 1984). Betty concluded her story:

"The main difference between my functioning as a beginning and as an experienced teacher is that as a beginning teacher the types of knowledge I had were disconnected, isolated. I had no idea how to integrate my content knowledge, pedagogical knowledge, and EK. Moreover, I wasn't even aware of the fact that such integration was essential to my success as a teacher. I believe that my reflections on the complexity of class management and student-teacher relations was most dominant in developing my EK and in developing my ability to synthesize these types of knowledge. Only after I was able to balance between these types of knowledge did the intensity of my ERs significantly decrease, no longer being the dominant aspect of my teaching."

Betty's reflection on her evolution as a teacher focuses on the importance of merging academic content, pedagogical, and emotional knowledge. In the beginning her deficiencies in EK created a situation according to which her emotions governed and directed her actions, and they were highly intense. With time, her ability to regulate her emotions, reflect on them to generate EK, minimized their intensity and dominance, and enabled her to recognize EK as equally important as other types of knowledge. It was, however, only after she realized that all types of knowledge were interconnected that she felt she became a good teacher.

Rose's story

Rose is 55 and she has 32 years of teaching experience. Rose's parents were both teachers. Her father was a mathematics teacher. Rose claims that "since I was a child I knew I would never be a teacher. I saw my parents working very hard and I didn't want to be like them." When she was 18 she started studying statistics at the university. She recalls: "I hated every moment there. The teachers were bad. We were more than 100 students in a class, and the teachers didn't know us personally. I was shy, and in such a large class I was embarrassed to ask questions or provide answers." By the end of the year, after failing most exams, she started to wonder whether she had chosen the right profession. Before the beginning of the school year her father suggested that she work as a substitute teacher in his school until the beginning of the university's academic year. She accepted the suggestion "just to save some money." However, "the moment I entered the class I knew – this is what I wanted to do! It was something about the chemistry with the students." Rose left the university and started to study in a small college, where she graduated as a mathematics and physics teacher: "I loved the college. There were no more than 10 prospective teachers in a class, and our teachers knew each of us personally. They encouraged me to ask questions and listened to what I had to say." After her graduation she started to teach mathematics in a middle-high school:

"I was young and naïve, and at the beginning I didn't realize that I was sent to teach classes no other teacher wanted. There were many disciplinary problems, but it didn't bother me. The other teachers didn't understand how I managed to survive these students...When I reflected on my experience at the university and the college, I realized that the alienated attitude at the university as opposed to the close and warm relations between the teachers and students in the college had a tremendous influence on my ability to persist in my studies. So I guessed that if I treated each student warmly and personally, not as a problematic person but as an individual, I would be able to see beyond my immediate emotional difficulties that might stem from disciplinary problems. And it worked... I knew that many students hated mathematics and found it very difficult. It was very important for me to reduce their fears. I knew this was one of the keys to my success as a teacher... Nothing however prepared me for the struggle with the school management. I never realized why the principal of the school was hostile. He didn't speak nicely to me and didn't support me as a new teacher. I tried very hard not to let this affect my work with the students. For me, closing the door of the classroom was like entering an airplane and landing in a different country... As I said, I was naïve and I had nothing to do with intrigues. By the end of the year the principal told me that he didn't want me to teach high-school classes anymore, only middle-school classes. He didn't explain why. He said that because I didn't teach the high level classes he didn't consider me important for the school. I felt insulted and humiliated, and although I loved the students I couldn't bear this humiliation and decided to leave this school."

Rose left the school with "hard feelings. My self-esteem was harmed, and I was confused. I didn't realize what had been disrupted." She found a job in another school, but the supervisor of the former school pleaded to return. She acceded to his request on the condition that she continue to teach her students. Rose feels that "I returned to that school as a winner. I gained back my self-esteem. However, the principal couldn't accept the fact that he was forced to have me back against his will. Emotionally, it was very hard to arrive to school every day. I had no idea how to confront him." Three years later her father told her that there was a vacant position in his school and she "went back to where it all started." This new school was highly selective in those days, and she started to work with "totally different students."

From Rose's story it appears that she had a high emotional self-awareness when she started to teach. Reflecting on her emotional experiences as an undergraduate student, she realized that personal and attentive relations with students are essential for developing their readiness to learn. The fact that by the time she started to teach she had already gained some relevant EK helped her handle successfully problematic disciplinary situations, and not to consider them threatening. In fact, we might say that even if there were any conflicts with the students, Rose put them aside since she was emotionally more occupied by an unexpected front – the bad attitude of the school principal. As a new teacher in school she expected to receive supportive

attention from the school management in general and from the school principal in particular. The principal's attitude hurt her feelings and gave rise to feelings of humiliation and insult in her. Her lack of EK regarding relations with management prevented her from confronting her emotions and coping successfully with the situation she encountered. Rose was not able to resolve the situation, and therefore, with her damaged self-esteem, she chose to leave the school. Trying to recover her self-esteem Rose agreed to return to the school, but during the following three years she did not manage to further develop her EK with respect to teacher-management relations, and she decided to leave the school again, this time forever.

As regards to her relationships with students, Rose believes that she had "a breakthrough when my daughter entered middle-school":

"It happened fourteen years ago, and I realized that my approach to the students was too academic. I didn't really know their emotional world. I understood that when they were angry or in bad mood it wasn't because they wanted to struggle with me, but merely because they were teenagers with emotional distresses. I became more curious about their emotional lives. I wasn't angry when they didn't do their homework. I talked to them personally and tried to be more attentive to their emotions... I tried to develop awareness about what might insult them, to recognize those with whom I could be cynical with, those who needed my encouragement, and those who needed my embrace. I stopped punishing them, because I didn't want to insult them... This emotional approach turned out to be beneficial for them as well as for me. I started to enjoy teaching more... to emphasize values and emotions, and to treat them as equal partners... As I said before, many students are afraid of mathematics, and I became more sensitive to this emotion, and I kept looking for various didactical approaches to help them overcome their anxiety."

Rose's further development of her EK as a teacher occurred when she started to develop her EK with respect to her own daughter. From her, Rose became aware of the reasons that underlie her students' anger and dispositions and started to be more involved in their emotional lives. Her new EK directed her towards developing personal emotional relationships with the students on the basis of each student's personality. Although she was already aware of their fear of mathematics, it was only after she established her EK that she was able to successfully integrate her EK and her didactical knowledge as well as her knowledge about the curriculum.

Five years ago the principal of the school retired, and a new principal started to administrate Rose's school: "This principal is bad for school. Since his first day at school he gathered around him 'yes-men' and formed cliques...I refused to join the 'right' clique and, like other teachers in my condition, I have to deal with his harassment. However, unlike my first school, I don't let it ruin me emotionally. I believe I have learned how to control my emotions, to neutralize them when necessary. I don't take it personally. He has his own personal problems, and I can't be responsible for that."

Rose's last excerpt shows that throughout the years she developed her EK regarding teacher-management relationships. When she had to face hostile behavior for the second time, she was already prepared and her ER towards the situation was not as intense as it had been the first time.

5. Conclusions

Teaching is an emotional practice and the use of emotions can be helpful or harmful (Hargreaves, 2000). Thus there is a need to learn about teachers' EK in order to be able to redirect it in desirable directions.

EK is about developing emotional understanding. The last term is constituted from two words which come from totally different areas. *Emotional* refers to activities ruled by instincts and intuition, while *understanding* refers to activities ruled by logic and cognition. The combination of these two terms implies the need to control and lead the emotions by cognitive means, such as understanding. Moreover, while didactical and content knowledge can be acquired in teacher training programs, EK is dynamically built as a result of human interaction. Moreover, EK is subjective and varies from one person to another. Both Betty and Rose describe EK as a knowledge base that is gradually built and which comes as a result of human interaction. When Betty and Rose made their initial steps as teachers, they were well equipped with didactical and curricular knowledge. Their preliminary EK however was influenced by their previous experiences as learners: in Betty's case – her experience as a pupil in school and in Rose's case – her experience as an undergraduate. Both Betty and Rose refer to EK concerning their interaction with students while Rose refers in addition to EK concerning her interaction with the school's principal. Considering Zembylas' (2007) distinction between the three planes of EK, although Betty and Rose refer to the individual, relational and socio-political planes of emotion, in our paper we relate merely to personal relationships. EK that relates to inter-personal relationships develops as a result of what teachers encounter during their professional lives. Namely, when facing crises in teacher-student or teacher-management relationships, coping with the situation produces an ER which in turn produces a practical reaction that can affect the situation itself. Considering Betty's and Rose's narratives, it appears that ERs differ in their intensity and focal points. The intensity is heavily dependent on the rate of familiarity with the focal point, the teacher's personality, social-cultural background, and more.

That the interviews represent retrospective perspectives of events the teachers experienced many years ago, strengthens the feeling that after all these years they served as milestones in building their EK. It is harder to reflect on ER than on cognitive processes since the first action might involve the exposure of weaknesses and difficulties. It is therefore worthwhile to consider Betty's suggestion to create a kind of support group which can help teachers safely make it through the hard start is unusual, since people often tend to avoid the exposition of their feelings in public.

Both interviewees managed to develop a certain level of ability to reflect on their emotions during their teaching practice. This ability enabled them to develop their emotional understanding regarding their relations with students, the school principal, and other colleagues.

In most professions people face new situations, experience frustration and helplessness, joy and satisfaction, and difficult individuals, among other challenges. The inability to reflect on circumstances and ER, to grow and develop into the profession, can lead one to experience negative feelings such as frustration. These feelings, although essential to the process of growth and development, have a tremendous influence on other aspects of one's personal life (Yaffe-Yanai, 2000). It is therefore important that teachers be able to reflect on their experiences, design and develop their EK, and learn to integrate the different types of knowledge they possess. It would be interesting to listen to the stories of teachers who chose to quit teaching in various phases of their professional lives, and compare their EK to those who persisted.

Our focus is on middle- and high-school mathematics teachers. It is reasonable to assume that elementary school teachers have different stories. It would be also interesting to examine the differences between lower-elementary and upper-elementary school teachers to learn how the students' age influences teachers developing EK.

HUMOUR AS MEANS TO MAKE MATHEMATICS ENJOYABLE

Pavel Shmakov & Markku S. Hannula

University of Helsinki & University of Turku, Finland

The traditional educational system is constructed in such a manner that it excludes humour as a unique live process for promoting knowledge and understanding. Informational communications is the basis of logical thinking instead of vivid dialogue that has an informative purpose. Present work represents an intermediate stage of research of influence of CheCha math method. In particular, humour as the affective factor in mathematical reflection is being considered. With the use this method, the positive emotions that result can influence how teaching material is perceived, can facilitate creation of joyful atmosphere in the classroom, and can help maintain creative state of mind in students.

Key words: problem solving, emotions, humour, classroom climate, motivation

INTRODUCTION

"...the comic thought, which with contradiction, and is strengthened by imagination, is capable of delivering pleasure by training and induces the pupil to participate in dialogue... Game and laughter are higher expressions of living and rejoicing of life" (Muñiz, 1996).

Anyone who has paid attention to great speakers would know that humour is an excellent method for eliciting sympathy from the audience and opening them up to your message. Every teacher also knows that a sense of humour is necessary to winning the hearts of students. Research has established that one's affective state has an effect on cognitive processes (see e.g. Hannula, 2006). How should this inform teaching? Should the teachers focus on creating an entertaining show for their students? Or would the teachers change their lessons into therapy sessions?

This study presents a teaching approach that is built around math problems that are for the student at the same time **Cheerful** (entertaining, funny, cool) and **Challenging** (difficult). We call this CheCha mathematics.

THEORETICAL FRAMEWORK

CheCha math method is based on three educational approaches: acknowledging the role of affect in math learning (Hannula, 2006), using humour in teaching (Grecu, 2008) and use of open-ended problems in math teaching (Pehkonen, 2004).

Affect in mathematical thinking and learning

In order to study affect in math education in contexts of actual classrooms there are three main elements to pay attention to: cognition, emotion, and motivation. Achievement without motivation is not sustainable, and neither is motivation without

enjoyment. All three domains have a more rapidly changing state-aspect and more stable trait-aspect. (Hannula, 2006)

One "fundamental principle of human behavior is that emotions energize and organize perception, thinking and action" (Izard, 1991). Research has confirmed a positive relationship between positive affect and achievement. It seems that the affective outcomes are most important during the first school years, as they are less likely to be altered later on. Two key elements of a desired affective disposition are self-confidence and motivation to learn (Hannula, 2006).

Advances in our understanding of the neuropsychological basis of affect (e.g. Damasio 1995, LeDoux, 1998) have radically changed the old view of the relationship between emotion and cognition. Emotions are no longer seen as peripheral to cognitive processes or as 'noise' to impede rationality. Emotions have been accepted as necessary for rational behaviour. Moreover, research has also shown – although not yet fully understood – that certain emotions facilitate certain type of cognitive processing (Linnenbrink & Pintrich, 2004).

Focusing on motivation we may find ways to influence what the subjects want to do, not only how they try to achieve it. In the existing literature, psychological needs that are often emphasized in educational settings are autonomy, competence and social belonging (e.g. Boekaerts, 1999). These all can be met in a classroom that emphasises exploration, understanding and communication instead of rules, routines and rote learning. However, this requires that all feel safe and perceive that they can contribute to the process. A possible approach to meet all these conditions would be the open approach, and more generally focusing on mathematical processes rather than products (Hannula, 2006).

Humour

Already Kant (1952) considered the nature of humour. He stated "Laughter is the result of expectation which suddenly ends in nothing" (p. 199). His classical statement has started considering humour as a mental mechanism resulting in laughter. As another early scientific approach to humour, Freud (1991) divided comic into wit, humour and actually comic. Many kinds of activity, including wit, are directed on reception of pleasure from intellectual processes. A person feels pleasure from suddenly released energy, which is splashed out in the form of laughter. From this perspective already, we can perceive how a good joke can generate a joyful atmosphere and create a positive emotional background of activity.

The comic, humorous contents can be reached in various ways and techniques. For example, Veatch (1998) suggests a list of types that are funny: finishing to the point of irrationality, satire, literal understanding of metaphors, irony, ambiguity, word-play, contradiction, discrepancy, excessive rationality and a deviation from the usual.

Each of these types of the comic can be expressed as a joke or a problem in math context. As an example of a math contradiction we take a joke, here framed within the world of Winnie the Pooh:

Pooh and Piglet sit on a small bench and talk. Eeyore has sent them a box. In the box there are ten sweets and a note. In the note Eeyore tells them to divide them: seven for Pooh and seven for Piglet. Piglet: "How is that? I do not understand. What do you think of it?" Pooh: "I do not even want to think. But I have already eaten my seven sweets".

Humour can also act as means of a psychological discharge, and promote efficiency of pedagogical activity. Suhomlinsky (1975) wrote:

I would name laughter as a back side of thinking. To develop ability to laugh in the child, to enhance his sense of humour - means to strengthen his intellectual forces, abilities, to teach him to think and to see the world wisely.

Greco (2008) has considered use of humour in teaching. She highlights seven basic functions of humour in pedagogical activity:

- 1) informatively-cognitive (Opens essential features and properties of subjects and the phenomena. Rejecting standard approaches, the humour bears in itself any discovery),
- 2) emotional (the Humour can act as means of creation of creative state of health and as means of emotional support)
- 3) motivational (The humour can serve as a stimulator of volitional processes)
- 4) communicative (the Person with humour is attractive for people)
- 5) developing (Humour promotes development of critical thinking, a sharpness of vision of the world, observation and consequently intellect)
- 6) diagnostic (by the laughter maintenance - at what the person laughs, it is possible to judge about his merits and demerits) and
- 7) regulative (the humour gives the chance to look at oneself from an unexpected angle, allowing self-evaluation).

In CheCha method most of these are relevant, the most important functions being on top of the list. Greco suggest the following techniques for designing of humour for educational tasks. These pedagogical techniques are paradox, finishing to the point of irrationality, comparison by the remote or casual attribute, return comparison, wit of absurd, pseudo-contrast or false opposition, a hint, a self-exposure of own faults, intentional ignoring of things that might cause laughter, and exaggeration of the certain features of behaviour.

Greco has offered also classification of means of the comic: 1) "word-play" based on violation of language norm (carrying of terminology over to a context unusual to it). Consider the following riddle: "*I am it while I do not know that I am. But I am not it when I know that I am. What am I?*" 2) Comparison, author's original neologisms, - based on artistic expressive means (double entendre, an ambiguity). Examples are

easy for finding in Carroll's books (2006, s. 50): “*Explain yourself!*” “*I can't explain myself.*” 3) Paradox, an example being the claim “*I am lying now*”.

Also Dzemidok (1993) distinguishes several humoristic methods: modification and deformation of the phenomena, unexpected effects and amazing comparisons, disproportion in attitudes and communications between the phenomena, imaginary association of absolutely diverse phenomena, creation of the phenomena which deviate from logic. As an example of the latter method consider the following:

There were only 3 students attending a professor's lecture in University. Suddenly 5 persons left the room. The professor said: "If 2 students enter this room, there is nobody attending."

Most types of humour and their techniques could be used at mathematics lessons. Thanks to entertaining tasks and comical contents of the problems the classroom climate promotes a positive interaction between the teacher and students. However, one must be aware that opportunities of humour as pedagogical means have their limits. Grecu (2008) gives several suggestions regarding these limits. She suggests that one should use humour gently and support humour of students. She also warns not to ridicule student's person, laugh at what the student is not able to correct or change or laugh at an involuntary mistake of the student. Rough joking would indicate lack of customs and disrespect of the student and hence is absolutely unacceptable for the teacher. Moreover, the teacher should avoid being the first to laugh at one's own joke, as it can cause the reaction opposite to expected.

Problem solving and open-ended problems

Problems are said to be open, if their starting or goal situation is not exactly given and they usually have several correct answers (cf. Pehkonen 2008). Open-ended problems emphasize understanding and creativity (e.g. Nohda, 2000, Stacey 1995). This would not mean lowering the expectations, quite the contrary. If an open task allows the solver to gain deeper and deeper insights (a "chain of discovery"; Liljedahl, 2005) it can facilitate a state of sustained engagement. This would also lead to more intensive working.

Research has shown that problem solving can be engaging and enjoyable for many students, but it does not attract everyone. Schoenfeld (1985) defined an individual's beliefs or "mathematical world view" as shaping how one engages in problem solving. For example, those who believe that math is no more than repetition of learned routines would be more likely to give up on a novel task than those who believe that inventing is an essential aspect of maths. Unfortunately, there are students who do not see the potential for engagement and enjoyment in a math problem. We see humour as a means to engage also those students who do not perceive math problems enjoyable to begin with.

THE FEATURES OF CHECHA MATH

This research is more about creating tools for teaching than about analysing the reality of classrooms. The work has been started based on the first author's pedagogical intuition as a teacher and his will to engage students with math. This research falls within didactical engineering (Artigue, 1994) or design research paradigm (Cobb, Confrey, diSessa, Lehrer, & Schauble 2003) and it has a clear practitioner approach: "How can the teacher use humour to engage students' interest in math?" Previous experience in teaching had shown that information, when presented in humoristic form, is more convincing and is more easily acquired. This approach has developed gradually over a few years into a teaching approach that assumes:

- * in the same assignment entertainment is combined with a set of difficulty levels;
- * during problem solving there are conditions for emotions to rise;
- * all students can participate actively in solving the assignment regardless of their abilities.

The educational space is constructed in such a manner that teamwork of the teacher and students accepts dialogue character and interest in mathematics is favored. While using CheCha method, we separate the following basic constructs: a) *entertainment in learning process*, b) *level of the problem's difficulty*, c) *plurality of problem solutions*. We refer to as *entertainment in learning process* the affective components which excite the interest, draw attention and/or create a joyful atmosphere. For example, as entertainment we assume appeal, extraordinary content, intriguing title and/or amusing formulations. *Level of the problem's difficulty* we define as the variable degree of solution's complexity, beginning from the "obvious", achievable for many children, proceeding to a more complicated. It is important that the simplest way not always guides to the right solution. *Plurality of problem solutions* is a construct that consists of variety of means and ways of solving problem on the same level of abstractness, understanding and complexity. Various approaches are possible in one problem and it is supposed to have both a set of ways of solving and sets of different solutions as a whole. For example, to create a problematic math situation such parameters, as incomplete condition, the overloaded contents, or introduction of "not existing in reality" factors are used.

RESEARCH METHODS

In this paper, we shall describe the method of creating mathematical assignments (CheCha problems) and evaluate the practice of CheCha math teaching. We explore

1. What mathematical problems are entertaining from the students' point of view?
2. How CheCha method influences the atmosphere in mathematics lessons?

The construction of CheCha problems

The technique of construction of such problems consists of certain stages. At the initial stage there is a search of "matrix" of a condition or its author's creation. Useful sources to find problems that can be developed into CheCha problems have been math jokes, E. Lear's (e.g., 2002) and L. Carroll's (e.g., 2006) books, collections of problems from math Olympiads. Chessboard has also been a good setting for such problems. The original problem is typically open or can be modified into an open problem, meaning that it has no unique and final solution.

The next principle is to consider age-typical interests of students, their specific personalities and personal preferences. Substantial richness of a context of a problem is carried out at a following stage. There is a transformation into a context that bears in it entertainment, extraordinary and comic flavour or lively situations. At the same time, level of difficulty and plurality of the solutions is considered, allowing a wide range of different levels of solutions and approaches.

Then the problem is introduced to students and there is the opportunity for feedback, which is stirring up cognitive activity through questions, solutions and discussions. The teacher observes and reflects upon students' thinking during problem solving, focussing on: the perception of a problem by students (acceptance or non-acceptance); questions asked by them (depth and breadth); a degree of understanding of the context. These help the teacher to find direction for task's development.

It is important to notice that for every area of math teaching and learning one can find or construct such CheCha problems. This may lead to creation of a new problem, or changing of the task. For example: *“Three tortoises go one after another along the road. The tortoise says, “Two tortoises follow my rear”. The second says, “One tortoise goes ahead”, “One goes back of me”. The third says, “Two are ahead”, “One creeps behind”. How can this be?”* One should note that this problem is more attractive than something about moving material points along a straight line, with particular coordinates. The most common answer here is that it is impossible. But, in fact, there can be the solutions. *“Three tortoises go...”*: the words of the third tortoise contradict each other. The solution might be that the last tortoise is lying! ...One tortoise is riding on another. ...There is a time lapse between the phrases, allowing one tortoise to run ahead. ...The fourth tortoise stays near or behind the last turtle, and begins moving after the first phrase of the third turtle... The road is circular... The road is triangular... There is a mirror behind the last turtle. When it looks at its back, it can see one more turtle. Progressing from considered examples, and, instead of tortoise, we turn to another object, e.g., cows. One more possible solution is the birth of a calf!

Using CheCha problems in teaching and feedback from students

Research was carried out in two Finnish schools (Espoo 2007-08 and Helsinki 2008-09), in 7th classes with different level of acquaintance with CheCha math method and various educational atmospheres. The first author was teaching in these schools.

1. In December, 2007 the first author surveyed students' preferences of entertaining features in maths. The questionnaire consisted of five questions of open and closed types, e.g. *"What in a math problem can be entertaining?"* Two questions were multiple choice questions concerning the respondents' view of entertaining maths. Respondents were 40 students from two seventh classes and one eighth class.

2. In February, 2008 a second questionnaire was given in the same school (Espoo) to the students, where they were asked *which kind of problems they preferred*. In this survey 40 seventh graders from the same three classes responded.

3. In September, 2008 another questionnaire was administered in a school in Helsinki. The data were collected in two 7th grade classes (40 students) within the first month of employment of first author as the teacher in this school. Students were asked to fill in a questionnaire and draw a picture of a topic "Me at a math lesson".

a. In the first class (19 respondents) there was a favourable educational atmosphere and teacher-student relations were built at dialogue level. The atmosphere was promoted by playing Chess, Go, Katamino and other intellectual games. This was a basis for the future introduction of the CheCha method.

b. A comparison group (for the same survey) was a seventh grade class (21 respondents) of another teacher, in which CheCha method was not applied.

RESULTS

1. When responding what can be entertaining in maths, the frequency of choices were humour (55 %), "something else" (27 %), "cutting and drawing" (25 %), "unusual names and properties" (13 %), "plurality of answers" (13 %), and "fabulousness of a plot" (10 %). Altogether 88 % of students mentioned reasons why maths can be entertaining, and 5 % of children had written "nothing" in their specification of what the 'something else' could be.

2. The students' task preferences has shown, that tasks of comic character were most popular (51 %), then were the tasks that could be solved using Lego or Chessboard (33 %), cutting and drawing (30 %), a fantastic plot (15 %) and unusual names and properties (12 %), (Figure 1).

3. a. In this second sample the preferences were slightly different (Figure 1). This time the most popular choice was cutting and drawing (58 %), then the comical character (47 %), the tasks solved with the help Lego and Chess of (26 %), further a fantastic plot (21 %) and unusual names and properties (11 %).

The results of this survey have shown that 74 % of the respondents mention reasons why mathematics can be entertaining. Half of the students mention chess, and 29 % the personality of the teacher as the defining factor.

In the drawing task, 63 % have drawn a joyful image of a math lesson, 11 % of respondents drew themselves thinking or pondering, 15 % represented subjects of maths presented in a positive light (e.g. a notebook with the tasks solved correctly).

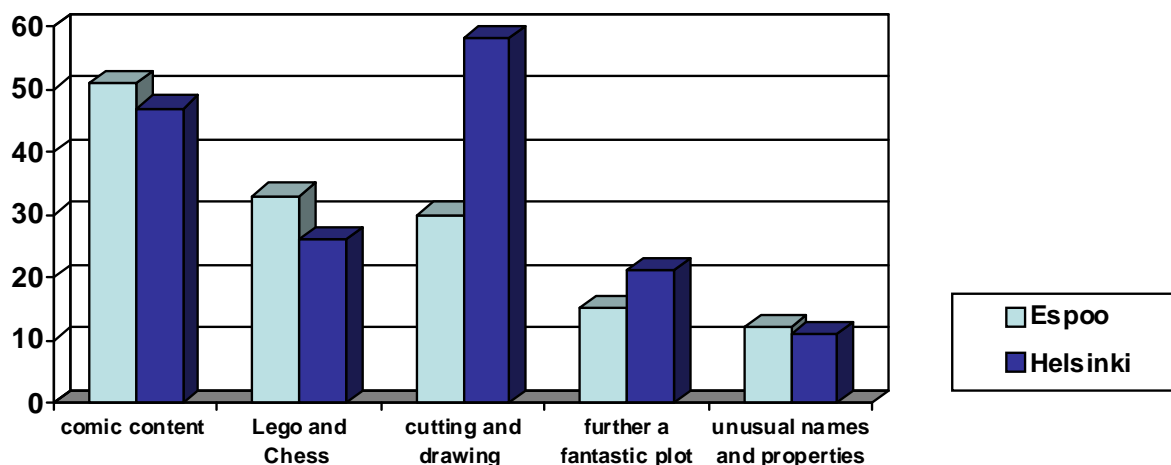

Figure 1. Students' responses to which types of tasks they prefer

When asked to continue the sentence "The CheCha-maths is ..." the most frequent answers were "Great!" (21 %) and "fun" (21 %). 16 % of students noted that it is simultaneously a game and study. There were also individual answers of such a character as "creative and interesting", "many-sided", "various" and "laughter".

3. b. The other survey in the class where CheCha maths was not applied produced somewhat different responses. For the question "It is possible to take pleasure at math lessons" only 26 % gave a positive answer, mostly responding utility of maths, instead any reference to its enjoyable nature. Also the drawing test did not show joyful atmosphere at a lesson. The priorities chosen by these respondents were cutting and drawing (67 %), the comical character (43 %), a fantastic plot (33 %), unusual names and properties (24 %) and the tasks solved with the help Lego and chessboard (10 %). On the offer to make definition "The entertaining maths is ..." the most frequent response was that such maths "is impossible" (29 %). Then was "drawing" (24 %) and there was a fair amount (29 %) of other positive characterisations (e.g. "games", "humour", "of a funny nature", "easy").

CONCLUSIONS

One growing branch in mass media is 'edutainment' where EDUcational purposes are combined with enterTAINING qualities and interaction possibilities (e.g. computer games). Could math education learn something from the edutainment business in order to deepen the students' engagement with maths? We strongly believe that it is

possible to develop suitable (open and multilevel) math tasks with attractive humorous flavouring, that make learning of maths very close to matter of laughter.

When this method was tried out and developed in different schools, the students' feedback points out how the teacher can use humour to engage students with maths:

1. From the students' point of view, entertaining tasks associated largely with humorous content. The longer students are working with humorous tasks, the higher percentage of students prefers such problems over other types of problems.

2. CheCha math method influences the atmosphere in the lesson. The use of intellectual games (or creating a favourable atmosphere in other ways) prepares the ground for the use of humour in the lesson. In an unfavourable atmosphere, comical assignments can lead to undesirable results. The importance of the overall receptive atmosphere was observed in fall 2008. In one of the 7th grade classes taught a part of students responded negatively to use of comic tasks, speaking about "irrelevance" of jokes. When math problems were not understood, the comic presentation of problems caused negative reaction in a part of children. However, tasks with fantasy characteristics did not cause negative reaction. Students were distracted into conversations among themselves, and they moaned about the inconvenient arrangement in a class (the uncomfortably big group was placed in a computer class, not suitable for math lessons). After a replacement into an ordinary classroom the atmosphere had changed into more positive. Playful statements and problems began to be perceived positively, increasing motivation to learn.

BELIEFS: A THEORETICALLY UNNECESSARY CONSTRUCT?

Magnus Österholm

Department of Mathematics, Technology and Science Education

Umeå Mathematics Education Research Centre (UMERC)

Umeå University, Sweden

In this paper I analyze different existing definitions of the term beliefs, focusing on relations between beliefs and knowledge. Through this analysis I note several problems with different types of definitions. In particular, when defining beliefs through a distinction between belief and knowledge systems, this creates an idealized view of knowledge, seen as something more pure (less affective, less episodic, and more logical). In addition, attention is generally not given to from what point of perspective a definition is made; if the distinction between beliefs and knowledge is seen as being either individual/psychological or social. These two perspectives are also sometimes mixed, which results in a messy construct. Based on the performed analysis, a conceptualization of beliefs is suggested.

Key words: belief, definition, individual, knowledge, social

INTRODUCTION

There exists plenty of research in mathematics education focusing on aspects of beliefs, in recent years evident by books covering this specific topic (e.g., Leder, Pehkonen, & Törner, 2002b). However, Thompson (1992) points out that although the topic has been popular in educational research for many years, little attention has been given to theoretical aspects of the concept of beliefs. Specifically for mathematics education, Op't Eynde, De Corte, and Verschaffel (2002) note the same type of lack of theoretical studies about beliefs.

In many studies, the term 'belief' is not explicitly defined, but it is assumed that the reader knows what is meant (Thompson, 1992). For some purposes this might suffice, and in general different types of definitions, from informal to extended types, could be suitable depending on the situation (McLeod & McLeod, 2002). In addition, a theoretical perspective can focus on different aspects, for example by being more or less philosophically or psychologically oriented. When Schommer (1994) discusses different types of beliefs as key concerns in the conceptualization of epistemological beliefs, she argues that interesting results, perhaps of a more applied type, can be achieved also without explicit focus on the more philosophical aspects, but that the inclusion of such aspects would improve the conceptualization of beliefs. A philosophical perspective can include what McLeod and McLeod (2002) describe as part of a more elaborate definition, such as relations to nearby concepts. For beliefs, this elaboration could include relations between beliefs, knowledge, and different affective constructs.

When studying beliefs, instead of analyzing and arguing around different types of definitions of beliefs, it seems most common to describe different definitions found in the literature and then choose one of these or create your own for the study in question (if a definition is at all given). Even if it is perhaps impossible to create a general definition that is suitable for all types of research (as noted by Abelson, 1979; McLeod & McLeod, 2002), there is a need to discuss and analyze different types of definitions. In the present paper the focus is on such analyses.

Purpose

As the title of the present paper implies, I am taking a critical perspective regarding the concept of beliefs and suggestions of how this construct can be defined. This critical stance has evolved from informal, personal reflections when having read different types of studies of beliefs, and similarly as Pajares (1992), having noted a certain messiness regarding definitions and properties of beliefs. I have not only noted such messiness when looking at the breadth of different studies, where plenty of different types of definitions or properties are described, but also when trying to analyze the internal coherence of singular articles regarding definitions and properties of beliefs.

The main purpose of the present paper is to dig deeper into these reflections, in order to see what types of problems seem to exist when trying to define beliefs and also if and how these problems can be resolved. In particular, I will suggest a type of reconceptualization of beliefs, emerging from noted problems around (1) the point of perspective taken when defining and describing properties of beliefs, and (2) relationships between beliefs and knowledge.

It is important to note that I am not suggesting that the ideas presented here should be seen as final in some sense, but that they primarily constitute a starting point in my attempts to reconcile with some experienced problematic issues, for continued discussions and reflections and for continued work on a larger research project (see Österholm, in press). Also, I am not suggesting that I am presenting an entirely new perspective, regarding the mentioned reconceptualization, but as can be seen by references given throughout the present paper, others have presented similar suggestions, although sometimes done from other perspectives or focusing on somewhat different aspects of beliefs.

Research about beliefs

Historically, the interest in educational research in the study of beliefs seems to come from realizing that a focus on “purely cognitive” factors (in particular, content knowledge) is not sufficient when trying to describe and explain students’ problem solving activities (Pehkonen & Törner, 1996; Schoenfeld, 1983) or teachers’ classroom behavior (Speer, 2005). The relationship between (content) knowledge and beliefs is thus a central aspect. This relationship is also the most commonly referred to when discussing the definition of beliefs, and different views about this

relationship can also be seen as a major reason for experiencing beliefs as a messy construct (Pajares, 1992).

Since there can be different types of knowledge, such as procedural or conceptual, while beliefs are usually formulated as statements, the comparison between knowledge and beliefs can focus on factual, declarative knowledge.

BELIEFS – AS SEEN FROM DIFFERENT POINTS OF PERSPECTIVES

Abelson (1979) describes a cultural dimension of beliefs; that if all members of some type of group have a specific belief, then they might not label it as a belief but as knowledge. This cultural dimension corresponds to what other authors describe as a social property of knowledge (e.g., Op't Eynde et al., 2002; Thompson, 1992); that for something to be seen as knowledge it has to satisfy some type of truth condition – a condition that is negotiated and agreed upon within a community (of practice). Thus, depending on what social community you belong to, you can have different views on what is seen as knowledge and what is seen as belief. From this perspective, when focusing on social aspects, the difference between belief and knowledge can be defined by saying that knowledge fulfills the mentioned social criteria but that beliefs do not, or perhaps *cannot*, since there can exist statements that cannot be evaluated using existing criteria within a certain community.

This relative property of beliefs highlights the importance of taking into account from what perspective a labeling of something as a belief or as knowledge is being done. In addition, there is also the possibility of changing perspective when deciding on the definition of beliefs, from defining beliefs from a social perspective to defining beliefs from an individual perspective. For example, when Leatham defines beliefs he describes the relationship between belief and knowledge by seeing that

there are some things that we “just believe” and other things that we “more than believe – we know.” Those things we “more than believe” we refer to as knowledge and those things we “just believe” we refer to as beliefs. (Leatham, 2006, p. 92)

This type of definition describes the relationship between beliefs and knowledge as a psychological property. A somewhat different defining property of beliefs, but also from the individual perspective, is given by Abelson (1979); that the believer is aware that others may believe differently. This property includes a social dimension but the distinction between beliefs and knowledge is still being done from the individual perspective, and is psychological in nature. From this perspective, when focusing on the individual, the difference between belief and knowledge can be defined by seeing beliefs as something related to uncertainty, either in relation to other parts of an individual's beliefs/knowledge or in relation to what others claim to believe/know.

Sometimes an author describes some defining properties of beliefs that are from an individual perspective and some other properties that are from a social perspective. For example, I have mentioned Abelson (1979) when describing both these

perspectives, and Pehkonen and Pietilä (2003) also include both these perspectives when differentiating between beliefs and knowledge. The simultaneous use of these different perspectives when defining a concept could be a cause for creating a messy construct. However, it is often difficult to decide if all given properties should be seen as part of a homogenous definition or as something that can be inferred from a (sometimes implicit) definition or from empirical results.

From this analysis we can see that a central distinction in the discussion of beliefs and knowledge is from what perspective a definition or description is given, whether these concepts are construed as individual or social. This distinction deals with whether the decision regarding differences between belief and knowledge is located in the individual (i.e., that it is psychological in nature) or if it is located in the social community. Independently of which of these perspectives is used when defining beliefs, there is also another aspect of different perspectives; that different persons can have different views on what is regarded as knowledge and what should be labeled as belief, that is, there is a relative property of beliefs. This property is caused by taking the relationship between beliefs and knowledge as a starting point when defining beliefs and is also based on a general view of knowledge (which has previously not been stated explicitly in the present paper), that knowledge is “not a self-subsistent entity existing in some ideal realm” (Ernest, 1991, p. 48), but that knowledge is seen either as an individual construction (what Ernest labels as subjective knowledge) or as a social construction (what Ernest labels as objective knowledge).

TYPES OF DEFINITIONS OF BELIEFS

Sometimes it can be difficult to analyze some of the definitions and properties of beliefs since authors do not always motivate or describe these defining properties in detail. For example, it is sometimes mentioned, without further explanation, that beliefs can be conscious or subconscious (e.g., Leatham, 2006; Pehkonen & Törner, 1996), but since the concept of consciousness in itself is very complex (e.g., see Velmans, 1991) it is difficult to interpret such a suggested property of beliefs. In particular, the interpretation becomes more difficult if some definition of beliefs has not been given, or if no connection is made between a certain property of beliefs and a given definition.

One way to define beliefs is to focus on the claim that a person believes that (or has the belief that) a certain statement is true. The question of what you mean by such a claim deals with the definition of beliefs. For example, a belief can be seen as a type of knowledge that is “subjective, experience-based, often implicit” (Pehkonen & Pietilä, 2003, p. 2), or as a personal judgment formulated from experiences (Raymond, 1997, p. 552). However, many such definitions seem to be of an informal type (as labeled by McLeod & McLeod, 2002), since they most often do not explicitly describe what is meant by all words used in the definition and how these words/properties create a construct different from nearby concepts.

Another way to define beliefs, or at least to describe some properties of beliefs, is to focus on relationships between different beliefs, and thereby describe characteristic properties of so-called belief systems. Certain differences between belief systems and knowledge systems can then be taken as a characterization of beliefs. In the literature it seems common to refer to Abelson (1979) and Green (1971, as cited in for example Furinghetti & Pehkonen, 2002; Leatham, 2006; Op't Eynde et al., 2002; Pehkonen & Pietilä, 2003; Raymond, 1997) who both have proposed such differences between the two kind of systems. Since references to belief systems seem quite common in the mathematics education literature, I will in the next section analyze the notion of belief system regarding the view of knowledge that is implicitly, and sometimes explicitly, created through the separation of belief and knowledge systems.

While a definition that focuses on a singular belief/statement can be done from both an individual and a social perspective, implicit in the type of definition that focuses on belief systems seems to be a view that such systems are psychological constructs.

Properties of belief systems – creating an idealized view of knowledge

There is no consensus in the research community on the positioning of beliefs on a cognitive-affective scale (Furinghetti & Pehkonen, 2002), but it is sometimes claimed that a difference between belief and knowledge systems is that the former has, or at least has a relatively stronger, affective component (Abelson, 1979; Speer, 2005). However, it is unclear why, for example, a certain belief about mathematics teaching should have a greater affective component than the knowledge of the relationship between the diameter and the circumference of a circle. The situation (or the several situations) when the knowledge about the circle has been dealt with could very well have been strongly loaded with affect, for example from the joy of discovering this relationship or the dislike of having another fact to memorize. Such existing affective components of knowledge are also pointed out by Pajares (1992).

Also, it is seldom explained in detail how or why beliefs should be regarded as 'more affective' than knowledge, and when McLeod (1992) describes a framework for the study of affect, it is pointed out that beliefs are not emotional in themselves but that the role of beliefs is one (central) factor when attitudes and emotional reactions to mathematics are formed.

Some claim that belief systems are more episodic in nature than knowledge systems; that beliefs have a closer connection to specific situations or experiences (Abelson, 1979; Speer, 2005). This property seems to lie close to the clustering property described by Green (1971, as cited in Leatham, 2006), which permits the belief system to consist of clusters of beliefs that can be more or less isolated from each other. Leatham (2006) describes this property as a means to explain the contextualization of beliefs and that a person can hold different beliefs that can seem to contradict each other, if these beliefs belong to different clusters. However, learning and thereby knowledge is also always situated and context dependent, "resulting in clusters of situated knowledge" (Op't Eynde et al., 2002, p. 25).

Another suggested difference between belief and knowledge systems is that belief systems are built up using quasi-logical principles while knowledge systems are built up using logical principles (Green, 1971, as cited in Furinghetti & Pehkonen, 2002). For example, it is claimed that relationships between beliefs cannot be logical “since beliefs are arranged according to how the believer sees their connections” and also that “knowledge systems [...] cannot contain contradictions” (Furinghetti & Pehkonen, 2002, p. 44). If a person’s knowledge system is not built up around how this person sees the connections between different components of the system, it seems unclear exactly who or what is creating the structure within the system. In this case knowledge is perhaps not referred to as an individual, psychological construct but seen as a social construct. However, also when seeing knowledge from such a perspective it becomes difficult to reconcile with the statement that knowledge systems cannot contain contradictions, since the history of mathematics includes examples of such contradictions, for example regarding the connection between convergence of series and the limit of the general term (see Leder, Pehkonen, & Törner, 2002a, p. 9). You could explain this by viewing knowledge as something absolute and thus maintaining that knowledge systems cannot be contradictory, by seeing contradictions as stemming from beliefs and not from knowledge.

In summary, regarding the relationships between beliefs and knowledge based on existing suggested properties of belief systems, knowledge is described as less affective, less episodic, and more logical and consistent. These properties create an idealized picture of knowledge, as something pure and not ‘contaminated’ with affect or context.

A PROPOSED CONCEPTUALIZATION

Based on the analysis about different types of definitions of beliefs that can be made from different points of perspectives, I here discuss a conceptualization of beliefs that take into account the criticism that has been put forward. I am not suggesting that this conceptualization is necessarily suitable for all types of studies or situations, but that it is one way to relate to some of the problems that seem to exist when defining and describing beliefs.

Beliefs are seen as being related to uncertainty in some way. From some observer’s perspective a statement can be labeled as a belief for different reasons, but all related to some degree of uncertainty, as described in the following examples.

The first example is that if a statement cannot be included in, or directly related to, some (traditional) existing (scientific) content domains, such as mathematics or pedagogy, it can be labeled as a belief. For example, Ernest (1989) and Schoenfeld (1998), who do not explicitly discuss the definition of beliefs, describe beliefs and knowledge as two separate categories. Included in these categories are *knowledge* about teaching and learning, and *beliefs* about the nature of teaching and learning,

where the former can be included in the domain of pedagogy while the latter perhaps cannot (but perhaps can be included in the domain of philosophy).

A second example of a reason for labeling something as a belief is if a statement contradicts something that is part of some scientific domain. For example, this is done by Szydlik (2000) who discusses content beliefs, which for example include to see the existence of gaps in the real line.

Both these examples are from a social perspective since they relate to domains (i.e., communities of practice), but the property of uncertainty was also mentioned earlier when discussing beliefs defined from an individual perspective. What an individual regards as belief is something that is more uncertain than knowledge. The level of uncertainty refers to how confident a person is that a statement is true. That is, a person has some (implicit) criteria from which it can be decided if something is labeled as belief or knowledge. Törner (2002, p. 80) describes this as measuring certainty on a scale from 0 to 1, where knowledge can be seen as a special case in his framework of beliefs, possessing the certainty degree of 1.

Thus, uncertainty can be seen as a more general aspect of beliefs, regardless of from what perspective the concept is defined, either the social or the individual.

Unlike uncertainty, an aspect that can differ depending on from what perspective beliefs are defined is whether a belief, when compared to knowledge, is seen as a different type of psychological object. From a social perspective it becomes difficult to motivate that beliefs and knowledge refer to such different types of objects since the difference by definition is a social construction. Therefore, when studying the behavior of individual persons (such as teachers' activities in classrooms or students' problem solving activities) the social perspective does not seem suitable when defining beliefs. This has also been highlighted by other authors, for example by arguing that

individuals (for the most part) operate based on knowledge as an individual construct. That is, their actions are guided by what they believe to be true rather than what may actually be true. (Liljedahl, 2008, p. 2)

Others have also suggested that one should focus on the study of conceptions as a whole, which includes what some label as beliefs and knowledge (e.g., Thompson, 1992). However, there could be a reason to study beliefs as defined from an individual perspective, such that beliefs and knowledge from this perspective can be seen as psychologically different types of objects, since experienced differences in the degree of uncertainty could affect behavior differently. Empirical studies seem necessary for deciding if there is a reason to make such a distinction or if it is more reasonable to see the whole of a person's conceptions.

These presented perspectives on beliefs mainly focus on singular statements and not on properties of a system of beliefs compared to a system of knowledge. This type of conceptualization is chosen because of the problems noted about the systemic view

when defining and describing properties of beliefs, in particular the tendency to create an ideal and problematic view of knowledge. Also, the presented perspectives put an emphasis on the person making a claim about relationships between beliefs and knowledge, which some authors also have noted, but have not taken as a more fundamental aspect.

CONCLUSIONS

In the present paper, two main issues have been highlighted through the analysis of existing definitions and descriptions of properties of beliefs:

- (1) The important issue of explicitly focusing on the point of perspective taken when defining and describing properties of beliefs, in particular the difference between taking a social or individual perspective regarding where the difference between belief and knowledge is located.
- (2) The problematic issue of trying to define, in an objective manner and focusing on the individual, the difference between beliefs and knowledge through the separation of belief and knowledge systems.

Due to these issues one can question the necessity of the concept of beliefs, since the difference between beliefs and knowledge is not construed as so absolute, but that the meaning of the concept can be relative with respect to the person labeling something as a belief. In this way, beliefs are not seen as being used for making an important theoretical distinction between belief and knowledge, but more seen as a linguistic tool to signal what type of object/statement is in focus, as seen from the person making a claim about beliefs. Thus, the notions of belief and knowledge may say more about an observer than they do about some important theoretical distinction between two types of entities “within” the person being observed. In this sense, the concept might have lost some of its theoretical importance.

The most central point in my analysis and criticism is directed towards certain contradictory aspects in the existing literature, in particular that a common psychological perspective presented through the distinction between belief and knowledge systems implies a more idealized view of knowledge than what is existent in the social perspective of knowledge. Most often, when aspects of both these perspectives are mentioned, there is no in-depth analysis of possible relationships or contradictions between these aspects. Even when Op't Eynde et al. (2002) perform a more in-depth analysis of the social perspective, they also claim the existence of a psychological difference between beliefs and knowledge, by mentioning the quasi-logical property of beliefs. I see this use of a mixture of different perspectives as a central cause for the creation of beliefs as a messy construct. Thus, a main topic when defining beliefs is to decide, based on what is being studied, which perspective is the most suitable one when defining beliefs, the social or the individual, and then to be consistent within this one perspective.

CATEGORIES OF AFFECT – SOME REMARKS

Wolfgang Schlöglmann

Institut für Didaktik der Mathematik, Universität Linz, Austria

Cognitive concepts were insufficient to explain some effects observed in mathematics learning, particularly differences in performance. So researchers began investigating the influence of affect on the learning process, using the concepts of beliefs, attitudes, emotions and values. This paper discusses questions connected with the theoretical status of these concepts.

Introduction

McLeod (1992) wrote in his survey paper, “Research on Affect in Mathematics Education: Reconceptualization”, that beliefs, attitudes and emotions are used in mathematics education research to describe a wide range of affective responses to mathematics. Although terms and concepts are often transferred from psychology to mathematics education, McLeod points out why such a transfer to the affective domain can be problematic:

Terms sometimes have different meanings in psychology than they do in mathematics education and even within a given field, studies that use the same terminology are often not studying the same phenomenon.... Clarification of terminology for the affective domain remains a major task for researchers in both psychology and mathematics education. (McLeod, 1992; 576)

There have been efforts to clarify the meanings of these concepts, particularly with respect to beliefs and attitudes. In a paper appearing in the collection, “Beliefs: A Hidden Variable in Mathematics Education”, Furinghetti and Pehkonen (2002) describe a process that clarifies some shared core elements commonly mentioned in characterizations of beliefs:

Using an international panel we looked for common background suitable in describing the characteristics of the concept of beliefs and the mutual relationship in the critical triad “beliefs – conceptions – knowledge”. (Furinghetti and Pehkonen, 2002; 46)

Even if it were not possible to reach a common shared definition of beliefs, the paper clarifies some of the common and contrasting meanings of this concept.

With respect to the problem of definition in the case of “attitude toward mathematics”, we find a situation analogous to the one described by Di Martino and Zan (Di Martino and Zan, 2001; Zan and Di Martino, 2008); namely, a

...lack of clarity that characterizes research on attitude and the inadequacy of most measurement. (Di Martino and Zan, 2008; 197)

In their analysis of academic papers, Di Martino and Zan found three types of definition of attitude toward mathematics: a “simple” definition where attitude toward mathematics is seen as being either a positive or negative emotional disposition toward mathematics; a multidimensional definition where three components constitute attitude – emotional response, beliefs regarding the subject

and behaviour related to the subject; and a bi-dimensional definition where attitude toward mathematics is seen as a pattern of beliefs and emotions associated with mathematics.

The lack of clarity in what “beliefs” or “attitude toward mathematics” means also has implications for research in the affective field. Thus Sfard writes:

Finally, the self-sustained “essences” implied in reifying terms such as *knowledge*, *beliefs*, and *attitudes* constitute a rather shaky ground for either empirical research or pedagogical practices – a fact of which neither research nor teachers seem fully aware. (Sfard, 2008; 56)

Hart, too, referred to this problem and wrote that

research on the affective domain in mathematics education is in need of a strong theoretical basis that will be developed only through sustained, systematic efforts over time. (Hart, 1989; 38)

All of this suggests we have to rethink the concepts used in research on affect, and, moreover, it seems necessary to consider the problem in a more general way: “Wherein lies the problem of defining concepts and, in relation to this, what is the status of research methods?” “Can results from other fields help us better understand the categories of affect?”

General aspects of concepts

In his paper, “Aspects of the Nature and State of Research in Mathematics Education”, Niss (1999) refers to a crucial fact permeating all research:

It is important to realise a peculiar but essential aspect of the didactics of mathematics: its *dual nature*. As in the case with any academic field, the didactics of mathematics addresses, not surprisingly, what we may call *descriptive/explanatory* issues, in which the generic questions are ‘what *is* (the case)?’ (aiming at description) and ‘*why* is this so?’ (aiming at explanation). Objective, neutral answers are sought to such questions by means of empirical and theoretical data collection and analysis without any explicit involvement of values (norms). (Niss, 1999; 5)

We use terms and concepts to describe and explain phenomena: therefore we have to see if this duality can be discerned in our terms and concepts.

In the literature on mathematics education numerous accounts exist of deep considerations of mathematical concepts (see, for instance, the Special Issue “Semiotic Perspectives in Mathematics Education” in *Educational Studies in Mathematics Education*, Saenz-Ludlow and Presmeg, 2006). In these papers, the focus is on the process of construction of the meaning of mathematical concepts. We therefore need to consider the process of constructing the meaning of concepts used in mathematics education research, with a special focus on affective concepts.

Let us discuss the meaning-construction-problem as encountered in the study of affect from a more general viewpoint; i.e. one that considers the ontological and other status of the concepts in the scientific research process, particularly in the way the latter’s relationship to a concept’s meaning.

In semiotics researchers analyse the relationship between symbols and referents. Frege discussed this in his important paper, “Zeichen, Sinn und Bedeutung (Sign, Sense and Meaning)”. Here, “meaning” represents the objective idea of a thing; “sense” contains the subjective interpretation made by a person relating to this thing; and “sign” designates the objective idea (Kilpatrick, Hoyles, Skovsmose, & Valero, 2005; Steinbring, 2005). In modelling the process of meaning construction, Steinbring (2005) uses the scheme of an “epistemological triangle”, in which sign/symbol, object/reference context and concept form the triangle’s corners:

Mathematics requires *certain sign or symbol systems* to record and codify knowledge... these signs do not immediately have a meaning of their own. The meaning has to be produced by the student or the teacher by establishing a mediation between *signs/symbols* and suitable *reference contexts*. (Steinbring, 2005; 22)

Sfard stresses the discourse aspect of a concept definition:

A concept is a symbol with its use. (Sfard, 2008; 111)

Within this concept definition, the term “symbol” includes more signifiers than words; and “use” refers to the use of a symbol in a discourse (Sfard, 2008; 236). This extension of the term “meaning of a symbol” to its use in a discourse process allows attention to be directed toward more perspectives (such as that of emotional reaction) than was possible in Frege’s classical concept of meaning. Otte refers to the important fact that all our perceptions include elements of interpretation as well as of generalization and therefore all knowledge is in a certain sense indirect knowledge and a function of symbols and representations (Otte, 2005; 231). Thus understanding concepts is a cognitive activity that is connected with intuition:

Thom, and Bruner as well, intend to draw attention to the fact that we cannot develop our cognitive activities if we do not believe in the reality of our intuitions, and that these intuitions or mental states nevertheless may be treacherous and without objective validity or reference. Subjective meaningfulness and objective validity may not coincide. (Otte, 2005; 231)

Reading this quotation, moreover, raises the question of how an individual acquires a concept. Two answers may be found in mathematics education research, depending on how the problem is viewed. Following the ideas of Piaget, intellectual growth results from a direct interaction between the individual and the world; on the other hand, according to social constructivism,

...whatever name is given to what is being learned by an individual – *knowledge*, *concept*, or *higher mental* function – all these terms refer to culturally produced and constantly modified outcomes of collective human efforts. (Sfard, 2008; 77)

We should probably accept that knowledge and concepts are outcomes of a cultural process and neither can be learned outside a discourse community. For instance, a learner needs help from an experienced person (Lave and Wenger describe this learning process as “legitimate peripheral participation” (Lave and Wenger, 1991)). Furthermore, we ought to consider the individual parts comprising the acquisition process. Lakoff and Nunez refer to the important role of metaphors:

One of the principal results in cognitive science is that abstract concepts are typically understood, via metaphor, in terms of more concrete concepts. This phenomenon has

been studied scientifically for more than two decades and is in general as well established as any result in cognitive science (although particular details of the analysis are open to further investigation). One of the major results is that metaphorical mappings are systematic and not arbitrary. (Lakoff and Nunez, 2000; 40 – 41)

This role of metaphors is important to keep in mind – especially if we transfer concepts, such as attitude, from other fields– because the borrowed concepts are combined with metaphors in our field to understand the concepts already present in our field. We must specify the metaphors required for using the concepts in our field, mathematics education.

A second crucial point is strongly connected to our use of language. We use words or symbols that are the endpoints of a process of objectification; and these words or symbols produce the illusion that they are in the same category as things, yet they can have no empirical manifestation:

After objectification, we often interpret metastatements, that is, statements about discourse, as statements about the extradiscursive world (...) This *ontological collapse* (a) may produce an *illusory dilemma*, (b) can result in *phony dichotomies* leading to tautologies disguised as causal explanations, and (c) is likely to lead us to *consequential omissions*; blinding us to potentially significant phenomena that cannot be described in ontologically “flattered” terms. (Sfard, 2008; 57)

In the light of this, we ought to keep in mind that concepts used in mathematics education research that are formulated in words have no empirical manifestation – and therefore no reference objects – and they get their meaning through the metaphors and associations that we imagine in connection with the symbol for the concept. In mathematics one can use a “realization tree” (Sfard, 2008; 165) to overcome, in a certain sense, the lack of a reference context; however, for concepts encountered in mathematics education we have no such realization tree.

The problem of meaning construction for affective categories

Research into affect was motivated by the fact that cognitive concepts were insufficient to explain some of the effects observed in mathematics learning (McLeod, 1992), such as differences in the outcomes of mathematics learning. To explain these differences, researchers used affective concepts such as attitudes and beliefs. Thus differences in mathematical performance were also viewed as a consequence of differences in attitudes or beliefs.

With reference to the general remarks on concepts in the previous chapter of the paper, in our context three components are important: the concept definition (independent of the formal state of this definition (see McLeod and McLeod (2002) for the case of beliefs); the associations and metaphors that combine with the concept definition; and the research methods that are used to investigate and measure the concept. It shall be argued below that with respect to the meaning-construction problem in mathematics education research, the components “concept definition” and “concept images” (or concept trees (Sfard, 2008)) are helpful, but the ontological

status of “research methods” is problematic, and the reason for this ought to be made widely understood.

Let us start with a definition of the affective categories, after Goldin (2002); also, in the following, we shall use the concept of beliefs to demonstrate the meaning-construction problem:

- (1) *emotions* (rapidly changing states of feeling, mild to very intense, that are usually local or embedded in context);
- (2) *attitudes* (moderately stable predispositions toward ways of feeling in classes of situations, involving a balance of affect and cognition);
- (3) *beliefs* (internal representations to which the holder attributes truth, validity, or applicability, usually stable and highly cognitive, may be highly structured);
- (4) *values, ethics, and morals* (deeply-held preferences, possibly characterized as “personal truth,” stable, highly affective as well as cognitive, may also be highly structured). (Goldin, 2002; 61)

In the following I also refer to the definitions of beliefs formulated by Op’t Eynde, De Corte and Verschaffel (2002) and Törner (2002; Goldin, Rösken and Törner, 2009):

Students’ mathematics-related beliefs are the implicitly or explicitly held subjective conceptions students hold to be true about mathematics education, about themselves as mathematicians, and about mathematics class context. These beliefs determine in close interaction with each other and with students’ prior knowledge their mathematical learning and problem solving in class. (Op’t Eynde, De Corte and Verschaffel, 2002; 27)

Törner uses constitutive elements (ontological, enumerative, normative and affective aspects) to define beliefs *B* as a quadruple $B = (O, C_0, \mu_i, e_j)$, whereby *O* is the belief object, C_0 the content set of mental associations, μ_i the membership degree function and e_j the evaluation map (Törner, 2002; Goldin, Rösken and Törner, 2009).

It is important to note that each of these definitions refers to descriptions of mental systems. These mental systems are activated in all situations in which mathematics is involved and these systems influence the thoughts and acts of a person in these situations (Furinghetti and Pehkonen, 2000; Hannula, 1998). The lack of reference objects for the concepts (all of which are discourse objects (Sfard, 2008)) leads to a problematic situation when attempting to give the concepts a meaning in the discourse process.

In the definitions we find certain keywords – “intensity”, “stability”, “structure” and “truth”. These keywords are supposed to lead to a meaning for the concepts: we therefore need to analyze them. Intensity is often described as “hot” or “cool” (McLeod, 1992), metaphors that are also used to describe affective states:

Affection, for example, is understood in terms of physical warmth. (Lakoff and Nunez, 2000; 41)

The terms “stability” and “balance” refer to a metaphor originating from physics and describing a state of equilibrium. In our case this term is used to evoke a twofold meaning. On the one hand, it is meant to capture the notion that some mental system always leads to the same endpoint that persists for an extended period; on the other

hand, it describes an equilibrium between the affective and cognitive systems. “Structure” refers to an ordering in the mental system that is clearly distinct from other systems. “Truth” is a metaphor borrowed from logic and used here in the singular sense that all utterances made by an individual are subjectively seen as true. However, all these keywords are also discourse objects and are therefore at the same level as the concepts that they are intended to give meaning to.

How do we proceed? Another opportunity to construct meaning for a concept is afforded by using insights from other scientific fields striving to understand the same phenomena. In our case we could use insights from neuroscience.

With respect to cognition and affect, neuroscience distinguishes two different systems: cognition and emotion. Both exist as a result of biological evolution, with the aim of aiding the individual’s survival (Wimmer and Ciompi, 1996; Damasio, 1999; LeDoux, 1998; Roth, 2001). Although located in different parts of the brain (Damasio, 1999; LeDoux, 1998; Roth, 2001), there are connections between the two systems that allow interactions. A very important consequence of the existence of these two systems is that we have to distinguish between “feeling” and “knowing that we have a feeling” (Damasio, 1999; 26); or “emotional reactions” and “conscious emotional experience” (LeDoux, 1998; 296).

For our problem we should note that although all processes on the neuronal level are not conscious, some of these processes lead to conscious results. We are aware only of these conscious parts of the processes. For remembrances, too, two memory systems exist with respect to emotions: an implicit emotional memory and an explicit memory of emotions (LeDoux, 1998). The implicit emotional memory operates unconsciously, is strongly connected to arousal systems and may often lead to bodily reactions. The explicit memory of emotional situations contains all the conscious knowledge of emotional situations, emotional reactions to objects, persons and ideas etc.. The most important consequence of this is that this memory system is part of the cognitive memory and there is no distinction between a remembrance of an emotion and a remembrance of a cognitive content (LeDoux, 1998). The fact that memory of emotions is cognitive has important consequences (Schlöglmann, 2002):

- 1) We have knowledge about our feelings, their origin and their effect. This knowledge is stored in memory systems as cognitive knowledge.
- 2) Memory of emotions is open to “rational” manipulation. That means we are able to think about our emotional remembrances, and that all verbal statements about emotional facts are controlled by cognition.
- 3) Knowledge of our affect with respect to objects and situations allows us to handle our affect at least in controlled situations (see Goldin’s example of the roller coaster experience (Goldin, 2002; 62)).
- 4) Humans are able to “construct” their remembrances in a way that they are able to live with this memory. Part of this process is forgetting unpleasant facts more easily than pleasant ones: our memory has suppression mechanisms to handle unpleasant remembrances (Roth, 2001).

Assimilation and accommodation processes lead to affective-cognitive schemata (Ciompi, 1999). The affective component is stored in two memories: in the implicit memory that works unconsciously but influences our actions and thoughts (Damasio developed the concept of “somatic marker” to explain this (Damasio, 2004; Brown and Reid, 2004)); and in the explicit memory that stores all the knowledge of affect with respect to people, objects and situations. Affective-cognitive schemata always contain both the unconscious and the conscious components. Repeated assimilation and accommodation processes in relation to a special problem leads to consolidation of the unconscious reactions, as well as to more and more conscious knowledge of feelings and emotional reactions. It provides information on the outbreak of emotional reactions and allows the development of strategies for handling such situations (Goldin, 2002; Schlöglmann, 2006)).

Neuroscientific research suggests that we ought to distinguish between reactions occurring within the two memory systems; however, according to neuroscience, we have no criteria to distinguish between knowledge and knowledge of our affective relationship to mathematics. This underscores the problem that a distinction is also difficult to formulate in philosophy (Österholm, 2009; Pehkonen and Pietilä, 2003), and helps us appreciate that the problem of defining affective categories, especially beliefs, must be considered at the discourse level. Yet we have seen that descriptions of affective categories as “discourse objects” themselves also use discourse objects (e.g. intensity, stability, structure, truth) together with some metaphors. We are in a circle situation: we are bound to define our concepts in terms that contain no reference objects.

On top of these considerations, in order to measure the categories, we need an operationalization of them, usually in terms of items of a questionnaire. The items are formulated by the researchers with the aim of grasping all of the important aspects of the definition, and are formulated as questions or simple statements. The attention of the responder is directed towards finding an appropriate answer or value on a scale. However, the items are more concrete than the definition, and we have a situation where the measurement methods are derived from theoretical concepts, while they themselves become an important part of the concept. This problem is inherent in all discourse objects.

Conclusion

The analysis of the problem of defining affective concepts shows that these concepts are objects of a discourse with no reference objects. To give these concepts a meaning we use discourse to clarify the meaning: in particular, by employing other terms and metaphors. However, these terms are often also objects of a discourse at the same level as the terms they are intended to give meaning to. In a discourse this obstacle can be successfully surmounted. In contrast, if we want to measure a concept, we must formulate the description of it mostly in the form of items of a questionnaire, and these items are a consequence of our definition – yet for the

purposes of the measurement they are the realization of the definition. The problem is that we cannot escape this situation. Therefore it is important to be aware of the problem. As a consequence of this state of affairs, researchers have developed numerous methods whose appropriateness depends on the complexity of the phenomenon at hand (for the case of beliefs research see (Leder and Forgasz, 2002)); indeed, in extending the basis of information about some phenomenon, more than one research method is often used to overcome, in a certain sense, the problem of defining a concept.

On the whole we can see three groups of methods: quantitative, qualitative and observational methods. The basis for quantitative methods is the questionnaire, together with the statistical methods used to handle the responses. Qualitative methods are mostly based on texts (protocols of interviews, essays, protocols of narratives and protocols of observations), and are used to look for keywords expressing affective or emotional reactions (see, for instance, Tsamir and Tirosh, 2009; Evans, 2002). Observations can also be used to look for keywords as well as other signs indicating emotional state, such as body language. (A small number of studies exist in which physiological facts are utilized.) All these efforts can help clarify the meaning of a concept, and, in a certain sense, overcome the theoretical obstacle in a discursive way.

INTRODUCTION

ARGUMENTATION AND PROOF

Maria Alessandra Mariotti, Università di Siena

Leonor Camargo, Universidad Pedagógica Nacional de Bogotá

Patrick Gibel, Université de Bordeaux

Kristina Reiss, München Universität

This chapter collects the contributions discussed during the working sessions of the WG2 at CERME6. The work of the participants of the Thematic Working Group on Argumentation and Proof was organized around the goals of

- Putting our research studies in relation to each other.
- Getting feedback for improving both our research work and our papers.

Each participant was expected to act as reactor to one of the other papers, presenting the key issues and posing questions to the author(s). Such intervention was aimed to trigger a collective discussion on the paper in focus as well on general issues.

Although they all share the issue of proof and argumentation, the contributions offer a quite varied spectrum of perspectives, both from the point of view of theoretical frameworks assumed and of issues in focus. The main themes that emerged from the papers were the frame according to which the working sessions of the group were organized, and it is the same frame we use to organize this introduction. These main themes were the following.

Historic and epistemological issues

Conjecturing and proving

Visual aspects in proving

Teachers and teaching of proof

Models to describe models to explain

HISTORIC AND EPISTEMOLOGICAL ISSUES

Historic and epistemological issues were specifically addressed in some of the papers presented. Molinini discusses mathematical explanation in Physics using the lens of history. His aim is to clarify how explaining a physical phenomenon via mathematics may foster its understanding and consequently may have a pedagogical value. As Avigad says: “We look to mathematics for understanding, we value theoretical developments for improving our understanding, and we design our pedagogy to convey understanding to students” (Avigad, 2008, p. 449).

The relationship between argumentation and proof is also addressed by Barrier, Mathé and Durrand-Guerrier. Taking a semantic approach the authors try to overcome the limits of previous discussions concerning the gap between argumentation and proof.

The function of proofs in the history of mathematics inspired the analysis presented by Hemmi and Lofwall that concerns the idea of *transfer*, that is the contiguity between proofs and methods for problem solving. The importance of proofs for the development of mathematics is compared with the opinion - shared by some of the mathematicians involved in the investigation - about the crucial role that certain proofs may have in the learning of mathematics.

Habermas' theory of rationality is proposed by Morselli and Boero as a research tool and a theoretical ground according to which new educational challenges can be pursued.

CONJECTURING AND PROVING: THE ROLE OF ARTEFACTS

The relationship between conjecturing and proving is addressed from the specific point of view of the contribution offered by artefacts, either in fostering the production of conjectures or in developing the sense of a theoretical approach. Our group's work in this area considers, in particular, three different artefacts, related to different mathematical domains: a linkage device to produce an ellipse – specifically the reconstruction of an ancient machine; a Dynamic Geometry environment – Cabri; a software for algebraic manipulation – Alnuset.

The papers present different potentialities offered by the use of such artefacts. The field of experience of linkages (mathematical machines) may be compared with that offered by a Dynamic Geometry System. Bartolini Bussi discusses direct manipulation, highlighting the potential of the exploration tasks, where a key request concerns the explanation of the functioning of the linkage. Exploration tasks are also discussed in the paper of Baccaglioni-Frank and Mariotti, where the authors present a model for describing and explaining the process of production of a conjecture, based on dragging strategies for grasping the relationship between geometrical invariant properties.

In her paper, Pedemonte discusses the use of a particular symbolic manipulator, Alnuset, with respect to enhancing the teaching and learning of proof in algebra.

VISUALIZATION

Some of our group's contributions address the issue of visualization in relation to proof and proving. Such issue is discussed from different perspectives, providing a good opportunity for reflecting on the diversity and the complexity of phenomena that are usually referred to as visualization. In fact, this issue was widely discussed in the working sessions, and the discussion provided a good opportunity to confront our

different epistemological assumptions as well as the different points of view about visualization. Exploring the use of visual reasoning is the goal of the paper of Bardelle. In her paper, she presents the results of a preliminary study concerning students' way of working with visual proofs. The difficulties in treating and accepting visual proofs described in Bardelle's study finds an echo in the paper of Biza, Nardi and Zachariades, where the authors elaborate on empirical results that clearly show the relationship between teachers' and students' beliefs. The instability of teachers' beliefs about the role of visual representation with respect to what counts as a valid proof has a counterpart in students' uncertainty on what counts as a proof. The role of visual reasoning was discussed not only with respect to the proving process but also with respect to the process of discovering and producing a conjecture. Difficulties emerge concerning the complexity of treating visual representation such as lack of basic geometrical knowledge or ambiguity of images from which it is difficult to extract useful information. However, the key issue concerns the uncertain status of images as argument for validating a statement. This issue brings to the forefront the role of the teacher in introducing students to a theoretical perspective in mathematics.

TEACHERS AND TEACHING PROOF

Several papers address the issue of teaching both in terms of teachers' mathematical competences and in terms of teachers' role in organizing and managing a learning environment that could (and should) enhance students' proving performances. In many countries – in Israel for instance – recent reform recommendations require that proof and proving become key components of classroom practice.

The paper of Barkai et al. reports on an empirical study showing how teachers are able to produce correct proofs of a given statement, but meet difficulties in understanding and evaluating the validity of students' arguments supporting the validity of the same statement. These results question the type of competences that teachers should have in order to face everyday practice with students' productions of proof. Along the same lines, the paper of Potari et al. discusses teachers' reaction to hypothetical classroom scenarios, specifically how teachers approach the refuting of students' claims. These results indicate teachers' misleading epistemological views about theorems and theory, as well about the role of counterexamples in mathematical reasoning.

These contributions enrich previous results concerning the relationship between teachers' beliefs and practices. At the same time they show the high complexity of treating visualization issues and the need of elaborating specific research questions that go beyond testing of teachers' ability of producing correct mathematical proofs.

Teachers' view of what constitutes a proof and its functions influences the choice of what is to be integrated into one's own teaching practices and consequently how students evaluate their own productions.

Shifting the attention from the teachers to the students, two papers address students' productions of proofs. The study presented by Back et al. aims at giving a clear picture of how students motivate their solutions and how these change throughout the course. The issue of evaluating students' productions of proofs is again the focus of this paper that discusses how students' justifications relate to both teachers' and textbooks' ways of justifying and explaining, focussing particularly on the opposition between verbal and symbolic expression. In this respect, the episode reported by Raman et al. is also significant. These researchers describe an episode in which students come very close to a proof (they reach something that a mathematician would have basically recognized as a proof), however they were not able to recognize their argument as a proof. That raises a natural but difficult question: why are students unable to recognize what they are saying as a proof? How to bridge the distance between students and experts in elaborating informal arguments into proofs?

More specific difficulties are described in the paper of Stylianides & Al-Murani and in the paper of Antonini & Mariotti. The first paper focuses on the possible coexistence of a proof and a counterexample for the same statement. Although the answers to a survey seemed to provide some evidence of such misconception, the interview data collected in the following suggest that students' responses originate from a particular interpretation of the given questions. The second paper focuses on difficulties related to indirect proof. Specifically, the paper discusses examples of abductive processes that are mobilized in order to produce explanatory hypotheses to establish what for the solver is a meaningful link between the contradiction produced in the indirect argument and the original statement to be proved.

No great discussion on didactic issues related to proof can be found in the contributions to the working group. The only exception is the specific example of a teaching intervention presented in the paper of Douek. In this paper, after a theoretical introduction, the author presents the outline of the didactic engineering, based on the notion of cognitive unity. The author highlights the crucial role of the situation for a student to engage him/herself in argumentative reasoning, nevertheless the difficulty of implementation clearly emerges from the reported results, raising many open questions.

CONCLUDING REMARKS

A considerable part of the discussion in the group was devoted to the illustration and the comparison of the different theoretical constructs that contributed to shape the different investigations, directing the researcher both in selecting the questions to be addressed and the ways to look for possible answers.

The opportunity of comparison that we had during the working sessions made us aware of the need and the usefulness of making theoretical assumptions explicit and clear. Similarly the comparison of different models and of their use in our investigations was very stimulating, suggesting possible integrations.

It is difficult to elaborate conclusions for a discussion group that spent a considerable amount of time exploiting the richness of diversity. In our discussion we were driven not only by the need of comparing but also by the curiosity of possible integration among different paradigms. This may constitute a program for our next up-coming meeting at CERME7.

UNDERSTANDING, VISUALIZABILITY AND MATHEMATICAL EXPLANATION

Daniele Molinini

REHSEIS, Université Paris 7

In this paper I focus on Mathematical Explanation in Physics and I analyse its interplay with the concepts of understanding and visualizability. Starting from a recent contextual approach to scientific understanding (De Regt & Dieks, 2005) I will try to see how an historical analysis of the formulation of a particular theorem could help to clarify the role of understanding and visualizability in mathematical explanation. My test case will be Euler's theorem for the existence of an instantaneous axis of rotation in rigid body kinematics. In particular, I will argue that the specific concept of vector space, defining a new standard of intelligibility, offers a good perspective in order to underline the dynamical character of mathematical explanation and its essential role in mathematical education.

1. INTRODUCTION

Different authors agree that the problematic of explanation is deeply connected to the debate about the nature of understanding in science. At the moment the major accounts of scientific explanation such as the Unificationistic (Friedman, 1974; Kitcher, 1981, 1989), the Causal (Salmon, 1984), the Pragmatic (Van Fraassen 1980; Acrhinstein, 1983) do not offer a satisfactory definition of understanding within their theories. While the authors and the supporters of those theories affirm that their particular accounts of explanation provide understanding, the notion of understanding remains still vague and is the cause of a series of controversies between philosophers of science. It seems quite plausible that a good explanation in science *must* provide understanding. But what is *understanding*? Is it really this “aha!” experience we are confronted with after some cognitive experience? And how can a good explanation provide understanding?

In this paper I will focus on the very specific notion of mathematical explanation, and in particular on the notion of mathematical explanation in physics. As clearly expressed by Mancosu in his studies on mathematical explanation (Mancosu 2005, 2008), we can have two different senses mathematical explanation:

In the first sense “mathematical explanation” refers to explanations in the natural or social sciences where various mathematical facts play an essential role in the explanation provided. The second sense is that of explanation within mathematics itself (Mancosu, 2008, p. 184).

Naturally, as pointed out by Shapiro (2000), mathematical explanation as intended in the first sense is connected to the more general problematic concerning the application of mathematics to reality and opens the mysterious problem of the “unreasonable effectiveness of mathematics in the natural sciences” (Wigner, 1967). However, leaving apart mysteries and ontological questions, many authors agree that it is possible to have a better comprehension of mathematical explanation of physical phenomena (MEPP) [1] starting from general discussions of scientific explanation and introducing an historical perspective (Tappenden, 2005; Kitcher, 1989). In this paper I will follow this line, getting my hands dirty *via* a bottom-up approach that starts from the mathematics itself. I will compare two different formulations of Euler’s theorem for the existence of an instantaneous axis of rotation in rigid body kinematics and I will try to discuss the concepts of understanding and visualizability under the light of dynamical MEPP. I assume as a starting point that in both the formulations the mathematical machinery has an essential role: they represent two mathematical explanations of the same physical fact. Naturally, in such a contextual analysis, the arena of mathematical education is of primary importance and I will offer a perspective in order to work in this direction.

In a recent series of papers De Regt and Trout have discussed the notion of understanding in science (De Regt, 2001, 2004, 2005; Trout, 2002, 2005). My point will be that, contrary to Trout’s idea that is impossible to give an objective epistemic role to understanding (Trout, 2002), some interesting ideas of De Regt’s account could be utilized in order to study the role of visualizability and understanding in mathematical explanations. I hope this study will make clear that MEPPs have a dynamical character, and in some case the role of understanding in them could be studied if we have at disposition conceptual tools like visualizability. After all, a number of new studies and a sort of “renaissance in visualization” (Mancosu, 2005, p. 13) have emerged during the last years in philosophy of mathematics and cognitive sciences. The impetus in this sense has been given for the most part by the rise of visualization techniques in computer science, from which has clearly emerged the heuristic and pedagogical value of visual thinking [2]. Naturally, I stress again, my analysis implicitly focus on the importance of mathematical activity and education. Explaining a physical fact via mathematics in order to make it understandable *is* a mathematical practice, and first of all a pedagogical practice. In particular, if I assume with De Regt and Dieks (2005) that understanding transcends the domain of individual psychology and is relative to scientific communities in a specific historical period (they call it the “meso-level in science”), the importance of the acquisition of skills should be take into account in a more complete analysis. As remarked by Jeremy Avigad (2008) in his discussion of the notion of understanding in mathematical proofs:

We look to mathematics for understanding, we value theoretical developments for improving our understanding, and *we design our pedagogy to convey understanding to students*. Our mathematical practices are routinely evaluated in such terms. It is therefore

reasonable to ask just what understanding amounts to (Avigad, 2008, p. 449. My emphasis).

So mathematical education is directly linked to the concepts of understanding, mathematical explanation and to the intelligibility standard of visualizability. In this direction: transitions in the formulation of Euler's theorem in mathematical (and physical) textbooks could be very helpful in order to study mathematical explanation in our sense and the variation of "what is considered more understandable" from a pedagogical point of view.

In the next Section I will briefly give an outline of the theorem and the two different mathematical explanations for the physical phenomenon. In Section 3 I will claim that MEPPs in this particular case have dynamical character, while in Section 4 I will focus on visualizability, understanding and on the particular role of vector space theory. I will defend the epistemic relevance of a contextual notion of understanding and I will put in evidence a shift in the notion of visualizability for this particular case of explanation. The final section will contain my conclusions and some epistemological and educational perspective.

2. EULER'S THEOREM

2.1 Euler's Original mathematical formulation in E177

Euler's contributions to mechanics are numerous and of primary importance. Between them, the remarkable fact that Euler was the first to prove the existence of an instantaneous axis of rotation in the kinematics of rigid body motion. He obtained the result of the instantaneous axis of rotation for the first time in his paper E177 *Decouverte d'un nouveau principe de Mecanique*. In this work Euler utilizes previous results in order to study the general motion of a rigid body with a fixed point and deduce the changes in the position and the velocity distribution from the given forces acting on the body [3]. His enterprise in the dynamics of rigid body motion in space was stimulated by the problem of the rotation of the Earth around its axis (as to explain the precession of equinoxes). The introduction of the perpendicular rectangular frame of reference permits Euler to apply Newton's second law separately with respect to each of the coordinates. This was brought about by a kinematical result: the instantaneous axis of rotation.

In the section *Détermination du mouvement en général, dont un corps solide est susceptible, pendent que son centre de gravité demeure en repos*, in order to study the velocity distribution, Euler introduces a cartesian system fixed in absolute space and assumes that a point Z of the body with coordinates x, y, z has velocities P, Q, R in the direction of the axis. The components of the velocity P, Q, R are functions of x, y, z . Euler's final purpose is to found those functions. He considers another point z "infiniment proche du précédent Z ", of coordinates $x + dx, y + dy, z + dz$ and velocities $P + dP, Q + dQ, R + dR$. After a mixed geometrical-analytical procedure

Euler is able to state that there are points, which have coordinates $(Cu, -Bu, Au)$, that do not move during time dt . In other words, those points are on a straight line through the origin, which is called the instantaneous axis of rotation [4].

... tous les points du corps, qui sont contenus dans ces formules $x=Cu$, $y=-Bu$, $z=Au$ demeureront en repos pendant le tems dt . Or tous ces points se trouvent dans une ligne droite, qui passe par le centre de gravité O ; donc cette ligne droite demeurant immobile sera l'axe de rotation, autour duquel le corps tourne dans le présent instant (Euler, 1750. p. 95).

Euler also added a geometrical proof of the existence of the instantaneous axis of rotation, discussing the infinitesimal motion of a spherical surface with a fixed point. The geometrical argument provided by Euler legitimates his analytical argument and holds not only for the instantaneous case but also for the discrete case.

2.2 A Modern formulation in Linear Algebra

As originally proved by Euler, the theorem for rigid body motion states that: “The general displacement of a rigid body with one point fixed is a rotation about some axis”. The motion of a rigid system in modern mechanics is described specifying at each instant the position of the points of the body with reference to a system of axis. To every point we associate a vector which belongs to an euclidean 3-dimensional space. The orientation of the rigid body in motion can be described at any instant by an orthogonal transformation, the elements of which may be expressed in terms of some suitable set of parameters. With the progression of time the orientation will change and the matrix of the transformation will evolve continuously from the identity transformation $\mathbf{A}(0)=\mathbf{1}$ to the general matrix $\mathbf{A}(t)$. Here we assume that at time $t = 0$ the body axes (the axes fixes in the rigid body) are chosen coincident with the space axes (a system of axes parallel to the coordinate axes of external space). The assumption that the operation implied in the matrix \mathbf{A} describing the physical motion of the rigid body is a rotation assures that one direction (the axis of rotation) remains unaffected in the operation and the same holds for the magnitude of the vectors. If we consider as the fixed point in the rotation the origin of the sets of axes (and not necessarily the center of mass of the object), the displacement of the rigid body involves no translation of the body axes and we can restate Euler's theorem in the following modern mathematical form: “Every matrix \mathbf{A} in $SO(3)$, with \mathbf{A} different from \mathbf{I}_3 , has an eigenvalue $+1$ with a 1-dimensional eigenspace” (Sernesi, 1993, p. 305).

A proof of the mathematical theorem in the form I have given involves the general concepts of matrix, vectors (in particular the more specialized concepts of eigenvalue and eigenvector), eigenspace, basis, orthogonality, bilinear forms (in particular the scalar product, which is a symmetric and non-degenerate bilinear form). All those concepts are included in linear algebra and their close interplay does not permit any

easy separate analysis of the elements which are found in the proof structure of such a theorem. Israel Klein pointed out this difficulty in his *History of Abstract Algebra*:

Among the elementary concepts of linear algebra are linear equations, matrices, determinants, linear transformations, linear independence, dimension, bilinear forms, quadratic forms, and vector spaces. Since these concepts are closely interconnected, several usually appear in a given context (e.g. linear equations and matrices) and it is often impossible to disengage them (Klein, 2007, p. 79).

The modern proof of the algebraical formulation is constructed into the general framework of linear algebra and the particular framework of euclidean 3-dimensional vector space \mathbf{R}^3 . Clearly, the proof's outcome is to show the existence of the eigenvalue $\lambda=1$ [5]. If we do not consider the concept of group, and we focus on the general concept of vector space, we could analyse the explanatory structure and make some relevant remarks.

3. SHIFT IN MATHEMATICAL EXPLANATION

It is clear that Euler did not have at disposition the modern concept of vector and vector space. But, as we can see from his papers, he did have the basic idea of geometrical transformation (point-to-point association in space and not transformation from physical magnitude to geometrical magnitude), which was central to his analysis. Differently from Euler's original argument, in which the mathematical explanation is given by a mixed geometrical-analytical argument by means of a geometrical space (and *via* a geometrical intuition [6]), the modern explanation of the existence of an instantaneous axis of rotation is given in the framework of linear algebra. Having the particular structure of euclidean 3-dimensional vector space is essential to Euler's theorem as formulated in modern terms because only the mathematical properties of a real vector space equipped with scalar product permit to "map" the properties of the kinematical system (angles, distances, orthogonality condition) into the algebraic structure.

In a recent paper Gingras (2001) has underlined how the shift in explanation and the "disparition of substances into the acid of mathematics" are an epistemic and an ontological effect of the process of mathematization started with Newton. As a consequence of an historical process concepts like determinant, matrix, orthogonality or transformation are today included in the mathematical apparatus of linear algebra and we could profit of their interplay without exit from this framework (i.e. the framework of abstract algebra). In other words: in the modern algebraical proof the geometrical part is already "included" in the structure of vector space and we do not need a geometrical argument [7]. It is very interesting to observe that Peano himself, in his *Analisi della teoria dei vettori*, remarked:

Thus the theory of vectors appears to be developed without presupposing any previous geometrical study. And since, by means of this theory, all of geometry can be treated,

there results thereby the theoretical possibility of substituting the theory of vectors for elementary geometry itself (Peano, 1898, p. 513).

After having proved the dynamical character of mathematical explanation (i.g. the mathematics is essential to both the two explanations but it *changes*), in the following Section I will use De Regt & Dieks's criteria for understanding and intelligibility in order to show how the theory of vector space offers a new conceptual tool of intelligibility and understanding.

4. UNDERSTANDING AND VISUALIZABILITY IN MEPP.

If I admit (and I do!) with De Regt & Dieks (2005) that visualizability constitutes a context-dependent standard of intelligibility, and only intelligible theories can provide an understanding of phenomena, then I can look at the shift between our two MEPPs in a more fruitful and interesting way. But, first of all, it is necessary to give a possible sense to the notions of visualizability, intelligibility and understanding.

As showed by De Regt (2001) being a spacetime theory is a necessary but not sufficient condition for visualizability. It might be objected here that I deal with mathematical entities and the term “spacetime” is very dangerous and misleading. Fortunately, I am referring to MEPPs and for my particular test case the conditions of necessity and sufficiency for visualizability are both fulfilled (Euler's geometrical framework and the framework of vector space theory both make the physical phenomenon *visualizable* in space -as a vector- at a particular time t , as could be seen from the diagrams we find in a common textbook of mechanics or mathematics). We can say that geometrical space in Euler and the modern concept of vector space *map* the physical space into a structure (a geometrical and a mathematical structure). In the case of vector space this mapping consists in an explicitly assumed isomorphism between the physical space and the 3-dimensional Euclidean space.

De Regt & Dieks (2005) propose two criteria for understanding and intelligibility: CUP (Criterion for Understanding Phenomena) and CIT (Criterion for the Intelligibility of Theories).

CUP: A Phenomenon P can be understood if a theory T of P exists that is intelligible (and meets the usual logical, methodological and empirical requirements).

The necessary connection between visualizability and understanding is made by De Regt through the Criterion for the Intelligibility:

CIT: A Scientific Theory T is intelligible for scientists (in context C) if they can recognize qualitatively characteristic consequences of T without performing exact calculations.

In the previous Criterion I substitute “Mathematical Theorem” for “Scientific Theory” and I assume the applicability of the CIT in both cases (with some differences that should be discussed). But how do we “recognize qualitatively

characteristic consequences of T without performing exact calculations”? A possible answer: through conceptual tools. In a particular historical or methodological context we have at disposition some conceptual tools and visualizability *could be* one of them [8]. In other words: visualizability is a conceptual context-dependent tool, i. g. a conceptual contingent tool which depends from the skill of the scientific-mathematical community and which is present during a precise historical period, and it *could* permit the intelligibility of a theory making possible the circumvention of the calculatory stage and the jump to the conclusion. So it is clear that also intelligibility is context-dependent. Naturally, as remarked by De Regt (2001), visualizability is not a necessary condition for intelligibility. Often other conceptual tools as abstract reasoning or familiarity could lead scientists and mathematicians to intelligibility as an immediate conclusion (see De Regt & Dieks, p. 156, for examples). Mathematical practice and theoretical physics are full of situations like this.

In Euler the tool of visualization is perfectly applicable in the classical geometrical framework (I call it Euclidean Geometrical Theory): point-to-point association and geometrical considerations offer the idea (a *visual idea*) of what is happening to the mechanical system in motion. The instantaneous axis of rotation could always be visualized in spacetime, and its existence could be established through a geometrical-intuitive reasoning [9]. In the modern explanation given in the framework of abstract algebra it might seem that this “chance” of intelligibility has been lost, but a deeper look shows that this is not completely true. The concept of 3-dimensional Euclidean vector space offers two new ways for obtaining the intelligibility (in line with CIT). Reading the modern formulation of Euler’s theorem a mathematician or a student could affirm “Yes, I see the eigenvalue +1”, just by looking at the formulation of the theorem in the matrix formalism. This is associated with the conceptual tool of familiarity, or abstract reasoning, and is related to a previous learning of matrix theory or other mathematical abilities. Instead of this approach, one can reach the same direct conclusion just by considering some general results in matrix theory and *visualizing* the eigenvector (the instantaneous axis) in the diagram [10]. The latter can be considered a new conceptual tool leading to the fulfilment of CIT. Naturally, the structure of $n \times n$ matrices with entries from \mathbf{R} and the structure of homomorphisms of a 3-dimensional space (over \mathbf{R}) into itself are isomorphic. From the last considerations is clear that visualizability still plays a very important role in understanding and in developing a fruitful strategy of mathematical education.

5. CONCLUSIONS AND PERSPECTIVES

MEPPs are context-dependent and have dynamical character. In particular, *via* a contextual approach to understanding, it is possible to recognize that the framework of linear algebra has defined new standards (or tools) for intelligibility which legitimate an explanation as “a good explanation” (an explanation which produces understanding). The understanding in this context is a payoff that directly comes from the availability of those conceptual tools. As I have showed, in the modern

formulation the understanding of the mathematical explanation for the existence of an instantaneous axis of rotation is obtained through *a double route* (visualization and abstract reasoning). I claim that this result might be very helpful in mathematical education and could offer a possible answer to Avigad's question "How do we design our pedagogy to convey understanding to students?" for the specific case discussed. A new interesting direction, as showed by Marcus Giaquinto in his studies on the epistemic function of visualization in mathematics (Giaquinto, 2005), could emerge from an analysis of visualization as a powerful educational tool in the context of discovery [11].

A better comprehension of mathematical explanation could profit from the historical study of the interplay between the proof structure of the theorem and the system of concepts that characterizes the explanatory structure. If a change in one of them influences the other, it could be interesting to study different formulations of Euler's theorem in textbooks in order to see how the mathematical explanation has been offered during this period and how it has changed in mathematical education. Naturally, the epistemological analysis of this paper opens the way to the more general question of how introduce proofs in classrooms and how concepts like explanation, understanding and visualizability should be taken into account in mathematical education.

NOTES

1. For shortness, from now on, I will refer to Mathematical Explanation of Physical Phenomena with the term MEPP.
2. For a panoramic of this field and the very interesting discussion of this point, including how computer graphics has helped to recognize mathematical structures such as Julia sets which would have been impossible to recognize analytically, see Mancosu (2005).
3. For a more precise reconstruction of Euler's argument in Euler (1750) see the paper "What we can learn about mathematical explanations from the history of mathematics" I've presented at *Novembertagung* Conference, in Denmark, 5-9 November 2008.
4. Euler does not use the word "instantaneous axis". He refers to it simply as "axe de rotation".
5. For a proof of the theorem see Sernesi (1993, p. 306).
6. The importance of the geometrical intuition in Euler emerges from the geometrical proofs he adds after his analytical arguments. The geometrical argument defines and legitimates the analytical procedure and is essential to the mathematical explanation of the existence of the axis.
7. Vector spaces firstly appear in their axiomatic form in Peano (1888).
8. Evidently, the intelligibility standard or tool of "casual connection" is of no interest in our discussion.
9. See Euler's geometrical argument or a modern geometrical argument (Whittaker, 1904, p. 2).

10. Here I am not claiming that the geometrical interpretation of matrices and eigenvectors is intrinsic in their definitions. I am assuming that under a particular “reading” (in our case Euler’s theorem in kinematics of rigid body motion), a subset of vectors of the vector space considered (the subset containing the instantaneous axis) has a geometrical representation in a diagram at time t (or a representation in a computer graphic simulation). A very good example of a case in which a precise situation is visualizable in the context of Vector Space Theory has been given by Artin (1957) and is discussed in Tappenden (2005).
11. For simple and interesting cases in which a case of visualization could provide the discovery of a theorem see Giaquinto (2005) or, in a different flavour, the famous Lakatos (1978).

ARGUMENTATION AND PROOF: A DISCUSSION ABOUT TOULMIN'S AND DUVAL'S MODELS

Th. Barrierⁱ, A.-C. Mathéⁱⁱ, V. Durand-Guerrierⁱⁱⁱ

LEPS^{i, iii}, Université Lyon 1^{i, iii}, LMLⁱⁱ, Université d'Artoisⁱⁱ

In this paper, we discuss the idea of a gap between argumentation and proof, an idea we think to be prevailing in the educational institution. Our claim is that the only use of propositional calculus is insufficient to the analysis of the validation process in mathematics and could artificially reinforce that idea of a gap. This claim can be understood as a criticism of Toulmin's and Duval's model, a criticism we hope to be a constructive one. We are then brought to the following proposal: taking explicitly into account the logical quantification and the mathematical objects in the models could help to explain mathematical creativity.

INTRODUCTION: THE PREGNANT IDEA OF A GAP

The issue at stake in this paper is the relationship between argumentation and proof. It seems to us that the assumption of a gap prevails in the educational institution. This prevalence could have major effects on mathematic education:

« Is it possible, yes or no, to shift from one to the other without too many efforts or misunderstandings?

[...]

If one answers No, one admits there is a gap between the cognitive processes of argumentation and the deductive reasoning at stake in a proof: the use of argumentation could not but maintain or even reinforce the obstacles and misunderstandings about what a proof is, because its discursive process acts against a valid reasoning process in ordinary language. » (Duval, 1992, p. 43, our translation)

Willing to take into account this gap between argumentation and proof, which is theorised in Duval's works, part of the teachers have been induced to put forward specifically the formal aspect of the proof (through structuring attempts like "I know that", "Now", "Therefore" for example) and to distinguish this aspect from the work on the content of statements. This phenomenon can be seen in Kouki's thesis (2008) through a survey carried out among six Tunisian teachers about learning and teaching of equations, inequalities and functions. Moreover, Kouki shows, through a more extended experimental study (involving 143 pupils and students in their transient period between secondary school and higher education) the consequences of these theoretical conceptions on the students' practices which tend to apply formal procedures as much as possible. In another context, Segal (2000) highlights the tendency of UK students to evaluate proof validity only from their formal aspect. There are a lot of examples of this phenomenon. We shall focus on two specific ones in order to point out the stakes of this issue.

Example 1

This example is taken from Barrier (2008) in which an extract of Battie (2003) is analysed. In this paper, a group of three students in scientific upper sixth form are asked to evaluate the following statement $\forall a \forall b (GCD(a,b) = 1) \Rightarrow (GCD(a^2, b^2) = 1)$. The group starts an argumentation built on the choice of some coprime natural numbers (3 and 2, 2 and 5, 9 and 17 then 4 and 15) and on the evaluation of the GCD of their respective square. Here is an extract of their dialogue (translated from French).

1. A : Or 125 and 16. They are relatively prime.
 2. I don't know.
- (Laughs)
3. You set 125 divided by 16 and you'll see... No, it is not the right way to do it. 16 by 16 is 4 2, 2 times 2/
 4. A : No, I think 16 and 125 are relatively prime.
 5. Yeah, when we square the things/
 6. A : Yeah, but we don't know, it's not written in the text book, but we can't prove it in the general case /
 7. Oh we make fun of it!
 8. A1 : We can't use it then. Well, I think, I really don't know, the teacher may have told it.

In (3), a student undertakes a prime factorization of 16. This method could be used for the emergence of a proof of the analysed statement. However, it seems to us that the students, influenced by their school culture regarding proof, disregard this possibility. They act as if the evaluation of a statement through an argumentation built on the manipulation of objects and the search for proof were two distinct and independent activities.

Example 2

Alcock & Weber (2005) analyse how thirteen student volunteers taken from first-term, first year introductory real analysis courses check the validity of the following proof (they were asked to determine whether or not the proof was a valid one):

Theorem. $\sqrt{n} \rightarrow \infty$ as $n \rightarrow \infty$

Proof. We know that $a < b \Rightarrow a^m < b^m$.

So $a < b \Rightarrow \sqrt{a} < \sqrt{b}$.

$n < n+1$ so $\sqrt{n} < \sqrt{n+1}$ for all n .

So $\sqrt{n} \rightarrow \infty$ as $n \rightarrow \infty$ as required.

The inference between the two last propositions is invalid. Exactly two students rejected the proof because they had familiar counter-examples. Their rejection was not founded on the recognition of a logical gap between the propositions. Three other students rejected the proof. They did it because they failed to recognize what they thought to be a proof structure. In particular, they argued that the definitions of the mathematical concepts involved in the argument were not used. Their decision seems to be grounded on exclusive formal considerations. From the point of view of mathematical activity, this is a misconception: definitions are not always employed in a mathematical proof and, above all, very few mathematical proofs are enough detailed so that their logical structure can be recognized without any work. To finish with this example, notice that while only two students refused the proof because of an invalid warrant, ten did it when the interviewer helped them to interpret " $n < n+1$ so $\sqrt{n} < \sqrt{n+1}$ for all n " as "the series is increasing" and " $\sqrt{n} \rightarrow \infty$ as $n \rightarrow \infty$ " as "the series is divergent". Our hypothesis is that this last intervention allowed the students to enter the semantic content of the proposition. Precisely, the translation into ordinary language could help them to go to a semantic interpretation in a familiar domain in which they know that there is some increasing and convergent series.

We shall now undertake a criticism of Duval and Toulmin's models which are often used in research in mathematical didactics about argumentation and proof (Mathé (2006), Tanguay (2005), Inglis & al. (2007), Pedemonte (2007, 2008)). Our main thesis is that using the proposition (in the sense of propositional calculus, as opposed to predicate calculus) as a basic element of modelling leads to overestimate the gap between argumentation and proof. In particular, we consider that taking into account mathematical objects and quantification in the didactical analysis allows a quite different approach to the validation process in mathematics.

BRIEF PRESENTATION OF DUVAL AND TOULMIN'S MODELS

We shall begin with a brief presentation of Duval's approach. Let us use Balacheff's presentation (2008, p. 509):

“Deductive reasoning holds two characteristics, which oppose it to argumentation. First, it is based on the operational value of statements and not on their epistemic value (the belief which may be attached to them). Second, the development of a deductive reasoning relies on the possibility of chaining the elementary deductive steps, whereas argumentation relies on the reinterpretation or the accumulation of arguments from different points of view. (Following Duval 1991, esp. p. 240–241).”

Duval often stands out that only argumentation lies on the content of propositions whereas what is important in a proof is the operating status of the proposition (in other words the way the proposition fits into the formal structure of the "modus ponens").

"This brings a first important difference between deductive reasoning and argumentative reasoning. The latter appeals to implicit rules which depend partly on the language

structure and partly on interlocutors' representations: therefore the semantic content of the propositions is essential. On the contrary, in a deductive step, the propositions do not intervene directly according to their **content** but according to their **operating status**, that is to the position previously assigned to them in the step process" (Duval, 1991, p. 235, our translation)

Duval especially focuses on this argument to support the idea that proof and argumentation involve very different cognitive processes. In this matter, Balacheff (2008, p. 509) points out that:

« One can imagine how this should raise question in our field considering that other researchers give a central role to “mathematical arguments” and “mathematical argumentation” in their consideration of what proof is.”

Recently, Toulmin's model has been used in many works focused on reasoning from a mathematics education viewpoint. The following example shows how Pedemonte (2008, p. 387) presents Toulmin's restricted model:

“In Toulmin’s model an argument consists of three elements (Toulmin, 1993):

C (claim): the statement of the speaker.

D (data): data justifying claim C.

W (warrant): the inference rule, which allows data to be connected to the claim.

In any argument the first step is expressed by a standpoint (an assertion, an opinion). In Toulmin’s terminology the standpoint is called the claim. The second step consists of the production of data supporting the claim. The warrant provides the justification for using the data conceived as a support for the data-claim relationships. The warrant, which can be expressed as a principle, or a rule, acts as a bridge between the data and the claim.”

This model has been used to analyse as well the production of arguments as the production of proof. In particular, Pedemonte uses this model to compare argumentation and proof relationships. Therefore the three elements (C, D, W) must be considered as more inclusive than the ternary structure of "modus ponens" (A, $A \rightarrow B$, B) used by Duval to analyse the proof in the sense where the Toulmin's model warrant is not necessarily a theorem. Nevertheless, these two models share a common point by both using the proposition in the sense of propositional calculus as a basic element of modelling. Mathematical objects and quantification are not explicitly taken into account in the model structure.

AN EXAMPLE OF USE OF A QUANTIFICATION THEORY

Several attempts have been made to use first-order theories in order to help analysing mathematical reasoning in our research team (natural deduction in Durand-Guerrier & Arzac (2005) and Durand-Guerrier (2005), Tarski's semantics in Durand-Guerrier (2008), Lorenzen's dialogic logic and Hintikka's game semantics in Barrier (2008)). The ambition of these theories is to allow for the relationships between the semantic

and syntactic aspects to be taken into account in the validation activities. On the contrary, Duval identifies a reasoning step when applying the "modus ponens" rule. He asserts for example:

«The deductive step process is well known. It is defined by the fundamental rule "modus ponens", also called Law of Detachment." (Duval, 1992, p. 43, our translation)

We also saw that Toulmin's model rested on the same type of ternary structure. Durand-Guerrier & Arsac (2005, p. 151-152) showed that this standpoint was insufficient for analysing proof, especially in the case of analysis. Furthermore, the only "modus ponens" rule cannot exhaust the propositional calculus insofar as other deductive rules are necessary (Vernant, 2006, Chapter 3). Nevertheless, the deductive step derived from the Law of Detachment prevails in proof learning at lower secondary school and certainly deserves special attention. Our contribution will rather focus on the theoretical effects of this restriction: we consider that restricting the model to the propositional calculus induces to overestimate the distinction between argumentation and proof. Let us consider how Duval (1992, p. 44-45, our translation) analyses the following text by Sartre:

« Jessica : Hugo ! You speak reluctantly. I watched you when you talked with Hoerderer :

0. He convinced you.

Hugo : 1. No, he didn't convince me.

2. Nobody can convince me that (one must lie to its friends).

3a. But if he had convinced me.

3b. It would be a reason more to shoot him.

4. Because it would prove that he would convince other guys. »

Duval asserts that this argumentation appeals to the following deductive step:

Premise: If he had convinced me

Warrant: Nobody can convince me that one must...

Conclusion: (it would prove that) he would convince other guys.

This modelling leads Duval to draw the fundamental differences between argumentation and proof. Indeed, the argumentation step as modelled by Duval is quite different from the proof step based on the "modus ponens". Our questioning on this model induces us to suggest an alternative interpretation of this argumentation step based on natural deduction (Durand-Guerrier & Arsac (2005)). We note that xCy is the assertion that « x has convinced y ». The first step of Hugo's reasoning may then be interpreted in the following way:

Data: $\forall x \neg (xCHugo)$ (2)

Inference rule: universal instantiation

Conclusion: $\neg(\text{HoedererCHugo})$ (1)

We shall go on with the analysis of the reasoning (setting apart the assertion (3b) and identifying (4) with «he would convince other guys », i.e. removing what seems to refer to metalanguage) in the following way:

Data : HoedererCHugo (3a)

Inference rule: existential generalisation

Conclusion: $\exists x\text{HoedererCx}$

Data: $\exists x\text{HoedererCx}$ (recycling)

$\exists x\text{HoedererCx} \rightarrow \exists x\exists y(x \neq y) \wedge \text{HoedererCx} \wedge \text{HodererCy}$ *

(implicit axiom)

Inference rule: modus ponens

Conclusion: $\exists x\exists y(x \neq y) \wedge \text{HoedererCx} \wedge \text{HodererCy}$ (4)

One shall notice that without the implicit axiom (*) (if Hoederer is able to convince one person, then he is able to convince two persons at least) the deduction from HoedererCHugo to $\exists x\exists y(x \neq y) \wedge \text{HoedererCx} \wedge \text{HodererCy}$ would be invalid. Therefore it is necessary, in a way, to complete the reasoning to make it valid. In this extract, one does not know whether the implicit theorem applied is part of a set of statements which are jointly accepted by Hugo and Jessica. However, this type of completion is not exclusive to argumentation, since in mathematics a fully explained proof would be much too long and therefore illegible. Weber (2008) puts forward an experimental study on how proofs are checked by mathematicians. This does not mean that the check is limited to the good practices of inference rules: proof checking, including validation, calls on not only a search for sub-proofs but also for informal or example-based arguments.

Now, an important question to be raised is the relationship between proof and proposition content. In the analysed example, we used an implicit axiom to complete the formal analysis of reasoning. This axiom is linked to a certain idea we have about the interpretation field objects (human beings in this example), what Duval calls the semantic content of propositions. In particular, the implicit axiom (*) is based on the idea that human beings are more or less homogeneous. The purpose of the following paragraph is to show that the content of propositions also intervenes in the proof construction.

« CONTENT » OF PROPOSITIONS AND PROOFS

We use here an experiment from Inglis & al. (2007). Andrew, an advanced mathematics student, is confronted with the conjecture « if n is a perfect, then kn is abundant, for any $k \in \mathbb{N}$ ». Notice that a perfect number is an integer n whose

divisors add up to exactly $2n$ and that an abundant number is an integer n whose divisors add up to more than $2n$.

ANDREW : Ok, so if n is perfect, then kn is abundant, for any k . Ok, so what does it, yeah it looks, so what does it mean ? Yeah so if n is perfect, and I take any p_i which divides this n , then afterwards the sum of these p_i s is $2n$. This is the definition. Yeah, ok, so actually we take kn , then obviously all kp_i divide kn , actually, we sum these and we get $2kn$. Plus, we've got also, for example, we've also got k dividing this, dividing kn . So we need to add this. As far, as basically, there is no disquiet, k would be the same as this. Yeah. And, how would this one go ? [LONG PAUSE]

INTERVIEWER : So we've got the same problem as up here but in general ? With a ... ?

ANDREW : Yeah. Umm, can we find one? Right, so I don't know. Some example.

INTERVIEWER : I've got some examples for you.

ANDREW : You've got examples of some perfect numbers ? OK, so 12, we've got $1 + 2 + 3 + 4 + 6$, then, ok, $+ 12$. [MUTTERS] But this is not ? Ok, perfect, I wanted perfect numbers. OK, so let's say six. Yeah, and we've got divisors 2, 4, 6, 12. Plus I claim we've got also divisors. Yeah actually it's simple because, err, because err, the argument is that we've also got 1 which is divisor, and this divisor is no longer here is we multiply.

At the beginning of the interview, Andrew manipulates the definition of the concepts involved in the conjecture but this strategy fails to construct a proof. Then, he asks for examples and begins to play a semantic game which involves several numbers. As Duval says, this game increases the belief of the students in the validity of the conjecture (the epistemic value of the conjecture). In this sense, those kind of games are cumulative. However that argumentation which is linked with the content of the conjecture seems to be the clue of the completion of Andrew's strategy in his former attempt of proof construction. This is the manipulation of the perfect number 6 which provides to Andrew the idea that for all n , 1 is a divisor of $2n$ which is not equal to any $2k$ (with k a divisor of n). Pedemonte (2008) provides several convergent examples concerning algebra. In particular, she stands for the need of an argumentation which would integrate what she calls abduction steps in the proof construction process. In our example, the purpose is to explain why 12 would be abundant, starting from the fact that it is abundant (this practice is sometimes called the *analysis of analysis/synthesis* dyade). The proof approach (the synthesis of the dyade) is based on this explanation (12 is abundant because 1 is a divisor of 12 which is not a double of any divisor of 6). Pedemonte (2007, p. 32-33) also gives an example of this type of approach in geometry. Besides, from experiments carried out in set theory and analysis, Weber & Alcock (2004) underline the weakness of syntactic proof procedures ("unwrap definitions" and "push symbols") compared with semantic procedures (which call on object instantiations).

ABOUT TOULMIN'S COMPLETE MODEL

In their above-mentioned paper, Inglis & al. (2007) advocate the use of Toulmin's complete model which includes three new categories: the backing, the modal qualifier and the rebuttal which are introduced as follows (p. 4) :

« The warrant is supported by the *backing* (B) which presents further evidence. *The modal qualifier* (Q) qualifies the conclusion by expressing degrees of confidence; and the *rebuttal* (R) potentially refutes the conclusion by stating the conditions under which it would not hold. »

The authors show that there are various types of *warrant* that the students (five students prepare a doctorate degree and one a master degree) connect with various *modal qualifiers*. They advocate the importance of inductive and intuitive justifications in the mathematical activity provided that these justifications are paired with the appropriate modal qualifier for the conclusion of the argument. They underline the interest for didactics researchers to use modal qualifiers specifically in the analysis process.

“The restricted form of Toulmin’s (1958) scheme used by earlier researchers to model mathematical argumentation constrains us to think only in terms of arguments with absolute conclusion.” (Inglis & al., 2007, p. 17)

In his *remark on Toulmin*, Jahnke (2008, p. 370) makes this argument his own and emphasises the role of open general statements in mathematics. It seems to us that the role assigned to modal qualifiers in Toulmin's model shows that it is very difficult, in the didactic of mathematics, to integrate mathematical objects and their manipulation into models which are basically built from the propositional logic and from a syntactic approach of the mathematical activity.

CONCLUSION

Barrier (2008) advocates the necessity to appeal to transactional and intra-world procedures (Vernant, 2007) in order to explain mathematical creativity, i.e. to take into account the students' specific interactions with mathematical objects and the following decisions. The quantification theories, in particular the theories which develop a semantic point of view, allow to explain the milieu's enrichment (Brousseau, 1997) along the proof processes. Durand-Guerrier (2008) also stresses the importance of the manipulation of objects in order to make mathematical practice fertile. This viewpoint seems to converge with Weber & Alcock's position:

“Just as most streets in a town intersect many other streets, at any given point in a proof, there are many valid inferences that can be drawn that might seem useful to an untrained eye [...]. Hence, writing a proof by syntactic means alone can be a formidable task. However, when writing a proof semantically, one can use instantiations of relevant objects to guide the formal inferences that one draws, just as one could use a map to suggest the directions that they should prescribe.” (Weber & Alcock, 2004, p. 232)

Obviously, every argumentation does not lead to proof, since the rules of the game are different in these two activities. In particular, in geometry, it is likely that the important gap between the different semiotic registers makes it more difficult to shift from an argumentation game to a proof game. As stated by Balacheff (2008, p. 509), it is necessary to bear this semiotic thinking in mind in order to understand Duval's approach. However, as we pointed it out in our examples, the assumption of an impassable gap between proof and argumentation is likely to hinder students' validation attempts. In particular, when validation is not immediate (we mean that it does not directly derive from the manipulation of the definitions of concepts involved in the statement of the proposition to be proven), it is often necessary to work on the content of the propositions. From a mathematical activity viewpoint, proof production seems to go with the familiarisation with mathematical objects.

WHY DO WE NEED PROOF

Kirsti Hemmi

Clas Löfwall

Linköping University, Sweden

Stockholm University, Sweden

We explore teaching mathematicians' views on the benefits of studying proof in the basic university courses in Sweden. The data consists of ten mathematicians' written responses to our questions. We found a variety of ideas and views on the function of proof that we call transfer. All mathematicians in the study considered proofs valuable for students because they offer students new methods, important concepts and exercise in logical reasoning needed in problem solving. The study shows that some mathematicians consider proving and problem solving almost as the same kind of activities. We describe the function of transfer in mathematics, exemplify it with the data at a general level and present particular proofs illuminating transfer that were mentioned by the mathematicians in our study.

INTRODUCTION

The various functions of proof in mathematics and mathematics education have been discussed by researchers during many years and they have gained a wide consensus in the mathematics education research community (Bell, 1976; De Villiers, 1990; Hanna, 2000). Especially the functions of conviction and explanation have been in focus in the field (e.g. de Villiers, 1991; Hanna, 2000; Hersh, 1993). However, Weber (2002) states that besides proofs that convince or/and explain there are proofs that justify the use of definitions or an axiomatic structure and proofs that illustrate proving techniques useful in other proving situations. Lucast (2003) studied the relation between problem solving and proof and found support for the importance of proofs rather than theorems in mathematics and mathematics education for example from Rav's (1999) philosophical article. Lucast considers proof and methods for problem solving as in principal the same and states that proving is involved in the cognitive processes needed for problem solving.

According to the mathematicians in our earlier study, there are proofs that can introduce new techniques to attack other problems in mathematics or offer understanding for something different from the original context. For example, they mentioned the method of completing the square in deriving the formula for the solution of the second degree equation as useful in problem solving [1] (Hemmi, 2006). We decided to call this function of proof for *transfer* and we remarked that it had neither been in the focus in the research on proof in mathematics education nor involved in the earlier models about the functions of proof. It is close to and partly overlapping the aspect Weber (2002) describes but not exactly the same. Recently, Hanna and Barbeau (2008) have started to explore this function from a point of view of philosophy and mathematics education [2]. Also they stress that it has been overlooked in mathematics education research.

Extended information about various functions of proof communicates something about the meaning of proof in mathematical practice, and the consciousness of them should therefore be important for how newcomers experience the practice. Some students in our earlier study who had difficulties to follow and understand proofs that were presented in the lectures expressed for instance the lack of examples from mathematicians about connections between proofs and problem solving.

Most often you don't have to be able to know anything of the proofs in order to solve problems. (Student – Intermediate course, 2004 in Hemmi, 2006)

They also advocated working manners and tasks where they could use the proofs in some ways in order to enhance their own engagement with proofs.

I mean tasks in which you are supposed to calculate something using proofs. At least for me, it is easier to understand if I really use them for something. (Student – Intermediate course, 2004 in Hemmi, 2006)

Our recent study contributes to the field by exploring mathematicians' often tacit knowledge concerning the teaching and learning of proof in the practice of mathematics. In this paper, we first describe the function of *transfer* from the perspective of history of mathematics and then present an analysis of a pilot study with ten mathematicians concerning their views on proof, in particular with respect to the function of *transfer* in the basic courses [3] of mathematics in Sweden.

TRANSFER IN MATHEMATICS

Proof has not always been a natural part of mathematical activity. In the old cultures in Babylonia, Egypt and China, mathematicians seemed to be only interested in presenting results which could be used in different applications and not in the question of how these results were obtained. They might have done verifications of results also, but if so, they did not think it was worth while to write them down. With the Greeks, the deduction style of mathematics was born and the emphasis was put rather on the questions of truth, foundations, logic, and proving than on practical applications. Their work in geometry which we know from Euclid's *Elements* has since then been a model for scientific thinking. It was not until the 1900th century that proofs in algebra and analysis could be performed with the same kind of logical strength that was done in the *Elements*. Nowadays, proving has been almost a synonym for doing research in mathematics and an enormous amount of mathematical proofs are produced every year.

A natural question to ask is why the deductive style in mathematics has been so successful? Nobody can question the importance and usefulness of mathematics in the modern society, but do we need the proofs? It is only the very results in mathematics that are used in other sciences and, in the end, they are important for the production of all the facilities we see around us. We think the "market" should have forced mathematics to use the "handbook" style if this turned out to be as (or more)

efficient as the "deductive style". For the Greeks it might have been possible to study proofs just because they thought it was an intellectual challenge, but in our society we think this is impossible.

However, the deductive style in mathematics has survived and been successful. One important reason for this is indeed that the proofs contain information of how to get other results and also often contain methods of calculation used for example in applications. As an example, consider Archimedes result about the volume of the sphere. It is of course interesting for applications to be able to compute the volume of a sphere, and with the formula in hand also some other problems maybe solved, e.g., the volume of a half sphere. But without the proof it is hard to find formulas for the volume of other bodies. Archimedes described the method he used to find the formula, which may be seen as a form of integration and is interesting for other applications. It is a heuristic argument based on his law of the lever. The method contains a lot of information which may be used to reach far beyond the original problem. For other examples of theorems where the proofs are far more interesting than the results, see Rav (1999).

There is certainly a consensus among mathematicians that the proofs contain much more information than just the verification of the results, but how do they think about this function of proof in the teaching context?

METHODOLOGY AND THEORETICAL STANCES IN THE PILOT STUDY

In August 2008, we e-mailed to 16 mathematicians at various universities. We presented the aim of the study and invited them to share their thoughts with us concerning the following questions.

1. Why do you think that students in basic courses should become familiar with proofs and proving or do you think they do not need to do so and in this case why?
2. What specific proofs/derivations do you consider as central in basic courses which you have taught?
3. Are there specific proofs/derivations in the basic courses that teach students techniques, concepts, procedures, strategies or offer other tools that are useful in other contexts, for example in problem solving?
4. Are there proofs not filling the criteria in question 3 but which you in any way consider as central in the basic courses, in that case which proofs and why?

To encourage the mathematicians to response, we stressed that the answers would not need to be exhausting, it was enough to give some examples. Ten mathematicians from five different institutions e-mailed their answers. Although the responses varied both in length and in content we obtained very rich data. We had also the possibility to contact the mathematicians and ask for complementary information.

We consider the mathematicians as *old-timers* in their *communities of practice of mathematics* (see Wenger, 1998). All the mathematicians in the pilot study had at least ten years experience of teaching and all of them have somehow been engaged in the teaching of elementary courses. Learning is conceived as increasing participation in the mathematical practice where proof is a central *artefact* with many functions (see Hemmi, 2006). According to the theory of Lave and Wenger (1991) artefacts and their significance to the practice can be more or less visible for the newcomers. This is called the *condition of transparency* of proof in the teaching of mathematics, i.e. how and how much to focus on various aspects and functions of proof and how and how much to use proof in doing and presenting mathematics without a focus on it as proof (see also Hemmi, 2008).

This is one of the aspects in the conceptual frame that was created by combining the social practice approach with theories about proof obtained from the didactical studies in the field. The other aspects, relevant for this study, are the functions of proof of *conviction*, *explanation*, *communication*, *intellectual challenge*, *aesthetic* and *transfer*. All these aspects are intertwined and partly overlapping but have to be separated in order to be able to analyse the data.

We analysed the data with help of NVivo software by firstly relating the mathematicians' responses to the aspects in the conceptual frame. Then, we used an open approach and looked at the issues enlightening the function of *transfer* from various points of view and connected these issues to the themes described in the introduction (Weber, 2002; Lucast, 2003; Hemmi, 2006; Hanna & Barbeau, 2008).

We interpret the mathematicians' utterances as representative of views belonging to the community, utterances that are influenced by the social, cultural and historical context of the same mathematics environment but also from other possible environments they are members of. The aim of the pilot study is to investigate the diversity of ideas among mathematicians analysing a small sample in order to later explore a larger sample. This is why we cannot generalise the results and there is no use to give exact numbers of mathematicians talking about various themes. We make very little quantifications when reporting the results.

First, we sum up the main reasons mentioned by the mathematicians for why they wanted to include proof in the basic courses. Then we provide some examples about utterances concerning the function of *transfer* at a general level. Finally, we present some specific proofs that according to the mathematicians involved this function.

RESULTS

All the ten mathematicians stated that students in the basic courses should become familiar with proofs and proving. This is interesting because in our earlier study which concerned only one department, most of the mathematicians said they did not deal with proof so much in the basic courses for various reasons (Hemmi, 2006). Yet, some of the mathematicians in the present study pointed out that there was no use to

prove for example statements concerning limits of functions rigorously for the students studying engineering, chemistry or other sciences. One mathematician even stated that one should try to “serve up” mathematics for such students with so few proofs as possible and concentrate on applications.

The mathematicians gave various reasons for why proof is important to include in the curriculum for the basic courses. Some of them stated that proof helped to make visible the difference between school mathematics and university mathematics for the students and that inclusion of proof in the curriculum helped students to leave their preconceived interpretations about what mathematics actually is. Proof should be included in the basic courses because proof is the soul and the backbone of mathematics. It is the very idea of doing mathematics. According to one mathematician, working with some proofs also offered possibilities to discuss what proof is. This refers to the aspect of *transparency*.

In line with our earlier study many mathematicians consider school mathematics as teaching students to apply rules they get through examples from the teacher or a textbook. According to the mathematicians, this manner does not lead to understanding of what mathematics is, “i.e., concepts and intuitive and logical reasoning about these concepts and their relationships”. Proof explains how the concepts are related to each other. This view refers to the function of *explanation*.

Another reason the mathematicians gave was that proof connects all mathematics, without proof “everything will collapse”. You cannot proceed without a proof. This refers to the *verification* function of proof.

Some mathematicians stressed that it was important to present proofs (or convincing arguments) for statements which are not conceived as evident by the students. This refers to the attempts to create possibilities for the students to experience the function of *conviction* of proof.

One mathematician stated that proof enhanced students’ interest towards mathematics by giving aha-experiences and also that students were curious about proof. The latter was confirmed by our study among university entrants. It showed that about 80 percent of students were interested in proof and wanted to learn more about proof when they came to the university (Hemmi, 2006). This refers to the function of *intellectual challenge*.

One mathematician also pointed out that it was important to present some “beautiful proofs” even if he thought it was difficult to find such proofs suitable for the basic courses. This refers to the function of *aesthetic*.

Finally, one of the mathematicians talked about proof as useful in the learning of mathematical language. This refers to the function of *communication*.

All the functions mentioned above are interconnected and partly overlapping. Some of the reasons presented in this section that the mathematicians mentioned for why

they wanted the students to meet proof in the basic courses are already connected to the function of *transfer*, the main target of this article.

Transfer at a general level

All mathematicians considered proofs more or less important in a manner that they taught students concepts and techniques needed in problem solving even if one of them mostly saw benefits at this level for other proving tasks. Some of the mathematicians stated that all essential proofs in the basic courses carried this function whereas others had difficulties to find examples of proofs involving this function at the basic level.

At a general level, many mathematicians mentioned that proofs helped students to learn *mathematical and logical reasoning* valuable in problem solving.

If one becomes accustomed to study proofs one gets practiced with mathematical reasoning, something one can draw great advantages of in problem solving. Problem solving is an art of formulation. (M4)

But they (the proofs) should also contribute to demonstrate and develop students' skills of logical reasoning. This is useful in many situations. One of the function of mathematics in the engineering program is this. (M8)

Yet, not all mathematicians considered this function of proof so important for engineering students as the one in the citation above.

Also the *understanding of generalisations*, especially with respect of the *models for problem solving* within mathematics or in applied sciences could be enhanced by studying proof according to some mathematicians.

They have to start to argue for the solutions of the problems for example in applications that they present, show that they are correct, so they can work in a manner not just filling in numbers in given models but tackle new problems. (M10)

One mathematician talked about the value of proof for problem solving because they helped students to learn and *understand new mathematical concepts*.

Mathematics is about defining concepts and to study how these concepts are connected. To understand the concepts you have to understand how they are connected to each other. [...] From the proof one should learn something about the concepts involved in it. (M8)

Even *technical proofs* were considered as valuable by one mathematician as they helped students understanding of problem solving.

Also the technical proofs are useful to do: the technique leads to better understanding of problem solving. (M1)

Here, the mathematician might mean that the proof techniques could be explicitly used in problem solving.

Proving and problem solving involved in each other

Some of the mathematicians stated already in their responses to the first question that they considered proving and calculating/problem solving as in principle the same activity (compare with Lucast, 2003). By highlighting this in the teaching they wanted to “demystify proof”.

I don't consider “proof” as something different from other mathematical activities – obviously it is about reasoning, calculating, being ingenious/creative, using one's knowledge and experiences and then drawing conclusions. To prove the rule of squaring a binomial, to give an elementary example, is of course just to perform the calculation. (M9)

I would like to extend the meaning of “proof” to refer to logical reasoning in general. In proofs one meets such reasoning in a concentrated form. But it is present also in problem solving and in mathematical discussions in general. (M4)

There is no difference in principle between proving and calculation. When a student carries out a computation in several steps, then these steps is a proof of the statement that the final result is the answer to the question. It is important that students at all levels get the insight that it is always reasoning which is the core of mathematics. (M6)

Most of the mathematicians talked about *transfer* only at a general level but there were some examples of specific proofs that we found valuable to present in order to later explore their potentials for further studies.

Some examples of proofs that teach students concepts or techniques

The mathematicians mentioned a number of proofs and exercises as valuable for students in order to learn techniques applicable in *other proving tasks*. This refers to the function Weber (2002) writes about. We have gathered their suggestions in the following table.

The relation in Pascal's triangle can be proved by **induction**

There are an infinite number of primes enlightens **proof by contradiction**

The square root of 2 is irrational. The students can then surely find other results where the number 2 is replaced by another integer.

$n(n+1)$ is divisible by 2 , if n is a positive integer. The same proof techniques can be applied in other proving tasks concerning divisibility.

Is it true that the proposition $P(x)$ holds for all real numbers x ?” where $P(x)$ is for instance an inequality. This trains the ability to see what is required of a proof, and that a refutation just needs a counter example which is very important in many proving tasks.

Open tasks. They encourage the willingness to investigate and make hypotheses – which then are to be proved or disproved.

The next citation is an example about how studying proofs or proving statements concerning the derivatives is seen to help students to become familiar with and learn to understand *new concepts and definitions*, in this case the notion of the limit of a difference quotient as a derivative.

The derivative is defined as the limit of a difference quotient, and you get a geometric interpretation as the slope of the tangent, but you also have the technical interpretation as change of rapidity (in a broad sense). Next you derive (prove) the rules for the derivative of a sum, product, ... and you derive the derivatives of the elementary functions. All these you may of course find in a table of formulas and you should moreover know them by heart, they are so important for the applications. But through studying the proofs you get opportunity to many times consider limits of a difference quotient, and in that manner consolidate the definition of the important notion of derivative. (M8)

The last quotation below is about the proof of the factor theorem. The factor theorem states that $x - \alpha$ is a divisor of the polynomial $f(x)$ if and only if $f(\alpha)=0$. We find the proof of this theorem as a good example of such proofs at an elementary level that allow mathematicians to highlight importance of studying the methods and notions in proofs.

We can begin with the factor theorem. The theorem expresses for sure an equivalence and it is interesting to discuss that one implication is obvious while the other is deeper. If you look at the actual proof you then see that the proof gives a bit more than what the theorem states. Indeed, the proof gives us information about the remainder even in the case where the remainder is not zero. (M4)

As an example of a problem where the proof of the factor theorem could be useful, consider the following: Determine the remainder, without carrying out the division algorithm when $x^4 + x^3 + x^2 + x + 1$ is divided by $x - 1$.

DISCUSSION

The study shows that the function of *transfer* is a natural way of thinking about proof for many mathematicians and all mathematicians express the importance of teaching proofs also in the beginning courses at university. Yet, one of them states that the students studying applied sciences do not need any proofs and some others that they do not need all the rigorous proofs. Only one mathematician did not think that proofs could be useful in problem solving at the basic level.

Some mathematicians wanted to look at proving and calculation/ problem solving in a similar way. The resemblance between proving and problem solving has been studied and discussed by Lucast (2003). This is an interesting point of view as we can also think the other way around, i.e., students can learn concepts and techniques in problem solving that they can use in proving tasks.

We find it interesting to note that the connection between proving and problem solving is something fundamental in the area of *constructive mathematics*, where

these two activities are considered to be not just similar but in fact the same (see Nordström & Löfwall, 2006). It could be fruitful to study the notions of proving and problem solving from the perspective of constructive mathematics in order to get more insight in their connections.

In school mathematics and also in the beginning courses at university it has been a tendency to avoid the word “proof” in order to not frighten the students (Hemmi, 2006). However, students lack discussions about what proof is and why it is needed. An important didactical question is how to in the best way highlight the connections between proving and problem solving in the teaching of mathematics. Consider for example the following citation:

To prove the rule of squaring a binomial, to give an elementary example, is of course just to perform the calculation. (M9)

The mathematician expresses here a view that proving, in this case, is just calculating but we could also take it the other way around and consider this calculation as proving.

We have shed light on the function of proof that we call transfer from historical point of view and explored mathematicians’ pedagogical views on it. We have described transfer at a general level and exemplified some proofs where connections to problem solving can be made visible. It is clear that mathematical proofs are carriers of mathematical knowledge and there are various ways of enlightening this for students.

However, we do not want to look at the function of transfer mechanically, even if there are situations where it is possible to just copy a proof technique to another proving task. In this paper, we have described transfer from the perspective of teaching mathematicians. We have to acknowledge that what experts consider as evident connections may be difficult to see for a learner. When studying transfer we have to study the learners’ personal constructions of similarity across proving and problem solving from their perspective (Lobato, 2003). Our study shows that there is a lot to explore in university mathematics regarding the ideas from the mathematicians’ personal experiences of proof in the learning and doing mathematics.

NOTES

1. Consider for example the following problem: Determine the centre and the radius of a circle $x^2+2x+y^2-4y=0$. It should be easier to solve it if one is familiar with the method of completing the square.
2. However, Hanna and Barbeau (2008) do not use the word *transfer* for this function.
3. With basic and elementary courses, we refer to the courses taught during the first semester. With intermediate courses we refer to the courses taught during the second semester.

PROVING AS A RATIONAL BEHAVIOUR: HABERMAS' CONSTRUCT OF RATIONALITY AS A COMPREHENSIVE FRAME FOR RESEARCH ON THE TEACHING AND LEARNING OF PROOF

Francesca Morselli and Paolo Boero

Dipartimento di Matematica, University of Genova, Italy

In this paper we draw from Habermas' construct of rational behaviour a construct for rationality in proving that we propose as suitable to investigate the teaching and learning of proof and generate new research developments. At first, we discuss our conception of the proving process, where cognitive and cultural aspects are shown to play a crucial role, and we present our adaptation of Habermas' construct as a way of taking into account both cognitive and cultural aspects. The adapted construct is shown to be useful in the discussion of some examples at tertiary level; finally, drawing from the analysis of the examples, we indicate some research questions (formulated in terms of the theoretical construct) that we feel worth to be explored.

Key-words: proof and proving, rational behaviour, Habermas, tertiary level

INTRODUCTION

The aim of our paper is to contribute to the debate on theoretical frameworks suitable to take into consideration the complex nature of the teaching and learning of proof.

When planning the teaching of theorems and mathematical proof and when analyzing students' difficulties in approaching them, we have at disposal several theoretical tools coming from epistemology, history of mathematics, psychology, and didactics of mathematics. In order to build a comprehensive framework for proof and its teaching and learning, encompassing the epistemological, psychological and didactical dimensions, we think that at first it is necessary to consider proof as a crucial component of mathematics and to look at mathematics from a cultural perspective. The definition of culture by Hatano & Wertsch (2001) suggests to consider mathematics as a multifaceted culture evolving through the history, which includes different kinds of activities and different levels of awareness, explicitness and voluntary use of notions, thus different levels of "scientific" mastery, according to the Vygotskian distinction between common knowledge and scientific knowledge (for further developments about mathematics as a culture, see Morselli, 2007). Within this cultural perspective we can situate the "culture of theorems" as the complex system of conscious systematic knowledge, activities and communication rules that refer to the processes of conjecturing and proving as well as to their final products. Consequently, we can describe the approach to theorems and proving as a process of scientific "enculturation" consisting in the development of a special kind of rational behaviour, characterized by the conscious mastery of the epistemic aspects of theorems (Mariotti et al., 1997; Balacheff, 1982) and by the intentional construction and control of the process that produces the proof, within a communication context

with its shared rules. From these considerations we can draw a link between the approach to theorems as a process of “scientific enculturation” and the three components of Habermas’ “rational behaviour” (the epistemic, the teleological and the communicative rationalities), as we will show in the subsequent section.

Another entry into the same line of thought derives from the process - product character of proving and proof. Balacheff (1982) points out that the teaching of proofs and theorems should have the double aim of making students understand what a proof is and learn to produce it. Accordingly, we think that, in mathematics education, proof should be treated considering both the *object* aspect (a product that must meet the epistemic and communicative requirements established in today mathematics - or in school mathematics) and the *process* aspect (a special case of problem solving: a process intentionally aimed at a proof as product). Here again we can identify potential links with Habermas’ elaboration about rationality.

PROVING AS A RATIONAL BEHAVIOUR

Habermas (2003, ch. 2) distinguishes three inter-related components of a rational behaviour: the *epistemic* component (inherent in the control of the propositions and their enchaining), the *teleological* component (inherent in the conscious choice of tools to achieve the goal of the activity) and the *communicative* component (inherent in the conscious choice of suitable means of communication within a given community). With an eye to Habermas’ elaboration, in the discursive practice of proving we can identify: an *epistemic* aspect, consisting in the conscious validation of statements according to shared premises and legitimate ways of reasoning (cf. the definition of “theorem” by Mariotti & al. (1997) as the system consisting of a statement, a proof which is derived according to shared inference rules from axioms and other theorems, and a reference theory); a *teleological* aspect, inherent in the problem solving character of proving, and the conscious choices to be made in order to obtain the aimed product; a *communicative* aspect, consisting in the conscious adhering to rules that ensure both the possibility of communicating steps of reasoning, and the conformity of the products (proofs) to standards in a given mathematical culture.

Our point is that considering proof and proving according to Habermas’ construct may provide the researcher with a comprehensive frame, within which to situate a lot of research work performed in the last two decades, to analyze students’ difficulties concerning theorems and proofs (see the four examples in the next Section) and to discuss some related relevant issues and possible implications for the teaching of theorems and proof (see the last Section).

If we are interested in the epistemic rationality side, i.e. in the analysis of proofs and theorems as objects, mathematics education literature offers some historical analyses (like Arsac, 1988) and surveys of epistemological perspectives (like Arzarello, 2007): they help to understand how theorems and proofs have been originated and have been

considered in different historical periods and how, even in the last decades, there is no shared agreement about what makes proof a “mathematical proof” (cf. Habermas' comment about the historically and socially situated character of epistemic rationality). Concerning the ways mathematical proof and theorems are (or should be) introduced in school as “objects”, several results and perspectives have been produced, according to different epistemological perspectives and focus of analyses. In particular, De Villiers (1990), Hanna (1990), Hanna & Barbeau (2008) discuss the functions that mathematical proofs and theorems play within mathematics and advocate that the same functions should be highlighted when presenting proof in the classroom, in order to motivate students to proof and allow them to understand its importance. By referring proof to the model of formal derivation, Duval (2007) focuses on the distance between mathematical proof and ordinary argumentation; he also considers how to make students aware of that distance and able to manage the construction and control of a deductive chain. Harel (2008) uses the DNR construct to frame the classification of students' proof schemes (we may note that they concern proof as a final product). We note that, in terms of Habermas' components of rationality, Harel's ritual and non-referential symbolic proof schemes may be attributed to the dominance of the communicative aspect, with lacks inherent in the epistemic component (cf. Harel's N, “intellectual Necessity”).

Concerning the proving process, some analyses of its relationships with arguing and conjecturing suggest possible ways to enable students to manage the teleological rationality. In particular, Boero, Douek & Ferrari (2008) focus on the existence of common features (“cognitive unity”) between arguing, on one side, and proving processes on the other, and present some activities (from grade I on), based on those commonalities, that may prepare students to develop effective proving processes. Research on abductive processes in conjecturing and proving (Cifarelli, 1999; Pedemonte, 2007) and the construct of “abductive system” (Ferrando, 2006) take into account some aspects of the creative nature of conjecturing and proving processes and the need of suitable educational choices to promote creativity. Boero, Garuti & Lemut (2007) suggest the possibility of smoothing the school approach to mathematical proof through unified tasks of conjecturing and proving for suitable theorems (those for which the same arguments produced in the conjecturing phase can be used in the proving phase). However Pedemonte (2007) shows how in some cases of “cognitive unity”, students meet difficulties inherent in the lack of “structural continuity” (when they have to move from creative ways of finding good reasons for the validity of a statement, to their organization in a deductive chain and an acceptable proof): her study suggests to consider the relationships between teleological, epistemic and communicative rationality (see the last Section).

SOME EXAMPLES

Morselli (2007) investigated the conjecturing and proving processes carried out by different groups of university students (7 first year and 11 third year mathematics

students, 29 third year students preparing to become primary school teachers). The students were given the following problem: *What can you tell about the divisors of two consecutive numbers? Motivate your answer in general.* Different proofs can be carried out at different mathematical levels (by exploiting divisibility, or properties of the remainder, or algebraic tools). The students worked out the problem individually, writing down their process of solution (including all the attempts done); afterwards, students were asked to reconstruct their process and comment it. The *a posteriori* interviews were audio-recorded. In (Morselli, 2007) several examples of individual solutions and related interviews are provided, and in particular it is shown how students' failures or mistakes were due to lacks in some aspects of rationality and/or the dominance of one aspect over the others.

For the present paper, we selected four examples. At first, we present two very similar cases, concerning students that are preparing to teach in primary school, and we show how the theoretical construct of rationality in proving may help to single out important differences between the two students, as well as different needs in terms of intervention. Afterwards, we present two cases concerning university students in Mathematics: the first one is a case of success, while the second one is a case of failure. These two cases were analyzed in (Morselli, 2006) with a special focus on their use of examples. Here we discuss those proving processes by means of our adaptation of Habermas' construct.

The four examples have the double aim of illustrating how our adaptation of Habermas' construct works as a tool for in-depth analysis, and introducing a discussion that will suggest further research developments.

Example 1: Monica

Monica considers two couples of numbers: 14, 15 and 24, 25. By listing the divisors, she discovers that "Two consecutive numbers are odd and even, hence only the even number will be divided by 2". Afterwards, she lists the divisors of 6 and 7 and writes: "Even numbers may have both odd and even divisors". After a check on 19 and 20, she writes the discovered property, followed by its proof:

Property: two consecutive numbers have only one common divisor, the number 1. In order to prove it, I can start saying that two consecutive numbers cannot have common divisors that are even, since odd numbers certainly cannot be divided by an even number. They also cannot have common divisors different from 1, because between the two numbers there is only one unit; if a number is divisible by 3, the next number that is divisible by 3 will be greater by 3 units, and not by only one unit. Since 3 is the first odd number after 1, there are no other numbers that can work as divisors of two consecutive numbers.

Monica carries out a reasoning intentionally aimed (teleological rationality): first, at the production of a good conjecture; then, at its proof. Proof steps are justified one by one (epistemic aspect) and communicated with appropriate technical expressions

(communicative aspect). The only lack in terms of rationality concerns the short-cut in the last part of the proof: Monica realizes that something similar to what happens with 3 (the next multiple is “greater by three units”) shall happen a fortiori with the other odd numbers that are bigger than 3 (“Since 3 is the first odd number after 1”), but she does not make it explicit. Her awareness (cf. epistemic rationality) is not communicated in the due, explicit mathematical form (lack of communicative rationality). Monica’s *a posteriori* comments on her text confirm the analysis:

Monica: (...) and then I have thought that 3 was the first odd number after 1 and so if 3 does not enter there, also the bigger ones do not enter there [from the previous text, we know that “there” means: between two consecutive numbers on the number line].

Interviewer: to make more general what you said with 3, what would you write now?

Monica: ehm... I have tried to go beyond the specific case of 3, but I do not know if I have succeeded in it.

Example 2: Caterina

Starting from the fact that two consecutive numbers are always one odd and one even, we may conclude that the two numbers cannot be both divided by an even number. Afterwards, we focus on odd divisors; we start from 1, and we know that all numbers may be divided by 1; the second one is 3. We have two consecutive numbers, then the difference between them is 1, then they will not be multiples of 3, since it will be impossible to divide both of them by a number bigger than 1.

Caterina is able to justify all the explicit steps of her reasoning (epistemic rationality), she develops a goal-oriented reasoning (teleological rationality) and illustrates her process with appropriate technical expressions (communicative rationality). Differently from Monica, in spite of a good intuition there is a lack in her reasoning: divisors greater than 3 are not considered. A posteriori, after having seen also the production of her colleagues, Caterina comments:

My reasoning is not mistaken: indeed, I reach the conclusion giving a general explanation, saying that, since there is no more than one unit between the two numbers, the only common divisor is 1. Nevertheless, I can not create a mathematical rule. Observing the other solutions, I think that the correct rule is the following: along the number line we note that a multiple of 2 occurs every two numbers, a multiple of 3 occurs every three numbers, hence a multiple of N occurs every N numbers. Then, two consecutive numbers have only 1 as common divisor.

From the objective point of view of epistemic rationality, Caterina’s argument was not complete, and in her comment she reveals not to be aware of it. From her subjective point of view, Caterina is convinced to have found a cogent reason for the validity of the conjecture (“not mistaken reasoning”, “general explanation”), thus to have achieved her goal (teleological rationality). Some colleagues’ solutions induce her to reflect on the lack of a “mathematical rule”; however she doesn’t seem to

consider this lack as a lack in the reasoning, but as a lack in the mathematical communication.

Example 3: Sara

Sara (attending the third year of the university course in Mathematics), after having discovered the property by means of two numerical examples (1-2, 2-3), writes down:

“Two consecutive numbers are “made up” of an even number, divisible by 2 ($=2n$, $n \in \mathbb{N}$) and an odd number ($=2n+1$, $n \in \mathbb{N}$). Let’s suppose that 1 is not the only common divisor, that is $\exists k$ such that $k|2n$ and $k|2n+1$. $2n = ka$, $a \in \mathbb{N} \rightarrow$ also in ka there must be the factor 2 $\rightarrow k=2c$ or $a=2d$; $2n+1 = kb$, $b \in \mathbb{N} \rightarrow$ since k is common, $k=2c$, or $b=2e$. But only the product of two odd numbers is an odd number \rightarrow I could not finish for a matter of time.”

Sara seems to be aware of the way a proof should be presented (communicative rationality), of the importance of algebra as a proving tool and of the usefulness of the proof by contradiction in a case like this (two important strategic choices concerning teleological rationality). In particular, in the *a posteriori* interview she tells that she felt comfortable with the method of proof by contradiction, due to the fact that the uniqueness of 1 as a common divisor had to be proven.

Even epistemic rationality works till the last part of her algebraic work, where she derives the incorrect conclusion that “ $k=2c$, or $b=2e$ ”. However Sara gets lost after a few manipulations. Why did it happen? It is possible that in this case the arguments successfully used in the conjecturing phase (based on the distinction between odd and even, and thus on divisibility by 2) were misleading when applied in the proving phase. Incidentally, here we see that in some cases cognitive unity may act as a burden, if not controlled. Indeed, Sara could have reached the proof easily by substituting $2n=ka$ in the expression $2n+1=kb$, but she didn’t take into consideration this strategy, she just focused on divisibility by two. Substituting $2n=ka$ in the expression $2n+1=kb$ would have required to move from the odd/even semantic-based argument to a pure algebraic manipulation, with a break in the continuity of the conjecturing and proving process. Probably, Sara got lost because, when orienting her proving process, she did not fully concentrate on the meaning of the expression “1 is not the only common divisor”, being still focused on the odd-even dichotomy. Even her mistake (when she derived “ $k=2c$, or $b=2e$ ” from the previous step) might have depended on her intention to get the absurd conclusion that $2n+1$ would have been even (indeed she wrote: “But only the product of two odd numbers is an odd number”). Thus her failure might be interpreted in terms of one of her strategic choices not fitting with the aim of the proving process and not supported by a rigorous checking of inferences (i.e. in terms of a combined lack on the epistemic and teleological dimensions of rationality).

Example 4: Valentina

Valentina (attending the third year of the university course in Mathematics) chooses to carry out her exploration through an algebraic manipulation.

Given $n \in \mathbb{N}$, if it is divisible by $d \in \mathbb{N}$, then the remainder of the division of n by d is 0 , that is to say $n \bmod d$ is 0 , that is to say in \mathbb{Z}_d $n=0$. When I consider $n+1$, reasoning in the same way I realize that dividing by d I get remainder 1 , that is to say $n+1=1$ in $\mathbb{Z}_d \forall d \neq 1$. Then, the only common divisor for n and $n+1$ is 1 .

The exploration carried out by Valentina seems to be very useful: at the same time Valentina discovers the property and proves it, since the reasoning is already carried out in general terms. In the subsequent excerpt from the *a posteriori* interview, Valentina describes her process of conjecturing and proving. Valentina, being aware of the potentialities and limits of numerical examples, chooses to use algebra also in the exploration phase. We may say that the epistemic dimension (awareness of the limits of numerical examples) supports the teleological one (choice of algebra in the exploratory phase).

Interviewer: Try to explain to a secondary school student how to find the property.

Valentina: I think that... beh, I would start reasoning on data, on the hypotheses, and trying to see links between them, seeing what happens in various cases?

Interviewer: do you mean using numerical examples?

Valentina: maybe, even if this could be dangerous because induction does not always works, I mean, if we have limited cases, it is not a good method, it could even be absolutely wrong. But one could start from them; afterwards of course it is necessary to prove it in general... [...] and just consider the hypothesis and try and think about them, from a general point of view, just...non numerical, but n , $n+1$, what they mean, and try exactly to think about them, what this data mean.

Let us come back to Valentina's production. After the first phase, in which Valentina discovers and proves the property at the same time, Valentina writes down: "That were my fist ideas. Now I try to write them down in a better way". This sentence leads to a phase of systematization of the final product.

Given $n \in \mathbb{N}$, n and $n+1$ have only one common divisor, that is 1 . In fact, $\forall d \in \mathbb{N}$ such that $d|n$, $d \neq 1$, $(n) = (0)$ in \mathbb{Z}_d , while $(n+1) = (1)$ in \mathbb{Z}_d because $(n+1) = (n) + (1) = (0) + (1) = (1)$, hence $d \nmid n+1$. From the other side, $\forall p \in \mathbb{N}$ such that $p|n+1$ and $p \neq 1$ I have that $(n+1) = (0)$ in \mathbb{Z}_p and that $(n) = (n+1-1) = (n+1) - (1) = (0) - (1) = (-1)$, hence $p \nmid n$. On the contrary, $1|n$ and $1|(n+1)$ because 1 divides any natural number.

In the subsequent excerpt from the *a posteriori* interview, Valentina shows to put a great care both in the process and in the construction of the final product.

Interviewer: ok. May I ask you why did you do a second part, in which you systematized what you wrote in the first part?

Valentina: the first part was... I gave the idea, I started to write down, in a sort of draft, in order to make my ideas clear to myself, in order to formalize what I had in my mind. Afterwards, I tried to write in a more formal way, because the

first part was really... writing down ideas, while in the second part I tried to write in a more “mathematical” way, in clearer way.

Interviewer: what do you mean by “more mathematical way”?

Valentina: ehm... maybe using less words, trying to be more synthetic, and trying to use a mathematical language, then with more symbolic notation, rather than words.

Interviewer: ok. But actually, as concerns the mathematical content...

Valentina: it is the same. It is more or less the same. Yes, yes.

We may note that Valentina is able to describe the features that, according to her, a mathematical proof should have. Nevertheless, Valentina is aware that the first part of her production is already acceptable, even if written in a less appropriate way. We may say that Valentina is able to manage the crucial dialectic between epistemic and communicative dimension: the second part is an amendment from the communicative point of view, but Valentina is fully aware of the fact that the communication is subordinated to the epistemic dimension, that is to say to the validity of the produced arguments.

DISCUSSION: TOWARDS FURTHER DEVELOPMENTS

The analysis of some examples had the double aim of showing the viability and usefulness of our adaptation of Habermas’ construct in the special case of conjecturing and proving, and of suggesting new research questions, in terms of this construct.

As concerns the first aim, we have seen how success and failure may be read in terms of different intertwinings between the three components of rationality, or dominance, or lack on one of them. We may add that in the case of Valentina the communicative component is strictly depending on the epistemic one; furthermore, the teleological component intertwines with the epistemic one (choice and justification of the arguments) and with the communicative one (other readers will check the production). More generally the previous analyses suggest the opportunity of a closer investigation into the relationships between epistemic rationality, communicative rationality and teleological rationality in the case of proof and proving. Concerning this issue we note that in the historical development of mathematics, subjective evidence (or even mathematicians’ shared opinion of evidence) revealed to be fallacious in some cases, when new, more compelling communication rules obliged mathematicians to make some steps of reasoning (in particular, those concerning definitions: see Lakatos, 1976) fully explicit.

From the educational point of view, while it is easy (for instance, by comparison with other solutions) to help Monica to make her reasoning more explicit (according to her need, as emerged from her comments), the intervention on Caterina is much more delicate: how to make her aware that the “mathematical rule” is not only a matter of

conventional, more complete communication, but also a matter of objective, cogent arguing involving the goal to achieve (an exhaustive argument)? And how to exploit texts that are complete (communicative aspect) in order to develop the need of an exhaustive argument (epistemic aspect), but at the same how to avoid that the necessities inherent in the communicative aspect prevail over the epistemic aspect (cf. Harel's "ritual proof schemes")? A direction for productive educational developments might consist in the elaboration of a suitable meta-mathematical discourse (see Morselli, 2007) for students (including an appropriate vocabulary), as well as in the choice of suitable tasks that reveal how intuitive evidence not developed into an explicit, detailed justification sometimes results in fallacious conclusions.

These considerations raise another problem: Habermas' construct offers only the possibility to evaluate a production process and its written or oral products, while in mathematics education we need also to consider a long term "enculturation" process. We are working now on the articulation between a cultural perspective to frame this process (see Morselli, 2007) and tools of analysis derived from Habermas' elaboration on rationality. Indeed, it is within the cultural perspective outlined in the introduction that we think possible to deal with the approach to theorems and proving in school as a process of scientific "enculturation" consisting in the development of a special kind of rational behaviour, the one derived from Habermas, that is presented in this paper. We are trying to refine the Vygotskian common concepts - scientific concepts dialectics in the case of theorems and proofs in order to get a frame where to situate the long term planning of the school approach to the culture of theorems. Habermas' construct contributes to it by suggesting three interrelated dimensions along which to develop students' skills in proving and students' (and teachers') awareness about crucial features of proving and proofs. The educational challenge consists in leading students to move from the ordinary argumentative practices of validation of statements in different domains to the highly sophisticated and culturally situated management of the components of a rational behaviour in the specific case of proving.

EXPERIMENTAL MATHEMATICS AND THE TEACHING AND LEARNING OF PROOF¹

Maria G. Bartolini Bussi

Università di Modena e Reggio Emilia (Italia)

bartolini@unimore.it

Aim of this paper is to discuss the role of experiments in mathematics for the teaching and learning of proof. I summarize some research findings from basic research studies and from teaching experiments. The examples comes from teaching experiments at all school levels on space and geometry by means of classical resources although some of the findings might be expanded to other subject areas and to ICT. They allow to frame the topic within the international literature on conjecture production and proof construction: they support the advantages of experimental approaches to the teaching and learning of proof and, at the same time, point at some critical points to be controlled in order to design appropriate teaching interventions.

INTRODUCTION

A growing interest is shown, at the international level, for the development of approaches to mathematics where the active participation of students is encouraged within a laboratory setting, with hands-on activities. The emphasis on experiments, manipulation and perception, measurement and examples is shared by the approaches developed within ICT environments (both DGE and CAS) and within classical technologies (straightedge, compass and ancient instruments). This experimental approach, where exploration plays a major role, seems appealing for students, who quite often find the evidence offered by a particular experiment much more convincing than a rigorous proof (Jahnke, 2007) and are bored by the request to produce also mathematical arguments. Hence, the appeal of experimental approach might be suspected of obstructing the development of mathematical styles of reasoning: some believe that hands-on activities are useful in either science centres or mathematical festivals, where popularization of mathematics is in the foreground, whilst are not useful and may be even risky in the mathematics classrooms, where the construction of mathematical meanings is at stake. In other words, many mathematics teachers are afraid that the need of mathematical proofs and of deductive arguments is put in a difficult position if experiments are given too much space in the mathematics classroom, at least in secondary schools. In the following, after a short review of literature, I present some effective experiments at all school levels where experiments and exploration have been combined with theoretical aims like conjecture production and proof construction.

¹ This study is jointly funded by the MIUR and the Università di Modena e Reggio Emilia (PRIN 2007B2M4EK on "Instruments and representations in the teaching and learning of mathematics: theory and practice")

SOME STUDIES CONCERNING PROVING IN THE MATHEMATICS CLASSROOM.

The literature on proof and proving is large and encompass different aspects. In the recent book on "Theorems in School" edited by P. Boero (2007), the following aspects are highlighted: the historical and epistemological dimension; curricular choices, historical traditions and learning of proof (including two national case studies); the cognitive dimension of the relationships between argumentation and proof; the didactical dimension including both teacher education and classroom practices. In the chapter authored by Bartolini Bussi et al. (2007), a mathematical theorem – for didactical purposes - is conceived as a system of statement, proof and theory. All these three components are important: the theory as a system of shared principles (sometimes called postulates or axioms and definitions); the statement as the result of a conjecturing process, where exploration through experimental activity is in the foreground, the proof as a sophisticated argumentation that is, on the one hand, connected with the conjecturing process, and, on the other hand, consistent with the reasoning styles of mathematicians (e. g. deduction from the accepted principles). This approach is consistent with Jahnke (2007), who speaks about ‘local theories’, i. e. small networks of theorems based on empirical evidence and claims: “There is no easy definition of the very term ‘proof’ since this concept is dependent of the concept of a theory. If one speaks about proof one has to speak about theories, and most teachers are reluctant to speak with seventh graders about what a theory is”. And Arzarello (2007) adds: "A statement B can be a theorem only relative to some theory; it is senseless to say that it is a theorem in itself: even a proposition like $2+2=4$ is a theorem in a theory A (e. g. some fragments of arithmetic)".

In the above sense, it is possible to speak about theorems also within primary school, provided that the theories are “germ theories”, drawing on empirical evidence, with the expansive potential to capture more and more principles. Germ theories, with principles constructed on empirical evidence, are crucial up to 8th grade; later, accordingly to curriculum, the reference to more and more structured mathematical theories is possible. So, for instance, in the teaching experiments below, the reference theory from grade 11th on is expected to be elementary geometry (either 2D or 3D) with some additional parts concerning either isometries or conic sections.

The links between argumentation and proof from a cognitive perspective have been carefully analysed by Pedemonte (2007) who devoted her doctoral thesis to the development of the idea of cognitive unity, meant as a kind of continuity between the production of a conjecture and the construction of the proof. Experimental research shows that proof is more ‘accessible’ to students if an argumentation activity is developed for the production of a conjecture: in fact this argumentation can be used by the student in the construction of proof by organising in a logical chain some of the previously produced arguments. These studies may have important consequences

on the teaching and learning of proof: to explain why rote learning of ready made proofs is not successful for most students; to select suitable problems, which might foster conjecture production before proof construction; to understand why in some cases proving remains difficult in spite of the previous conjecturing process.

In the following sections I shall quote very quickly some experiments where conjecturing and proving were promoted, at different school levels and with different organization.

EXAMPLES FROM LONG TERM TEACHING EXPERIMENTS

In the attached table, some paradigmatic examples are quoted from long term teaching experiments developed as coordinated studies by different research teams. All the tasks concern a conjecture production before proving construction. They appear, however, different from each other.

Three tasks (tasks 1,2,3) concern individual activity, to be solved in paper and pencil setting; three tasks (tasks 4,5,6) concern small group activity, to be solved in writing after the exploration of a material object. The exploration is free in the case of sunshadows (task 4), whilst it is guided by sheets or by the teacher himself in the two cases from secondary school (tasks 5 and 6). The tasks 1 and 3 are construction problems: they require to produce a drawing and to justify the validity of the used method. The expressions "Explain" mean, in a language accessible for young learners, to justify the drawing process with reference to a shared (germ) theory. The task 2, on the contrary, seems to be given in a discursive way. Yet the explanation requirement with reference to a shared (germ) theory is implicit, as a part of the tacit rules shared within the classroom involved in these experiments. In the last three tasks proof is not explicitly required. Actually the focus is on the production of the conjecture. This is an intentional choice, because the problems are quite demanding. The tasks 4 and 6 concerns 3D geometry, that is usually not well mastered by secondary school students. The task 5 is difficult: the conjecture concerns a rotation around the lower point (O) in the Fig. 3. Actually to recognize it, it is necessary to "see" two line segments (OP and OP') that do not exist, to realize that they are always equal and, more generally, to be able to "see" invariants during the motion. The teachers, for the tasks 4, 5 and 6 had designed, according to the shared theoretical framework, an intermediate step where to collect and discuss the conjectures, before entering the proving process. In the task 4, students are explicitly requested to produce a general statement. This expression was used in those classrooms to foster the production of statements with universal quantifiers (all, always, and so on) and hopefully in conditional form (if ... then) to pave the way towards the construction of a proof with specified hypothesis and thesis.

Gr.	GERM THEORIES (REF)	CONJECTURES - PROBLEMS <i>THE TASK - TO BE SOLVED IN WRITING</i>	SETTING MATERIAL
1. Gr.2 - 8	The invariance of alignment in perspective drawing (Bartolini Bussi, 1996)	The centre of a table drawn in central perspective. <i>Draw the small ball in the centre of the table. You can use instruments. Explain your reasoning.</i>	Individual task (Fig. 1)
2. Gr.2 - 8	Motions of geared wheels (Bartolini Bussi et al., 1999)	The motion of trains of toothed wheels. <i>What about three wheels geared with each other?</i>	Individual task No material
3. Gr.4 - 8	The equality of the distance of the centres of two tangent circles to the sum of radii (Bartolini Bussi et al., 2007)	The drawing of a circle tangent to two given circles. <i>Draw a circle with a radius of 4 cm tangent to the given circles (radii 3 and 2). Explain carefully the method. Explain carefully why it works.</i>	Individual task (Fig. 2)
4. Gr.6 - 8	Mathematical model of sunshadows. Basic properties of lines, planes, parallelism and perpendicularity (3D geometry) (Boero et al., 2007)	The parallelism of sunshadows of sticks. <i>In recent years we observed that the shadowsof two vertical sticks on the horizontal ground are always parallel. What can be said of the parallelism of shadows in the case of a vertical stick and of an oblique stick? Can shadows be parallel? At times? When? Always? Never? Formulate your conjecture as a general statement.</i>	Small group work. Pens, pencils, notebooks, rulers, to reify lines and planes
5. Gr.11	Elementary geometry (3D geometry). Definitions and properties of isometries. (Bartolini Bussi & Pergola, 1996)	The isometry (rotation) produced, as a correspondence, by a pantograph. After a guided exploration of the pantograph. <i>If P and P' are two writing points, draw two corresponding figures. Which are the common properties of the two figure? Can they be superimposed? Does it exist a simple motion which superimposes them? Describe it.</i>	Small group work. A pantograph with graphite leads in P and P' (Fig. 3).
6. Gr.12	Elementary geometry (3D geometry). Metric definition of conics. Equations of conics (Bartolini Bussi, 2005)	The conic obtained by cutting a cone in a suitable way. The task is given orally by the teacher. <i>You have to obtain an important property of parabola [...]. As you see, [the parabola] is in a 3D space, on the surface of the cone [...]. you have to discover the relationship between the green line segment [AE in the Fig. 4] and this line segment [EB in the Fig. 4].</i>	Small group work. A 3D model of a cone with a normal cutting plane (Fig. 4).

Figure 3. The pantograph

Figure 4. The parabola

At all ages, the dynamic exploration of a suitable problem situation has a crucial role both at the stage of conjecture production and during the proof construction. In particular, as to the conjecture production "the conditionality of the statement can be the product of a dynamic exploration of the problem situation during which the identification of a special regularity leads to a temporal section of the exploration process, which will be subsequently detached from it and then "crystal" from a logic point of view ('if ... then')"; and as to the proof construction, "for a statement expressing a sufficient condition ('if ... then'), proof can be the product of the dynamic exploration of the particular situation identified by the hypothesis" (Boero et al, 2007, p. 249 ff.). This phenomenon has been observed by Boero et al. (2007) for the task 4 about sunshadows, by Bartolini Bussi & Pergola for the task 5 about the pantograph (Bartolini Bussi & Pergola, 1996) and in other ongoing experiments on either transformation or curve drawing devices. As concrete manipulation of materials is not spontaneous and guaranteed with elder students, who had already spent years to learn (or better to be taught) that mathematics is just a mental activity, the teacher has to foster it in a very coercive way: concrete exploration in demanding tasks is quite often the only effective way to promote dynamic exploration. Younger pupils, on the contrary, were accustomed to explore and to evoke exploration when no concrete object was available.

THE PROCESSES

The six situations above, although in different modes, have been designed to foster cognitive unity between the conjecturing and the proving phases. I shall not try to summarize here the observed processes concerning them all: they are complex, long standing, different (also for students' age) and all available in the international literature. Rather I shall illustrate another simple case of conjecture production and proof construction at secondary school level (from grade 10 on, according on the curriculum), concerning a curve drawing device. I shall narrate the stories of dynamic exploration that show up when secondary school students are given this curve drawing device to foster reasoning, conjecturing and proving (another example is discussed by Bartolini Bussi, in press).

I shall collect some evidences from the field notes of the exploration sessions in both school classrooms and the Laboratory of mathematical Machines (www.mmlab.unimore.it), to highlight the patterns that emerge. The two parts of the fig. 5 show (on the left) a drawing from the XVII century treatise by van Schooten (1657, p. 339) and (on the right) a photo of the brass copy reconstructed on a wood platform (40 cm x 40 cm) by the team of the Laboratory of Mathematical Machines at the Department of Mathematics of Modena, to be used with secondary and university students. The students are supposed to know some early properties of conics, e.g. the string and pencil drawing of an ellipse (together with the ellipse metric definition).

Fig. 5a and 5b: Van Schooten's Ellipsograph

There are several ways to explore the artefact (in order to produce a conjecture and to construct a proof of the conjecture) that span from strongly to weakly guided ones. In general, strongly guided exploration is suitable to the short term sessions (at most 2 hours, including the introduction and the conclusion of the hands on activity, Maschietto & Martignone, in press) which take place when a classroom come to the Laboratory, whilst weakly guided exploration is suitable to classroom activity, when the teacher plans to spend more time on the same topic. Actually with a weak guide, the time may expand, not matching the time constraints of a short visit to the Laboratory.

A) Strongly guided exploration. Students are given a worksheet where a layout of the artefact is drawn with coding letters (examples: <http://www.mmlab.unimore.it/online/Home/VisitealLaboratorio/Materiale/articolo10005163.html>) and are suggested to identify the fixed points, the trajectories of the moving points (e.g. G and F), the length of the bars, and so on. After this exploration, they are asked to conjecture the name (if any) of the trajectory of the point E (intersection of GH and FI in the fig. 5a) tracing it with a graphite lead on the wooden platform. The drawing is soon recognized as an arch of an ellipse and the conjecture is produced. Then the process of proof construction is to be started. We shall comment it later.

B) Weakly guided exploration: students are given the artefact and the information that it may draw curves; they are given the burden to produce conjectures and to prove them. A graphite lead to trace the trajectory of points is available with no special emphasis on this experiment: they can decide to use it or not. The artefact is without coding letters (Fig. 5b) and actually the need of coding may be one of the outcomes of the exploration to understand each other (Bartolini Bussi & pergola, 1996). When the students explore for some minutes the motion without drawing the arch, they may recognize a well known (although hidden) figure. HIGF (fig. 5a) is an isosceles trapezium with diagonals (HG and FI) and sides (FG and HI) given by brass bars, whilst the bases FH and GI have a variable length and are not reified by bars. The figure is not trivial to be noticed, as the two bases are not visible. Usually the students rotate G around H and observe the figure. Sometimes they seem fascinated by this rotation. They stay silent for minutes. They try to look at the artefact from different perspectives, also standing and moving around the table. They assume strange postures, twist their necks to follow the motion, point at the bars and follow the motion with the finger in the air, move the bars forward and backward to look for invariants and test them stopping the continuous process. In the small group work, sometime a conflict arises, when the speed of the motion controlled by the actor does not match the exploration planned by the observer. At one point they "see" the trapezium and notice that $EG = EI$ and $FE = FH$. When a student has "seen" the trapezium, this figure is immediately shared with others. When the trajectory of E is eventually drawn they have at disposal what they need to link the conjecture with the metric property of ellipse.

I have described two 'antipodal' exploration processes with a lot of mixed cases in between. The weakly guided one is enjoyed by experts. The strongly guided one suits novices' needs to avoid frustration: it aims at encouraging to handle the artefact and at scaffolding the process. In both cases the demanding part is not the conjecture production, especially when drawing by the graphite lead is encouraged. Actually, as soon as the user draws the curve, the conjecture springs up, because only a limited set of curves is known by students: it is neither a circle nor a parabola nor an hyperbola, hence it must be an ellipse. The demanding task in this case concerns proof construction. This situation is different from the one of the tasks 4 and 5 above, where also conjecturing is really demanding.

In the strongly guided exploration, the worksheet suggests some ways to explore the properties of the artefact. Yet, in order to notice the properties, measuring by rulers is suggested. Measuring requires to stop the motion and to transform the experience of continuous motion into the observation of a finite set of frames. The focus risks to be on measuring parts of still figures.

In the weakly guided exploration, the focus shifts on the observation of dynamically changing shapes and their invariants. The students have to move and observe. Their process seems time wasting and not effective and has to be monitored by a walking teacher who moves from one group to another showing how to explore the artefact, with changing speeds and, maybe, no word. The initial 'weak' guide seems to require a stronger teacher's control. The students do not need (and usually do not wish) to measure bars by a ruler. As soon as they notice some invariants, they use their hands: they pretend to pick up the line segment EG between forefinger and thumb and to rotate it until it matches EI. They repeat the action on the pair FE and FH. Silent gestures seem to be enough to convince them. Maybe words and deductive chains are missing. Writing and justifying (by symmetry, for instance) the equality:

$$HE + EI = HE + EG = HG$$

that represents the metric property of ellipse with foci H and I is the boring counterpart of a relationships discovered by making "infinitely many" experiments, during the continuous motion of G around H.

In both cases of exploration, if the drawing is produced too early, the attention is focused on the final result of drawing rather than on the dynamical process of drawing. I shall consider this later.

There is a difference between the strongly guided exploration, that foster the production of statements concerning pointwise construction of the trajectory and the weakly guided exploration, that foster the production of statements concerning the global construction of the trajectory by a continuous motion. This difference is epistemological and mirrors the ancient pointwise construction of curves and the modern (as from the 17th century) construction of curves by a continuous motion of a machine. In the pointwise construction, there is a gap between the statements concerning a particular point E obtained when the artefact is in a given position and the generalization to a whichever point of the trajectory. This gap might obstruct the proof construction, requiring additional arguments.

The situation is different, yet recalls the one analysed by Pedemonte (2007) and concerning the construction of proofs by mathematical induction. She analysed the sum of the interior angles of an n-sided convex polygon, but the reasoning might be applied to many cases of induction. The well known formula: $(n - 2)$ times 180° , may be conjectured in at least two ways, that draws on experimental activity and that are called: result pattern generalization (the cases of n-sided convex polygons are analysed separately, adding the measures of the interior angles, for $n=3$, $n=4$, $n=5$ and

so on); process pattern generalization (from an $(n-1)$ -sided convex polygon, for $n=3, 4, 5$ and so on, a new n -sided convex polygon is obtained by the juxtaposition of a triangle, whose sum is 180°).

The result pattern generalization does not help much to construct the proof by mathematical induction, because the argumentations used have no counterpart in the proof. On the contrary the process pattern generalisation paves the way towards the proof, showing how it is possible to shift from $n-1$ to n . Pedemonte (2007) says that in the second case there is a structural continuity between the conjecture production (by argumentation) and proof construction (by induction). Students may succeed in proving the conjecture also after a result pattern generalization, but they must reconstruct a suitable argumentation that links the conjecture to the proving process.

The shift to the analytic frame suggested in the Laboratory worksheets is an intentional break of the structural continuity, because the analytic frame is supposed to be the familiar context where conics are studied in secondary schools.

DISCUSSION

Some conclusions may be drawn from the quoted examples and research outcomes. First, there are good reasons to believe that conjecturing through exploration before proving might be very useful. Yet, when conjecture production is too fast, it might offer no element to be used in the proving process. Hence it is useful to look for strategies that slow down the conjecture production and encourage effective exploration of the problem. The time spent in conjecture production is not wasted and may be recovered in the proof construction. Second, it is not possible to give general rules about which exploration is effective in the conjecture production. In the last example, I have contrasted strongly guided and weakly guided explorations, which are only two examples of a very rich set of possibilities. What to choose in a classroom situation? The teacher's decision has to be contextualized and depends on a lot of issues: the time constraints, the curriculum, the students' qualifications and so on. This last issue is related to teacher education. The teacher's knowledge in order to design and to manage in the mathematics classroom this kind of activities is complex and does not fit in the space of this paper. A systemic approach to teacher education is now in the foreground in the literature on didactics of mathematics.

CONJECTURING AND PROVING IN DYNAMIC GEOMETRY: THE ELABORATION OF SOME RESEARCH HYPOTHESES

Anna Baccaglioni-Frank*

Maria alessandra Mariotti**

*Università degli Studi di Siena & University of New Hampshire

**Università degli Studi di Siena

Research has shown that the tools provided by dynamic geometry systems impact students' approach to investigating open problems in Euclidean geometry. We particularly focus on types of processes that might be induced by certain uses of tools available in Cabri. Building on the work of Arzarello (Arzarello et al., 1998) and Olivero (1999, 2002), we have conceived a model describing some cognitive processes that may occur during the production of conjectures and proofs in a dynamic geometry environment and that might be related to the use of specific dragging schemes. Moreover, we hypothesize that such cognitive processes could be induced by introducing students to the use of dragging schemes.

Key words: conjecturing, dynamic geometry, dragging schemes, abductive processes, cognitive unity

INTRODUCTION

The contribution of a DGE to students' reasoning and proving is particularly evident during the investigation of open problems, since this process involves making conjectures (Mariotti, 2006). Instead of a static-conjecture built in a paper-and-pencil environment in a DGE a dynamic-conjecture [1] can be developed. Moreover, in a DGE, the invariant geometrical properties of a construction, which lead to conjectures, can easily be grasped. An interesting question is: what kind of support can a DGE provide first during the development of a conjecture and then during the production of a proof? The answer seems to depend on the nature of the problem. On one hand the ease to immediately grasp certain invariants seems to inhibit some argumentation processes that lead to finding useful elements for the construction of a proof. On the other hand, research has shown that a DGE can foster the learners' constructions and ways of thinking, and that it can help overcome some cognitive difficulties that students encounter with conjecturing and proving (e.g. Noss & Hoyles, 1996; Mariotti, 2002; De Villiers, 2004).

Building on the work of Olivero and Arzarello (Olivero, 1999; Arzarello et al., 1998), we have conceived a model of cognitive processes that can occur during the conjecturing stage of open problem investigations in a DGE. Through a qualitative study, our final goal is to give a detailed description of some cognitive processes related to conjecturing and proving, and of how a DGE might foster such processes, thus providing a base for further research and for the development of new curricular activities.

ORIGIN OF OUR HYPOTHESES

In the following paragraphs we will briefly outline the theoretical framework which the ideas are embedded in.

Semiotic Mediation and Semiotic Potential of an Artifact

A DGE like Cabri, which contains “objects” such as points, lines, circles, and ways to “manipulate” the objects, is a microworld (Papert, 1980; Balacheff & Kaput, 1996) built to resemble the mathematical world of Euclidean geometry. A key aspect of microworlds in mathematics education is that the “objects” included offer the opportunity for the user to experiment directly with the “mathematical objects” (Mariotti, 2005, 2006), because the logical reasoning behind the objects in the microworld is designed to be the same as that behind the real mathematical objects that they represent.

Recent research has developed the ideas of *tool of semiotic mediation* and of *semiotic potential of an artifact*:

“...any artifact will be referred to as a tool of semiotic mediation as long as it is (or it is conceived to be) intentionally used by the teacher to mediate a mathematical content through a designed didactical intervention” (Bartolini Bussi & Mariotti, 2008).

Computers in general, and a DGE in particular, are considered to be tools of semiotic mediation (Mariotti, 2006; Bartolini Bussi & Mariotti, 2008). However, the mediation can occur successfully only if their semiotic potential is exploited. Therefore it becomes necessary to study ways that foster exploitation of such potential. This was a main goal we had in mind when we started developing our hypotheses.

A First Theoretical Model and the Dragging Schemes

The dragging tool can be activated by the user, through the mouse. It can determine the motion of different objects in fundamentally two ways: direct motion, and indirect motion. The *direct motion* of a base-element (for instance a point), that is an element from which the construction originates, represents the variation of this element in the plane. The *indirect motion* of an element occurs when a construction has been accomplished. In this case dragging the base-points will determine the motion of the new elements obtained through the construction. The use of dragging allows one to feel “motion dependency”, which can be interpreted in terms of logical dependency within the geometrical context (Mariotti, 2002, p. 716). Starting from these phenomenological perspectives, a refined analysis of the dragging tool can highlight its semiotic potential that can be exploited by the teacher in school practice.

The use of Cabri in the generation of conjectures is based on the interpretation of the dragging function in terms of logical control. In other words, the subject has to be capable of transforming perceptual data into a conditional relationship between hypothesis and thesis. The consciousness of the fact that the dragging process may

reveal a relationship between geometric properties embedded in the Cabri figure directs the way of transforming and observing the screen image (Talmon & Yerushalmy, 2004). At the same time, that consciousness is needed to exploit some of the facilities offered by the software, like the ‘locus of points’ or ‘point on object’. Such a consciousness is strictly related to the possibility of exploiting the heuristic potential of a DGE (Mariotti, 2006).

The theoretical model presented by Olivero, Arzarello, Paola, and Robutti (Olivero, 2000; Arzarello, et al., 1998, 2002) addresses expert solvers’ production of conjectures, and how abduction marks the transition from the conjecturing to the proving phase, when a passage from “ascending control” to “descending control” occurs. Abduction guides the transition, in that it seems to be key in allowing solvers to write conjectures in a logical ‘if...then’ form, a statement which is now ready to be proved. Arzarello et al.’s analysis of subjects’ spontaneous development of dragging modalities led to the determination of a classification (Arzarello et al., 2002), which researchers have referred to as the “dragging schemes” (Olivero, 2002).

Abduction

In the previous section, the notion of abductive processes is mentioned. Peirce was the first to introduce the notion of abductive inference, and compare it with other inferences, such as deduction and induction. According to Peirce,

“abduction looks at facts and looks for a theory to explain them, but it can only say a “might be”, because it has a probabilistic nature. The general form of an abduction is: a fact A is observed; if C was true, then A would certainly be true; so, it is reasonable to assume C is true” (Peirce, 1960, p. 372).

Recently, researchers have renewed interest in abduction. In particular, Magnani defines abduction in a way that we find quite useful. According to him abduction is,

“the process of inferring certain facts and/or laws and hypotheses that render some sentences plausible, that explain or discover some (eventually new) phenomenon or observation; it is the process of reasoning in which explanatory hypotheses are formed and evaluated” (Magnani, 2001, pp. 17-18).

Moreover, the following distinction of direct abduction versus creative abduction will be useful for our study. *Direct abduction* is when the “rule” used in the abductive process consists of a theorem that is already known to the student; while *creative abduction* is when the “rule” of the abduction consists of something new, that is not previously known by the student (see also Magnani, 2001; Thagard, 2006). Other researchers have studied various uses of abduction in mathematics education (Reid, 2003), and abductive processes in relation to transformational reasoning (Simon, 1996; Cifarelli, 1999; Ferrando, 2006). The basic idea is that an abductive inference may serve to organize, reorganize and transform problem solvers’ actions (Cifarelli, 1999). Abductive processes have also been observed by Arzarello et al. (1998) during the development of conjectures when students were using the dragging schemes, as

mentioned above. In the next section we describe how our work builds on that of Arzarello et al., trying to study in detail the processes that occur during the conjecturing stage in open problem investigations, how these processes may be fostered, and what they might lead to during the phase of proof production.

OUR HYPOTHESES

While Olivero, Arzarello, Paola, and Robutti (Olivero, 2000; Arzarello, et al., 2002) focused their attention on the subjects' use of the dragging schemes during the development of a conjecture, we concentrate on the abductive processes that may be induced by certain dragging schemes. Arzarello et al. observed that abduction occurs during solvers' use of the dragging schemes. Moreover, they claim that the production of conjectures is based on abductive processes. Thus, it seems that the use of certain dragging schemes may foster abductive processes, and, consequently, the production of conjectures. To some extent, the dragging schemes can be seen as cognitive artefacts (Norman, 1991). We would like to investigate the relationship between the use of the dragging schemes and the development of abductive processes. In order to accomplish this investigation we need to induce solvers' use of dragging schemes, so we decided to introduce students to the specific dragging strategies. This way we seem to be able to induce the use of specific dragging schemes for the solution of open problems and, consequently, the appearance of abductive processes.

Below is a hypothesis of what might occur as a solver, who has been introduced to the dragging schemes, approaches an open problem in a DGE.

- Step 1: conscious use of different dragging strategies to investigate the situation – after *wandering dragging*, in particular *dummy locus dragging* (or *lieu muet dragging*) to maintain a geometrical property of the figure (*intentionally induced invariance*, or III), and use of the *trace tool*.
- Step 2: consciousness of the locus (*lieu*) that appears through *lieu muet dragging* – this marks a shift in control from ascending to descending – and description of a second invariance (*invariance observed during dragging*, or IOD).
- Step 3: hypothesis of a conditional link between the III and the IOD, to explain the situation.
- Other forms of dragging may be performed: *line dragging*, *linked dragging*, and the *dragging test*.
- Step 4: formulation of a conjecture of the form 'if IOD then III' (product of the abduction).
- Step 5: production of a mathematical proof of the conjecture (or attempt of it). Potential re-formulation of the conjecture.

The Notion of *Path* and an Example

Another hypothesis that we advance is that there is a key element, the *path*, that plays a fundamental role in the abductive process. In this section, we will try to introduce the concept of *path* and its significance for the model.

One of the dragging schemes, *lieu muet dragging*, involves dragging a point with the intention of maintaining a given property of the figure (which becomes the III). Some regularity may appear during this dragging stage, leading to the discovery of particular constraints that the dragged point has to respect (expressed in the IOD). Because of their origin from dragging, such constraints may be interpreted as the property of the point to belong to a particular figure. In mathematical terminology, that of course may not be consistent with students' way of thinking, we can speak of a hidden locus (*lieu muet*). Such locus can be made explicit by the trace tool, through which it appears on the screen (*lieu parlante*). During lieu muet dragging the solver notices regularities of the point's movement and conceptualizes them as leading to an explicit object. We refer to this object as a *path* when the solver gains consciousness of it, as generated through dragging, and consciousness of its property that if the dragged point is on it, a geometrical property of the Cabri figure is maintained. In this sense a *path* is the reification (Sfard, 1991) of a *lieu* that can now be used in a "descending control" mode (Arzarello et al., 2002). Zooming into Step 2, above, we observe that this is the point of the process in which the notion of *path* arises, and we can add a Step 2bis to indicate the (potential) geometric interpretation of the *path*, in order to (potentially, after Step 3) perform *line dragging*, *linked dragging*, and the *dragging test along such path*.

We believe that the *path* plays an important role in relation to the abductive processes that can be used to develop conjectures in a DGE. In particular, recognition of a *path* can act as a bridge, fostering the formulation of a conjecture. In fact, the *path* can be used during the abductive processes, but then it may no longer appear (or it may appear in a different form) in the formulation of the conjecture. Below, we zoom into a way in which abductive processes may take place and lead to a derived conjecture, and then we provide an example of the model in use during an activity.

- Intentionally Induced Invariance (III): the solver tries to maintain a certain geometrical property.
- Invariance Observed during Dragging (IOD): the solver notices that when he/she drags a certain basic point X along the *path*, the III seems to be maintained.
- Product of abductive process: it becomes reasonable for the solver to assume that if point X lies on the *path* (description of the IOD), the III is true.

If the path is recognized as a particular geometrical figure *F*, the derived conjecture may be: if X lies on F, the III is true.

Activity: Draw three points A, M, K, then construct point B as the symmetric image of A with respect to M, and point C as the symmetric image of A with respect to K.

Construct point D as the symmetric image of B with respect to K. Drag M and make conjectures about ABCD. Then try to prove your conjectures.

Fig 1: Dragging with the trace tool can help a student notice a *locus* (or *lieu*).

Fig 2: M is being dragged along the path (*line dragging*).

A Response [2]: Through *wandering dragging* solvers may notice that ABCD can become different types of parallelograms. In particular, they might notice that in some cases ABCD seems to be a rectangle (they can choose this as the III). With the intention of maintaining this property as an invariant, solvers might mark some configurations of M for which this seems to be true, and through the trace tool, try to drag maintaining the property, as shown in Fig 1. This can lead to noticing some regularity (IOD) in the movement of M, which might lead to awareness of an object along which to drag (the circle of diameter AK, potentially not yet recognized as “a circle”). At this point, when such awareness arises, we can speak of *path* with respect to the regularity of the movement of M.

If solvers recognize the path to be a familiar geometrical object, like in this case, they might be inclined to constructing it, as shown in Fig 2, and dragging along it (*line dragging*), or even linking the free point to it (*linked dragging*) and performing a *dragging test*. Through this abductive process, as an attempt at explaining the experienced situation, as Magnani describes (Magnani, 2001), solvers

may hypothesize a conditional link between the III and IOD. At this point the abduction leads to a hypothesis of the form ‘if IOD then III’, leading to a conjecture like the following: “If M is on the circle of diameter AK, then ABCD is a rectangle,” or (if they discover or derive a property of the base-points which is equivalent to M lying on the circle): “If AKM is a right triangle, ABCD is a rectangle.”

In the case of the first conjecture, here is how we hypothesize the abduction (*creative abduction*) might go.

- III: ABCD is a rectangle.
- IOD: when M dragged along the *path*, fact A seems to be true. The path is a known geometric figure: the circle of diameter AK.
- Product of the abduction: If point M lies on the circle of diameter AK, ABCD is a rectangle.

This product of the abduction coincides with a formulation of a conjecture. However, solvers might also perform a second abduction (this time a *direct abduction*) linking the property “M belongs to the circle” to a property of the base-points of the construction. In this case this may lead to a formulation of the conjecture like: “If the triangle AMK is a right triangle (with $\angle AMK$ as the right angle), ABCD is a rectangle.” In this case the further elaboration of the geometrical properties recognized in the path will have led to a key idea (Raman, 2003) of a possible proof. In particular, this idea together with that of triangles AMK and ABC being similar, should be enough for students to successfully provide a proof to their conjecture. In this sense, abductive processes involving the notion of *path* (as a reified concept the solver is aware of) might be a step towards the achievement of cognitive unity [3] (Boero, Garuti, & Mariotti, 1996; Pedemonte, 2003).

Some Research Questions

Given the hypotheses outlined above, we propose some general questions for a research study. First, it would be interesting to investigate what forms of reasoning (abductive, deductive, ...) are actually used (and how) during the conjecturing stage of an open problem in a DGE. In particular, if subjects use *lieu muet* dragging, what is the role of the *path*? Can our model be confirmed (even in a potentially modified version)? Second, how does a DGE contribute to the development of the proof of a conjecture? It would be interesting to compare the dragging schemes (if any) used during this stage to those used during the conjecturing stage. It might also be insightful to investigate the forms of reasoning used during the conjecturing stage in the cases in which subjects do produce a proof. Finally, it would be interesting to study whether it is possible to detect a relationship between the forms of reasoning analyzed, and, if possible, to describe such a relationship.

EXPERIMENTAL DESIGN AND POTENTIAL CONCLUSIONS

We propose to structure the study in the following general way: by a selection of the subjects, the introduction of the subjects to the dragging schemes, finally open-problem-activity-based interviews on pairs of students. We will use results from the pilot study to refine the model, the research questions, and the activities proposed during the interviews. In the results of this study we hope to be able to include: a description of some cognitive processes that occur during the conjecturing stage of the investigation of open problems in a DGE; and validation of the model (or of a revised version of it), or motivations for rejecting it as a useful descriptive model. Therefore, this study should help gain better comprehension of specific cognitive

processes. In particular, we hope to gain some insight into how abductive processes may occur, whether they can be fostered by preliminary introduction of the dragging schemes, and how the notion of *path* may foster the formulation of conjectures.

A secondary objective is to gain insight into how a DGE contributes to the development of proofs. The activities proposed during the interviews will all be open problems in which students are asked to make conjectures and then try to prove them. The *path* might also play a role in the generation of a proof, in that it may be a part of the “reorganization and transformation” that occurs with abductive reasoning (Cifarelli, 1999). This might very well be new powerful tool for the solver to use in a potential proof (or solution of the problem) as an aid to gain cognitive unity, as mentioned above. In this case, it would be reasonable to hypothesize that if the dragging schemes were to foster abductive processes, and abductive processes were to foster cognitive unity, then introducing the tool of the dragging schemes to the students a priori might accelerate and facilitate the entire process of making a conjecture and reaching a proof for it.

If our hypotheses are confirmed, and the dragging schemes and the notion of *path* do contribute positively to the formulation of conjectures (and potentially of proofs), we will recognize them as tools of semiotic mediation, with a semiotic potential that could be exploited by teachers. In this case, teaching experiments, which introduce the dragging schemes at a class-level, should be carried out, in order to further investigate how the teacher can exploit the semiotic potential of the dragging schemes in the classroom practice. Later, large-scale quantitative research on the induction of cognitive processes through introduction of the dragging schemes could be conducted, with the didactic objective of implementing the teaching of the dragging schemes in school curricula.

NOTES

1. With “static” and “dynamic” referred to conjecture, here we intend to emphasize the nature of the conjecture’s origin.
2. This is only one of the many possible responses leading to this specific conjecture. Of course different students might reach this conjecture in different ways. Moreover there are many different conjectures that students can formulate by focusing their attention on different geometric invariants (in this case, having ABCD be a kite, a rhombus, or a square).
3. Boero et al. introduce cognitive unity as follows: “During the production of the conjecture, the student progressively works out his/her statement through an intense argumentative activity functionally intermingled with the justification of the plausibility of his/her choices: during the subsequent proving stage, the student links up with his process in a coherent way, organizing some of the justifications (“arguments”) produced during the construction of the statement according to a logical chain” (Boero, Garuti, & Mariotti, 1996, p.113).

THE ALGEBRAIC MANIPULATOR OF ALNUSET: A TOOL TO PROVE

Bettina Pedemonte

Istituto per le Tecnologie Didattiche – CNR Genova

This report is devoted to analyzing the influence of an algebraic system, the Algebraic Manipulator of ALNUSET on students' construction of proof in proving equivalence among expressions. Results of an experiment, carried out with students at the second year of Upper Secondary school, are presented to show in which way this manipulator can be used in the educational practice to enhance the teaching and learning of algebraic proof.

INTRODUCTION

As underlined in the introduction to the special issue of ZDM on didactical and epistemological perspectives on mathematical proof (Mariotti and Balacheff, 2008), research work about mathematical proof has been growing in the last decade. Different perspectives (historical and epistemological issues, cognitive ones, didactical transposition of mathematical proof into the classroom) are taken into account framing the proof from different points of view. The actual invitation addressed to educational researchers is to find complementarities in this variety of approaches to make them converge (Balacheff, 2008). This required effort has double goal. On one hand, it could mean an acknowledged awareness of what connects and what separates our works, and on the other hand, it could strongly contribute to teaching and learning of proof in everyday classes. Finally, this effort could make possible the connection between educational research and the school context making our research work effective and fruitful.

Due to my concern for this aspect, I have been studying to find “effective supports” to the didactical transposition of mathematical proof into the classroom. Starting from evidence highlighted by existing research works about students' difficulties in approaching proof, I show a possible way to use technological artefact in the classroom to support the teaching and learning of proof effectively. In this report I present a part of this work in progress. In particular, some interesting results of an experiment carried out with students at the second year of Upper Secondary School are reported.

STUDENTS DIFFICULTIES IN LEARNING PROOF

Students' difficulties in learning mathematical proof have been pointed out by many different research works. In this report I am particularly interested in two of them: students do not see the usefulness of a mathematical proof and they do not understand its language and symbolism.

A new balance between the need to produce logical argument and the need to provide an argument that explains, communicates and convinces seems to be necessary (Healy and Hoyles, 2000). Various authors point out the importance of the explicative and justificative roles of proof (Hanna, 1989, 2000, Harel and Sowder, 1998) that often are not grasped by students. The importance of proof should go beyond the establishment of mathematical truth. A broader vision of proof is expected: proof should provide students with important mathematical strategies and methods for solving problems. (Hanna and Barbeau, 2008).

This new approach to proof could effectively support students in seeing the usefulness of a mathematical proof but other difficulties could come out and they have to be considered. For example, the deductive nature of proof and its symbolism should be explained and justified too. Research results highlighted the great difference between argumentation and proof both from a semantic point of view (Duval, 1995) and from a structural one (Pedemonte, 2007); it is important to distinguish between truth and validity from a logical point of view (Durand-Guerrier, 2008). Logical structure, language and symbolism are important aspects in the construction of proof but they remain often hidden for students. Proof can appear to students as a sub-minimal code with no vital information for understanding (Alibert and Thomas, 1991).

Furthermore, some studies highlight the role of the proof as theoretical organization. These studies focus on the importance of introducing students to the axiomatic structure of proof and to a theoretical perspective (Mariotti & al., 1997). Their aim is to help students access the meaning of theorem and support them in the transition from the need of justifying to the need of validating within a mathematical system (Mariotti & al., 1997).

In general, all these studies show that the role of proof in the educational practice is not well defined and very often difficulties emerge because some aspects of proof are not explicit for students and they are not well explained by teachers.

In teaching proof, certain often implicit aspects need to become part of explicit educational goals (Hemmi, 2008). Through the notion of “transparence”, Hemmi contributes to solve the dilemma to make more or less visible to students some important aspects concerning proof. The concept of transparency (Lave and Wenger, 1991) combines two characteristics: visibility and invisibility. Visibility concerns the ways that focus on the significance of proof (construction of the proof, logical structure of proof, its function, etc.). Invisibility is the form of “unproblematic interpretation” and integration to the activity (Hemmi, 2008, p. 414). It concerns the proof as a justification of the solution of a problem without considering it as a proof. It has been underlined that “*Proof as an artifact needs to be both seen (to be visible) and used and seen through (to be invisible) in order to provide access to mathematical learning*” (Hemmi, 2008, p. 425). The lack of transparency in the

teaching of proof regards the lack of knowledge about proof techniques, key ideas and proof strategies.

These considerations offer important insights to make the transposition of mathematical proof into the classroom effective.

In this context I intend to contribute through the Algebraic Manipulator of Alnuset. This system can be used in teaching and learning algebraic proofs to make rules and axioms used visible in proof processes and to make theoretical aspects usually implicit in algebraic manipulation emerge. The aim of this report is to show in which way the Algebraic Manipulator can be used in the educational practice to enhance the teaching and learning of algebraic proof.

ALNUSET

Alnuset is a system developed in the context of ReMath (IST - 4 - 26751) EC project for students of lower and upper secondary school (yrs 12-13 to 16/17). It is constituted by three integrated components: the Algebraic Line component, the Algebraic Manipulator component, and the Functions component. Even if the educational relevance of this system emerges better through the integrated use of these three components, in this paper I only consider the Algebraic manipulator component to show how it can be used to modify the approach to the algebraic proof.

To have a more complete idea about this system you can see the report presented in group 7 by Chiappini G., and Pedemonte B. of this edition of CERME.

The Algebraic Manipulator of Alnuset: a tool to prove

The Algebraic Manipulator component (AM) of Alnuset is a structured symbolic calculation environment for the manipulation of algebraic expressions and for the solution of equations and inequations.

Its operative features are based on pattern matching and rewriting rules techniques. In the AM these techniques are used in a different perspective with respect to the CAS where the basic rules (commutativity, associativity, etc.) are used internally in a sequence generally not controlled by the user, to produce a higher level result, like “factorize” or “combine”. As a consequence, the techniques of transformation involved in CAS can be obscure for a non expert user.

In the AM, pattern matching is based on a structured set of basic rules that correspond to the basic properties of operations, to the equality and inequality properties between algebraic expressions, to basic operations among propositions and sets. These rules are explicit for students. They appear as commands on the interface made active only if they can be applied to the part of expression currently selected.

An expression is transformed into another through this set of rules. Students can see the transformation of an expression as result of the application of a rule to it.

$(x-1) \cdot (x+1)$

$(x-1) \cdot x+(x-1) \cdot 1$

$x \cdot x-1 \cdot x+(x-1) \cdot 1$

$x \cdot x-1 \cdot x+x \cdot 1-1 \cdot 1$

$x \cdot x-1 \cdot x+x-1 \cdot 1$

$x \cdot x-1 \cdot x+x-1$

A sequence of rules (chosen from the left panel) are applied to the initial expression $(x-1)(x+1)$. At each step, the rule is applied to the green sub-expression, producing the expression on the next line. The last line shows the current selection ($x \cdot x$ in yellow), and one of the 7 rules highlighted in yellow can be applied to this sub-expression.

Moreover, the system allows the student to create new transformational rules (user rules) once these new rules have been previously derived. This feature also present in the L'Algebrista (Cerulli, Mariotti, 2003) is important because it can be used to construct an idea of structured theory.

In the following I show how the AM can be used to provide a good “transparency” (Hemmi, 2008) for the concept of proof. This system can be used to introduce proof in Algebra making visible the rules and procedures of manipulation supporting the comprehension of proof as part of a theoretical system. Moreover, the AM could be used to propose problems involving proof without a direct focus on it. For space reasons, in this report only the role of Alnuset as tool allowing the “visibility” of some important concepts about algebraic proof is analysed.

TEACHING EXPERIMENT

In this section, students’ resolution processes of some tasks involving the construction of proof in the AM of Alnuset are analysed. They are taken from a set of data collected from an experiment carried out in a class of 24 students of the second year of Upper Secondary School (15-16 years old) in the context of ReMath EC project.

The main aim of this experiment was to analyse the role of Alnuset in a teaching experiment centred on algebraic expressions and propositions. The experiment lasted ten weeks, with a 2-hour section each week. The first part of the teaching experiment

focused on algebraic expressions (equivalent expressions, opposite expressions, reciprocal expressions). In this part, a specific section was devoted to the manipulation of expressions. In this report I present results of this section.

During the previous weeks students had used the AM of Alnuset only twice.

Students worked in pairs with the AM of Alnuset under the supervision of the teacher and the researcher.

In the following, tasks proposed to students during the section are presented.

Tasks

- a) Use AM to prove that $(2+3)*5-25$ is equal to 0
Use AM to prove the same equality starting by 0.
Is this the only equivalence that it is possible to prove starting by 0?
- b) Use AM to prove that $(2/5+4/5)*5/6$ is equal to 1
Use AM to prove the same equality starting by 1.
Is this the only equivalence that it is possible to prove starting by 1?
- c) In solving tasks a) and b) you have used two specific commands, both in direct and indirect ways: the command to add two opposite expressions ($A+-A\leftrightarrow 0$) and the command to multiply two reciprocal expressions ($A*1/A\leftrightarrow 1$). Have you observed any difference in the direct and indirect use of these commands? If yes, what differences? In your opinion, is it more difficult to accomplish proofs based on the direct use or proofs based on the indirect use of these commands? Why?
- d) Try to prove that the expression $a/b+c/d$ is equivalent to the expression $(a*d + b*c)/bd$. If this proof is difficult for you, try to prove the equivalence between the two expressions starting from $(a*d + b*c)/bd$ and then to come back step by step in order to work out the more complex proof.
Use the accomplished proof to create a new manipulation rule.
- e) Try to prove that the expression a^2-b^2 is equivalent to the expression $(a+b)(a-b)$. If this proof is difficult for you, try to prove the equivalence between the two expressions starting from $(a+b)(a-b)$ and then to go backward, step by step, in order to work out the more complex proof. Use the accomplished proof to create a new manipulation rule.
- f) Use AM to transform the following expressions using, if necessary, the rules created in the previous tasks:

$$x^2-4; \quad x^2-1; \quad \frac{x+2}{x+1} + \frac{x+1}{x-2}$$

Tasks a) and b) introduce the two rules $A+-A\leftrightarrow 0$ and $A*1/A\leftrightarrow 1$ instantiated on specific examples. Task c) supports reflections about the direct and indirect use of these rules. Tasks d) and e) require to prove the rules $a/b+c/d = (a*d + b*c)/bd$ and $a^2-b^2 = (a+b)(a-b)$ using the two rules $A+-A\leftrightarrow 0$ and $A*1/A\leftrightarrow 1$. Task f) is useful to strengthen the use of the new proved rules.

Tasks a), b) and c)

The solution of task a) in the manipulator is reported in the following table. In the first part there is the manipulation from the numerical expression to 0 and in the second part there is the manipulation from 0 to the expression.

$(2+3) \cdot 5 - 25$	0	The second proof (right) is more difficult for students with respect to the first one (left). In the second proof, the equivalence needs a step that obliges the user to write 0 as addition of two opposite numbers (25-25). This is not obvious for students who in general are not able to manage it.
$(5) \cdot 5 - 25$	$25 + -25$	
$25 - 25$	$25 - 25$	
$25 + -25$	$5 \cdot 5 - 25$	
0	$(2+3) \cdot 5 - 25$	

The application of the rule $0 \Rightarrow A + -A$ requires to understand that 0 can be expressed as sum of two opposite expressions. The problem is that there are infinite possibilities that can be considered to replace 0.

In the same way, to apply the rule $1 \Rightarrow A \cdot 1/A$ students have to replace 1 with two reciprocal expressions.

$(\frac{2}{5} + \frac{4}{5}) \cdot \frac{5}{6}$	1	The second proof (right) is more difficult for students with respect to the first one (left). In the second proof, the equivalence needs 2 steps that oblige the user to write 1 as multiplication of two reciprocal numbers ($5 \cdot 1/5$ and $6 \cdot 1/6$). As in the previous case, this is not obvious for students who are not able to replace 1.
$(2 \cdot \frac{1}{5} + \frac{4}{5}) \cdot \frac{5}{6}$	$6 \cdot \frac{1}{6}$	
$(2 \cdot \frac{1}{5} + 4 \cdot \frac{1}{5}) \cdot \frac{5}{6}$	$6 \cdot 1 \cdot \frac{1}{6}$	
$((2+4) \cdot \frac{1}{5}) \cdot \frac{5}{6}$	$6 \cdot 5 \cdot \frac{1}{5} \cdot \frac{1}{6}$	
$((6) \cdot \frac{1}{5}) \cdot \frac{5}{6}$	$6 \cdot \frac{1}{5} \cdot 5 \cdot \frac{1}{6}$	
$6 \cdot \frac{1}{5} \cdot \frac{5}{6}$	$6 \cdot \frac{1}{5} \cdot \frac{5}{6}$	
$6 \cdot \frac{1}{5} \cdot 5 \cdot \frac{1}{6}$	$(2+4) \cdot \frac{1}{5} \cdot \frac{5}{6}$	
$6 \cdot 1 \cdot \frac{1}{6}$	$(2 \cdot \frac{1}{5} + 4 \cdot \frac{1}{5}) \cdot \frac{5}{6}$	
$6 \cdot \frac{1}{6}$	$(\frac{2}{5} + 4 \cdot \frac{1}{5}) \cdot \frac{5}{6}$	
1	$(\frac{2}{5} + \frac{4}{5}) \cdot \frac{5}{6}$	

As shown by the results of the experiment, in general these rules are used by students in their manipulations in paper and pen environment, in a completely implicit way. Most students are able to transform an expression into another one using these rules but they are not able to explicit them. In better cases they are able to use these rules as computational techniques but they are rarely able to justify them.

Analysis of results of tasks a), b) and c)

The results analysis of the experiment shows that most students constructed the direct proof in tasks a) and b) even if for task b) the intervention of the teacher was often necessary. Students knew the result of the sum $2/5 + 4/5$ but they were not able to make it in the AM because they didn't manage the properties and rules hidden in the

technique of addition of two fractions.

The construction of the inverse proofs (from 0 to the expression $(2+3)*5-25$ and from 1 to $(2/5+4/5)*5/6$) was not easy for them. As expected, difficulties emerged when students had to replace 0 as sum of two expressions and 1 as multiplication of two expressions.

Only observing the previously constructed direct proof some students (6 groups out of 12) were able to construct also the inverse proof, following step by step the direct proof and going backwards to the initial expression. Here is the dialog between two students while constructing the proof from 0 to the expression $(2+3)*5-25$.

I: But in which way can we prove this equivalence starting from 0?

F: perhaps...

I: wait a moment... if $a+-a$ is 0 it is also true that 0 is $a+-a$

F: yes, of course

I: then if $25-25$ is 0 it is also true that 0 is equal to $25-25$... then we can write in this way

F: following step by step the previous proof

The AM allowed students to make explicit rules $A+-A \Leftrightarrow 0$, $A*1/A \Leftrightarrow 1$ and to understand the intrinsic difference that characterises the two directions of the rules. Let's see the following example (answers reported in the copy of a group of student):

“a) Starting with 0 it is possible to prove whatever equivalence having 0 as result. So there are infinite equivalent expressions to 0. b) Starting with 1 it is possible to prove that 1 can be replaced by all reciprocal expressions having 1 as results. c) In our opinion it is easier to produce proofs based on the direct use of the command $A+-A \Leftrightarrow 0$, because in the inverse case it is necessary to look for the opposite expression, while the direct use of the command only requires the application of the correct axiom. For the rule $A*1/A \Leftrightarrow 1$ the principle is the same, but in this case consider reciprocal expressions and not opposite expressions”.

Answers given by these students to task c) show that they have developed awareness about the role of the two rules and the way they can be used in manipulation.

Tasks a), b), and c) allowed students to reflect deeply on these rules that are usually used in the algebraic manipulation in a completely “invisible” way. The AM of Alnuset allowed students to “make visible” these rules and their use in the construction of the proofs.

Tasks d), e) and f)

Task d) and task e) are very useful in approaching proof and in particular they are effective to understand the idea of theoretical systems. As a matter of fact, only when the rules $a^2-b^2 = (a+b)(a-b)$ and $a/b+c/d = (a*d + b*c)/bd$ are proved they can become new user rules and they can be used to prove expressions as those proposed in task f).

A possible solution of the task e) in the AM is reported in the following table.

$a^2 - b^2$	$(a+b) \cdot (a-b)$	<p>It is better to begin from the second proof (right) because in the first proof (left) it is necessary to insert 0 and replace it with the sum of the two opposite expressions ab and $-ab$.</p> <p>Once the proof is accomplished students can solve it as a new rule: the following one.</p> <div style="border: 1px solid black; padding: 5px; margin: 10px 0;"> <p style="text-align: center; background-color: #e06699; color: white; margin: 0;">User Rules</p> $a^2 - b^2 \Leftrightarrow (a+b) \cdot (a-b)$ </div> <p>This user rule can be used in the successive manipulations.</p>
$a^2 + 0 - b^2$	$(a+b) \cdot a - (a+b) \cdot b$	
$a^2 + a \cdot b + -(a \cdot b) - b^2$	$a \cdot a + b \cdot a - (a+b) \cdot b$	
$a \cdot a + a \cdot b + -(a \cdot b) - b^2$	$a \cdot a + b \cdot a - (a \cdot b + b \cdot b)$	
$a \cdot a + a \cdot b + -(a \cdot b) - b \cdot b$	$a \cdot a + b \cdot a + -(a \cdot b + b \cdot b)$	
$a \cdot (a+b) + -(a \cdot b) - b \cdot b$	$a \cdot a + b \cdot a + -1 \cdot (a \cdot b + b \cdot b)$	
$a \cdot (a+b) + -1 \cdot (a \cdot b) - b \cdot b$	$a \cdot a + b \cdot a + -1 \cdot a \cdot b + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot a \cdot b - b \cdot b$	$a \cdot a + b \cdot a + -(a \cdot b) + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot a \cdot b + -(b \cdot b)$	$a \cdot a + a \cdot b + -(a \cdot b) + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot a \cdot b + -1 \cdot (b \cdot b)$	$a \cdot a + 0 + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot a \cdot b + -1 \cdot b \cdot b$	$a \cdot a + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot b \cdot a + -1 \cdot b \cdot b$	$a^2 + -1 \cdot b \cdot b$	
$a \cdot (a+b) + -1 \cdot (b \cdot a + b \cdot b)$	$a^2 + -1 \cdot b^2$	
$a \cdot (a+b) + -1 \cdot (b \cdot (a+b))$	$a^2 - 1 \cdot b^2$	
$a \cdot (a+b) + -1 \cdot b \cdot (a+b)$	$a^2 - b^2$	
$(a + -1 \cdot b) \cdot (a+b)$		
$(a + -b) \cdot (a+b)$		
$(a-b) \cdot (a+b)$		
$(a+b) \cdot (a-b)$		

A lot of steps are necessary to prove the equivalence $a^2 - b^2 = (a+b)(a-b)$ in the AM of Alnuset, because manipulation requests students to make rules and axioms that are necessary to prove the equivalence explicit.

In the same way it is possible to produce the proof of the equivalence $a/b + c/d = (a \cdot d + b \cdot c)/bd$.

Analysis of results of tasks d), e) and f)

Tasks d) and e) required a lot of efforts by students. Nevertheless, these tasks were very fruitful to understand the meaning of proving a rule starting by a basic set of rules and axioms. Students who tried to prove the two equivalences $a/b + c/d = (a \cdot d + b \cdot c)/bd$ and $a^2 - b^2 = (a+b)(a-b)$ inserting the first expression ($a/b + c/d$ or $a^2 - b^2$) were not able to begin the manipulation. All students were forced to follow the suggestion given by the text of the tasks inserting the second expression and manipulating it. Also in this case the solution was not obvious. Some difficulties concerned denotative aspects: deletion of superfluous parentheses, application of properties in order to make the expression match with the rule to be applied, and so on. Nevertheless, in some cases, difficulties concerned “conceptual aspects” usually invisible in the ordinary manipulation in the paper and pen environment. For example, students were not confident with rules such as $a-b = a + -b$ and $-a = -1 \cdot a$. Thus steps concerning the

application of these rules were often introduced by the teacher. Let's see the dialogue of two students during the resolution of task d).

S: This is a specific product... Insert in Alnuset the expression a^2-b^2

L inserts the expression in AM

S: and then?

L: I really have no idea....

S tries to apply some rules without success.

L: Perhaps... it is better to start from the other side. Try to insert $(a-b)(a+b)$

S inserts the expression in AM and then she applies the distributive law.

She is not able to sum $-ab + ab$ because she was not able to transform the expression $aa+ba-(ab+bb)$ into the expression $aa+ba-ba-bb$.

L: What? We are not able to add these two expressions. We know that the solution is 0 but...

S: in which way can we find this result?

Teacher: You have to apply the rules $a-b=a+-b$ to transform $-(ab+bb)$ into $-1(ab+bb)$...

S: Ah ok! We try...

Students complete the proof and they try to perform the inverse proof.

Even if it was really hard for students to solve the tasks, the constructed proofs obliged them to make explicit axioms and rules that are used step by step during the transformation of an expression into another.

In general, students were very proud of their proofs and they liked a lot to save the proved rules as new rules that could be used in their successive proofs. Task f) was solved by most students without any difficulty. In this task they eventually realised that the previously proved rules were useful to prove other new rules.

CONCLUSIONS

The results of the experiment might show that the AM of Alnuset does not help students construct proofs and makes proofs more complicated for them. In a sense this is true - a lot of students are able to transform $(a+b)(a-b)$ into a^2-b^2 in paper and pen environment and perhaps it is not so important to be able to make the inverse transformation. The problem is that in school practice, algebra is usually considered as a body of rules and procedures for manipulating symbols. Students are usually able to develop calculus but they are not aware of the axioms and theorems they are using in performing it. Thus, algebra is taught and learned as a language and emphasis is put on its syntactical aspects. In this context, algebraic proof appears as a grammar structure made of a sequence of formulae connected by calculus rules. In this way, the meaning of proof is completely lost. Despite this, rigorous proof is generally considered as a sequence of formulae within a given system, each formula being either an axiom or derivable from an earlier formula by a rule of the system. The AM of Alnuset supports this kind of proof though in a different way. Each step in the manipulation is produced by the application of a rule that has to be chosen by the student from a set of rules. If the choice is not correct it could be very difficult for the student to construct the proof. During the experiment the intervention of the teacher often supported students that were unable to accomplish the task. Notwithstanding this, at the end of the experiment, students were able to explicit rules used during

their proofs spontaneously. Also during ordinary school practice, students justified their steps making the rule used in the transformation explicit. This kind of approach required a lot of effort but it supports the awareness of what it is an algebraic proof and in which way a mathematical theory can be constructed.

VISUAL PROOFS: AN EXPERIMENT

Cristina Bardelle

Università degli Studi del Piemonte Orientale “A. Avogadro”

The main goal of this paper is to start a preliminary study of the basic features of visual proofs in mathematics and their use in mathematics teaching. The investigation, based on college mathematics students, shows a very poor use of visual reasoning in mathematical tasks involving figures. Moreover, students’ use of visual semiotic systems is not spontaneous but seems to need some special training. Some of the ways of working students usually adopt when dealing with visual proofs have been identified, showing that most often diagrams are not seen as representations of complete processes, but rather as ready-made aids to solve problems.

INTRODUCTION

Many researchers have stressed the importance of visual reasoning in the learning of mathematics and have remarked that research in mathematics education has still a lot to develop about this topic (see e.g. Dreyfus 1991, Jones 1998, Presmeg 2006). In this perspective this paper focuses on visual proofs i.e. on proofs where the deductive steps are based on figures, diagrams or graphs. This means that the inferences are possible through just the reading of the figures. Although geometrical figures will be taken into account only, the expression ‘diagrammatic proof’ or ‘visual proof’ will be used in a more inclusive sense. At this regard, a number of works, such as Nelsen’s books (1993, 2001) have provided a wide selection of examples of visual proofs from different sources. In literature visual proofs are usually presented with no comments in verbal language (i.e. without words), but only based on diagrams, possibly equipped with numbers, letters, arrows, dots, or other signs and sometimes associated with symbolic expressions; the reconstruction of the proof is left to the reader. Nowadays visual arguments are far to be considered legitimate arguments for rigorous proofs probably due to the fact that they can easily misread and therefore lead to wrong inferences. Anyway their importance as an aid for the discovery of new results and the production of more formal proofs is widely recognized. In the last decades interest in visual proofs has grown up leading to both new mathematical investigations and applications to mathematics education. On the side of mathematical investigations above all we mention the work of Barwise and Etchemendy (1991) and further developments in the same line such as Jamnik’s study (2001). From the educational viewpoint the role of visual reasoning in mathematics teaching has been taken again into account and emphasized (see e.g. Dreyfus 1991, Dvora & Dreyfus 2004, Hanna 1989, Presmeg 1997, 2006).

The main goal of this paper is to identify the main difficulties in the use of diagrams in mathematics, in particular in the extraction of information. For this purpose some visual proofs have been taken into account. In the experiment I am describing some statements with the corresponding diagrammatic proofs have been given to

mathematics sophomore and third year students. Such proofs have been presented without any explanation on the inference steps implicit in the figures. The work is also aimed to compare the processes involved in visual proofs to those involved in the standard ones. Diagrams are not relevant only in relation to visual proofs, but they can also support either standard proof processes (i.e. proofs based on a verbal or symbolic text) or problem solving. Indeed the heuristic role of figures is widely recognized both by mathematicians and by mathematics educators. Therefore some features of diagrammatic proofs will be taken into account, which might be relevant from the educational viewpoint and to explore the opportunities that they can provide in order to improve the approach to mathematical theorems.

THEORETICAL FRAMEWORK

The production or the understanding of a diagrammatic proof involves constructing and treating (detaching, reversing, superposing, translating,...) figures and extracting information from them. All these operations will make evident the inferential steps that make up a visual proof of a statement. Moreover a diagrammatic proof is developed for a particular value of the domain of validity of the theorem but anyway it represents the proof for all values of the domain (character of generality, Barwise & Etchemendy 1991).

We did not find in literature a theoretical framework closely focused on visual proofs in mathematics education. Although here we are focusing on visual proofs that are based on geometrical figures, we take into account some different works about visual reasoning and visualization that could help us to interpret difficulties about this topic.

First of all, according to Fischbein (1993), geometrical figures are mental entities (named also ‘figural concepts’) which possess conceptual and figural characters at the same time. In this frame, as other studies in geometry, we refer to figures as the mental entities which possess properties imposed by, or derived from axiomatic systems and to drawings as their (external) representations. A major problem in the use of diagrams and figures is the potential conflict between conceptual and perceptual features of figures. Fischbein’s theory is very helpful at this regard. Fischbein argues that ‘...figural concepts constitute only the ideal limit of a process of fusion and integration between the logical and figural facets’ (Fischbein 1993, p.150). In particular visual proofs involve some logical questions concerning the nature of deductions based on diagrams and figures. Actually, it is to be considered that visual proofs are bound to correspond to some extent to proofs in the standard mathematical sense. In this work I do not mean to question the rigorousness of diagrammatic proofs (on this topic see Barwise & Etchemendy (1991), Jamnik (2001), Hanna & Sidoli (2007), Allwein, G. & Barwise J. – Eds. (1996) and references therein) but I assume that they can be regarded as legitimate mathematical processes.

Another main difficulty encountered by students is due to the lack of coordination of systems of semiotic representations (Duval 1993). Working with a visual proof requires a continuous interplay between the semiotic system of figures and the semiotic systems involved in the statement, usually verbal texts or symbolic expressions. Like Duval, I assume that semiotic systems are not neutral carriers of meanings but can contribute to the construction of meaning themselves. This explains the attention I am going to pay to semiotic systems through this paper.

AN EXPERIMENT

At the Università del Piemonte Orientale, in Italy, in the context of a course devoted to mathematical proof, we have given a group of 13 sophomore and third year undergraduate Mathematics students a number of tasks requiring to look at diagrammatic proof of some statement and to reconstruct such a proof (i.e. to describe how the proof could be extracted by the figure). The tasks have been administered as written tests and they were followed by interviews in order to better understand the arguments written by students.

The problems are the following:

Task 1.

The picture on the right represents a visual proof of the Pythagoras' theorem.

- Describe such a proof.
- Reconstruct the figure in the case that the legs of the right-angled triangle have the same measure.

Task 2.

The picture on the right represents a visual proof of the theorem

$$\sum_{i=0}^{+\infty} r^i = \frac{1}{1-r} \quad \text{for } 0 < r < 1.$$

Describe such a proof.

The statements are in two different fields of mathematics: the Pythagoras' theorem and the geometric series. Pythagoras' theorem is customarily associated to visual representations, whereas the latter is less common (at least in Italy), as the convergence of the geometrical series is usually proven using a combination of algebraic and analytical arguments. So this visual proof is very unusual for Italian mathematics college students. The choice of theorems from different fields is aimed at finding common features and common difficulties related just to visual reasoning. As the results show, students find this kind of problems very difficult. The main difficulty is due to the fact that the drawing is a static object while a proof is made of an ordered sequence of inference steps. A drawing presents in a whole all written data and the reader has to choose the order of the construction and how to extract the information.

Analysis of task 1. Here the construction of the drawing may not present so many problems since it is not required a precise order of construction as far as one recognizes that there is a particular disposition of six right angle triangles. Troubles can arise when trying to find correspondences between the statement and the picture. This task is mainly based on visual arguments. Students could meet with difficulties in the identification of the area of the square built on the hypotenuse (Fig.1) and above all of the areas of squares whose sides are the legs of the right triangle (Fig.2) since they are not bounded with segments. Such a problem is related to the rearrangement of the figure.

Fig.1

Fig.2

Therefore students could meet with difficulties from the perceptual side, as they might fail to spot the appropriate triangles or squares. In fact, as pointed out by Duval (1993) graphical sign can be either a help or a hindrance in understanding diagrams.

Analysis of task 2. In this case the reconstruction of the drawing itself is a difficulty. It requires the conceptualization that such a construction is made of infinitely many steps and that it proves that the series is convergent. All this requires a good conceptualization of the real numbers and their representation on the line. Moreover students could meet difficulties, not only with perceptual aspects, but above all with the lack of coordination of three different semiotic systems. One has to recognize that

$\sum_{i=0}^{+\infty} r^i = \frac{1}{1-r}$ is a proportion, then to translate it in the graphical system and finally to identify it in the given figure.

RESULTS

Task 1.

First of all in this task few students only provided an explicit description of the construction process of the figure. In this visual proof, the construction of the drawing is not related to the understanding of the proof since they succeed to achieve it even if with deductive arguments not based upon the whole picture but on some parts of it only. In particular, notice that some students do not feel the necessity to prove themselves that the tilted figure that looks like a square is indeed a square. In this case the perceptual facet is not controlled by the conceptual one. Second, all of them introduced letters a , b , c to indicate the measure of the sides of the triangle in order to find correspondence between the formula $a^2+b^2=c^2$ and the figure. Finally, students addressed the first task in three different but not necessarily separate ways:

1. *Modifying the formula in order to find correspondence with the figure*

Some students tried to connect the formula $a^2+b^2=c^2$ to the figure and to identify just c^2 in the picture to the right. They were not able to do the same for a^2 and b^2 . Then they wrote down $(a+b)^2-2ab=c^2$ most likely because they could find $(a+b)^2$ and $2ab$ in the picture too, as shown below:

This way the students recognized the remaining area a^2+b^2 in the figure on the right. This kind of proof is mostly based on visual arguments except for the initial modification of the formula.

2. Area computation

This strategy is the most common in problems of this kind. It consists in calculating the area of the external figure in two different ways and then comparing the results to obtain the required relationship.

In the first problem they calculated the area of the square of side $a+b$ i.e. $(a+b)^2$ and then the same area as the sums of the five subfigures (four triangles and a square of side c) i.e. $4\frac{ab}{2}+c^2$. Comparing the two expressions they got the Pythagorean theorem through algebra. In this case they did not consider the dashed lines in the picture on the right.

3. Figures as plain tools

The figure is not seen as a process embodying the proof of a statement but just as a tool that can be used to occasionally pick some piece of information useful to get a proof.

For example in this problem four students considered just the tilted square of side c and its five subfigures (four right-angled triangles and the square of side $a-b$). Actually they did not consider the dashed lines in the figure on the right. Comparing the area of the square of side c calculated as c^2 with the same area but regarded as the sum of the areas of the five subfigures one obtains the result as in point 2 (*Area computation*).

Another student just considered the rectangle

defining a the short side and b the long one. Then she used a so called “circular argument” or “begging the premise” (cf. Weston, 2000), i.e. she used the Pythagoras’ theorem to get $c = \sqrt{a^2 + b^2}$ and hence squaring both sides she got the Pythagoras’ theorem $c^2 = a^2 + b^2$.

Notice that also the answers in point 2. (*Area computation*) denote that the figure is not seen as an autonomous process of proof.

Task 2.

The Problem 2 proved the most difficult one. Nobody succeeded in understanding this visual proof. So a hint was given to them while they were solving the task. It was told them that a fundamental tool for its comprehension was the similitude of triangles and in particular the proportionalities between corresponding sides of the triangles. After that some of them succeeded to recognize that $\triangle PST$ and $\triangle PQR$ are

similar and they found the correspondence between the formula and the sides of triangles.

As a first result we have that students were able to match labels with the formula, and to understand the meaning of the dots ‘...’. As second finding we have that most students did not reconstruct the drawing. The reasons are three:

1. Students understood the need to reconstruct the drawing. Such construction is a necessary step in order to consider the visual proof as a process. Unfortunately they are not able to do such a reconstruction. One can see this outcome from the following excerpts:

A: Consider a square of side of length 1 ($l = r^0$) PQMS and construct a right-angled triangle PST such that the shorter leg is $\overline{PS} = r^0$ and one finds that the longer leg \overline{ST} is the sum of infinite segments having measure respectively r^0, r^1, r^2, \dots

(Student A understood that the measure of \overline{ST} is not an assumption but a finding of the construction but he could not prove that result, as it became clear from the interview) or

B: I can not understand how in the figure r^2 comes out from r .

2. Students considered figures just as plain tools. This is evident in task 2:

C: ...from figure I can see that \overline{PS} measures 1, \overline{ST} measures $\sum_{i=0}^{+\infty} r^i, \dots$

Student C did not see that $\overline{PS} = 1$ is an assumption while $\overline{ST} = \sum_{i=0}^{+\infty} r^i$ is the result of a deductive steps and in particular it means that the series converges.

3. Students understood the need to reconstruct the drawing but they failed to do it since they considered it trivial.

Finally some students could conclude the proof using the help given to them, but we distinguish

- students who were able to prove that the triangles PST and PQR are similar because they recalled this notion;
- students who did not recalled this notion or never learnt it.

In this case the problem is that even if students had a good knowledge of similitude of triangles they failed to introduce such “new” tool which could not be directly extracted by a simple manipulation of the objects already appearing in the proof.

General discussion

One of the main findings of this work is that visual proofs are not seen as processes but the figures are just plain tools which help to find results. The investigation of the protocols highlights that the unsuccessful results of this kind of tasks are due not only

to the semiotic system of figures or to the conflict between the conceptual and figural nature of visual proofs but it comes out that the concept of mathematical proof is not understood enough. This conclusion comes out above all from the fact that students do not feel the need for reconstructing the drawing. Moreover, in the first problem students used just some parts of the figure and not the whole of it, that is some students did not attribute values at every graphical sign, as it is explained in the analysis of the first task. Also this behaviour, in some cases, is due to a misunderstanding of the nature of the process of visual proofs. In fact the role of graphical signs and more in general of the perceptual learning of a figure is very important both in a positive and in a negative sense (Duval 1993). Perception can be a useful tool only if it is controlled by conceptual processes as pointed out by Fischbein.

Second it comes out that one of the main obstacles is the lack of geometrical knowledge: notions like similitude and congruence of triangles, Thales' theorem, etc. are hardly known, which severely prevents any attempt to work with the figure. This situation is found in the problem about the geometrical series. For example one of the fundamental steps for understanding this visual proof is to notice that the triangles $\triangle PQR$ and $\triangle PST$ are similar. No one spotted this geometrical fact. There might be two reasons of it. First, students have never learnt this or they have forgotten it. Second, they could not easily call to mind this notion, actually they knew something on similitude of triangles but they were not used to work with it. This means that students are not aware that there are some theorems, techniques, tools, which they can exploit when facing triangles. The fact is that Italian students work very little or do not work at all on the visualization of geometrical figures (for further details see Mariotti, 1998). Moreover, the time given for solving the task is not sufficient to remember or to reconstruct this notion. However, the necessity to use tools and constructions which are not directly related to objects at hand is a common feature in mathematical proofs, which do not refer to visual proofs only. Students could not overcome the difficulty of introducing such new elements in the visual proof we proposed them. Moreover, students were not even able to exploit the symbolic expression in the statement, since it would have required to represent it as a proportion, that in Italy is given prevalently by $\left(\sum_{i=0}^{+\infty} r^i\right):1=1:(1-r)$, and then into the figural system. The difficulty about the introduction of new elements, however, is not peculiar to visual proofs only. Indeed the first task does not present this problem. In this case all students succeeded in grasping the result even if in an improper way, for example using the figure just as a tool to extract information. Here one has just to manipulate the formula of the Pythagorean Theorem or manipulate its figure; there is no need to introduce new constructions, techniques, assumptions, tools, etc.

Finally the analysis of protocols shows that students prefer to work with algebra instead of using visual arguments coming from manipulation of figures. The visual

proof in task one is only of visual nature but no one addressed it with just visual arguments. Just one student used prevalently visual arguments (see strategy 1), but even in this case there was a preliminary modification of the formula.

CONCLUSION

This explorative research outlines the lack of skills in visual reasoning by a group of Italian mathematics college students. This lack is due to different reasons: poor knowledge of certain basic mathematical tools, poor acquaintance with the use of figural representations, conflict between the conceptual and perceptual nature of diagrammatic proofs and sometimes poor understanding of the concept of mathematical proof itself. Besides, the research points out that it is very difficult to learn proofs without being able to pick and use some basic pieces of mathematical knowledge. In this context tasks like those presented in this work might help students to develop a correct use of deductive method when working with figural representation and not only in the field of geometry but also in other context as in the second task presented. Obviously graphical representations in different mathematical settings can present different features related to different concepts. For example, in the case of the geometrical series one has to take into account the graphical representation of real numbers and of their properties. According to Duval, the coordination of at least two different semiotic systems of representation of a concept can improve its understanding. In particular I think that the passage from verbal and symbolic representations into the figural one and vice versa could be very fruitful. Moreover I think also that problems like the second one can help to overcome the trend to deal with mathematical subjects in isolation. Since, as our result confirms, the use of graphical representation presents a lot of difficulties, its use requires a particular training in order to exploit its potential. In this perspective tasks like those presented in this work could help students to develop some important tools to approach also other mathematical problems such as standard proofs.

TEACHERS' VIEWS ON THE ROLE OF VISUALISATION AND DIDACTICAL INTENTIONS REGARDING PROOF

Irene Biza*, Elena Nardi* and Theodossios Zachariades**

*University of East Anglia (Norwich, UK), **University of Athens (Greece)

In this paper we explore secondary teachers' views on the role of visualisation in the justification of a claim in the mathematics classroom and how these views could influence instruction. We engaged 91 teachers with tasks that invited them to: reflect on/solve a mathematical problem; examine flawed (fictional) student solutions; and, describe, in writing, feedback to students. Eleven teachers were also interviewed. Here we draw on the interviews and the responses to one Task (which involved recognising a line as a tangent to a curve at an inflection point) of two teachers. We do so in order to explore potential influences on the didactical contract regarding proof that these teachers are likely to offer their students. One such influence is the clarity and stability of their beliefs about the role of visualisation.

Key Words: teacher beliefs, proof, visualisation, tangents, didactical contract

INTRODUCTION

'The emphasis that teachers place on justification and proof no doubt plays an important role in shaping students' 'proof schemes'¹ (Harel & Sowder, 2007, p827). The not very extensive research in this area (p824) shows that this emphasis is insufficient both in terms of extent and in terms of quality. Internationally in most educational settings – even those with an official curricular emphasis on proof – little instructional time is dedicated to proof construction and appreciation (p828). Furthermore teachers' own proof schemes are often predominantly empirical and teachers do not always seem to understand important roles of proof other than verification (p836). For example, in Knuth's (e.g. 2002) study of practising secondary mathematics teachers, while all teachers acknowledged the verification role of proof, they rarely talked about its explanatory role. With regard to their proof schemes many of the interviewed teachers: felt compelled to check a statement on several examples even though they had just completed a formal proof; considered several of given non-proofs as proofs; and, accepted the proof of the converse of a statement as proof of the statement; and, found arguments based on examples or visual representations to be most convincing.

One of the aims of the study we report in this paper is to explore the relationship between teachers' pedagogical and epistemological beliefs about proof and their intended pedagogical practice (e.g. Cooney et al, 1998; Leder et al, 2002). Here we report some findings that relate to their beliefs about the role of visualisation.

¹ Harel & Sowder's (1998) term which describes an individual's and a community's perception of proof. They distinguish between external conviction (authoritarian, ritual, non-referential symbolic), empirical (inductive, perceptual) and deductive (transformational, axiomatic) proof schemes.

In the last twenty years or so the debate about the potential contribution of visual representations to mathematical proof has intensified (e.g. Mancosu et al, 2005), not least because developments in IT have expanded this potential so greatly. Central to this debate is whether, how and to what extent, visual representation can be used not only as evidence and means of insight for a mathematical statement but also as part of its justification (Hanna & Sidoli, 2007). For example, Giaquinto (2007) argues that visual means are much more than a mere aid to understanding and can be resources for discovery and justification, even proof. Whether visual representations need to be treated as adjuncts to proofs, as an integral part of proof or as proofs themselves remains a point of contention.

Visualisation has gained analogous visibility within mathematics education. Its richness, the many different roles it can play in the learning and teaching of mathematics – as well as its limitations – are increasingly being written about (e.g. Arcavi, 2003). These works address a diversity of issues, including: mathematicians' perceptions and use of visualisation; students' seeming reluctance to engage (and difficulty) with visualisation; etc. (Presmeg, 2006). Overall we still seem to be rather far from a consensus on the many roles visualisation can play in mathematical learning and teaching. So, while many works clearly recognise these roles, several (e.g. Arcavi, *ibid.*) also recommend caution with regard to 'the 'panacea' view that mental imagery only benefits the learning process' (Aspinwall et al, 1997, p315).

One of the aims of the study we report in this paper is to contribute to the above debate as outlined in the work of Presmeg, Arcavi and others through exploring secondary mathematics teachers' beliefs about the role of visualisation as evident in the reasoning and feedback they present to students. The specific part of the debate our study aims to contribute to concerns the relationship between these beliefs and teachers' intended pedagogical practice. Our particular interest is in the potential influences on the didactical contract (Brousseau, 1997) that teachers offer their students with regard to the role of visualisation. One such potential influence is the clarity and stability of teachers' belief systems (Leatham, 2006). Below we briefly introduce the study.

THE STUDY AND THE TANGENT TASK

The data we draw on in this paper originate in a study, currently in progress in Greece and in the UK, in which we invite teachers to engage with mathematically/pedagogically specific situations which have the following characteristics: they are hypothetical but likely to occur in practice and grounded on learning and teaching issues that previous research and experience have highlighted as seminal. The structure of the tasks we ask teachers to engage with is as follows – see a more elaborate description of the theoretical origins of this type of task in (Biza et al, 2007): reflecting upon the learning objectives within a mathematical problem (and solving it); interpreting flawed (fictional) student solution(s); and, describing, in writing, feedback to the student(s).

In what follows we focus on one of the tasks (Fig. 1) we have used in the course of the study. The Task was one of the questions in a written examination taken by candidates for a Masters in Mathematics Education programme. Ninety-one candidates (of a total 105) were mathematics graduates with teaching experience ranging from a few to many years. Most had attended in-service training of about 80 hours.

Year 12 students, specialising in mathematics, were given the following exercise:

‘Examine whether the line with equation $y = 2$ is tangent to the graph of function f , where $f(x) = 3x^3 + 2$.’

Two students responded as follows:

Student A

‘I will find the common points between the line and the graph solving the system:

$$\begin{cases} y = 3x^3 + 2 \\ y = 2 \end{cases} \Leftrightarrow \begin{cases} 3x^3 + 2 = 2 \\ y = 2 \end{cases} \Leftrightarrow \begin{cases} 3x^3 = 0 \\ y = 2 \end{cases} \Leftrightarrow \begin{cases} x = 0 \\ y = 2 \end{cases}$$

The common point is $A(0, 2)$.

The line is tangent of the graph at point A because they have only one common point (which is A).’

Student B

‘The line is not tangent to the graph because, even though they have one common point, the line cuts across the graph, as we can see in the figure.’

- In your view what is the aim of the above exercise?
- How do you interpret the choices made by each of the students in their responses above?
- What feedback would you give to each of the students above with regard to their response to the exercise?

Figure 1: The Task

The first level of analysis of the scripts consisted of entering in a spreadsheet summary descriptions of the teachers’ responses with regard to the following: perceptions of the *aims* of the mathematical exercise in the Task; mathematical *correctness*; *interpretation/evaluation* of the two student responses included in the Task; *feedback* to the two students. Adjacent to these columns there was a column for commenting on the approach the teacher used (verbal, algebraic, graphical) to convey their commentary and feedback to the students across the script. On the basis of this first-level analysis we selected 11 of the participating teachers for interview. Their individual interview schedules were tailored to the analysis of their written responses and, mostly, on questions we had noted in the last column of the spreadsheet. Interviews lasted approximately 45 minutes and were audio recorded.

The mathematical problem within the Task in Fig. 1 aims to investigate students' understanding of the tangent line at a point of a function graph and its relationship with the derivative of the function at this point, particularly with regard to two issues that previous research (e.g. Biza, Christou & Zachariades, 2008; Castela, 1995) has identified as critical:

- students often believe that having one common point is a necessary and sufficient condition for tangency; and,
- students often see a tangent as a line that keeps the entire curve in the same semi-plane.

The studies mentioned above attribute these beliefs partly to students' earlier experience with tangents in the context of the circle, and some conic sections. For example, the tangent at a point of a circle has only one common point with the circle and keeps the entire circle in the same semi-plane.

Since the line in the problem is a tangent of the curve at the inflection point A the problem provides an opportunity to investigate the two beliefs about tangency mentioned above – similarly to the way Tsamir et al (2006) explore teachers' images of derivative through asking them to evaluate the correctness of suggested solutions. Under the influence of the first belief Student A carries out the first step of a correct solution (finding the common point(s) between the line and the curve), accepts the line tangent to the curve and stops. The student thus misses the second, and crucial, step: calculating the derivative at the common point(s) and establishing whether the given line has slope equal to the value of the derivative at this/these point(s). Under the influence of both beliefs, and grounding their claim on the graphical representation of the situation, Student B rejects the line as tangent to the curve.

With regard to the Greek curricular context, in which the study is carried out, the Year 12 students (age 17/18) mentioned in the Task have encountered the tangent to the circle in Year 10 in Euclidean Geometry and the tangent lines of conics in Analytic Geometry in Year 11. In Year 12, they have been introduced to the tangent line to a function graph as a line with a slope equal to the derivative of the corresponding function at the point of tangency. Although in Years 11 and 12 the tangent is introduced as the limiting position of secant lines, this definition is rarely used in problems and applications. The students' mathematics 'specialisation' mentioned in the Task refers to the students' choice of mathematics as one of the curriculum subjects for more extensive study in Years 11 and 12.

The discussion we present in this paper is based on a theme that emerged from the first-level data analysis and was explored further in the interviews: the teachers' *beliefs about the role of visualisation in mathematics (epistemological) and in their students' learning (pedagogical)*. This theme emerged largely from our observation that, in their scripts, the majority of the teachers distinguished between (and often juxtaposed) Student A's *algebraic* approach and Student B's *graphical* approach. Most of these teachers included in their comments an evaluative statement regarding

the sufficiency/acceptability of one or both approaches. And often they referred explicitly to their beliefs about, for example, the **sufficiency/acceptability of the graphical approach**; or about the **role visual thinking may play in their students' learning**. The teachers' responses also appeared significantly influenced by the mathematical context of the problem within the Task; namely, by their **own perceptions of tangents** and their own views as to whether the line in the Task must be accepted as a tangent or not.

For example, with regard to the teachers' evaluation/interpretation of Student B's solution and feedback to Student B we scrutinised the scripts and designed the interviews with reference to questions such as: does the teacher turn the student away from the graphical approach (which may have led the student to an incorrect claim) and towards an algebraic solution in order to help the student change their mind about whether the line is a tangent or not? Does the teacher compare and contrast the algebraic solution to Student B's solution or do they proceed directly to the presentation of an algebraic solution? What types of examples/counterexamples, if any, do they employ in this process? What is the teacher's position towards Student B's grounding their claim on the graph and, generally, towards the validity of graphical argumentation as proof? Etc.. We presented a preliminary analysis of the above in (Biza, Nardi & Zachariades, 2008). This analysis suggested that there was substantial variation amongst the participating teachers in terms of the stability and clarity of their beliefs about the role of visualisation (epistemological and pedagogical). In what follows we present evidence from the scripts and interviews of two teachers, Spyros and Anna², whose cases exemplify this variation. Of particular interest in the accounts that follow is the interplay between the teachers' beliefs and their (stated) pedagogical practice. The data is translated from Greek.

SPYROS

Spyros has about fifteen years of teaching experience in secondary education. In his written response to the Task he described what led Student A and Student B to their respective answers. His feedback to the students was brief and stated rather generally. He emphasised the significance of mathematical definitions (in this case; the definition of tangent) and juxtaposed students' understanding and use of the definition with what he called 'intuitive' perception of the concept. He did not refer to any specific procedure through which the students could have determined whether the line is a tangent or not. At the same time he focused almost entirely, but rather generally, on the conceptual understanding of the definition and its 'history' in mathematics. We invited him to the interview in order to explore further his references to the 'history' of the concept and elaborate his feedback to the students.

² We note that Spyros is one of the 38 (out of 91) teachers who rejected Student B's claim that the line is not a tangent. Anna is one of the 25 teachers who agreed with Student B's claim. There was some evidence of support for Student B's claim in the scripts of another 18 teachers and there were also 9 blank or half-completed scripts.

During the interview he stated that he had not thought about the relationship between the circle tangent and the tangent to a curve. He recognised that Student A had regarded having a unique common point as a sufficient condition for tangency and stressed that this condition is neither sufficient nor necessary. He also described counter-examples that could help Student A reconstruct their image of a tangent line.

While discussing Student B's response we asked him to elaborate on whether he would accept an argument based on a graph. His answer was firm: 'No, first of all it is not an adequate answer in exams'. (We note that in the Year 12 examination, which is also a university admission exam, there is a requirement for formal proof). We asked him to let aside the examination requirements for a moment and consider whether an argument based on a graph would be adequate mathematically. He replied: 'Mathematically, in the classroom, I would welcome it at lesson-level and I would analyse it and praise it, but not in a test'. Asked to elaborate he says: 'Through [the graph-based argument] I would try to lead the discussion towards a normal proof...with the definition, the slope, the derivative etc.'. Asked to justify he says:

This is what we, mathematicians, have learnt so far. To ask for precision. For axiomatic... we have this axiomatic principle in our minds. Whatever I say I prove on the basis of axioms, on the basis of theorems, on the basis.... And this is what is required in the exams. And we are supposed to prepare the students for the exams.

In the above, Spyros's statement is clear: while he cannot accept a graph-based argument as proof, he recognises graph-based argumentation as part of the learning trajectory towards the construction of proof. He seems to approach visual argumentation from three different and interconnected perspectives: the *restrictions of the current educational setting*, in this case the Year 12 examination; the *epistemological constraints* with regard to what makes an argument a proof within the mathematical community; and, finally, the *pedagogical role* of visual argumentation as a means towards the construction of formal mathematical knowledge.

These three perspectives reflect three roles that a mathematics teacher needs to balance: educator (responsible for facilitating students' mathematical learning), mathematician (accountable for introducing the normal practices of the mathematical community) and professional (responsible for preparing candidates for one of the most important examinations of their student career). Spyros' awareness of these roles, and their delicate interplay, is evidence of the clear and stable didactical contract he appears to be able to offer to his students. Below we discuss a rather different case.

ANNA

Anna is a recent graduate with about four years of teaching experience in private tuition. In her written response to the Task she agreed with Student B's claim that the line is not a tangent. She interpreted Student A's answer as an implication of

accepting the uniqueness of the common point between the line and the curve without examining the ‘nature’ of this point (she pointed out that an infinite number of lines pass through one point). She attempted to reconstruct Student A’s views through reference to graphs and then to the definition. She did not elaborate on the use of the definition; she simply cited the related formula but did not apply it in the case of the function in the Task. She accepted Student B’s graphical approach. She stressed that students are rarely at ease with the graphical approach and are often reluctant to use it. She however wrote that she would draw Student B’s attention to the fact that a graphical approach is not always feasible. Therefore, she wrote, she would demonstrate the ‘analytical’ way through an appropriate worksheet in which she would use a function with a hard-to-construct graph. For a ‘more complete repertory’ she would encourage Student A to use graphs and Student B to use the analytical approach. We invited Anna to the interview because of her emphasis on the necessity of the algebraic approach in cases where the graphical approach is not possible – not because of her concern for its validity. Also because we wanted to explore further how this sat alongside her overt appreciation of Student B’s solution.

Anna, between writing the response and being interviewed, had realised that she should accept the line as a tangent. In the interviews, she attributed her, and the students’, ‘misunderstanding of tangents’ to earlier experience with circle tangents.

I thought that the tangent should be always like the circle tangent, but this is wrong. Because the student in question made the graph and saw it was horizontal and cuts the graph in half, he considered that this is not right, that’s why... he expected to see something like [*she gestures a line touching the graph without splitting it*].

When we asked her to describe the algebraic solution she managed only with extensive help on our part.

While discussing Student B’s response we asked Anna if she would accept Student B’s graphical solution as correct if the student had concluded with the acceptance of the line as a tangent. She said: ‘I think that we have to do all the procedure’ because ‘the line could be here, [*showing on the graph*] higher or lower, where it isn’t a tangent’ and ‘I cannot decline that it isn’t tangent but also I cannot say that it is. Don’t I have to do some...’. When we asked her why, in the light of these reservations, she accepted the graphical explanation in her *written* response, she replied: ‘I accepted it because he said that it wasn’t and I had in my mind that when I see the line splitting [*the graph*] there is no other choice, whatever it was’. So, would she accept a graphical solution, in general? ‘If it is correct, I would accept it’, she replied. Would she accept student B’s solution as correct if the student indicated on the graph that, although the line intersects the curve, the intersection point is an inflection point, as, for example, in the case of $f(x)=x^3$? She replied: ‘I would accept it [...] it is not necessary to use the algebraic method with formulas and all that, that’s what I believe. [*hesitating*] I am not sure this is correct [*awkward laugh*]’.

She then added:

Simply, I believe that students are not so familiar with graphical representations... and, for them, it is easier to use formulas...they see this as a methodology, as... I do not believe that they have gone into depth so that they know how to construct graphs perfectly and know how to interpret them well and this is why most of them usually use algebraic formulas. [...] Because to make a graph and analyse it you have to have understood something very, very well... to own it, completely, while for this [the algebraic formula] you learn how, somewhat blindly, and you solve it, that's what I believe. In any case if [the claim] was correct I would accept it because I would see that the student understood it better than someone who can follow the algebraic formulas... now I don't know, am I right? What do you think?! [to the interviewer]

Later on in the interview, we asked her what would happen if the inflection point wasn't at 2.00 but very close to it (e.g. at 2.02). That made her uncertain about the accuracy of the graph. She then reconsidered her previous statement and said: 'So I believe that the best is that the students do the algebra and then make the graph [awkward laugh]'. She elaborated her change of mind as follows:

I simply believe that after we solve through the algebraic formulas and find the result, then it is good to tell the students to make the graph because sometimes they reach the end and say 'ok, I found it' without having realised in their mind how it would look roughly and as soon as they see a graph they cannot answer immediately and I believe this is what happened to me... that is I was used to see circle tangents and it had crossed my mind... subconsciously that all of them must be like that ... all tangents have to be like that because I was not familiar with graphs.

In the above Anna's beliefs about the acceptability or not of a visual argument appear unstable. She appears ready to accept a visual argument without any algebraic justification if the information in the image constitutes, for her, clear and convincing support for a claim. She regarded the image in the Task as sufficient evidence for determining that the line is not a tangent – also drawing on her belief that a tangent cannot intersect the graph. However she stated clearly that to prove that the line *is* a tangent an algebraic argument was necessary. Later, she stated that she could accept a *correct* statement based on the graph. When we shook her faith in the graph she declared the algebraic solution necessary. While initially she did not speak of validation of the visual statement through reference to mathematical theory, she asked for such validation when she realised that the image could be misleading.

Many times in her interview she returned to her appreciation of visual representation and argumentation as evidence of a student's in-depth understanding and as an important means towards students' construction of mathematical knowledge. She did not specify whether she meant *formal* mathematical knowledge (for example, proof). Furthermore her views with regard to the sufficiency and acceptability of a visual argument appeared rather ambivalent and heavily dependent on the specific images involved in the discussion. In this sense the didactical contract she appears to be able to offer to her students seems less clear and stable than that of Spyros.

CONCLUDING REMARKS

Spyros' clear insistence on the class' collective arrival at a formal proof as closure to the lesson is distinctly different from Anna's fluctuation between cases where she would and would not accept a visual argument. Her willingness to rely, occasionally, on imagery in order to support a claim is 'a practice that may mislead students into thinking that such are acceptable mathematical 'proofs' and reinforcing the acceptability of their empirical proof schemes.' (Harel & Sowder, 2007, p829). Furthermore, her own criteria about what makes a visual argument acceptable appeared very personal and rather fluid. Within the unstable didactical contract that this vagueness might imply, how would her students distinguish between when a visual argument is acceptable and when not? In the already compounded didactical contract of school mathematics such vagueness can be detrimental.

A clearer contract could be as follows: in a classroom discussion where a visually-based (incorrect) claim is proposed, the class employs the algebraic, formal approach to convince the proposer about the incorrectness of their claim. Even when a visually-based (correct) claim is unequivocally accepted by the whole class, the class still employs the algebraic approach to establish the validity of the claim formally. In both cases visualisation emerges as a path to insight and proof as the way to collectively establish the validity of insight. In both cases there is a pedagogical opportunity for linking imagery with algebra and for embedding the algebra in the immediately graspable meaning in the image.

The above suggest a role for proof in the mathematics classroom that is not disjoint from the creative parts of visually-based classroom activity and that reflects an essential intellectual need. We conclude with quoting Harel & Sowder's (2007, p836) statement regarding this intellectual need:

The subjective notion of proof schemes is not in conflict with our insistence on unambiguous goals in the teaching of proof – namely, to gradually help students develop an understanding of proof that is consistent with that shared and practised by the mathematicians of today. The question of critical importance is: What instructional interventions can bring students to see an intellectual need to refine and alter their current proof schemes into deductive proof schemes.

MODES OF ARGUMENT REPRESENTATION FOR PROVING – THE CASE OF GENERAL PROOF

Ruthi Barkai, Michal Tabach, Dina Tirosh, Pessia Tsamir, Tommy Dreyfus

Tel Aviv University¹

In light of recent reform recommendations, teachers are expected to turn proofs and proving into an ongoing component of their classroom practice. At least two questions emerge from this requirement. Is the mathematical knowledge of high school teachers sufficient to prove various kinds of statements? And does their knowledge allow the teachers to determine the validity of an argument made by their students? The results of the present study point to a positive answer to the first question in the framework of elementary number theory (ENT). However, the picture is much less positive with respect to the second one.

THEORETICAL BACKGROUND

The calls for enhancing students' abilities to prove and to refute mathematical statements appear prominently in various reform documents of different countries (e.g., Israeli Ministry of Education, 1994; National Council of Teachers of Mathematics [NCTM], 2000). In the NCTM document, reasoning and proof is one of five process standards for all grade levels. Still, there is a need to clarify what proof is in the classroom context. Stylianides (2007) made an attempt in this direction:

Proof is a mathematical argument, a connected sequence of assertions for or against a mathematical claim, with the following characteristics:

- It uses statements accepted by the classroom community (set of accepted statements) that are true and available without further justifications;
- It employs forms of reasoning (modes of argumentation) that are valid and known to, or within the conceptual reach of, the classroom community; and
- It is communicated with forms of expression (modes of argument representation) that are appropriate and known to, or within the conceptual reach of, the classroom community. (p. 107).

Stylianides' (2007) definition talks about the classroom community as the authority to determine the correctness of a proof. However, the teacher, as the representative of the mathematics community, has a special role in the endeavor. He needs to be attentive to both – the mode of argument for a

¹ The research was supported by THE ISRAEL SCIENCE FOUNDATION (grant No. 900/06)

given statement (such as general proof, counter example, supportive example), as well as the mode of argument representation (such as numerical, verbal or symbolic), to be able to determine the correctness of a justification.

To what extent are teachers prepared to implement proofs and proving as part of their classroom practice? Relatively little is known on teachers' subject matter knowledge in this area. Dreyfus (2000), following Healy and Hoyles' (1998) work with high school students, presented 44 secondary school teachers with nine justifications to the universal claim "The sum of any two even numbers is even". He found that most secondary school teachers easily recognized formal proofs, but had little or no appreciation for other types of justifications such as verbal, visual or generic ones. Knuth's (2002b) findings suggest that secondary school teachers recognized the variety of roles that proofs play in mathematics. Noticeably absent, however, was a view of proofs as tools for learning mathematics. Many of the teachers held limited views of the nature of proof in mathematics and demonstrated inadequate understandings of what constitutes proofs.

In a different study on in-service high school teachers' knowledge of elementary number theory (ENT), only a third of the 36 teachers provided counter examples to the (false) universal statement "All commutative actions are also associative" (Zaslavsky & Peled, 1996).

These studies focused solely either on universal or on existential statements. Tirosh (2002) presented the same group of elementary and middle school teachers with both universal and existential ENT statements. Tirosh and Vinner (2004) analyzed 38 prospective middle-school teachers' written answers to questionnaires on the issues of constructing and evaluating proofs and refutations in ENT. They found that about 20% of the prospective teachers incorrectly argued that some of the existence theorems in the questionnaires are false (e.g., "There exists a real number b so that $a + b < a$ "). Furthermore, about half of the prospective middle school teachers incorrectly argued that numerical examples that satisfy existential statements are just examples and could not be regarded as mathematical proofs. These responses suggest that some prospective teachers develop a general view that a mathematical statement is true only if it holds for "all cases", a view which is adequate for universal statements but not for existential ones.

The present study addresses a high school teacher's knowledge with respect to universal and existential statements in the area of ENT. It aims to give a preliminary answer to the following two questions. Is the mathematical

knowledge of high school teachers sufficient to prove ENT statements? And does their knowledge allow the teachers to determine the validity of an argument made by their students?

Note: the work of Tirosh (and Vinner) and Dreyfus differ from the work presented here in the population and the mathematical statements.

METHOD

Participants

A group of 50 high school teachers participated in the research. All teachers had some experience teaching in high school. Ms R was one of the teachers. Ms R was chosen as focus teacher for this study on the basis of her answers to the set of questionnaires below.

When participating in our project, Ms R had been teaching for five years in a high school, working with high-achieving students from a high socio-economic background. In parallel, she was studying for her Master's degree in mathematics education. The program included a number of mathematics courses and a number of psycho-didactical courses.

Tools

In one of these courses, the participants' mathematical knowledge was analyzed through their written reactions to two questionnaires that dealt with six ENT statements. No time-limit was imposed for the work on the questionnaires. In this section we briefly describe each of the questionnaires.

Predicate	Always true	Sometimes true	Never true
Quantifier			
Universal	S1. The sum of any five consecutive natural numbers is divisible by 5.	S2. The sum of any three consecutive natural numbers is divisible by 6.	S3. The sum of any four consecutive natural numbers is divisible by 4.
	<i>True/General proof</i>	<i>False/Counter example</i>	<i>False/Counter example</i>
Existential	S4. There exists a sum of five consecutive natural numbers that is divisible by 5.	S5. There exists a sum of three consecutive natural numbers that is divisible by 6.	S6. There exists a sum of four consecutive natural numbers that is divisible by 4.
	<i>True/Supportive example</i>	<i>True/Supportive example</i>	<i>False/General proof</i>

Table 1. Classification of the six statements

The Prove-Questionnaire was intended to identify the participants' production of proofs (validations and refutations) to various (true or false) statements. The questionnaire included six ENT statements (statements S1-S6 in Table 1). The statements were chosen to include one of three predicates (always true, sometimes true or never true), and one of two quantifiers (universal or existential). Clearly, the validity of a statement is determined by the combination of its predicate and its quantifier. Three of the statements are true (S1, S4, S5), and the other three are false (S2, S3, S6). Table 1 displays the six statements according to their quantifier and predicate; their truth value as well as a suitable proof method are also indicated. The participants were asked to examine each of the statements, to determine whether it is true or false, and to prove their claim.

The True or False-Questionnaire was intended to check the participants' identification of the correctness of 43 justifications for the six statements they had proven before, between six and nine justifications for each statement, using numerical, verbal or symbolic modes of arguments representations. For each justification, the participants were asked to determine whether it verifies (refutes) the statement, and to explain their evaluation. The justifications were presented as if they were written by students in various modes of argument representations.

In analyzing teachers' answers to the first and second questionnaire we related to the modes of argumentations as well as to the mode of argument representations.

RESULTS AND DISCUSSION

In this section we first present the participants' answers to the *Prove-Questionnaire*, with examples of Ms R's proofs. Then we discuss the participants' answers to the *True or False-Questionnaire*. Here we narrow the discussion to five justifications which relate to two statements – S1 and S6. We chose these two statements because they require general proofs. We present in detail the answers of Ms R to each justification, followed by a brief description of the results for all participants with regard to the same justifications.

Prove-Questionnaire

All the teachers produced correct proofs to each of the six statements. That is, the modes of argumentation the teachers chose for each statement were appropriate. Their proofs were presented in one of two modes of argument representation – symbolic or numeric (see Table 2).

All participants used the symbolic mode of argument representation for statements S1 and S6, which required a general mode of argumentation. About half of the participants produced numerical examples to refute the universal statements S2 and S3, and the majority of the participant provided a single numerical example to validate the existential statements S4 and S5. None of the participants provided several examples to prove or refute a statement. These findings indicate that the participants who used numerical examples knew when an example is sufficient for proving a statement.

	S1	S2	S3	S4	S5	S6
Numeric	---	50	44	72	80	---
Symbolic	100	50	56	28	20	100

Table 2: Percentages of modes of argument representation produced by the participants (N=50)

We present Ms R's proof for statement S1 which is a universal, always true:

Let's denote five consecutive numbers by $a, a+1, a+2, a+3, a+4$. Their sum is:
 $a+a+1+a+2+a+3+a+4 = 5a+10$.

$(5a+10):5 = a+2$. $a+2$ is a natural number for any a that is a natural number.
 Therefore the statement is true.

As we can see, the proof that Ms R provided related to all the cases in the domain, used correct inference rules, is concise, and thus exemplifies a sound proof.

Ms R's proof for statement S6, an existential, never true statement shows similar characteristics:

Let's check: a is a natural number. $(a+a+1+a+2+a+3):4=(4a+6):4$

We divide the last expression by 2, obtaining $(2a+3):2$. But, $2a+3$ is an odd number (the sum of even, $2a$ and odd, 3), and therefore is not divisible by 2.
 The statement is not true.

Again Ms R correctly identified the need for a general mode of argumentation, and used a symbolic mode of argument representation.

True or False-Questionnaire – Ms R's explanations.

We now focus on the two statements that required general proofs, meaning that the general mode of argumentation should be used. Yet, such an argument can be displayed in at least two modes of argument representation – verbal and symbolic. Five sets of justifications, Ms R's judgments, and her explanations are presented. A short discussion follows each set.

Example 1: Verbal justification to statement S1 and Ms R's explanation

The given correct justification:

Moshe claimed: I checked the sum of the first five consecutive numbers: $1+2+3+4+5=15$ is divisible by 5. The sum of the next five consecutive numbers is larger by 5 than this sum (each number is bigger by 1 and therefore the sum is bigger by 5), and therefore this sum is also divisible by 5. And so on, each time we add 5 to a sum that is divisible by 5, and therefore we always obtain sums that are divisible by 5. Therefore the statement is true.

Ms R's judgment: Moshe's argument is not correct.

Ms R's explanation

Moshe checked the case $1+2+3+4+5=15$, which can be accidentally true. In proving one needs to generalize, and therefore Moshe's justification is not correct.

From Ms R's explanation we can learn that she correctly identified the mode of argumentation needed for proving S1. Yet, she failed to notice the coverage aspect in Moshe's justification.

Example 2: Verbal justification to statement S1 and Ms R's explanation

The given correct justification

Mali claimed: I first tried the first ten examples of 5 consecutive numbers:

$$\begin{array}{lll} 1+2+3+4+5=15 & 2+3+4+5+6=20 & 3+4+5+6+7=25 \\ 4+5+6+7+8=30 & 5+6+7+8+9=35 & 6+7+8+9+10=40 \\ 7+8+9+10+11=45 & & 8+9+10+11+12=50 \\ 9+10+11+12+13=55 & & 10+11+12+13+14=60. \end{array}$$

I saw that the statement is true for the first ten. All other sums of five consecutive numbers are obtained by adding multiples of 10 to one of the listed sums (for instance, the sum $44+45+46+47+48$ is obtained by adding multiples of 10, 5 times 40, to the sequence: $4+5+6+7+8$ that I checked before). Since multiples of 10 are also divisible by 5, the statement is true.

Ms R's judgment: Mali's argument is not correct.

Ms R's explanation

Here also there is no generalization to all the natural numbers, and therefore this is incorrect. It is not a proof.

From Ms R's explanation in this case we can learn that Ms R is concerned with the mode of argumentation. She did not identify the cover aspect in Mali's correct verbal justification.

Example 3: Symbolic justification to statement S1 and Ms R's explanation

The given incorrect justification

Ayala claimed: Among any five consecutive numbers, there is one that is divisible by 5. Let's look at a sequence of five consecutive numbers : $5x$, $5x+1$, $5x+2$, $5x+3$, $5x+4$ ($5x$ is divisible by 5). The sum of this sequence is: $5x+(5x+1)+(5x+2)+(5x+3)+(5x+4)= 25x+10$, and $25x+10$ is divisible by 5 for any x . Therefore the statement is true.

Ms R's judgment: Ayala's argument is correct.

Ms R's explanation

x represents any number, and therefore the proof is general.

Ms R's explanation in this case relates to two important observations. x represents any number, and in this sense the justification is general. However, $5x$ represents a multiple of five, and thus the sequence 1, 2, 3, 4, 5, for instance, is not included. Hence, Ayala's justification is correct for only a subset of the cases that one needs to relate to in order to prove S1. Ms R failed to notice this flaw in Ayala's justification.

Example 4: Verbal justification to statement S6 and Ms R's explanation

The given correct justification

Moshe claimed: I checked the sum of the first four consecutive numbers: $1+2+3+4=10$, ten is not divisible by 4. The sum of the next four consecutive numbers is obtained by adding 4 to this sum (each of the four numbers in the sum grows by 1, so the sum grows by 4). It is known that adding 4 to a sum that is not divisible by 4 will yield a sum that is not divisible by 4 either. And so on, each time we add 4 to a sum that is not divisible by 4, and therefore we always obtain sums that are not divisible by 4. Therefore the statement is not true.

Ms R's judgment: Moshe's argument is not correct.

Ms R's explanation

Moshe chose an example, and on the basis of this example he concluded that there are no such four numbers. But maybe if he would have picked up four other numbers it could have been correct.

Once more, Ms R's reaction exemplifies her view that Moshe's verbal explanation is an example. Again she correctly determined that for this statement an example is not an appropriate mode of argumentation.

Example 5: symbolic justification to statement S6 and Ms R's explanation

The given incorrect justification

Ayala claimed: Among any four consecutive numbers, there is one that is divisible by 4. Let's look at a sequence of four consecutive numbers : $4x$, $4x+1$, $4x+2$, $4x+3$ ($4x$ is divisible by 4). The sum of this sequence is: $4x+(4x+1)+(4x+2)+(4x+3) = 16x+6$. $16x$ is divisible by 4 for any x , while 6 is not divisible by 4. So, the sum $16x+6$ is not divisible by 4. Therefore the statement is not true.

Ms R's judgment: Ayala's argument is correct.

Ms R's explanation

Ayala proved the claim for all four numbers, and hence it is not possible to show that there are four numbers, hence the justification is correct.

The same phenomenon as in example 3 is evident again in Ms R's reaction. On the one hand, it shows that she fully understands the mode of argumentation needed, but on the other hand she fails to recognize whether the given justification carries the general aspect needed.

It seems that for Ms R, the symbolic mode of argument representation, assures that the cover aspect of the proof is taken care of. Also, for Ms R, a verbal mode of argument representation is judged to be merely a numerical example.

One may wonder whether Ms R is unique in her judgments. Let's return to the entire population of 50 participants and check how many teachers made similar choices as Ms R.

For the first statement (S1), 34 percent of the participants rejected the correct verbal justifications (Examples 1 and 2), on the ground that they are not general, and at the same time accepted the incorrect symbolic justification (Example 3), on the ground that it is general. As Ms R, these teachers correctly identified the mode of argumentation needed for each statement.

For the last statement (S6), 26 percent of the participants rejected the correct verbal justification (Example 4), on the ground that it is not general, and at the same time accepted the incorrect symbolic justification (Example 5), on the ground that it is general. Also in this case, the teachers correctly identified the mode of argumentation needed for each statement.

Twenty percent of the participants were consistent in their answers, that is made the same choices as Ms R in the cases of the five justifications presented above.

SUMMING UP AND LOOKING AHEAD

The present study addressed the following two questions. Is the mathematical knowledge of high school teachers sufficient to prove mathematical statements from the field of elementary number theory? And does their knowledge allow the teachers to determine the validity of an argument made by their students?

Our findings indicate that the participants were able to produce correct proofs and refutations to the statements presented. While the teachers chose correct modes of argumentation for each statement, it was evident that they were concerned with this aspect in the second questionnaire.

The picture emerging from the *True or False-questionnaire* seems more complex. About a third of the teachers failed to identify as universal the general-cover aspects of the given arguments in verbal modes of representation. These findings substantiate similar findings reported by Dreyfus (2000), that teachers tend to perceive verbal proofs as deficient because they lack symbolic notations. However, Dreyfus (2000) found that teacher tended to reject verbal justifications. Our findings indicate that teachers had difficulties in understanding verbal justifications, but they did not reject them as such. Teachers' difficulties with verbal justifications are particularly worrying in light of the results reported by Healy & Hoyles (2000), namely that high school students not only preferred verbal proofs due to their explanatory power but also that their verbal arguments were more often deductively correct than their arguments in other modes of representation, yet at the same time they expected to get low grades for such proofs.

A quarter of the participants failed to identify when symbolic justifications did not cover all cases in the domain. These findings substantiate findings reported by Knuth (2002b): "In determining the argument's validity, these teachers seemed to focus solely on the correctness of the algebraic manipulations rather than on the mathematical validity of the argument" (p. 392). When being presented with an algebraic justification, the teachers' focus was on the examination of each step, ignoring the need to evaluate the validity of the argument as a whole.

The everyday practice of teachers involves a constant evaluation of students' justifications for statements. It is likely that verbal or symbolic justifications of the kinds presented in our study, will emerge during interactions with students. Therefore, it is important that teachers will be familiar with verbal justifications and able to judge their validity.

MATHEMATICS TEACHERS' REASONING FOR REFUTING STUDENTS' INVALID CLAIMS

Despina Potari*, Theodossios Zachariades* and Orit Zaslavsky**

*University of Athens, ** Technion - Israel Institute of Technology

This study investigates secondary school mathematics teachers' reasoning for refuting students' invalid claims in the context of hypothetical classroom scenarios. The data used in this paper comes from seventy six teachers' responses to a student's invalid claim about congruency of two given triangles and from interviews with a number of them. Some teachers responded to the claim by trying to refute it. Two main approaches to refuting the student's claim were identified: 1. by using known theorems; 2. by using counterexamples. Teachers' difficulties to generate correct counterexamples were traced. Moreover, a rather narrow meaning of the theorems and their use to refute invalid claims was manifested.

INTRODUCTION

Reasoning and proof are considered fundamental aspects of mathematical practice both in the practice of mathematicians and in the practice of students and teachers (Hanna, 2000). A large number of studies in mathematics education have explored students' justifications and proof strategies (e.g., Healy & Hoyles, 2000; Harel & Sowder, 1998). Refuting conjectures and justifying invalid claims requires reasoning that goes beyond the syntactic derivations of deductive proof which has been traditionally the focus of high school mathematics. It mainly involves the generation of counterexamples, the development of logical arguments that are grounded on exploration and experimentation, which are related to the construction of mathematical meaning and understanding. Balacheff (1991) discusses the diversity of ways of dealing with a refutation by referring to the epistemological work of Lakatos (1976) and to his own experimental study with high school students. Lin (2005) also demonstrates the complexity of the process by identifying the different types of arguments that secondary school pupils developed to refute false conjectures.

The process of evaluating and refuting students' claims is central to teacher practice. This often requires the teacher to give on the spot appropriate explanations that often involve the use of examples or counterexamples. Although the process of exemplification is highly demanding it has not been extensively investigated with regard to the teacher (Bills, Dreyfus, Mason, Tsamir, Watson & Zaslavsky, 2006). Desirable choice of examples depends on teacher's subject matter knowledge (Rowland, Thwaites & Huckstep, 2003) on her teaching experience (Peled & Zaslavsky, 1997) and on her awareness of students' prior experience (Tsamir & Dreyfus, 2002). The generation of examples and counterexamples in geometry gets a special meaning as the visual entailments of examples pose certain constraints (Zodik & Zaslavsky, 2008). In this paper, we investigate how teachers respond to students' invalid claims in the context of Euclidean geometry.

THEORETICAL BACKGROUND

We briefly present below the main theoretical constructs that framed our study. These include teacher knowledge, the process of refutation, and the nature and use of counterexamples.

The process of evaluating and refuting students' invalid claims strongly relates to mathematics teacher knowledge. Stylianidis and Ball (2008) studied the characteristics of teacher knowledge for reasoning and proof. Zodik and Zaslavsky (2008) also attempted to capture the dynamics of secondary mathematics teachers' choice and generation of examples in the course of their teaching. They offer an example-based teaching cycle with respect to teacher knowledge, the planning stage and the actual lesson.

The process of refutation has been mainly studied under the epistemological framework of Lakatos (1976) (e.g., Balacheff, 1991; Larsen & Zandieh, 2007). Lin (2005) developed a categorisation of students' refutation schemes. Accordingly, he distinguished between rhetorical arguments (reasons relative to the person spoken to), heuristic arguments (reasons taking into account the constraints of the situation), and mathematical proofs (the process of generating correct counterexamples).

Peled & Zaslavsky (1997) distinguished between three types of counterexamples suggested by mathematics teachers: specific, semi-general and general examples. Semi-general and general examples offer some explanation and ideas how to generate more counterexamples. Related to teachers' generation of counterexamples is the theory of personal *example spaces*, which encompasses examples that are accessible to an individual in response to a particular situation (Bill et al, 2006). Zazkis & Chernoff (2008) introduced the notions of *pivotal example* and *bridging example* and highlighted their role in creating and resolving cognitive conflict.

The study reported here is part of a larger study that investigates teachers' ways of responding to students' false claims. In this paper, we explore the different types of arguments that teachers use in dealing with an invalid claim in the context of geometry, an area where research is rather scarce.

METHODOLOGY

Seventy six teachers who were all candidates for a Masters in Mathematics Education programme participated in the study. Six of them were primary school teachers with an education degree, while the rest had a mathematics degree. Thirty of these were secondary school practicing mathematics teachers.

The teachers took a three hour exam as part of the selection process for the Masters programme. In this exam they had to respond in writing to five tasks in which they were asked to react to hypothetical teaching events. Four of these hypothetical events were related to the process of dealing with students' arguments and claims. Their written responses were analyzed from both mathematical and pedagogical perspectives. On the base of this analysis, 45 teachers were interviewed individually

in order to explore further their reactions and justifications. Each interview lasted about 15-30 minutes. One researcher interviewed the teachers while another one took notes of the conversation. Since these interviews were part of the selection process, we refrained from using any audio or video recordings, in order to avoid negative effects on the candidates.

In this paper we analyse the data based on the test and the first set of interviews concerning one of the tasks.

The task

The task was the following:

In a Geometry lesson, in grade 10, the teacher gave the following task:
 Two triangles $AB\Gamma$ and EZH have $B\Gamma=HZ=12$ and $AB=EH=7$ and the angles $A\Gamma B$ and EZH equal to 30 degrees. Examine if the two triangles are congruent.
 Two students discussed the above task and expressed the following opinions:
 Student A: The two triangles have two sides and an angle equal. Therefore they are congruent.
 Student B: We know from the theory that two triangles are congruent when they have two sides and a contained angle equal. Therefore, the given triangles are not congruent.
 If the above dialogue took place in your classroom, how would you react?

The task refers to a hypothetical classroom scenario which focuses on issues of learning and teaching mathematics. Further discussion about the importance of this type of tasks as a research tool for exploring teachers' thinking can be seen in Biza, Nardi & Zachariades (2007). This task was based on an example discussed and analysed by Zodik & Zaslavsky (2007). Its mathematical content, the properties of the triangles and their congruence, is part of the Euclidian Geometry course taught in grade 10 in Greek high schools. In the task, student A expresses his belief that if two triangles have two sides and one angle that are respectively equal then they are congruent. He seems to over-generalize the theorem "if two triangles have two sides and the contained angle that are respectively equal then they are congruent."

Figure 1: A geometric construction of a counterexample

There are at least three different approaches to refute the claim of this student. The first one is to provide a specific counterexample based on a geometric construction using a ruler and compass (Figure 1).

In this case we may continue and prove a general geometric theorem based on the geometrical construction, namely, that two sides (a and b , where $a > b$) and the angle (β) opposite the smaller side determine exactly two distinct triangles that are not congruent, except for a special case where $\sin(\beta) = b/a$. In the latter case the triangle is necessarily a right-triangle, therefore it is uniquely determined, that is, all triangles with these givens are congruent. The second approach is to prove this general theorem and apply it to the specific given case. The third approach is the use of the sine and cosine laws in trigonometry. By applying the cosine rule for the given angle, we determine the third side, and find that there are two possible values for its length. By applying the sine law we find that there are two possible angles opposite the larger side (a) – an acute one and its supplementary angle. An interpretation of this calculation and the verification of the existence of triangles with these sides or angles lead to the conclusion that there are two (and only two) distinct non-congruent triangles satisfying the givens.

RESULTS

Classifying teachers' justifications

In this section, we present a classification of teachers' justifications based on their written responses. Out of the seventy six mathematics teachers three did not reply while eight considered the given triangles congruent. The remaining sixty five teachers acknowledged that the given triangles were not necessarily congruent. Sixty-three of them gave an explicit justification to their assertion. These justifications were grouped in categories which are presented in the tree diagram in Figure 2. The numbers in brackets indicate the number of teachers' responses that fall in each category.

Out of 63 teachers, 18 justified their claim by drawing on mathematical theorems relevant to the problem and 45 asserted that a counterexample was needed to justify their claim.

Reasoning based on known theorems:

As mentioned above, this type of responses was manifested by 18 teachers. Only two gave a full valid proof. The rest gave invalid proofs that included proof-like arguments.

Valid proof. Interestingly, although the context is geometry, the two teachers who gave valid proofs based them on trigonometry. One of them (T64) used the sine rule, and the other (T32) used the cosine rule, as described earlier.

Figure 2: Mathematics teachers' justifications of the assertion that the two given triangles are not necessarily congruent

Invalid proof-like arguments. The remaining sixteen teachers provided invalid proof-like arguments to support their claim by maintaining that none of the known theorems about the congruence of two triangles applies in this case. The following example indicates the latter case: “Student A replied without considering the known criteria for congruence of triangles. I would encourage him to draw the two triangles so that to realise that these criteria cannot be applied” (T10). These teachers believed that this reasoning offers a valid proof for refuting student A’s claim.

Reasoning based on counterexamples:

This type of responses was manifested by 45 teachers. Only 11 gave a specific counterexample with correct justification.

General reference to a counterexample. Eight teachers only made reference to the need to give a counterexample by stating that they themselves or their students would give a counterexample. For example, T23 simply mentioned that “... to convince him (Student A) we could show him some triangles that have two sides and one angle equal but are not congruent” while T18 suggested asking the students: “... to experiment with the shapes and to make many different trials. So, Student A would see a good counterexample that would contradict his view”.

Specific counterexamples: The remaining 37 teachers in this category, constituting half of the participants, gave a specific counterexample. Twenty of them provided *incorrect counterexamples*. For example, some sketched two triangles that appeared to satisfy the given conditions and claimed that these triangles were not congruent although in their drawing these triangles seemed congruent. Thus, we consider this to be non-appropriate examples. Other examples had too many constraints - thus were non-existent. For example, T72 drew two triangles that seemed symmetrical in his

attempt to produce two triangles that were not congruent (Figure 3), however, they seemed congruent.

Figure 3: The drawing of T72

Some teachers considered the variation of a pair of angles but without giving specific measures. Others drew two triangles by attributing specific values to the angle contained between the two given sides. For example, T74 wrote: “I would ask the students to make two triangles $AB\Gamma$ and EZH with $B\Gamma=ZH=12$, $AB=EZ=7$, the angles $A\Gamma B$ and EZH equal to 30 degrees, the angle $AB\Gamma$ equals 90 degrees and the angle EZH equals 45 degrees”. In both cases, as it appeared also from the interviews and will be analysed further below, several teachers did not think about the existence of the suggested triangles and did not notice that they were suggesting non-existing cases.

Six teachers gave counterexamples that were *seemingly correct with no justification*. They drew two triangles which satisfied the given conditions for which the angles opposite to the sides of length 12 seemed supplementary, like in the appropriate counterexample. They claimed that this was a counterexample but did not give any justification for their claim. Finally, eleven teachers gave a *correct counterexample with justification* by constructing geometrically the two triangles that had the given elements and were not congruent. Some of them suggested to explore further with the students the situation and to formulate relevant theorems. For example, after the geometrical construction of a counterexample T33 wrote: “I would ask the students to try to prove that if one triangle has two sides and the angle opposite to one of these sides equal to the corresponding sides and angle of another triangle, then the corresponding angles that are not contained in the two sides are either equal or supplementary”.

Emerging epistemological issues

The issue of existence of a (counter)example

As shown in Figure 2, over one third of the teachers (26) had not considered the problem of existence in their initial responses. In the interviews, the teachers who had not justified the process of constructing a counterexample as well as those who gave an incorrect example, were asked about its existence: “How do you know that the triangles you have drawn exist?”. Some of them argued for the existence of their counterexample by inferring from a familiar theorem, recalling an image, or describing the drawing process. Following are some examples of their arguments:

“I have seen this counterexample in a textbook” (T32, recalling an image)

“If I remember well, there is a theorem that says that the non-contained angles are equal or supplementary”. (T40, inferring from a theorem)

“The sum of their angles is 180 degrees...They can be constructed...I can vary the angles” (T69, inferring from a theorem)

“I made them; I measured its sides with a ruler”. (T30, describing the drawing process)

When asked to consider the issue of existence, most of the teachers responded immediately that they had to check the existence of the suggested triangles. However, there were some who seemed to believe that the question about the existence of a triangle with specific properties had no meaning. Typical responses were:

“Yes, why can't we? Do we have to prove it?” (T46)

“Is it possible not to exist?” (T60)

“I thought that it is sure that there are two triangles (satisfying the given conditions) which are not congruent. So, I opened a bit the angle and I moved the side to that direction.” (T73)

Another issue that emerged and was related to the problem of existence was the number of possible counterexamples. There were teachers who believed that there was more than one counterexample and in some cases they described a process of generating an infinite number of triangles (for example, T69, T73 mentioned above). This finding concurs with the findings of Zodik & Zaslavsky (2007).

During the interviews, we observed that some of these teachers started to think about ways of constructing appropriate counterexamples. For example, T39 sketched two triangles and commented: “If we draw on the board two triangles $AB\Gamma$ and EZH with the given elements and the angles $AB\Gamma$ and EZH to be acute - one smaller than the other – it is easy to verify by using transparent paper that the two triangles are not congruent”. In the interview she formed a new hypothesis that: “if in both triangles (satisfying the given conditions) all angles are acute, they are congruent while they must be different if one triangle is acute-angled and the other obtuse.” Later in the interview, she used the sine-rule trying to prove her hypothesis. However, she did not manage to construct geometrically the suggested triangles. On the other hand, T32 had given as a counterexample two triangles, one right-angled and the other isosceles. In the interview she initially recalled a known theorem “that one pair of angles can be equal or supplementary” and finally she gave a correct geometrical construction of the counterexample.

The issue of over-reliance on familiar criteria

Another issue that emerged from our data was the use of theorems for justifying refutable (invalid) claims. A number of teachers believed that the non applicability of the known relevant theorems implied that the claim was wrong. In particular, some teachers concluded that the two triangles were not necessarily congruent as none of the three commonly used criteria about the congruence of triangles could be applied. For example, in his written response T11 reminded the (hypothetical) student these

three criteria, and added that “the problem statement does not satisfy the criterion S-A-S ... so from the given data we cannot conclude that the two triangles are congruent”. The above argument was the only one that the teacher gave for justification. T47 also expressed a similar view in his written response. In the interview, although this belief was challenged by one of the researchers, it seemed to be rather strong as demonstrated in the following extract:

- T47: The two triangles are not necessarily congruent
 R: How do you know this?
 T47: We cannot apply the criterion S-A-S.
 R: Ok, a known criterion cannot be applied. But how do you know that there is no other way to prove the congruence of the two triangles?
 T47: We cannot prove the congruence with the criteria we teach.

In the above cases, the teachers seem to base their reasoning on the principle that we can infer that two triangles with given properties are congruent only if these properties satisfy one of the three commonly used criteria (S-S-S, S-A-S and A-S-A). So, since these conditions were not explicitly given in the task, some teachers (falsely) inferred that these triangles cannot be congruent, while others claimed that they were not necessarily congruent. Although the latter claim may reflect legitimate logical inference, it may also have flaws and lead to wrong conclusions. For example, if the length of shorter side of the two triangles of our problem were 6 instead of 7, then the above kind of reasoning would lead to the conclusion that the two triangles are not necessarily congruent, while in fact, in this case the two triangles are right-angled and thus are indeed congruent.

It should be noted that even though the above way of refuting invalid claims is not a mathematical valid proof, in some cases it can be used as a tool for posing conjectures. For example, in his written response T21 initially stated that the known criteria could not be applied and then gave a geometrical construction of the counterexample.

CONCLUDING REMARKS

From the seventy six mathematics teachers of our study only thirteen refuted correctly the invalid claim of student A, eleven by constructing a counterexample and two by using theorems. Some of the characteristics of teachers’ reasoning that were identified in this study are similar to those reported by Lin (2005) in the case of students. For example, there were teachers who confirmed the invalid claim, others who suggested the possibility of a counterexample without generating it, and few who actually constructed a counterexample accompanied by a mathematical proof.

In our study, teachers seemed to draw on their personal example spaces in order to generate counterexamples. It should be noted that in the case of Student A's (false) claim, a carefully thought through construction of an appropriate counterexample is needed. Teachers who just randomly sketched two triangles were not able to come up

with an appropriate counterexample. In this problem, there is only one counterexample. This counterexample can be seen according to Mason and Pimm (1984) as a generic example, in the sense that it can reflect and lead to the general case (as illustrated in Figure 1). Similarly, in terms of Zaslavsky and Peled (1997) this counterexample has a high explanatory power. However, thinking of it for the first time turned out to be a strong demand on the teachers.

The two main phenomena that emerged from our study should be of great concern: overlooking the question whether an example exists, and over-relying on familiar theorems and criteria. Our findings illustrate how these two phenomena may lead to invalid inferences. Similar to Zodik and Zaslavsky's (2008) findings, there were several instances where teachers considered a non-existing example as if it existed, and did not seem to be aware of this issue at all. The second phenomenon reflects teachers' beliefs that a claim can be refuted if “all” the relevant theorems that they know (mostly those that are included in the school textbooks) cannot be applied. This conception indicates a misleading epistemological view of theorems and their status in mathematical reasoning.

In this paper, we focused mainly on teachers' mathematical knowledge as reflected in their responses. Pedagogical aspects of their knowledge that emerged from our data have not been discussed here. These aspects may provide a more comprehensive account of what is entailed in dealing with students' invalid claims.

ACKNOWLEDGMENT

STUDENT JUSTIFICATIONS IN HIGH SCHOOL MATHEMATICS

Ralph-Johan Back, Linda Mannila and Solveig Wallin

Åbo Akademi University, Finland

In this paper, we continue our previous work on evaluating the use of structured derivations in the mathematics classroom. We have studied student justifications in 132 exam solutions and described the types of justifications found. We also discuss the results in light of Skemp's (1976) framework for relational and instrumental understanding.

Keywords: student justifications, structured derivations, high school, instrumental and relational understanding

INTRODUCTION

The ability to justify a step in, for instance, a proof can be considered a skill that needs to be mastered, at least to some extent, before proof is introduced. In a wider sense, proof can even be regarded as justification (Ball and Bass, 2003). Unfortunately, students are not used to justify their solutions (Dreyfus, 1999). It is common for teachers to ask students to explain their reasoning only when they have made an error; the need to justify correctly solved problems is usually de-emphasized (Glass & Maher, 2004). Consequently, without the explanations, the reasoning that drives the solution forward remains implicit (Dreyfus, 1999; Leron, 1983).

A previous study (Mannila & Wallin, 2008) indicated that high school students can improve their justification skills in one single course. In this paper, we will present the results from a follow-up study, focusing on the types of justifications given by the students. We will first discuss some related work and also give a brief introduction to the approach used when teaching the course. The main research questions are the following: What types of justifications do students give in a solution? Do the types of justifications change as the course progresses, and in that case how?

RELATED WORK

Justifications as a condition for proof

The importance of proof and formal reasoning for the development of mathematical understanding is also recognized by the National Council of Teaching Mathematics (NCTM), which issues recommendations for school mathematics at different levels. According to the current document (NCTM, 2008), students at all levels should, for instance, be able to communicate their mathematical thinking, analyze the thinking of others, use mathematical language to express ideas precisely, and develop and evaluate mathematical arguments and proof. While discussing mathematical ideas is important, communicating mathematical thinking in writing can be even more efficient for developing understanding (Albert, 2000).

To think mathematically, students must learn how to justify their results; to explain why they think they are correct, and to convince their teacher and fellow students. “[M]athematical reasoning is as fundamental to knowing and using mathematics as comprehension of text is to reading. Readers who can only decode words can hardly be said to know how to read. ... Likewise, merely being

able to operate mathematically does not assure being able to do and use mathematics in useful ways.” (Ball & Bass, 2003; p. 29)

Justifications are not only important to the student but also to the teacher, as the explanations (not the final answer) make it possible for the teacher to study the growth of mathematical understanding. Using arguments such as “Because my teacher said so” or “I can see it” is insufficient to reveal their reasoning (Dreyfus, 1999). A brief answer such as “ $26/65=2/5$ ” does not tell the reader anything about the student’s understanding. What if he or she has “seen” that this is the result after simply removing the number six (6)?

Types of understanding and reasoning

A review of literature on mathematics education shows that there is an interest in studying the distinction between being able to apply a determined set of instruction in order to solve a mathematical problem and being able to explain the solution by basing it on mathematical foundations. Several frameworks have been presented for investigating types of learning and understanding.

Skemp (1976) discusses two types of understanding named by Mellin-Olsen: *relational* (“knowing both what to do and why”) and *instrumental* (“knowing what”, “rules without reasons”). People who exhibit an instrumental understanding know how to use a given rule and may think they understand when they really do not. For instance, getting the correct result when applying a given formula is an example of instrumental, not relational, understanding. One typical example can be found in equation solving, where students learn to “move terms to the other side and change the sign”, without necessarily knowing why they do it.

Sfard (1991) investigates the role of algorithms in mathematical thinking and discusses how mathematical concepts can be perceived in two ways: as objects and as processes. Pirie and Kieren (1999) present a theory of the growth of mathematical understanding and its different levels. More recently, Lithner (2008) has created a research framework for different types of mathematical reasoning, distinguishing between two main types: *imitative* and *creative*. Imitative reasoning is rote learnt and can be divided into two subtypes: memorised reasoning, where the student, for instance, solves a problem by recalling a full answer given in the text book or by the teacher, and algorithmic reasoning, where a problem is solved by recalling and applying a given algorithm. The other main type, creative reasoning, includes a novel reasoning sequence, which can be justified and is based on mathematical foundations. One of the main differences between imitative and creative reasoning is that the former does not necessarily involve analytical and conceptual thinking, whereas such thinking processes are essential to creative reasoning.

STRUCTURED DERIVATIONS

Structured derivations is a logic-based approach to teaching mathematics (Back & von Wright, 1998; Back & von Wright, 1999; Back et al, 2008a). The format is a further development of Dijkstra's calculational proof style, where Back and von Wright have added a mechanism for doing subderivations and for handling assumptions in proofs. Using this approach, each step in a solution/proof is explicitly justified.

In the following, we illustrate the format by briefly discussing an example where we want to prove that $x^2 > x$ when $x > 1$.

- Prove that $x^2 > x$: *task*
- $x > 1$ *assumption*
- ||- $x^2 > x$ *term*
- ≡ { Add $-x$ to both sides } *justification*
 $x^2 - x > 0$ *term*
- ≡ { Factorize } ...
 $x(x - 1) > 0$
- ≡ { Both x and $x-1$ are positive according to assumption. Hence, their product is also positive }
T

The derivation starts with a description of the task (“Prove that $x^2 > x$ ”), followed by a list of assumptions (here we have only one: $x > 1$). The turnstile (||-) indicates the beginning of the derivation and is followed by the start term ($x^2 > x$). In this example, the solution is reached by reducing the original term step by step. Each step in the derivation consists of two terms, a relation and an explicit justification for why the first term is transformed to the second one.

Another key feature of this format is the possibility to present derivations at different levels of detail using subderivations, but as these are not the focus of this paper, we have chosen not to present them here. For information on subderivations and a more detailed introduction to the format, please see the articles by Back et al. referred to above.

Why use in education?

As each step in the solution is justified, the final product contains a documentation of the thinking that the student was engaged in while completing the derivation, as opposed to the implicit reasoning mentioned by Dreyfus (1999) and Leron (1983). The explicated thinking facilitates reading and debugging both for students and teachers. According to a feedback analysis (Back et al., 2008b), students appreciate the need to justify each step of their solutions. They also find that the justifications makes solutions easier to follow and understand both during construction and afterwards.

Moreover, the defined format gives students a standardized model for how solutions and proofs are to be written. This can aid in removing the confusion that has commonly been the result of teachers and books presenting different formats for the same thing (Dreyfus, 1999). A clear and familiar format also has the potential to function as mental support, giving students belief in their own skills to solve the problem. Also, as solutions and proofs look the same way using structured derivations, the traditional “fear” of proof might be eased. Furthermore, the use of subderivations renders the format suitable for new types of assignments and self-study material, as examples can be made self-explanatory at different detail levels.

STUDY SETTINGS

Data collection

The data were collected during an elective advanced mathematics course on logic and number theory (about 30 hours in class) that was taught at two high schools in Turku, Finland, during fall 2007. All in all, twenty-two (22) students completed the course at either school and participated in the study (32 % girls, 68 % boys). The students were on their final study year.

The course included three exams held after 1/3, 2/3 and at the end of the course. The exams were of increasing difficulty level, i.e. the first was the easiest and the last the most difficult one. Two assignments from each were chosen for the analysis. Hence, we have in total analyzed 132 solutions (six solutions for each student) written as structured derivations.

The assignments analyzed were the following:

- A1: Determine the truth value of the expression $(x^2 + 3 \leq 7 \wedge y < x - 4) \vee x + y \leq 5$, when $x = 2$ and $y = 4$.
- A2: Solve the equation $|x - 4| = 2x - 1$.
- A3: Use de Morgan's law $(\neg(p \wedge q) \Leftrightarrow \neg p \vee \neg q)$ to determine if the expression $(\neg p \vee \neg q) \wedge (p \wedge q)$ is a tautology or a contradiction.
- A4: Prove that $b^2 - d^2 = ad + bc - ab - cd$ if $a + b = c - d$.
- A5: Prove or contradict the following: For any integers m and n , it is the case that if $m \cdot n$ is an even number, then both m and n are even.
- A6: Prove that $2 + 14^{30} \equiv_{13} 106 + 27^{30}$.

The topics covered in assignments A1 and A2 were familiar to the students from previous mathematics courses. The aim of these assignments was mainly to let students practice structured derivations and writing solutions using the new format.

The topics covered in the rest of the analyzed assignments (A3-A6) were new to the students. A3 and A4 focused on logical concepts and manipulation of logical expressions, whereas A5 and A6 covered number theory.

Method

The data collected, i.e. the justifications, were of qualitative nature. Qualitative data are highly descriptive, and in order to interpret the information, the data need to be reduced. In this study, a content-analytical approach was chosen for this purpose. The basic idea of content analysis is to take texts and analyze, reduce and summarize them using emergent themes. These themes can then be quantified, and as such, content analysis is suitable for transforming textual material into a form, which can be statistically analyzed (Cohen, 2007).

A first round of the content analysis was done by one of the authors, who analyzed 18 solutions from E1 and 24 solutions from E2. This initial coding resulted in a first view of the types of justifications. The authors discussed the results and agreed on how to combine the detailed justifications into higher-level categories. Next, all solutions were analyzed using the preliminary categories as the coding scheme. The second round analysis showed that the categories found in the

initial phase were sufficient for covering all justifications found in the 132 solutions. A quantitative approach was then taken in order to be able to illustrate the results graphically.

The use of both quantitative and qualitative methods has several benefits. Mixed methods avoid any potential bias originating from using one single method, as each method has its strengths and weaknesses. A mixed methods approach also allows the researcher to analyze and describe the same phenomenon from different perspectives and exploring diverse research questions. Whereas questions looking to describe a phenomenon (“How/What..?”, our first research question) are best answered using a qualitative approach, quantitative methods are better at addressing more factual questions (“Do...”, our second research question) (Cohen, 2007).

RESULTS

The content analysis revealed five main justification types:

- *Assumption*: Referral to an assumption given in the assignment directly or in a rewritten format.
- *Vague/broad statement*: A very brief and uninformative justification type: “logic” or “simplify”.
- *Rule*: Referral to a name of a rule or a definition, e.g. the rule for absolute values, tautology, congruence etc. In some cases, the justification also included the rule explicitly written out in text.
- *Procedural description*: An explanation of *what* is done in the step, i.e. a description including a verb. E.g. “add $2x + 4$ to both sides”, “move 3 to the other side and change the sign” and “calculate the sum”.
- *Own explanation*: An explanation for *why* the step is valid in own words and/or with symbols, e.g. “ $2k^2 + 2k$ is an integer if k is an integer. Therefore $2(2k^2 + 2k)$ is an even integer”. In some justifications a mathematical definition was written out in own words, e.g. “ $2 \equiv_{13} 106$ because $2 - 106 = -104$, $13 \mid -104$ ”.

Figure 1 illustrates the proportion of different justification types found in the assignments respectively. The diagram also shows how the types of justification used varied depending on the assignment.

Some justification types are highly assignment specific. For instance, assumptions can naturally only be used in assignments where assumptions are present. In such assignments, it is common for the assumption to be used only once or twice, and the proportion of this type of justification will be rather low. The analysis showed that all students but one were able to handle assumptions correctly already in the first exam, i.e. after 1/3 of the course.

The use of rules can also be considered assignment specific. For instance, when manipulating logical expressions, rules become important as these make up the basis for the manipulation. When students gave a rule as a justification, most usually stated only the name of the rule, whereas only a few also wrote out the rule itself. In the final and most difficult assignment, where the rule was central to the solution, a larger proportion of students (46 %) had written it out explicitly, compared to those who had only provided the name of the rule (22 %).

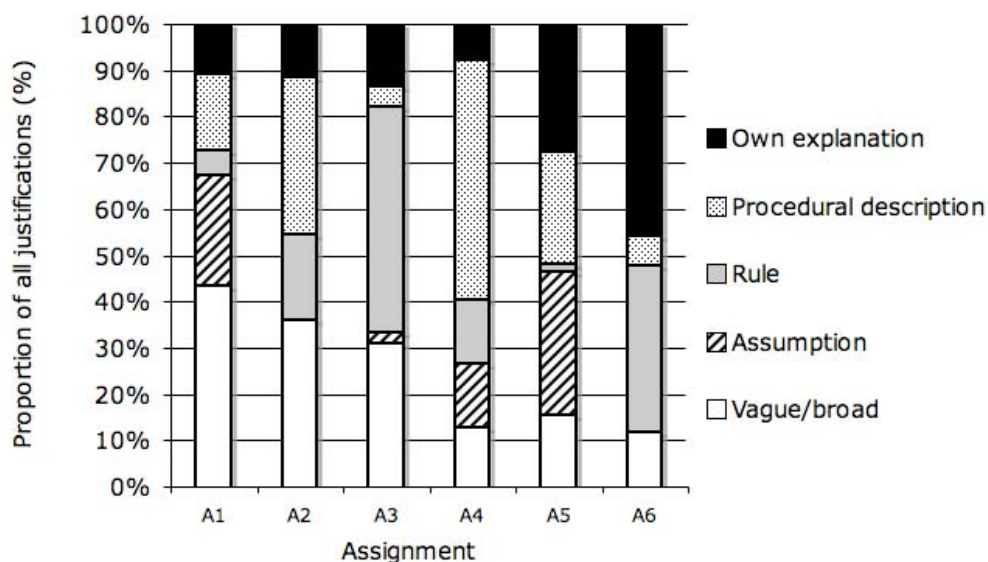

Figure 1: The proportion of justifications of different types in the six assignments

In addition to these specific dependencies, the analysis also revealed some other relationships. The assignments in the first exam (A1-A2) were not trivial but still familiar to the students (determine the value of an expression and solve an equation), who consequently mainly used short justifications (vague/broad, assumption, rule). Given the nature of equations, the solutions to A2 also contained a large proportion of procedural descriptions (“move 3 to the other side”).

In the second exam, students faced assignments (A3-A4) that were not as familiar anymore. In A3, students were to make explicit use of logical rules, which, as stated above, naturally has an impact on the types of justifications: almost half of all justifications referred to a given rule. The following assignment, A4, called for a formal proof (the Finnish high school curriculum does not include proofs in any other course than the elective one described in this paper). As the expression used in the proof was an equation, the main justification type used was, again, procedural descriptions.

The third exam (A5-A6) is probably the most interesting one from a research perspective. The assignments were in a completely new domain, with which students had no prior experience: constructing proofs in number theory. Thus, these assignments have potential to provide insight into how students use justifications when adventuring into a new terrain. As indicated in the diagram (figure 1), the proportion of own explanations increased, in particular at the expense of the less informative justification type “vague/broad”.

DISCUSSION

As seen above, the justification types changed throughout the course. Whereas some of the variation (e.g. the use of assumptions and rules) is a direct result of the nature of the task at hand, some seems to be more related to the perceived level of difficulty.

For instance, the most noticeable changes are found for “vague/broad” justifications and “own explanations”: whereas the former dominate the solutions early on, their frequency decreases towards the end as the number of the latter increases. The first exam was easier than the final one, and as easy assignments include more “straightforward” steps, students may not have seen the need

to justify those steps in any more detail. Rather, students seem to find the need to justify more carefully as the assignments become more difficult. Consequently, the occurrence of own explanations increase. Similarly, it is understandable that students are reluctant to write lengthy justifications when solving tasks similar to tasks they have solved many times before, whereas they may feel a need for writing more careful justifications in assignments that deal with new topics. This is supported by the results from our feedback study, where students found “extra writing” unnecessary for simple tasks (Back et al., 2008b).

Can justifications aid in assessing understanding?

Only two justifications types, “own explanations” and “procedural descriptions”, involve students writing in their own words. There is an important difference between these types. In a “procedural description”, students write *what* they do, but not why they have chosen or are allowed to do so. The “own explanation”, on the other hand, also gives information regarding *why* the step is valid.

This is closely related to Skemp’s instrumental and relational understanding (1976). Own explanations are clearly relational, but the remaining four types (vague/broad, assumption, rule, procedural descriptions) cannot easily be mapped to either type of understanding. We will therefore refer to own explanations as “relational justifications” and the other four types as “instrumental justifications”.

Although Skemp argued that instrumental justifications such as “move -3 to the other side” are examples of an instrumental approach to understanding, we do not think the situation is as black-or-white. For instance, a simple justification such as “logic” may be the result of complex thought processes. Knowing that students are not keen on writing, one can also assume that students may choose to write a short justification even in places where they could have been more expressive in order to indicate their understanding. An instrumental justification simply does not reveal enough information about whether the student has truly understood what he or she has done. Ruling out the possibility of relational understanding in such situations requires more than a mere justification.

To exemplify this, we now look at three different solutions to an assignment involving absolute values. The absolute value rule referred to below is the following: $|x| = c \Leftrightarrow (x = c \vee x = -c) \wedge c \geq 0$

- **Tom:** *instrumental justification, relational understanding*

Tom did not use the rule for absolute values learnt in class, but rewrote the expression in a way showing that he had really understood the absolute value concept. The solution was correct and indicated a relational understanding of absolute values.

$$|x - 4| = 2x - 1$$

\Leftrightarrow { rewrite the absolute value }

$$(x - 4 = 2x - 1 \wedge 2x - 1 \geq 0) \vee (-x + 4 = 2x - 1 \wedge 2x - 1 \geq 0)$$

- **Layla:** *instrumental justification, instrumental or relational understanding*

Layla used the absolute value rule and solved the problem correctly. Despite the correct solution, we cannot know whether Layla understood the concept or merely used a rule she had learnt that “should work” for this type of problems.

$$|x - 4| = 2x - 1$$

⇔ { rule for absolute values }

$$(x - 4 = 2x - 1 \vee x - 4 = -2x + 1) \wedge 2x - 1 \geq 0$$

- **Joe:** *instrumental justification, instrumental understanding*

Just like Layla, Joe also justified the initial step with “the rule for absolute values”. However, he used the rule incorrectly, as he “forgot” the second part of it (the requirement on x).

$$|x - 4| = 2x - 1$$

⇔ { rule for absolute values }

$$x - 4 = 2x - 1 \vee x - 4 = -2x + 1$$

This was a rather common error in our study (made by almost 36% of all students in assignment A2). Had Joe had a relational understanding for absolute values, the additional requirement would have been clear to him even if he had forgotten what the rule looked like.

Thus, it seems as if one can in fact conclude that a given instrumental justification is *not* an example of relational understanding – this is the case if the step is incorrect as for Joe above. However, doing the opposite, i.e. concluding that an instrumental justification to a correct step is relational, is not as straightforward.

Is a clearly relational approach always needed?

In high school mathematics, much time is spent on things like solving equations and simplifying expressions. Thus, to a large extent it boils down to using rules, and consequently a seemingly instrumental approach becomes dominant. However, this is foregone by the teacher explaining the theory behind the rules and the definitions. If the student later uses the rules in an instrumental or a relational way is up to how well he or she understood the theory. If the underlying concept is not clear to the students, the rules are most likely applied without reasons, i.e. instrumentally. One area of high school mathematics where relational understanding most likely becomes more evident is in textual problems, where students first need to formalize the problem specification. In order to correctly specify the problem, the student needs to understand the problem domain and the underlying concepts. Relational understanding is naturally also important when constructing proofs.

Furthermore, sometimes a justification with a seemingly instrumental approach is the best one that can be given. Take for example a complex trigonometric expression. Finnish high school students have a collection of rules that they can always have with them, even on exams. One can hardly require them to start explaining rules in order to be allowed to apply them. What is essential in such a situation is that they a) have an underlying understanding for trigonometry, b) know how to apply trigonometric rules correctly, and c) are able to manipulate the expression into a form where one of the many rules can be applied correctly.

As another example we can take equation solving and the “add -3 to both sides” type of instrumental justification mentioned above. Let us say we have two students: one who understands that whenever you have an expression of the form $a = b$, you can add the same value to both sides without changing the truth value of the full expression ($a + c = b + c$), and another who knows that

one should move “lonely numbers” to the other side while changing the sign. Both of these students would probably use similar justifications, but only one of them would have a relational understanding. This student would, however, hardly write out the rule ($a = b \Leftrightarrow a + c = b + c$), which would be needed in order for the teacher to be able to distinguish the justification from that given by the other student.

Justifications and validity of steps

As was described above, a seemingly “correct” justification can lead to an incorrect derivation step. This can happen for several reasons, one being the one exhibited by Joe above: not completely remembering a rule. Careless mistakes in a step do not seem to correlate with the type or the accuracy of the justification. Only a small number of this type of errors was found (in 9 % of the assignments throughout all three exams), which was also supported by students’ feedback as they pointed out that they made fewer careless mistakes using structured derivations than what they usually do (Back et al., 2008b).

CONCLUDING REMARKS

The type of justification chosen in a certain situation is closely related to the assignment and/or the step at hand. For example, assumptions or rules will not be used in problems where there are no assumptions or rules to apply. Our findings suggest that students choose the level of detail in their justifications mainly based on the difficulty level of the task at hand: in tasks that are familiar, students tend to opt for broad and vague justifications, whereas justifications which say more come into play as the topics covered are new and/or the assignments become more difficult. Especially justifications written in own words are of great importance to the teacher for understanding a solution and the student’s thinking; this is not necessarily the case for vague and broad justifications.

The study presented in this paper is a continuation on earlier qualitative studies on the use of structured derivations in education. Previous results indicate that students appreciate the approach (“it takes me longer, but I understand better”) and that it improves students’ justification skills as soon as during one single course (Mannila & Wallin, 2008). Furthermore, we have found that explicit justifications make students think more carefully when solving a problem (Back et al., 2008b). With this study, we now also have a rather clear picture of how students justify their solutions and how the justifications change throughout the course.

Getting students to clearly document their solutions step by step is a step forward, although “judging” the justifications is everything but straightforward. Thus, many questions still remain. Is it possible to teach a way of writing “good” justifications? And if we want to try, what characterizes such justifications? Another aspect, not considered so far, is related to teachers and course books. How do teachers justify their solutions when teaching using structured derivations? How are examples justified in texts? In order for students to develop relational understanding, we believe that it is essential that examples are explained freely (“using own words”) as often as possible.

“IS THAT A PROOF?”: AN EMERGING EXPLANATION FOR WHY STUDENTS DON’T KNOW THEY (JUST ABOUT) HAVE ONE[†]

Manya Raman^{*}, Jim Sandefur^{**}, Geoffrey Birky^{**}, Connie Campbell^{***}, Kay Somers^{****}

Umeå University^{*}, Georgetown University^{**}, Millsaps College^{***}, Moravian College^{****}

This paper describes an episode taken from the third year of a design experiment aimed at improving the teaching and learning of proof at the university level. In the episode, students come enticingly close to having a proof, at least as judged by competent outsiders. However the students themselves, while satisfied with their result, abandon it when asked to write up a formal proof. We offer an analysis of this episode and offer questions for further study.

Key words: Proof, Tertiary Level, Key Ideas, Technical Handle, Design Experiment

INTRODUCTION

Design experiments, or “developmental research” as this work is often called in Europe, are becoming increasingly common, at elementary, secondary, and even tertiary education (e.g. Brown 1992, Collins 1999, van den Akker, Branch, Gustafson, Nieveen, & Plomp, 1999, Lesh 2002). The goal is to find theoretically grounded answers to practical questions of the classroom, done in as natural a setting as possible, with as Brown puts it, the “the blooming, buzzing confusion” that one can sometimes find in real classrooms, under real pressures, with real constraints and opportunities.

While the potential of merging theory and practice is quite alluring for many reasons, the practical and conceptual realities of doing so remain challenging. As Kelly (2002) suggests: if design experiments began in the early 1990’s as a sort of art, they are emerging in recent years as a type of science, guided by increasingly rigorous methodology and increasingly useful results. But specifying exactly what this science consists in, that is, how to merge research and practice in a mutually advantageous way, is still a matter of debate, discussion, and development.

This paper is an emerging product of a design experiment aimed at improving the teaching of proof at the university level. The research team, consisting of two

[†] This research is supported by NSF grant number DUE-0736762.

mathematics educators and three mathematicians, came together with the aim of improving the teaching of “Introduction to Proof” courses, a type of course used frequently in American universities to help students prepare for the rigor of the theoretical courses like abstract algebra and analysis¹. The idea was to use videos of students struggling, and eventually succeeding, at proving claims that are known to be hard for students in this type of course, as a basis for discussion. These videos can be used both as a professional development tool for teachers who want to better understand student difficulties with proof and as a curriculum resource for class discussion to help students be more aware about their own mathematical thinking.

After three rounds of testing and piloting, we now have a fairly stable set of curricular materials, which include (1) carefully edited videos of students working on proofs that many other students find difficult, (2) materials to help teachers use these videos, both for their own understanding of student thinking and for classroom use. These materials have been tested in four colleges in the United States in the context of “Introduction to Proof” courses taught by members of the research team and their colleagues. We also are generating a number of research articles, this being one example, that probe questions of mathematical thinking that enhance and/or inhibit proof production.

We consider our particular marriage of theory and practice to be a happy one. The central questions which drive our research—how to reconcile student and faculty thinking about proof and proving—grew naturally from our experiences as teachers struggling to make the best of our own “Introduction to Proof” courses. While not eliminating common sense and experience as legitimate grounds for interpreting data, we felt a real need to move into theoretical territory to help make sense of some of the mysteries of mathematical thinking.

This paper describes one part of this theoretical journey. We begin by describing an episode that our team found particularly compelling. In the episode, students come enticingly close to finding a proof but do not seem to notice that they have done so. Rather than convert what outside observers recognize as a “key idea” of a proof into a formal proof, they abandon the idea and take a different, and ultimately unsuccessful path. This episode is useful for a starting point in understanding the nature of key idea in the process of proof production, but also points to some fuzziness about the notion of key idea, which a more theoretical analysis can help clarify.

FRAMING

The methodology for this project, for which this paper is one small part, follows the program set out by Cobb, et al (2003). The design is highly interactive and

¹ See Alcock (2007) for a similar project, focusing primarily on professional development, which has been successfully piloted in the US and UK.

interventionist, involving gathering and indexing of longitudinal data from a number of sources, including videos of classroom practice, individual and group interviews with teachers and students, journal and email records from the teachers, written records of student work, and audio and video records of behind-the-scenes discussion among the research team. Like Cobb, et al, we see this design experiment as a “crucible for the generation and testing of theory.” It is the tangible pressures of classroom realities that provide a needed spark for the theory to develop and crystallize, and one of the goals of this paper is to make part of that process visible to both research and practitioner communities.

The central research questions involve characterizing the trajectory of proof development in a way that both helps us see where students sometimes go wrong and also gives some guidance towards how to teach students to prove in a more effective way. In particular, as we traced one particular episode in which students struggled, came close, and eventually failed to find a proof we wanted to know (1) what were the critical “moments” when there was opportunity for the proof to move forward, and (2) what is the nature of these moments. In the end we found three such moments, which seem to play a critical role in proof production. These moments do not necessarily occur in every proof, nor do they necessarily occur in the order in which we present them, but they seem to be critical in the sense that if one is present, the proof can move forward in a fairly significant way, and if one is absent, it is quite possible that the proof will not move forward (or that a proof will be produced without a full sense of understanding).

The first moment is the getting of a key idea, an idea that gives a sense of “now I believe it”². The key idea is actually a property of the proof, but psychologically it appears as a property of an individual (we say that a particular person “has a key idea” if it appears that they grasp the key idea of a proof.) We refer to “a” key idea rather than “the” key idea, because it appears that some proofs have more than one key idea. While a key idea engenders a sense of understanding, it does not always provide a clue about how to write up a formal proof.

The second moment, is the discovery of some sort of technical handle, and gives a sense of “now I can prove it,” that is, some way to render the ideas behind a proof communicable³. The technical handle is sometimes used to communicate a particular

² More elaborated discussions of “key idea” can be found in Raman (2003), Raman & Weber (2006), and Raman & Zandieh (in progress). A key idea can be thought of as a certain kind of intuition that has both a public and private character: public in the sense it can be mapped to a formal proof, private in the sense that it is personally understandable as a sort of primary, or *prima facie*, experience. For a careful discussion about intuitions see Bealer (1992).

³ The term “technical handle” here is akin to the term “key insight” in Raman & Weber (2006). We have chosen to change the term in part because it sounded too similar to “key idea” which has a very different character, and in part because the technical aspect of this “moment” seemed central to

key idea, but it may be based on a different key idea than the one that gives an ‘aha’-feeling, or even on some sort of unformed thoughts or intuition (the feeling of ‘stumbling upon’.)

The third moment is a culmination of the argument into a standard form, which is a correct proof written with a level of rigor appropriate for the given audience. This task involves, in some sense, logically connecting given information to the conclusion. We assume that for mathematicians the conclusion is probably in mind for most of the proving process. But for students, the theorem might sometimes be lost from sight, adding a sense of confusion to their thinking processes.

In the data below we will illustrate how each of these moments occurs in the midst of proof production before turning more critically to trying to understand the nature of key idea.

THE EPISODE

The following example illustrates the presence and/or absence of these three moments as students work on the following task:

Let n be an integer. Prove that if $n \geq 3$ then $n^3 > (n+1)^2$.

Students were videotaped working on this task in the presence of the research team, and upon their completion, were asked questions about their thinking. Afterwards, the research team watched and discussed the videos. We were drawn to one part of the proof process that turned out to be a genuine mystery—an episode, near the beginning, in which the students generate what the faculty identify as a correct proof, but what the students, at least at some level, do not recognize as one.

Details: In the first two minutes of working on this task, the students made an observation that the professors identified as a key idea of the proof, namely that a cubic function grows faster than a quadratic. Rather than trying to formalize this idea, the students switched to an algebraic approach, what we label as a technical handle, to try to get to a proof. They wrote $n^3 > n^2 + 2n + 1$ which they manipulated into $n(n^2 - n - 2) > 1$ and then $(n-2)(n+1) > 1/n$.

The students then noticed that if $n \geq 3$ then the terms on the left are both positive integers so the product is a positive integer. And since n is an integer greater than 2, the right hand side is going to be between 0 and 1. They wrote these observations as

if $n \geq 3$ (line break) $n-2 > 0$ (line break) $n+1 > 0$ (line break) $0 \leq 1/n \leq 1$

its nature. The distinction between “key idea” and “technical handle” might appear at first sight to be similar to the distinction Steiner (1978) makes and Hanna (1989) builds on between proofs that demonstrate and proofs that explain. However, it is possible that a key idea gives rise to a proof that demonstrates or explains, and a technical handle can also lead to both kinds of proofs.

and seemed quite pleased with their reasoning, one student nodding and smiling as the other one wrote the last line.

S2: Yeah.

S1: This is if n is greater than 3, if n is greater than or equal to 3.

S2: Yeah.... Cool.

At this point in the live proof-writing, the three professors were convinced that the students had a proof. They believed that “all” the students needed was a reordering of their argument. To show $n^3 > n^2 + 2n + 1$, it suffices to show $(n-2)(n+1) > 1/n$, which one can establish by showing that the left-hand side is a positive integer while the right is between 0 and 1.

However, it turned out that the students, despite being pleased with their argument, were less than sure that they were near a formal proof. A professor asked the students “Is that a proof?” and S1 replied, “That’s what I’m trying to figure out.” As the students moved to now write up the proof, they switched to a new track, trying a proof by contraposition. This attempt ended up turning into a confusing case analysis in which they tried to prove the converse of the contrapositive and investigated many irrelevant cases.

AN EVOLVING EXPLANATION

That students can come so close to a proof without recognizing it is probably familiar to most experienced teachers⁴. *Why* the students are not able to recognize that they are so close is another, more difficult, question. Here we show how looking at the three “moments” of the proof, described above, allows us to compare what the students did in this problem with an idealized version of what faculty might have done.

The moments are represented graphically in Figure 1 below, with the blue line representing the “ideal” (professor-like) proving process, and the red line representing the students’ process⁵. The marks m_i indicate the points in the proof at

⁴ Another example can be found in Schoenfeld (1985) where two geometry students have what the researcher is convinced is a correct “proof” but when asked to write it up, they draw two columns and abandon all their previous work.

⁵ In creating this “idealized” version of a proof, we depict a continuity between the key idea and the technical handle, although we realize in practice that many proofs are made without the author being able to connect the two. The question about whether there exists such a connection, even if it has not been found, is an open one. We also realize that the process of proof development is not linear, even for an able mathematician, in many cases. This picture points out more the over-all trajectory of the proof, with minor false-paths ruled out. Further the heights of the peaks could vary.

which different moments are achieved: m_1 for the key idea, which both faculty and students achieved (though the students may not realize this), m_2 for the technical handle (which students in this case see as disconnected from their key idea), and m_3 for the organization of the key idea and/or technical handle into a clear, deductive argument (which in this case the students never reach.)

Specifically, m_1 is recognizing that cubic functions grow faster than quadratic ones. m_2 is choosing an algebraic approach, factoring the polynomials before and after the inequality sign. We label this as a technical handle even though the students do not know from the beginning where this might lead⁶. m_3 is connecting the assumption that $n \geq 3$ with the conclusion that $n^3 > (n+1)^2$. In this case, the students never reached m_3 , and in fact—during their attempt to write a formally accepted proof, they seem to lose sight of what they are proving.

Figure 1: Comparing student (red) and faculty (blue) proof strategies

In the episode above, the students find two key ideas: one that cubics grow faster than quadratics, and another, after students have written $(n-2)(n+1) > 1/n$, that the right-hand term is trapped between 0 and 1 while the left grows indefinitely. Neither of these ideas gets developed into a formal proof. The curved line between m_1 and m_2 represents how students move towards a technical handle and end up at the second key idea.

⁶ The labeling of technical handle here is a bit tricky. If the students are not themselves aware of the way to link their algebraic manipulation to a proof, is it misleading to say they have found a technical handle since technically they do not seem to register that they “know” how to prove it. We have tentatively labeled this moment as a technical handle anyway, in part because as outside observers we can see that this algebraic manipulation could lead to a correct proof. In addition, while the students might not see exactly how to extract a formal proof from their algebraic arguments, they seem to take their arguments to be convincing and that they have grounds for making a formal argument.

The crucial distinctions between the “ideal” graph and the “student” graph are the breaks at m1 (students do not try to connect their key idea to a technical handle) and m2 (students lose sight of the conclusion and end up trying to prove a converse.) Our data indicate that these breaks are not merely cognitive—it isn’t that the students do not have the mathematical knowledge to write a proof, since they articulate the essence of the proof after three minutes. The problem is epistemological—they don’t seem to understand the geography of the terrain. Expecting discontinuity between a more intuitive argument and a more formal one, the students abandon their near-perfect proof for something that appears to them more acceptable as a formal proof.

Of course it is not always possible to connect key ideas to a technical handle, or to render a technical handle into a complete proof. But what distinguishes the faculty from the students is that the faculty are aware that this connection is possible, and might even be preferable given that sometimes it takes little work—in this case a simple reordering of the algebraic argument would suffice for a proof. As one professor in the study said:

“It became clear that to formalize meant something different to them and to us. To us, formalize seemed to mean ‘simply clean up the details’. To them, it seemed to mean ‘consider rules of logic and consciously use one’.”

Recognizing the difference between radical jumps that need to be made to move mathematical thinking forward and local jumps that allow one to delicately transform almost rigorous arguments into rigorous ones might be an essential difference that mathematics teachers can learn to recognize, diagnose, and communicate to their students.

FURTHER QUESTIONS

The episode and analysis described above, raise a number of questions which we would like to discuss briefly here.

1. Nature of key idea/technical handle

One nice feature of the episode above is that the identification of key idea and technical handle came fairly easy, with relatively little debate or discord among members of the research team. But are the notions of key idea and technical handle so clear that they can be picked out in any setting, for any proof? For this we need to continually refine the definitions (and in this paper we have actually backed away from a technical definition and given more general descriptions.) An ongoing research project of our team involves looking at a broad number of theorems, identifying key ideas and technical handles for different proofs, and refining the definitions based on that data.

2. Context of discovery vs. context of justification

The distinction between context of discovery and context of justification⁷, which has had a significant influence on epistemology and related fields, might be useful for understanding why students do not realize they have a proof. Taking the distinction to be psychological (which was not the original intent, but serves our purpose here), it seems natural to suggest that in the process of proving one has a phase of discovery and a phase of justification.

In the episode above, the students seem to be missing an important half of this combination. They sort of “discover” the key idea without seeing it as a justification⁸. Perhaps being able to toggle between the different contexts is a marker for mathematical maturity, and somehow central for being able to identify a proof as a proof. Specifically, the key idea might involve some combination of seeing the idea as a product of discovery and a grounds for justification (a thing to be justified). This is just a hypothesis, and a more careful analysis of the distinction between discovery/justification is needed to be able to substantiate it.

3. A Fregean telescope?

Another way of seeing the difference between student and faculty understandings in this episode might have to do with a deep connection (or lack of connection) between mathematical objects and the way they are grasped by the mind. This suggestion is highly tentative: to use Frege’s distinction between “sinn” (roughly, sense) and “bedeutung⁹” (roughly, reference) to better understand this relationship (Frege (1892/1997)).

Frege uses the following analogy to explain the difference between sinn and bedeutung: imagine a person looking at the moon through a telescope. The moon is a bedeutung, an object in the world, with a public status. The image on our retina is a sinn, the personal sense we have of that object, which has a private status. The telescope is sort of like a thought that connects the two—it has public status, in the sense that anyone can look through it, but it somehow makes an otherwise difficult to grasp object intelligible to the human mind.

Without going deeply into the way Frege extends this analogy to mathematics (in part because there are tricky moves, both going from the bedeutung of an *object* to the bedeutung of a *sentence*, and going from natural language to

⁷ For the original distinction see Reichenbach (1938), and for a critical discussion of this distinction in contemporary philosophy and history of science see Schickore & Steinle (2006).

⁸ Wright (2001) warns about misinterpreting the word “discover”. He points out that we would not say someone “discovered” the South Pole if they did not realize it was there. It is with this warning in mind that we use the term “discover” in quotation marks.

⁹ We retain the German names since the English translations are not completely accurate.

mathematical language) it might be useful to think if there is an analogy to the telescope in the episode described above.

Could it be that students stand facing some (to them) far away star, and with the aid of a telescope the public could be rendered private? If so, what would the telescope be, and is it something that we could better encourage students to develop and/or use as they learn to prove? Or is it possible that there is no telescope at all, just as when I look at the coffee mug on my desk, I feel I am simply getting sense data of the mug, without any mitigation. Perhaps the mind simply grasps key ideas. If so, then, what explains why some people grasp them and others don't?

This is perhaps merely a rephrasing of the central mystery found in the episode above. But by placing this mystery in a Fregean context (which also allows access to his critics), perhaps we gain some conceptual tools to try to better understand, not only the mystery, but also what we can do about it.

These questions mark a few of the places where we think it might be productive to push for a deeper analysis and where we see possibilities to connect to existing research. We are especially excited about the potential to use results from the field of epistemology where questions about the relation between mental representations and the external world (of which we consider mathematics to be a part) have been discussed extensively. In the next phase of our project, we plan to devote increasing time to developing and refining our theoretical ideas. We welcome any and all suggestions that can help us do so.

“CAN A PROOF AND A COUNTEREXAMPLE COEXIST?”

A STUDY OF STUDENTS’ CONCEPTIONS ABOUT PROOF*

Andreas J. Stylianides

Thabit Al-Murani

University of Cambridge, U.K.

University of Oxford, U.K.

Despite the importance of proof and refutation in students’ mathematical education, students’ conceptions about the relationship between proof and refutation have not been the explicit focus of research thus far. In this article, we investigate whether high-attaining secondary students have the misconception that it is possible to have a proof and a counterexample for the same mathematical statement. The data consisted of 57 student surveys augmented by follow-up interviews with 28 students. While analysis of the survey data alone offered considerable evidence for the existence of the misconception among several students in our sample, subsequent analysis with the inclusion of the interview data showed no evidence of the misconception. Implications for methodology and research are discussed in light of these findings.

INTRODUCTION

Despite the fundamental role that proof and refutation play in mathematical inquiry (e.g., Lakatos, 1976) and the growing appreciation of the importance of these concepts in students’ mathematical education (e.g., Lampert, 1992; Reid, 2002), students’ conceptions about the relationship between proof and refutation have not been the explicit focus of research thus far. The lack of research that aimed to investigate specifically students’ conceptions in this area creates a gap in the field’s understanding of how students perceive the standards of evidence in mathematics. Yet, existing research literature on proof and refutation allows us to make a hypothesis about students’ conceptions regarding the possible coexistence of a proof and a counterexample for the same statement.

Specifically, research studies identified two student conceptions whose combination gives rise to the hypothesis that some students believe that it is possible to have a proof and a counterexample for the statement. The first conception that some students have is that counterexamples do not really refute: students tend to treat valid counterexamples to general statements as exceptions that do not really affect the truth of the statements (Balacheff, 1988). The second conception that some students have is that proofs do not really prove: students have difficulties to understand that a valid proof confers universal truth of a general statement thus making further checks superfluous (Fischbein, 1982). However, we point out that the hypothesis that some

* The data reported in this article were collected and analyzed with support of an Economic Social and Research Council (ESRC) grant to the first author (RES-000-22-2536). The opinions expressed in the article are those of the authors and do not necessarily reflect the position of the ESRC.

students believe that a proof and a counterexample can coexist was derived by us considering findings from different studies that used different samples and methods and that were conducted in different cultural settings. So, the hypothesis is not attributed to any of those studies and should become the explicit focus of research.

In this article, we aim to contribute to this domain of research by reporting findings from an investigation of the possible existence of the aforementioned misconception among high-attaining secondary students. In this investigation, we used survey data from 57 students and follow-up interviews with 28 of them. With the interviews, we aimed to clarify some student responses to the survey and to test the tentative conclusions we had drawn from our analysis of the survey data.

BACKGROUND

The research was part of a *design experiment* (see, e.g., Schoenfeld, 2006) that was conducted in two Year 10 classes in a state school in England. The school had 165 Year 10 students (14 to 15 years old) who were set in seven classes according to their performance on a national assessment they took at the end of Year 9. A total of 61 students from the two highest attaining classes participated in the research.

Motivated in part by studies that showed that even high-attaining secondary students tend to have limited understanding of proof (Coe & Ruthven, 1994; Healy & Hoyles, 2000; Küchemann & Hoyles, 2001-03), the design experiment aimed to generate research knowledge about possible ways in which classroom instruction can help these students develop their understanding of proof. The design experiment involved development, implementation, and analysis of the effectiveness of a collection of lesson sequences that extended over one to three 45-minute periods. Each lesson sequence was intended to promote issues of proof in the context of mathematical topics and student learning goals that were consistent with the provisions of the English national curriculum, treating proof as a vehicle to mathematical sense making. As far as proof was concerned, the lesson sequences aimed to offer students opportunities to develop their understanding of the limitations of empirical arguments and of the importance of proof in mathematics, to construct proofs for true mathematical statements, and to formulate counterexamples for false mathematical statements. However, the issue of the possible coexistence of a proof and a counterexample for the same statement was not explicitly discussed in the classes.

The definition of proof that guided the work on proof within the two classes was an adapted version of the conceptualization of proof elaborated in Stylianides (2007, pp. 291-300). The following definition was used in the first lesson sequence in each of the two classes as part of students' introduction to the notion of proof.

An argument that counts as proof [in our class] should satisfy the following criteria:

1. It can be used to convince not only myself or a friend but also a sceptic. It should not require someone to make a leap of faith (e.g., "This is how it is" or "You need to believe me that this [pattern] will go on forever.")

2. It should help someone understand why a statement is true (e.g., why a pattern works the way it does).
3. It should use ideas that our class knows already or is able to understand (e.g., equations, pictures, diagrams).
4. It should contain no errors (e.g., in calculations).
5. It should be clearly presented.

The definition was discussed and referred to by both classes several times during the course of the design experiment, and it can be considered to reflect the classes' "idealized" shared understanding of the criteria for an argument to qualify as a proof.

METHOD

Data Sources

The data for the article are derived from: (1) 57 student responses to a survey that we administered to the two classes at the end of the third lesson sequence of the design experiment (some students were absent the day we administered the survey), and (2) follow-up interviews with 28 students. The students completed the survey part way through the design experiment, after they had been given learning opportunities to develop understanding of different issues related to proof as described previously.

Five cards have the odd numbers 1, 3, 5, 7 and 9 printed on one side, and the even numbers 2, 4, 6, 8 and 10 printed on the other side.

1	3	5	7	9
2	4	6	8	10
on the other side	on the other side	on the other side	on the other side	on the other side

The cards are dropped on the floor and spread out.

Amina, Ben, Carol and Davor are discussing whether this statement is true:

When two of the visible numbers are even, the five visible numbers add up to 27.

Ben's answer

I tried all odd numbers first and got 25:

$$1 + 3 + 5 + 7 + 9 = 25.$$

If I change one odd number to an even number, the total will be 1 bigger.
So if I have two even numbers, the total will be 2 bigger.
So the total will be 27.

So Ben says it's true

Carol's answer

I wrote down these numbers:

1, 2, 3, 4, 9.

Two of the visible numbers are even but the total is 19. So you do not always get 27.

So Carol says it's not true

Figure 1: A mathematical problem and two sample solutions to the problem

Survey

The survey presented the students with a true statement contextualized in a mathematical problem, four sample solutions to the problem, and some open-ended and multiple-choice questions (figures 1 and 2); in this article we focus on students' evaluations of only two solutions (Ben's and Carol's).

Open-ended questions:			
1. Whose answer is closest to what you would do? Explain your answer.			
2. Whose answer would get the highest mark from your teacher? Explain your answer.			
3. Whose answer would get the lowest mark from your teacher? Explain your answer.			
Multiple-choice questions:			
For each of the following, circle whether you agree, don't know, or disagree.			
The statement is:			
When two of the visible numbers are even, the five visible numbers add up to 27.			
<i>Ben's answer ...</i>	agree	don't know	disagree
shows you that the statement is always true	1	2	3
only shows you that the statement is true for some examples	1	2	3
shows you why the statement is true	1	2	3
<i>Carol's answer ...</i>	agree	don't know	disagree
shows you that the statement is not true	1	2	3
shows you why the statement is not true	1	2	3

Figure 2: Open-ended and multiple-choice questions.

The survey derived from one used in the Longitudinal Proof Project (Küchemann & Hoyles, 2001-03; Technical Report for the Year 8 Survey, pp. 93-94). We added the third open-ended question and the probes inviting students to explain their answers. We hoped these additions would increase the survey's potential to reveal student thinking about the possible coexistence of a proof and a counterexample. While this issue does not seem to have been one that Küchemann and Hoyles aimed to explore (ibid, pp. 6-7), we thought the survey offered an excellent opportunity to do this: some students might not notice the (subtle) mistake in Carol's solution and consider it a valid counterexample to the statement, while at the same time recognize the value of Ben's deductive argument and consider it a proof for the statement.

Interviews

We interviewed 28 students based on their responses to the multiple-choice and open-ended questions in the survey. Most interview sessions began with us asking the

students to review their responses to the survey and then to explain which survey question they found the hardest. This general interview probe was followed by specific probes for the students to elaborate on particular responses in their scripts.

Procedure and Analysis

Patterns in students' responses were identified and used to formulate hypotheses about their conceptions. Interview data were then used to test/refine the hypotheses.

With regard to students' conceptions about the coexistence of a proof and a counterexample, our analysis of the survey data focused on those scripts that contained evidence to suggest the potential existence of the misconception. Specifically, we focused on the scripts that contained evidence of one or more of the following "inconsistencies": (1) the student found a mistake in Carol's solution and said that she would get the lowest mark from the teacher but agreed with the sentence that Carol's solution showed that the statement was not true; (2) the student said that the highest mark from the teacher would go to both Ben's and Carol's solutions; and (3) the student agreed both with the sentence that Ben's solution showed that the statement was always true and with the sentence that Carol's solution showed that the statement was not true.

We coded the type of evidence that was present in the scripts into two categories – strong or weak – depending on the degree of confidence that it gave us as researchers for the existence of the misconception. Specifically, we considered that strong evidence was offered by those scripts that had either "agree" or "don't know" in the first multiple-choice questions for both Ben's and Carol's solutions, and that included no relevant disconfirming evidence in the open-ended questions. The scripts that we considered offered weak evidence for the existence of the misconception had again either "agree" or "don't know" in the first multiple-choice questions for both Ben's and Carol's solutions, but included some relevant disconfirming evidence in the open-ended questions (e.g., they offered evidence that the student was aware that Carol's solution had a mistake in it). For each of the strong or weak evidence categories we used the interview data to examine the extent to which there was, overall, evidence to suggest that the students actually had the misconception. Also, we used the interview data to seek possible explanations (from the students' point of view) for the "inconsistencies" that we identified in their scripts.

RESULTS

General Findings

Our analysis of the survey scripts showed that 16 out of the 28 students interviewed exhibited some evidence to suggest the existence of the misconception that a proof and a counterexample can coexist. Of these, ten scripts showed strong evidence and six showed weak evidence for the misconception. Our subsequent analysis of the

interview data revealed that the students in each group (i.e., strong or weak evidence group) tended to offer similar justifications for their choices.

Regarding the strong evidence group, our interview data suggested that the inconsistencies in students' responses derived from them considering Ben's and Carol's solutions in isolation from one another when they were completing the survey. While discussing their responses with the interviewers, however, all the students in this group became aware of the potential inconsistency between their evaluations of Ben's and Carol's solutions, presumably because the interviewers' questions directed (implicitly or explicitly) students' attention to the relationship between their evaluations. Yet, the manner in which the students became aware of this inconsistency and how the awareness played out in the interviews varied.

On the one hand, some students realized the mistake in Carol's solution without any prompting from the interviewers and immediately dismissed her solution. As a result of this dismissal, there was no opportunity for the interviewers to explore further whether these students would experience any sense of conflict that a proof and a counterexample can coexist. On the other hand, some other students needed explicit prompting from the interviewers to reflect on whether or how their evaluations of Ben's and Carol's solutions fitted together before they appreciated the potential inconsistency between these evaluations. Believing that Carol had found a genuine counterexample, these students attempted to resolve the emerging conflict by assuming there was a flaw in Ben's argument, which however they were unable to identify. The interviewers then helped these students see the mistake in Carol's solution and realize it was not a genuine counterexample. As a result of this realization, the students subsequently rejected Carol's solution, but this rejection was not always accompanied with endorsement of Ben's solution as a proof.

Regarding the weak evidence group, our interview data suggested that the students in this group seemed to be aware of the following 'inconsistency' we identified in their scripts: the students pointed out the mistake in Carol's solution in their response to the open-ended questions, but in the first multiple-choice question for Carol's solution they agreed that the solution showed the statement was not true.

During the interviews, the students argued, with different degrees of clarity, that, in spite of the mistake in Carol's solution, her reasoning should be valued because her logic was correct and she had disproved a statement, albeit a different one from that in the problem. Consequently, none of these students changed their minds about their evaluations of Carol's solution during the interview. The issue of the misconception was not pursued further by the interviewers, as the students were already aware that Carol's argument was not a counterexample to the particular statement.

To sum up, there is no evidence from our interviews to suggest that any of the 16 students we originally identified as potentially having the misconception actually had it. Furthermore, the interview data showed that any potential conclusions that could be drawn from the survey data alone would be insecure, as students appeared to have

good reasons for ‘inconsistencies’ we identified in their scripts. For this reason we do not report findings with students we did not interview.

Illustrative Case 1: The Case of Emily

The first case is of a student we call Emily, whose responses to the survey showed strong evidence of the misconception. Emily’s script had “agree” in the first multiple-choice question for Carol’s solution and “don’t know” in the corresponding question for Ben’s solution. Furthermore, in response to the second open-ended question, Emily wrote that both Ben and Carol would receive the highest marks from the teacher and justified her thinking as follows:

Ben: It [Ben’s solution] is carefully thought out and written down in an understandable and clear manner.

Carol: She has shown when it [the statement] is not true.

During the interview Emily explained her thinking about Carol’s solution as follows:

The question was saying [that] when two of them [the visible numbers on the cards] were even that the answer is always 27, but she proved that it’s not, so she answered the question that was being asked.

In regard to Ben’s solution, Emily said:

It [Ben’s answer] was very, like, well set out and easy to understand and I think that was how I would have done it cause the other answers are like gabbling on a bit and they don’t really explain why it’s [the statement is] true or false.

She explained further that her “don’t know” response in the first multiple-choice question for Ben’s solution was because Ben “didn’t show that it’s always true, he only showed it for some numbers.” When asked whether she thought Ben had a proof, Emily said that Ben “needed to maybe expand it [his solution] a bit more to convince people that it was true” and noted that Ben could come up with a proof if he worked a bit harder on his solution.

After summarizing what Emily said about the two arguments, the interviewer asked Emily how her two evaluations fitted together. Realizing the inconsistency between the evaluations, Emily laughed and said: “they don’t [fit together] because Carol’s proved that it’s wrong and so it’s impossible to prove that it’s true... cause it’s not true!” Asked what she thought was going on with the two arguments, Emily asserted:

They [Ben and Carol] have both tried different ways and got different answers, so if they kept working at it, if Ben kept working on his [solution], he would eventually figure out that it’s not true.

The interviewer then helped Emily to see the mistake in Carol’s solution. Once Emily realized the mistake, she exclaimed: “Oh, so she [Carol] could be wrong... so hers is wrong then.” On reviewing her original responses to the multiple-choice questions for Carol’s solution, Emily decided to change her response to the first question from “agree” to “disagree,” because, as she said, Carol “hasn’t followed the instruction.”

Emily concluded that Ben's solution "might be true" but she decided not to change her responses to the multiple-choice questions for his solution.

Illustrative Case 2: The Case of Evans

The second case is of a student we call Evans, whose responses to the survey showed weak evidence of the misconception. Evans' script had "agree" in the first multiple-choice questions for both Ben's and Carol's solutions, an indication of the existence of the misconception. Furthermore, Evans' responses to the first two open-ended questions showed particular appreciation of Ben's solution: he wrote that Ben's solution would be close to what he would do and that the solution would get the highest mark from his teacher "[b]ecause [it] shows working and offers convincing proof." Yet Evans' response to the third open-ended question offered disconfirming evidence of the existence of the misconception as it indicated that he was aware of the mistake in Carol's solution and said that Carol's answer would get the lowest mark from the teacher. In a series of two interviews, we tried to understand the reasoning for the apparent contradiction in Evans' evaluation of Carol's solution.

Evans was aware that Carol's solution had a mistake in it, but on the basis that she applied a correct mathematical method and that this application warranted recognition, he consciously agreed that she had shown the statement was not true.

Well what she [Carol] has done is like impossible because 1 and 2 can't be seen at the same time, so then I would have disagreed because that can't be true. But seeing as though she has shown that she's thought it through and like, with her own reasoning she's come to an answer, then I would have put she technically has [shown the statement is not true] but she's got it wrong. [...] Carol tried to prove the statement wrong, so one counterexample was enough. She had the logic right but she didn't succeed to come up with a correct counterexample.

This interview excerpt shows that Evans evaluated Carol's solution from her own point of view and that he understood the fundamental idea that a single counterexample suffices to refute a general statement. Evans considered that Carol's solution embodied understanding of the latter idea, even though the counterexample she offered did not satisfy, as he observed, the problem's conditions.

When pressed by the interviewer to explain his thinking further, Evans described the different evaluation standards that he perceived existed in exams and in class work:

In an exam you don't get marks for the proof, do you? You get marks for showing your working and actually getting the answer in the end. But it [Carol's solution] does show the proof and everything. I don't know, it depends on what sort of question it is... if it's like what we're doing proof and stuff [referring to the proof work in class] then that [Carol's solution] would probably get the highest mark if that was what it was marked on... but in the exam it would be marked differently because it's not about how you are thinking, it's about getting the answer and getting the working and everything right.

The interviewer did not raise explicitly the issue of the possible coexistence of a proof and a counterexample, as Evans was clearly aware that Carol's argument was not a valid counterexample to the particular statement in the problem.

DISCUSSION

Although our analysis of the survey data alone offered considerable evidence (both weak and strong) for the existence of the misconception that a proof and a counterexample can coexist, our subsequent analysis with the inclusion of the interview data showed no evidence of the misconception. The size of the mismatch between the findings of the two analyses might have been influenced by what we considered as evidence for the possible existence of the misconception in our analysis of the survey data. Nevertheless, the existence of the mismatch reinforces and exemplifies the point that student responses to surveys may, by themselves, offer a rather limited insight into students' conceptions and that follow-up interviews with selected students are important for the construction of a more trustworthy picture of students' conceptions.

The latter statement is more than a reiteration of the well known methodological principle that triangulation of multiple data sources allows the examination of research questions in more nuanced ways than when using a single data source. The statement is also a cautionary remark that conclusions about students' conceptions that are based only on analysis of students' responses to surveys may be seriously misleading. This should not be taken as a criticism of the use of surveys in examining educational issues in general, but rather as a concern that the complexity that surrounds the particular issue of students' conceptions about multifaceted mathematical ideas may not be possible to be illuminated satisfactorily on the basis only of survey data. Of course this is not a black and white situation. The extent to which survey data alone can help illuminate complex issues depends on several factors: the methods that were used to validate a survey, the kinds of questions included in the survey, the conditions under which the survey was administered, the coding scheme used to analyse the survey data, etc.

In spite of the limitations in the conclusions that could be drawn based on the survey data alone, the survey offered a meaningful context in which we discussed during our interviews with students their ideas about the possible coexistence of a proof and a counterexample. This discussion was done with reference to Ben's deductive argument, which could be considered a proof, and Carol's purported counterexample. Carol's argument worked particularly well for the purposes of our research, as the subtle mistake in it passed unnoticed by several students, thereby helping us meet the challenge of presenting the students with a believable "counterexample" to a true statement. Ben's argument did not work as well as Carol's argument: students like Emily recognised the value of Ben's argument, but they did not accept it as a proof, primarily because they thought it needed "unpacking." The fact that some students did not consider that Ben's argument qualified as a proof gave them an "easy" way to

resolve the problematic situation regarding the possible coexistence of a proof and a counterexample: these students suspected a mistake in Ben's argument and thus felt less hesitant to endorse Emily's counterexample. Given that the statement in the problem was true, it would not be difficult to strengthen Ben's argument in the survey so that more students would accept it as a proof; this modification in the survey would increase its potential to elicit students' conceptions about the possible coexistence of a proof and a counterexample.

Future research on students' conceptions in this area can use this modified version of the survey. Also, it would be useful if future research used an additional problem that asked students to evaluate a valid counterexample and a believable "proof" for a *false* statement. This would complement our examination in this study, thus contributing to the development of a more comprehensive approach to eliciting students' conceptions about the possibility of having a counterexample and a proof for the same statement. The fact that our research did not reveal this misconception does not mean that there are no students who have it; less advanced students, younger students, or students with fewer experiences with proof are more likely to have the misconception than the students who participated in our research.

ABDUCTION AND THE EXPLANATION OF ANOMALIES: THE CASE OF PROOF BY CONTRADICTION[^]

Samuele Antonini^{*}, Maria Alessandra Mariotti^{**}

^{*} Department of Mathematics, University of Pavia, Italy

^{**} Department of Mathematics, University of Siena, Italy

Some difficulties with proof by contradiction seem to be overcome when students spontaneously produce indirect argumentation. In this paper, we explore this issue and discuss some differences between indirect argumentation and proof by contradiction. We will highlight how an abductive process, involved in generating some indirect argumentation, can have an important role in explaining the absurd proposition, in filling the gap between the final contradiction and the statement to be proved and in the treatment of impossible mathematical objects.

Key words: proof, argumentation, abduction, proof by contradiction, indirect argumentation.

INTRODUCTION

The relationship between argumentation and proof constitutes a main issue in mathematics education. Research studies have been based on different theoretical assumptions, proposing different approaches and consequently different didactical implications (Mariotti, 2006). In some studies (see, for example, Duval, 1992-93), a distance between argumentation and proof is claimed, while in others, without forgetting the differences, the focus is put on the analogies between the two processes and their possible didactical implications (Garuti, Boero & Lemut, 1998; Garuti & al., 1996). As a consequence, the authors hold the importance for students to deal with generating conjectures, and highlight that this activity can promote some processes that are relevant in developing students' competences in mathematical proof.

Elaborating on this first hypothesis, concerning the continuity between the argumentation supporting the formulation of a conjecture and the proof subsequently produced, Pedemonte (2002) developed the theoretical construct of *Cognitive Unity* in order to describe the relationship (continuity or break) between the argumentation process and the related mathematical proof in the activity of conjecture's production.

In this paper, we aim to investigate the relationships between argumentation and proof in the case of proof by contradiction. The reference to the framework of *Cognitive Unity* is of the interest for this study for the following reason. Although important difficulties have been identified in relation to this type of proof (see Antonini & Mariotti, 2008; 2007; Mariotti & Antonini, 2006; Antonini, 2004;

[^] Study realized within the project PRIN 2007B2M4EK (*Instruments and representations in the teaching and learning of mathematics: theory and practice*), jointly funded by MIUR and by University of Siena.

Stylianides, Stylianides & Philippou, 2004; Wy Yu, Lin & Lee, 2003; Thompson, 1996; Leron 1985), in the literature we find evidence of arguments, spontaneously produced by students, that can be considered very close to proof by contradiction (see Antonini 2003; Reid & Dobbin, 1998; Thompson, 1996; Freudenthal, 1973; Polya, 1945). In fact, as reported by Freudenthal:

“The indirect proof is a very common activity (‘Peter is at home since otherwise the door would not be locked’). A child who is left to himself with a problem, starts to reason spontaneously ‘... if it were not so, it would happen that...’ “ (Freudenthal, 1973, p. 629)

We call *indirect arguments* the arguments of the form ‘*if it were not so, it would happen that...*’. Indirect arguments seem to be more like to appear in the solution of open-ended problems, as a natural way of thinking in generating conjectures, when one needs to convince oneself that a statement is true, or to understand because a statement is true.

Therefore, it seems important to study differences and analogies between proof by contradiction and indirect argumentation, and this is what we are going to do in the following sections.

DIFFICULTIES WITH PROOF BY CONTRADICTION

According with the terminology of the model presented in (Antonini & Mariotti, 2008, 2007), given a statement *S*, that we called a *principal statement*, a proof by contradiction consists in a couple of proofs: a direct proof of another statement *S**, that we call the *secondary statement*, in which the hypotheses contain the negation of *S* and the thesis is a contradiction (or a part of it); and a *meta-theorem* stating the logical equivalence between the two statements, the *principal* and the *secondary*. Here, we analyse two aspects and their relationships: the link between the *principal statement* and the contradiction achieved through the proof of the *secondary statement*; the treatment of impossible mathematical objects in both the argumentation and the proof.

The link between the contradiction and the *principal statement*

The link between the final contradiction and the principal statement is a source of difficulties for students (see Antonini & Mariotti, 2008). It can happen that such difficulties are openly shown when they appear astonished and disoriented after the deduction of an absurd proposition. This is the case for example of Fabio, a university student (last year of the degree in Physics), who explains very well this type of difficulty:

Fabio: Yes, there are two gaps, an initial gap and a final gap. Neither does the initial gap is comfortable: why do I have to start from something that is not? [...] However, the final gap is the worst, [...] it is a logical gap, an act of faith that I must do, a sacrifice I make. The gaps, the sacrifices, if they are small I can do them, when they all add up they are too big. My whole argument converges towards the sacrifice of the logical jump of exclusion, absurdity or exclusion... what is not, not the direct thing. Everything is fine,

but when I have to link back... [Italian: “Tutto il mio discorso converge verso il sacrificio del salto logico dell’esclusione, assurdo o esclusione... ciò che non è, non la cosa diretta. Va tutto bene, ma quando mi devo ricollegare...”]

Fabio identifies two gaps (he speaks also of a “*jump*”!) in a proof by contradiction: an initial gap and a final gap. According to our model, the initial gap corresponds to the transition from the statement S to the proof of S^* , and the final gap corresponds to the opposite move, from the proof of S^* to the conclusion that S is proved. The perception of these gaps makes Fabio feel unsatisfied, as if something were missing. In fact, he can accept the proof but he is not convinced, as he says it is “*an act of faith that must be done*”.

The treatment of impossible mathematical objects

It may happen that, at the beginning of a proof by contradiction, some of the mathematical objects have some characteristics that are absurd and strange, in an evident way. These mathematical objects are proved to be impossible in some theory. For this reasons, difficulties can emerge in the treatment of these absurd objects. As discussed in (Antonini & Mariotti, 2008; Mariotti & Antonini, 2006) difficulties may occur in the construction of the proof of S^* , but difficulties may also emerge after the proof of S^* is achieved, when absurd objects have to be discarded. In fact, at the end of a proof of S^* , once a contradiction is deduced, one has to realize that some of the objects involved do not exist; actually, they have never existed. As explained by Leron:

“In indirect proofs [...] something strange happens to the ‘reality’ of these objects. We begin the proof with a declaration that we are about to enter a false, impossible world, and all our subsequent efforts are directed towards ‘destroying’ this world, proving it is indeed false and impossible. We are thus involved in an act of mathematical destruction, not construction. Formally, we must be satisfied that the contradiction has indeed established the truth of the theorem (having falsified its negation), but psychologically, many questions remain unanswered. What have we really proved in the end? What about the beautiful constructions we built while living for a while in this false world? Are we to discard them completely? And what about the mental reality we have temporarily created? I think this is one source of frustration, of the feeling that we have been cheated, that nothing has been really proved, that it is merely some sort of a trick - a sorcery - that has been played on us.” (Leron, 1985, p. 323).

Our research interest is in exploring whether and how these difficulties may be overcome when students spontaneously produce indirect argumentation. Two elements seem important to take into account: on the one hand the indirect argumentation as a product and its differences with a proof by contradiction, on the other hand the processes involved in producing the argumentation (see also Antonini, 2008). In this paper we focus on the hypotheses that in many cases the students try to fill the gap between the contradiction and the statement in order to re-establish a link

and at the same time to give a new meaning to the “objects of the *impossible world*”, so that they can be modified without being discarded.

THE ABDUCTIVE PROCESS

Abduction is one of the main creative processes in scientific activities (Peirce, 1960). Magnani defines abduction as

“the process of inferring certain facts and/or laws and hypotheses that render some sentences plausible, that explain or discover some (eventually new) phenomenon or observation; it is the process of reasoning in which explanatory hypotheses are formed and evaluated” (Magnani, 2001, pp. 17-18).

The main characteristic of abduction is that of deriving a new statement that has the power of enlightening the relationship between the observation and what is known.

Many studies in mathematics education have dealt with abductive processes in students thinking: in problem-solving activities (Cifarelli, 1999), in generation of conjectures (Ferrando, 2005; Arzarello et al., 2002; Arzarello et al., 1998), argumentation and proofs (Pedemonte, 2007).

In this paper, through the analysis of a case study, we will show how an abductive process could assume a fundamental role in the production of indirect argumentation. Through an abduction a new statement is produced that has no logical need but allows one to make sense of the absurd and strange proposition and, in this way, to overcome the gap between the contradiction and the *principal statement*.

A CASE STUDY

The following open-ended problem was proposed to Paolo and Riccardo (grade 13), two students that, according to the evaluation of their teachers, are high achievers.

Problem: What can you say about the angle formed by two angle-bisectors in a triangle?

What follows is an excerpt of their interview. After a phase of exploration, the students generated the conjecture that the angle S (figure 1) is obtuse. Afterwards, the students started to explore the possibility that the angle S might be a right angle.

61 P: As far as 90, it would be necessary that both K and H are 90 degrees, then $K/2 = 45$, $H/2 = 45$...180 minus 90 and 90 degrees.

62 I: In fact, it is sufficient that the sum is 90 degrees, that $K/2 + H/2 = 90$.

63 R: Yes, but it cannot be.

64 P: Yes, but it would mean that $K+H$ is ... a square [...]

Figure 1: The angle between two angle bisectors in a triangle.

- 65 R: It surely should be a square, or a parallelogram
- 66 P: $(K-H)/2$ would mean that [...] $K+H$ is 180 degrees...
- 67 R: It would be impossible. Exactly, I would have with these two angles already 180, that surely it is not a triangle.
- [...]
- 80 R: [the angle] is not 90 degrees because I would have a quadrilateral, in fact the sum of the two angles would be already 180, without the third angle. Then the only possible case is that I have a quadrilateral, that is, the sum of the angles is 360.

The episode can be subdivided in three parts: the development of a first argumentation (61-63), the introduction of a new figure, the parallelogram (64-67), the production of the final argumentation (80). This last argumentation is expressed by Riccardo, after the students are explicitly asked to write a mathematical proof.

The argumentation developed in the first part (61-63) is indirect: assuming that the angle between two angle bisectors of a triangle is a right angle, the students deduce a proposition that contradicts a well known theorem of Euclidean Geometry. From the logical point of view, the deduction of the contradiction would be sufficient to prove that this triangle does not exist, or, equivalently, that the angle S is not right, thus concluding the argumentation. But, although convinced that the angle S cannot be a right angle, the students do not feel that the argumentation is concluded and they look for an explanation for the anomalous situation. In fact, the subsequent part (64-67) seems to have the goal to complete the argumentation; in particular, the students seem to look for an explanation to the false proposition " $K+H=180^\circ$ ". An explanation is found by formulating a new hypothesis: the figure is not a triangle, it is a parallelogram. In this case, it is true that the sum of two adjacent angles ($K+H$) is 180. In search of an explanation the original triangle fades becoming for the students an indeterminate figure that have to be determined in order to eliminate the anomalous consequences. In 67, Riccardo makes clear that the figure can be transformed during the argumentation. His expression "*surely it is not a triangle*" means "this figure is not a triangle" and it must be something else. Differently, in a proof by contradiction, as the proof that could arise from the first part of the argumentation (61-64), the figure is well determined, it is a triangle and it is not possible to modify it. Once a contradiction is deduced, it is proved that this figure does not exist. In this case, the triangle would be part of the "false, impossible world" and it would have had a temporarily role: at the end of the proof we know that it does not exist. Actually, it has never existed.

When the new case is selected and because this new case can solve the anomaly, Paolo and Riccardo seem to be satisfied. In 80, Riccardo summarizes the argumentation in what for him is a mathematical proof. The fact that the angle S is not right is not proved by contradiction but is based on the analysis of different cases: triangle, square, parallelogram. The figure is determined, and it is not a triangle, as

we have thought at the beginning of the argumentation. This argument seems very convincing for students, more than the argument based on deriving a contradiction.

The key point in the development of the argumentation is the generation of the new case that is the identification of the parallelogram. This process can be classified as an abduction, in fact an explanatory hypothesis is produced and evaluated, as Riccardo says “[the quadrilateral] it is the only possible case”.

The assumption of the parallelogram transforms a false into a true proposition. This argument allows students to overcome some of the difficulties that might be raised by a proof by contradiction (figure 2). In particular:

Figure 2: An abductive process in an indirect argumentation

- The false proposition - “in a triangle the sum of two angles is 180° ” – becomes a true proposition related to the new explanatory hypothesis (in a parallelogram the sum of adjacent angles is 180°);
- The mathematical object (the triangle) is considered an indeterminate object that is identified only through the abduction with the goal to explain the anomaly. Then the mathematical object is changed and not discarded as it happens in a proof by contradiction. The problem of treatment of mathematical object at the end of proof by contradiction highlighted by Leron (1985) is bypassed.

- Differently to what happens with proof by contradiction, a link, that is not only logical, between the *secondary statement* and the *principal statement*, is constructed: it is not possible that S is right because otherwise the triangle would become a quadrilateral.

As the previous example shows, in geometry, the identification of the case that can explain the anomaly and allow getting out of the “impossible world” seems to be related to the transformation of figures. Most of the students asked to solve the problem of angle bisectors provided arguments based on transforming the triangle in a quadrilateral or in two parallel lines.

Further researches are necessary to corroborate this hypothesis and investigate whether it can be extended to other context. In fact we hypothesize that also in contexts other than Geometry abduction can be for students the key to come out from the anomalous situation that occurs in proof by contradiction. In order to support this extension to other contexts, we report now a short episode concerning the algebra domain.

ABDUCTION AND PROOF BY CONTRADICTION IN ALGEBRA: AN EXAMPLE

In a questionnaire proposed to 68 secondary school students (grade 10, 11, 12) and 19 university students, a proof by contradiction of the incommensurability of the diagonal of a square with its side was presented. We aimed to investigate the recognition and the acceptability of this type of proof. In the presented proof, it is assumed that the ratio is a rational number, expressed by the fraction m/n where m and n are two natural numbers (with n different from 0). Then it is deduced that the number n is both odd and even. The students were asked to choose one of the following answers to explain what it is possible to conclude:

- This is not a proof*
- There is a mistake in some passages, but I can not identify it*
- There is a mistake, that is (specify the error):*
- We have not proved anything, because being even or odd has nothing to do with what we wanted to prove*
- We have proved what we wanted, in fact:.....*
- Other (specify):*

The 25 per cent of the students gave the correct answers and the 35 per cent chose the answer d). This expresses the feeling that something is missing and let us suppose the need to see a link between the contradiction and the statement. A hint in this direction comes from one of the answers. One student (grade 12) marked the correct answer and explained:

“we have proved what we wanted in fact one of the two numbers [the number n] is not a

natural number and then the ratio is not a ratio between two natural numbers”

The argument provided does not refer to what could be recognized as the *meta-theorem*, explaining the logical equivalence between the *principal statement* and the *secondary statement*, and thus rejecting the existence of the mathematical object m/n .

Differently, this student does not reject the initial assumption that the ratio is rational from the contradiction “ n is even and odd”, rather he changes the nature of the number n coherently (in his opinion) with the deduced proposition. If m/n is not a rational number, as we have believed before, everything is explained.

Inferring the explaining hypothesis that number n , odd and even at the same time, is not a natural number is the product of an abduction. The hypothesis that n is not a natural number can explain the anomaly “ n is odd and even” and, at the same time, it offers a link between the deduced proposition and the principal statement: n is not a natural number and then the ratio m/n is not a rational number. A link between the contradiction and the statement is now established and the proof can be accepted.

CONCLUSIONS

Main difficulties with proof by contradiction are related to the link between the contradiction and the statement to be proved, to the treatment of the impossible mathematical objects during the construction of the proof and at the end, to the need of discarding the mathematical objects involved in the proof of the *secondary statement*. The feeling of frustration that may emerge at the end of a proof by contradiction, as clearly expressed by Fabio’s words, is accompanied by the need of giving a meaning to the absurd proposition, the need of establishing a stronger link with the principal statement and adjusting the “false, impossible world”.

The analysis of the episodes proposed above shows how abductive processes may be mobilized to produce explanatory hypotheses. The system of relationships represented in the diagram of figure 2 shows the key role of the abductive process and highlights some differences between indirect argumentation and proof by contradiction.

Interpreting these results in terms of Cognitive Unity leads us to point out the distance between indirect argumentation as it is spontaneously developed and the scheme of a proof by contradiction. In particular, it clearly appears the distance between the *meta-theorem* - providing the equivalence between the *principal* and the *secondary statement* - and the abductive process that might emerge in an indirect argumentation. The question rises whether and how such distance can be filled through an appropriate didactical intervention.

Of course, further investigation is necessary to better understand the differences between argumentation and proof by contradiction and to identify and analyse other processes that could be important for the production and the development of indirect argumentation.

We think that the comprehension of these processes is fundamental for teachers to identify, explain and treat students' difficulties with proof. We also believe that indirect argumentation, even if it presents significant differences with proof by contradiction, should be promoted, in particular through open-ended tasks. As Thompson writes:

“If such indirect proofs are encouraged and handled informally, then when students study the topic more formally, teachers will be in a position to develop links between this informal language and the more formal indirect-proof structure.” (Thompson 1996, p.480)

As regards the transition from the argumentation to proof by contradiction, further researches are necessary to identify the tools to construct the didactical activity to face the gaps and promote the acceptability of method of proof by contradiction.

APPROACHING PROOF IN SCHOOL: FROM GUIDED CONJECTURING AND PROVING TO A STORY OF PROOF CONSTRUCTION

Nadia Douek

IUFM de Nice, UMR – ADEF Université de Provence

This paper presents some aspects of an ongoing research aimed at leading students (through activities of conjecturing, guided construction of proof and story making of the rationale of the proof) to become aware of some salient features of proving and theorems. Theoretical elaboration as well as an example of didactic engineering concerning Pythagoras' theorem will be outlined.

I INTRODUCTION

School approach to theorems has been a subject of major concern for mathematics education in the last two decades. Students' learning to produce proofs and their understanding of what does proof consist in (Balacheff, 1987) have been considered under different perspectives and with different aims: among them, how to make the students aware of the differences between proof and ordinary argumentation (Duval, 1991, 2007); how to favour students' access to the theoretical character of proof (M.A.Mariotti, 2000); how to exploit "cognitive unity" (which for some theorems allows students to exploit the arguments they produced in the conjecturing phase to construct the proof) in order to smooth the school approach to theorems (Boero, Garuti & Lemut, 2007); in what cases of cognitive unity do students meet difficulties in the passage from an inductive or abductive reasoning, to the deductive organization of arguments (lack of structural continuity: Pedemonte, 2007, 2008); what are the common aspects between ordinary argumentation and proving, and how to prepare students to proving by relying on those aspects (Douek, 1999a, 1999b; Boero, Douek & Ferrari, 2008). Previous research work helps us to formulate and situate some educational problems that arise in the school approach to theorems: how to tackle theorems for which cognitive unity does not work, or (if cognitive unity can work) when students meet important difficulties due to the lack of structural continuity? How to make the students aware of some salient characters of proving and proof? And how to lead them into some specific competencies of proving activity? In this paper we propose a possible way to tackle these problems in an integrated way. The idea is to guide students' constructive work on proving, then to help them focusing on the characteristics of the organisation of proof.

This paper presents a theoretical and pragmatic elaboration about how to deal with theorems for which cognitive unity does not work, and approach the rationale of a proof at first stages of proof teaching and learning. The theoretical elaboration also frames the accompaniment of students through two aspects of proving activity: exploration (in order either to find a statement, or to find reasons for validity of a statement); and organisation of reasons (or arguments), in the perspectives of

producing a proof, or of understanding the links between statements or arguments in a proof. Our hypothesis is that the rationale of a proof can be approached early in the school context through “story making” situations, preceded by suitable activities of conjecturing and guided proof construction, and related classroom discussions. We provide an example of such a didactical engineering concerning Pythagoras' theorem.

II FRAMING PROOF CONSTRUCTION

Inspired by Lolli's analysis of proof production (see Arzarello, 2007), we consider proving as a cognitive, culturally situated activity engaging four modes of reasoning:

1) Heuristic exploration. It occurs when one tries to interpret a proposition or to produce a proposition or an example. One has in mind a target but the main focus is not on attaining the target through an acceptable mathematical reasoning. Any accidental event, writing, metaphor, may move the exploration activity. This type of reasoning is typically open to divergent paths.

2) Organisation of reasoning, making explicit the threads of reasoning holding propositions together. When a proposition seems pertinent, a calculation promising, a writing efficient, one searches for a convincing coherent link to a local goal or to the global one. The links may be theoretical reasons of validity. The intentional and planning characters are typical of this mode, and abduction is a good example of it. Deductive reasoning is not yet a priority. Such organisational intention may concern partial arguments or the whole of the argumentation aimed at proof construction.

3) Production of a deductive text following mathematicians' norms. Once ideas of proof are brought to light, they must be organised in a deductive reasoning.

4) Formal structuring of the text, to approach a formal derivation. This mode will not at all be approached in the school context we are considering.

These four modes could be considered as successive phases of a proof construction, as different moments with different intentions. But in fact, as reasoning modes, they seldom do appear separately. Not only the succession of modes can vary and loop, but even two or more of them may intervene very closely in one phase aiming mostly at exploring or at writing a deductive text, for instance.

Methodologically, the consideration of these phases based on a cognitive analysis in terms of the four modes offers didactical tools to organise teaching-learning situations into sequences with clear didactical goals. As we refer to phases of predominant modes of reasoning, a didactical goal can be to lead the students to be aware of the processes they have to go through within a specific phase, essentially to favour students openness in exploration and their rational control in organising reasoning. But no exploration is blind nor any reasoning organising is totally controlled: when we analyse a phase of exploration activity, we ought to capture some reasoning organising activity, etc... (see sequence 1, in V).

The different modes and phases of reasoning involve several cultural rules of validity,

and they affect the delicate game of changes from what is allowed or even needed for one mode, to what is allowed or needed for another. For instance abductive reasoning is typical of mode 2 but is not allowed in modes 3 and 4, and student will have to move from it towards deductive reasoning, which is not easy. We can also consider the use of examples (pertinent in mode 1 and 2 but not acceptable in modes 3 and 4), and the conscious handling and conversion of different semiotic registers according to different modes of reasoning (Morselli, 2007; Boero, Douek & Ferrari, 2008).

This analysis leads us to give a special role to argumentation both as an intrinsic component of reasoning, and as a didactical tool to manage the different modes of reasoning and the relationships between them in a conscious way, keeping into account specific cultural rules (to be mediated by the teacher).

III ARGUMENTATION IN PROOF AND PROVING

In this paper, an "Argument" will be "A reason or reasons offered for or against a proposition, opinion or measure" (Webster), including verbal arguments, numerical data, drawings, etc. An "Argumentation" consists of one or more logically connected "arguments". Proof itself is an argumentation. But other argumentations play an important role in proving. Mode 2 is specially based on argumentative activity: discussing the use of a theory or a mathematical frame to produce a step of reasoning relies on a meta-mathematical argumentation (Morselli, 2007). It is not really part of a proof, but is needed to produce it. Analogies may implicitly affect mode 1 reasoning or be explicit arguments in mode 2 (Douek, 1999a, 1999b).

For teaching and learning purposes, argumentation is a fruitful means to control the validity of reasoning (as the legitimate use of examples and, or transitions from one mode of reasoning to another with their different cultural rules). We are therefore interested in two levels of argumentation: as part of the proving tasks, specially for producing and organising arguments (mode 2); and in discussing procedures, as a means to assimilate and master elements of proving processes.

Convergent structure of argumentation in a proof

In general, an argumentation is made of more elementary ones that may be organised in various ways (converging towards a conclusion, or being parallel as when producing different explanations, etc.). In a proof, the elementary argumentations may form a linear chain, each conclusion being input as an argument for the following argumentation, thus forming one whole "line of argumentation". But in many cases of proof, argumentation may contain parentheses "blocks", or side argumentation branches that meet the main line to input a supplementary data or argument. A parenthesis might be considered as a secondary line of argumentation. This description underlines the possible hierarchical relations between various argumentations involved in a proof (Knipping, 2008), which is a difficult matter for students who are being introduced to proof (see the Example for a suggestion).

IV EDUCATIONAL ASPECTS

In the early stages of proof teaching and learning, students can be smoothly introduced to theorems and proofs by conjecturing and proving activities provided that cognitive unity works (Boero, Garuti & Lemut, 2007). In particular exploratory activity (Mode 1) and justification (Mode 2) can be introduced at early stages. In a suitable educational environment, 7th and 8th graders are able to produce conjectures for non trivial arithmetic or geometric situations, and move (under a loose guidance by the teacher) towards constructing general justifications. Comparison of students' productions and classroom discussions about them, orchestrated by the teacher (Bartolini Bussi, 1996; Bartolini Bussi & al, 1999) allow students to appreciate some relevant cultural requirements of conjectures and proofs, like their generality and the conditionality of statements (Boero, Garuti & Lemut, 2007), and to become aware of processes favouring conjecturing and proving.

In the following we will focus on mode 2 reasoning, specially in the organisation of reasoning phases; then in the didactical engineering we will also consider mode 1 more specially related to conjecturing.

In spite of their usefulness to initiate students into conjecturing and proving, in those cases in which cognitive unity works well, with no difficulties due to the lack of structural continuity (Pedemonte, 2007, 2008), the peculiar argumentative structure of a proof does not emerge as an object of reflection for students. Indeed the fact that both easy-to-prove theorems must be proposed for a smooth approach to theorems, and that the students themselves are able to enchain the arguments in an autonomous way, make artificial and rather empty the discussion about the specific argumentative arrangement of those arguments. However students must be enabled to move from theorems for which cognitive unity works to theorems (like Pythagoras') for which proof cannot consist in the deductive arrangement of arguments produced by conjecturing. For other theorems students can meet difficulties in moving from creative ways of thinking (abduction, induction) typical of conjecturing to deductive arrangements of the produced arguments (Pedemonte, 2007). In both cases proving needs a strongly guided activity; and teachers' guidance can even initiate students into the mechanisms inherent in the Mode 2 reasoning, and open the perspective of Mode 3. Drawing from theoretical reflections, we make the hypothesis that the inherent argumentative activities could be promoted through debates (with real others) about arguments and their relations on one side, and story making on the other.

The debate

Classroom debates, if well oriented and guided, stimulate efforts of expression and explanation. These efforts, in turn, favour the consciousness of the logical rules and their range of validity. For instance, discussing a statement may bring students to methodological and meta mathematical reflections such as: producing an example to support the statement can be an efficient step in the exploratory phase, but is not a valid argument when organising a general mathematical justification; some semiotic

registers (like drawing) are crucial for exploration, and may be for organising reasoning, but insufficient to produce a suitable argument in a deductive reasoning. Such discussions question cultural rules of mathematical reasoning and mathematical knowledge too. Also the relation between arguments and the construction of lines of argumentation (mode 2) can be discussed in a debate, which draws students' attention to the goal of the line of argumentation in relation to its steps.

Making a story

Logic is concerned not with the manner of our inferring, or with questions of technique: its primary business is a retrospective, justificatory one - with the arguments we can put forward afterwards to make good our claim that the conclusions arrived at are acceptable because justifiable conclusions.

This quotation from Toulmin (1974, p. 6) inspires the hypothesis that in order to grasp the rationale of a proof, students may make an individual story from the ideas and calculations involved in a reasoning that validates the statement. We emphasise the story that connects steps and fragments with reasons, in order to serve the conclusion, and not particularly the story of how the steps occurred in one's mind (Bonaffé, 1993), nor of how learning has evolved through time (Assude & Paquelier 2005). The goal is that the students recognise the involved lines of argumentation, their possible hierarchical relations, and their role in the logical combination that produces the proof. At least at first stages of proof learning, these individual story makings need to be prepared by suitable tasks of guided construction of proof and by related debates putting into evidence some crucial "steps" of Mode 2 reasoning.

In our theoretical construction, debates and story makings should be considered together and arranged as a dynamic system of complementary situations. Individual story making involves students in an active personal reconstruction of the rationale of a proof, while a debate on the work done in individual tasks of conjecturing and guided proving (and story making as well) offers both openness to other possible combinations and regulation. We expect this system to draw students' attention to the "components" of the story. The deductive structure of the proof (through mode3) will consist of a particular relating of the pertinent components of a story.

Students need to be gradually initiated in both activities, possibly before the activities on theorems in order to establish a suitable didactical contract (Brousseau, 1986). However story making, in the case of theorems, shows particularities that need a careful mediation through sequencing suitable tasks.

Before illustrating the above theoretical reflection by an example, let us present the main activities we wish students to develop and their co-ordination, and give methodological precisions concerning the planned experiment:

- To associate exploration and conjecturing to enhance mode 1 (without excluding other modes).
- To stimulate proving the conjecture(s); either cognitive unity can work and thus the

students are able to produce a proof, or it cannot work and the teacher offers a task to guide them towards the proof.

- To engage the dynamic system of collective debate / individual story-making, starting from discussing some of students' productions, to enhance mode 2 (without excluding other modes). In case cognitive unity could not work, students would not be in a good condition to understand the proof nor to learn much of it, and this dynamic becomes particularly crucial.

The analysis of the experimentation should concern: Students' engagement in the proposed activities; and the evolution and the differences between the various individual productions. Observing the discussion (or its video registration), we need to track: How student's individual production reappears in the collective discussion; how the student hold his/her position in front of other's, and if some elements of consciousness awakened during discussion. However, some students may not take active part in the debate. The final individual production of story telling that follows should help completing the analysis. Comparing this individual production with the previous one (proof construction or proof reconstitution), one can see if the debate helped to bring to consciousness the necessity of some types of reasoning and the necessity of avoiding some others. The form of storytelling may reveal hierarchies of the types of reasoning and more particularly the linearity of the argumentation.

Another slightly different proving situation might follow to examine: transfer of the various reasoning competencies; the various methods; and the level of awareness of the variability of rules of validity.

V AN EXAMPLE CONCERNING PYTHAGORAS THEOREM

Pythagoras theorem was chosen for two reasons: it is an important and early met theorem in school mathematics; and it is not difficult to get the conjecture through a loosely guided path, while the construction of a proof needs a strong guidance by the teacher (cognitive unity cannot work, because the geometric constructions needed for the usual proofs are not suggested by the work done in conjecturing). Teachers' guidance, classroom discussions and story making will allow students to approach the rationale of the proof and offer occasions for learning about proof and proving.

First sequence: “Discovering” Pythagora's theorem, expressing the conjecture and making sense of it

Students have not only to grasp the theorem, but also to develop some proving skills (though no proving activity is demanded in this phase) and prepare for the further work; thus the activity on Pythagoras' theorem is prepared by Task 1 (an individual production on another theorem), followed by classroom discussion:

Task1: Consider the statement: "In a triangle of sides a , b and c , $a+b$ is always smaller than c ". Is it true? always? Why? Prepare yourself to explain how you checked it and why you think it is true, or it is not, or what makes you doubt.

No triangle is presented by the teacher; students are encouraged to draw some triangles for a check, if they did not do it spontaneously. This task aims at exploration through testing examples, and (specially in the discussion) at leading the students to express the rationale of the activity and to make visible the generality of the proposition they produce. An expression like “we wanted to see if it is true that... so we tried to verify it with four examples” is encouraged: such simple story making reflects an ability (and invites) to reconstruct the logical skeleton of the activity they went through. It bridges a Mode 1 reasoning with a Mode 2, and prepares Task 2.

Task 2 (individual): Now if we consider the squares of the lengths, instead of the lengths themselves, the situation is different. See if a relation between the squares of the lengths of the sides of a triangle exists. Once you think you produced a valid statement (a "conjecture"), put it clearly in words to explain it to other students.

Right angled, acute and obtuse triangles, are presented on the worksheet. Afterwards a collective discussion guided by the teacher is engaged to share and discuss the conjecture(s) produced, and the ways followed to produce them; and to attain and share acceptable expressions of the conjecture(s) (according to mathematical standards). An incomplete conjecture or an erroneous one may offer fine opportunities to make explicit the important elements of the theorem (in particular the condition of validity of Pythagoras' theorem, i.e. the angle being right) and their role.

Task 3 (individual): Write down the conjecture as now you think it should be. Explain it and illustrate it with some examples.

The teacher concludes with the standard formulation of Pythagoras' theorem.

Concerning proof learning, this first sequence aims at involving students in Modes 1 and 2: Exploring (drawing, measuring, calculating, induction when modelling and producing algebraic expressions, repeating procedures and modifying data) mostly in mode 1; and, mostly in mode 2, organising the exploitation of the gathered data, classifying them in order to find some rule, expressing results as general (everyday language being acceptable), etc; discussing and justifying propositions, and organising the steps of exploration in relation to a goal. Classifying and modelling are as much in mode 1 and mode 2. The explicit intentions of exploration and of organisation are satisfying sign in my opinion, as a main didactical goal is to enhance the processes students have to go through.

Second sequence: Guiding Pythagoras' theorem proof, and teaching/learning to organise the steps of reasoning into lines of argumentation

Given that cognitive unity cannot work, students are guided by means of individual and collective activities; then they reconstruct the lines of argumentation.

Task 4 (individual): Here we study the proof of the theorem we have conjectured, you will be guided towards this proof. Consider a right angled triangle with sides a , b , c . We use it to build the square A (see below). Its central square S is of area c^2 .

I) Can you describe how A can be obtained by using only our squared triangle? explain why S is a square (of area c^2)?

II) Try to write the area of A in two different ways (you may need to arrange the four identical square triangle differently). Find and explain the two ways.

III) How can this help us to validate our conjecture?

A geometrical reasoning is expected to intertwine with an algebraic reasoning in order to attain the equality between the areas. If needed, some supplementary tasks can be inserted either for the whole group or for some students.

After students' individual work, the teacher orchestrates a collective discussion (Bartolini Bussi, 1996) concerning the reasoning that allows to prove the steps of argumentation and the calculations and why they are needed, and in particular, the connection between geometrical arguments and algebraic arguments. The interactions must be based on their own reasoning productions, their insights and their shortcomings. Therefore the teacher selects elements of students' production to provoke fruitful interactions. Two complementary levers can help maturing students' awareness of the reasoning organization "rules", and their specificity in contrast to exploration reasoning: analyzing elements of reasoning, and rising direct methodological questions in the debate. The aim is to favor the elaboration of some satisfactory reasoning about the quality of which the student may agree, and, on another hand, to characterize some insufficiencies found in some produced reasoning. The parts of debate concerning specific algebraic or geometric steps and some sort of gap filling reasoning (directly concerned by the activity) need to be intertwined with methodological reflection about the validity of a reasoning, its communicability, the bases on which it can be accepted by another (indirect, implicit activity in student's individual production). Open "methodological" questions may be: how exploration and induction had been produced (algebraic induction); which different rules allow a reasoning to be valid (in exploration, measures and experiment are welcome, in proving deductive reasoning is needed, here based on elementary geometry and on algebraic calculus); and, in reasoning organization, how to come to such reasoning, and why (in particular how exploring the disposition of the four rectangles may favour algebraic exploration). This double level of discussion concerning the activity, on one hand, and the meaning and mathematical rules of the activity, on the other, is theoretically developed by M.A.Mariotti (2000) based on M.Bartolini Bussi's mathematical discussion theoretical frame.

Task 4 is formulated and organised in a way to approach a story making of the proof.

The subsequent discussion of the organisation of the lines of argumentation and the insertion of "blocks" of arguments/calculations in the main line is meant to prepare students to write a "story".

Third sequence: story making

Task 5 (individual): Write down how you organized your steps of reasoning to reach a general justification of the conjecture, and justify why those steps are important

This task is particularly important for the students who were not productive in the previous sequence. It should allow them (as well as the others) to grasp and reconstruct the rationale of the proof. Here is the kind of arguments we hope the students produce:

first (*block 1*) we calculate the area of A, then (*block 2*) we organised differently the calculation of the area (or we organised differently the disposition of the triangles) so that we found another algebraic expression of the are, because (*looking forward to the final goal*) surface measures of squares are written as algebraic squares. So we think that a^2 , b^2 and c^2 will appear and will be related (*possibility to rejoin the main line*). So, we can write the algebraic equality, and find the relation after transformations.

Mode 2 reasoning is needed for this task in block 2: students must go through an abductive reasoning ("how can I find a^2 and b^2 in this big square?") while deduction prevails in block 1 and will prevail afterwards, till the end.

It is important to notice with the students that the algebraic equality is the principal aim (and first to come to the mind, since it is near to the conclusion we want to reach) but that we have to begin with geometrical considerations, which are like parentheses besides the principal aim. Thus the reasoning is made of a principal line of argumentation and side parentheses involving geometrical reasoning and calculations, whose conclusions flow into the main argumentation line. Getting familiar with mathematical proof practices (like moving from a geometrical frame to an algebraic one, using geometry only for strategic purposes...) is a particular aspect of this work.

Difficulties inherent in the classroom implementation of the proposal

Comparing the proposal with the style of teaching of most teachers, and keeping into account my first experiences of work with teachers on this subject, I must say that teachers meet some difficulties in engaging in a coherent classroom implementation of the proposal. One difficulty consists in the fact that "To produce a conjecture" is a task that does not fit the most frequent didactical contract in our schools (statements are usually presented and illustrated by the teacher, and learnt by students who repeat and apply them afterwards; the same for proofs). Another is that teachers tend to identify student's task of reasoning and the task of explaining the rationale of a reasoning as bearing the same learning targets. And, finally, the presentation and management of the tasks in a way that guides students' work but does not prevents

creativity is not easy; however, if creativity is not practised, there would be no sense in making a story out of a series of calculations.

INTRODUCTION

ON “STOCHASTIC THINKING”

Andreas Eichler, Universität Münster, Germany

and

Maria Gabriella Ottaviani, “Sapienza” University of Rome, Italy

Floriane Wozniak, University Lyon, France

Dave Pratt, University of London, England

OVERVIEW

The Working Group 3 discussed 8 three aspects that reflect the diversity of the research approaches on stochastic thinking:

- theoretical issues of stochastic thinking,
- teachers' professional development, and
- students' learning in respect to their success in solving stochastic tasks.

The connective aim of all approaches was the students' learning of stochastic concepts, and the students' awareness that it is possible to use stochastics to cope with specific real situations. These aspects of the students' stochastic literacy (for the term statistical literacy see Gal, 2004), however, were discussed using three different perspectives, i.e. the stochastic content (C), the teaching of stochastics (T), and the students' learning about stochastics (S), that shape a didactical triangle referring to stochastics instruction.

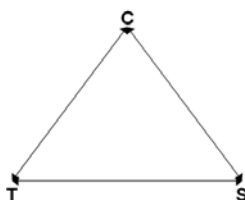

Figure 1: Didactical triangle involving three different perspectives on stochastics instruction, i.e. the content, the teachers, and the students

In the following we will introduce the papers that match one of the three perspectives, and we will sketch some results of our discussion.

STOCHASTICAL CONTENT

Stochastics is a cocktail of statistical ideas and probabilistic ideas. Although the latter thesis seems to be trivial, there is a lot of evidence that the emphasis on statistics and probability in curricula varies, often according to knowledge and feelings of the teachers. In the same way, the topics of interest to researchers vary over time.

Currently the focus of research concerning statistics is, for instance, on distributions, averages, variability (including informal inference, and co-variation and correlation), and graphs (Shaughnessy, 2007). Concerning probability the research focus is on random, sample space, and probability measurement (Jones, Langrall, & Mooney, 2007).

The research referring to these subjects has two aims:

- to clarify the notions, meanings or definitions of stochastic concepts. In our group, for instance, the talk of Hasan Akyuzulu deals with the undefined concept of risk highlighting the connection between risk and defined stochastic concepts.
- to develop and to evaluate teaching approaches that facilitate students' learning in respect to the different stochastic concepts. Matching this aspect, Herman Callaert discusses in his paper obstacles of the students' learning that emerge through ambiguous notations and explanations of stochastic concepts in widely-used text books and software.

Concerning the aspect of stochastic content, we, finally, discussed the recommendation of professional organisations regarding stochastics instruction. To this aspect, Irini Papaieronimou identifies in her paper many recommendations about the teaching of probability from four US professional organisations. We are concerned that there is insufficient support to effect a didactical transposition. Further, we noted an omission: such recommendations do not include the need for teachers to understand what it is that students know (as opposed to misconceptions).

TEACHING OF STOCHASTICS

A repeated claim towards the research on stochastic thinking is to increase the effort of investigating the teachers' knowledge and the teachers' beliefs concerning stochastic concept, and the learning and teaching of stochastics (Shaughnessy, 2007). According to this claim, we discussed two research approaches that concern both, the stochastics teachers' knowledge, and the stochastics teachers' beliefs.

- Carmen Batanero, Pedro Artega, and Blanca Ruiz discuss in their paper the knowledge of prospective primary Spanish teachers referring to statistical graphs based on the theoretical Framework of Curcio (1989). They found that some of the teachers were unable to use even basic statistical graphs, and that, in fact, only one third were able to draw a reasonable conclusion.
- the paper of Andreas Eichler refers to an analysis of "ordinary" upper secondary teachers' planning of stochastics instruction, the teachers' classroom practice and their students' learning. His report focus on teachers having differing orientations across two dimensions: seeing mathematics as: (i) emphasising applications or a formal subject; (ii) being dynamic or static.

The report gives some evidence about different modes of students' learning concerning their awareness of the benefit of stochastics in the real life.

We concluded on the one hand, that the teaching of stochastics needs to offer students experiences of statistics and probability before theoretical perspectives are introduced. On the other hand, we stated that there is much research to do to understand the teachers' knowledge and the teachers' beliefs about stochastics that both in some sense determine the students' learning of stochastics.

LEARNING ABOUT STOCHASTICS

Finally, we discussed three considerably different research approaches focusing students' learning in respect to their success in solving stochastic tasks.

- The paper of Zoi Nikiforidou and Jenny Page provides a psychological experiment on children (age 5 or 6 years), in which the children made decisions based on posterior information. The results of this research give some evidence that even such young children have some understanding of ideas that may be the roots of probability or inference. This result argues against the Piagetian framework.
- The paper of Theodosia Prodromou and Dave Pratt concerns students (15 years of age) using a computer simulation. This research yielded that it was possible to design a computer simulation such that students were able to make use of ideas about causality to make sense of distribution. In this sense, the deterministic and the stochastic worlds are not disconnected but connected through levels of complex causality.
- Finally, Sofia Anastasiadou provides in her paper a study referring to children's meaning-making with respect to set theory. She found that the students were not able to recognise the mathematical concept across differing representations. Perhaps the lack of transfer could be attributed to the students lack of preparation: time to discuss, interact and work on related tasks.

Although the papers focusing on the students' learning match some of the claims to the research into stochastics education, the three research approaches mentioned above showed the diversity of possible research questions in this field.

CONCLUSIONS

The papers of Working Group 3 highlighted the diversity of research approaches focusing on stochastic thinking. However, we concluded with three claims for future research that often combine several perspectives on the teaching and learning of stochastics that shape a didactical triangle (fig. 1):

- We need empirical results that give evidence, how we can support the implementation of recommendations from professional organisations.

- We need empirical based strategies we support teachers to be more connectionist in their approach.
- We need to research how students can transfer ideas from one domain to another. Reference could be made to connectionist theoretical frameworks.

One of the problems to achieve these claims is that it is sometimes not possible to transfer results yielded into mathematics education on stochastics education due to the fundamental difference of stochastics in contrast to other mathematical disciplines. For instance, the role of context is very different in statistics from in mathematics. Mathematics as a discipline aims to be decontextualised whereas statistics may draw on context. However, in both mathematics and stochastics learning, the students must experience the underlying ideas in meaningful contexts.

Another problem seems to be that stochastics instruction in Europe still emphasise probability, and, for this reason, studies in the field of stochastics education often focus on probability. Hence, we hope to see more research in statistics in future conferences of the ERME. Otherwise, we are afraid that statistics will be lost from CERME. But also, we as educationalists fear this might parallel a loss of statistics to mathematics education.

However, stochastics and, in particular, statistics are certainly useful to many subjects and to citizens in general but it is also important to mathematics education.

CHANCE MODELS: BUILDING BLOCKS FOR SOUND STATISTICAL REASONING

Herman Callaert

Center for Statistics, Hasselt University, Belgium

herman.callaert@uhasselt.be

A good understanding of chance models is crucial for mastering basic ideas in statistical inference. Mature students should be introduced to the concepts of inference through a study of the underlying chance mechanisms. They should learn to think globally, in models. In an introductory course, these models should have their own clear and unambiguous notation. Fuzziness and flaws, as encountered by our students in textbooks and software, may hamper their learning process seriously. The above claims are based on my experience as an instructor for university students. They should be substantiated by systematic research on the potential advantage of “thinking in models”, possibly also for younger pupils.

INTRODUCTION

From my experience as a teacher of statistics, thinking in models is a stumbling block for many mature students when they are confronted with the basic concepts of statistical inference. As long as students do not master the connection between underlying chance mechanisms and statistical conclusions, procedures like the construction of confidence intervals remain “black boxes”. The main problems with confidence intervals have been discussed in a previous paper (Callaert 2007) where the ability of “thinking backwards” was shown to be essential. After seeing the data, the main question was: “how did those data come to me?” This is a question about an underlying probability model as an ideal mathematical construct for modelling outcomes in a physical world. Those models are the main theme of the current paper.

This paper has two parts. It first shows how mathematical mature students can be introduced to chance models at all places, from populations over samples to statistics. A simple example illustrates how the models are built. It points at the same time to the fact that a clear and unambiguous notation is crucial for acquiring clear and unambiguous insight. Students discover the need for distinguishing a population mean from a sample mean, or an “observable” chance model from an “unobservable” but fixed parameter. Many of the inaccuracies found in research papers, textbooks and software packages have their origin in a lack of insight in underlying chance models. Some examples are given in the second part of this paper.

The current text is focused on mathematical mature students (using explicit mathematical notation). The underlying concepts however are very fundamental and it certainly is worthwhile finding out what can be done with younger pupils. Research

by Prodromou (2007) and Prodromou and Pratt (2006) is most interesting in this respect. They look at the connection between a *data-centric* and a *modelling* view on distributions, and write that: “*The modelling perspective reflects the mindset of statisticians when applying classical statistical inference*”. How and at what age can the connection with statistical inference be made?

THE POPULATION AS A CHANCE MODEL

From the very start, it is important that pupils not only are interested in “what” comes to them but also in “how” it comes to them. When they are allowed to build their own chance mechanisms, it is clear that (after some time and some experiments) they focus on both aspects. Nice examples can be found in a variety of research papers, such as in the study carried out by Pratt (1998) where children are able to manipulate “the underlying chance mechanism” (workings box). Another example is described in a paper by Cerulli et al. (2007) where they write:

The Random Garden is a microworld, for representing random extraction processes. The tool consists of a sample space (the *Garden*) a *Bird* and a *Nest*. When the user gives a number to the *Bird*, a corresponding number of objects is extracted (with repetitions) from the *Garden* and deposited in the *Nest*

In that study, one team of pupils creates not just a Garden but a *Random Garden*. This means that the pupils not only think about the composition of the garden (the flowers and trees) but they also know that the *Bird* will extract objects “at random and with replacement”. A competing team of pupils has to guess the *Random Garden* after they have inspected a *Nest*. That the objects in the *Nest* came “at random and with replacement” is key information and it is used (rather implicitly) by the competing team when they look at bar graphs and counters. One of the important consequences of the setup of this study is that pupils start discussing (and understanding) the concept of “equivalent chance mechanisms” (called equivalent gardens). If the study would have been set up differently, with the same flowers and trees but with a *Bird* that extracts objects not at random or without replacement, the “*Guess my Garden Game*” would have been completely different. This aspect might be stressed even more in such types of studies since it is important to find out at what age pupils are able to “think in models” and what kind of strategies can be used for enhancing (and evaluating) this type of thought-processes.

The above examples refer to studies with younger pupils (such as 11-12 years old). At a later stage the concrete objects in populations (such as flowers or colored

segments) are replaced by numbers. But the basic question about a population stays unaltered: “which numbers will come to me and with what probability?” For mathematical mature students, comfortable with abstract notation, it is helpful to make a distinction between a chance model and its outcomes. In line with the notation for random variables, a chance model can be denoted by a capital letter (such as X) and outcomes by the corresponding small letter x . An example of such a “population chance model” is what I call a *red die*. Physically, it is just a regular die (falling on each side with probability $1/6$) but the numbers on the faces have been changed. There are 3 faces with a 1, 2 faces with a 3, and one face with a 6. The way in which outcomes from this population appear is governed by a throw of this red die. Hence, one will never see a number 2 but, for example, one will get a number 3 with probability $2/6$, denoted as $P(X=3)=2/6$. The next table gives complete information about this population X .

x	1	3	6
$P(X=x)$	$\frac{3}{6}$	$\frac{2}{6}$	$\frac{1}{6}$

Table 1. The population X described by its chance model

Remark that also in the continuous case it is customary to describe a population by providing at the same time the range of the values and their chance behavior, as reflected by statements like: “we work with a normal $N(124;16)$ population”.

THE SAMPLE AS A CHANCE MODEL

Once students get used to look at populations from the perspective of chance models one would think that the step towards looking at a sample from the same perspective is straightforward. For most of my students, this was not evident. The following (simple) example became a real eye-opener for many of them.

What happens when one takes a sample of size $n=2$ from the population X described in table 1 (the *red die*)? The main point here is that students have to answer the question *before* they actually take the sample. Hence, the question: “What will be the result of the first draw?” is not answered by “How can I know?” (reasoning only about specific outcomes *after* an experiment has been carried out) but by “I can tell you, *beforehand*, every possible value together with its probability”. And then of course it is not difficult to come up with the chance model X_1 for the first draw. The second draw X_2 has the same behavior.

x_1	1	3	6
$P(X_1=x_1)$	$\frac{3}{6}$	$\frac{2}{6}$	$\frac{1}{6}$

Table 2.

x_2	1	3	6
$P(X_2=x_2)$	$\frac{3}{6}$	$\frac{2}{6}$	$\frac{1}{6}$

Table 3.

A model for a sample of size $n=2$ now follows easily from tables 2 and 3. The model is denoted by (X_1, X_2) and its outcomes by (x_1, x_2) . It is instructive for students to construct this model for themselves arriving at table A1 (appendix) or at an urn model with random draws from the urn (figure 1).

The insight that a sample result (x_1, x_2) is nothing but one of the possible outcomes of an underlying chance mechanism (X_1, X_2) is very important. It creates the appropriate context for a proper understanding of the behavior of the sample mean (or of any other statistic constructed from a sample).

Figure 1.

THE SAMPLE MEAN AS A CHANCE MODEL

Continuing the above example, it takes just a few minutes to find all possible values of the sample mean together with their corresponding probabilities (see table A2 in the appendix). This leads to the following model:

\bar{x}	1	2	3	3.5	4.5	6
$P(\bar{X} = \bar{x})$	$\frac{9}{36}$	$\frac{12}{36}$	$\frac{4}{36}$	$\frac{6}{36}$	$\frac{4}{36}$	$\frac{1}{36}$

Table 4. The sample mean $\bar{X} = \frac{X_1 + X_2}{2}$ described by its chance model

Simulation tools might be extremely useful for learning statistical concepts but it is my experience that mature students (and secondary school mathematics teachers) also need an explicit confrontation with the more abstract tool of “thinking in models”. For many of them, the behavior of a sample mean is better understood in the context of chance models like table 4 than through the experience that a simulated bar chart or histogram is an approximation of a so-called sampling distribution. Properties like: “the mean of the sample mean is the population mean” can be discovered through simulations, but a clear view on underlying models surely can enrich insight in this discovery. In either case, an unambiguous notation is needed as a support to students for distinguishing populations from samples, and chance models from their outcomes. The next sections illustrate some problems.

EXAMPLES FROM TEXTBOOKS

During the past couple of decades reform in statistics education at the school level has been extensive in the United States. It has resulted in the production of new textbooks by authors such as: Yates, Moore and Starnes (2003) [YMS], Watkins, Scheaffer and Cobb (2004), Agresti and Franklin (2007), and many others. All these

books use capital letters (such as X) for random variables and small letters (such as x_1, x_2, \dots) for their outcomes. This is nice since this notation makes a clear distinction between an underlying chance process and a particular outcome. But once students start sampling, their attention is drawn to particular outcomes and the notation for underlying models, such as (capital) \bar{X} for the sample mean, is gone. Paul Velleman, author of *ActivStats*, says: “*Convention in the introductory course is to emphasize the observed values, which are usually not thought of as random. Every text I know uses a lower case \bar{x} to represent the sample mean. The r.v. version is a hypothetical construct of which the sample mean at hand is one realization. A bit sloppy at times, but, I think, less confusing for students*” [(1999) personal communication]. The experience I have with my students tells me the opposite. On p.525 of [YMS] one reads: “The sampling distribution of \bar{x} describes how the statistic \bar{x} varies in all possible samples from the population. The mean of the sampling distribution is μ , so that \bar{x} is an unbiased estimator of μ ”. The fact that \bar{x} stands for an outcome while at the same time it is said that \bar{x} is unbiased is confusing. The problem persists in the chapter on hypothesis testing where one reads on p.568 that $\bar{x}=0.3$ and that $P(\bar{x} \geq 0.3)$ is needed for computing the p-value. But probability statements are

statements
about chance
processes.
Hence, the p-
value is the
probability

In Example 10.9 the observations are an SRS of size $n = 10$ from a normal population with $\sigma = 1$. The observed mean sweetness loss for one cola was $\bar{x} = 0.3$. The P-value for testing	$H_0: \mu = 0$
	$H_a: \mu > 0$
is therefore	$P(\bar{x} \geq 0.3)$

that (under the null hypothesis) the chance process \bar{X} generates values which are at least as large as the observed outcome \bar{x} . Notation is crucial here and the above phrase should be written as $P(\bar{X} \geq \bar{x})$. If $\bar{x}=0.3$ in the sample of one student while $\bar{x}=0.4$ in the sample of another student, they now can start with the same notation $P(\bar{X} \geq \bar{x})$. Afterwards, they only have to plug in their \bar{x} -value for arriving at $P(\bar{X} \geq 0.3)$ [or at $P(\bar{X} \geq 0.4)$] as meaningful expressions.

EXAMPLES FROM SOFTWARE

Software can provide powerful educational tools and can create unique opportunities for gaining insight in statistical concepts. This is not only true for our students but also for adults who (sporadically) need to carry out a statistical analysis. At those instances, people often use their favorite package as a fast resource, both for ideas and for computations. From a “statistical literacy” point of view, one would hope that statistical information encountered in widespread packages is clear and accurate.

Excel

When your student says that, in a one-sided two-sample t-test, the null hypothesis assumes that the two means are equal and the alternative hypothesis says that one

mean is larger than the other, you might be willing to consider the answer as correct. But when he writes $H_0: \bar{x} = \bar{y}$ versus $H_1: \bar{x} > \bar{y}$ you can't believe your eyes. In his notation, he tries to find out whether the mean in his first sample is larger than the mean in his second sample $\bar{x} > \bar{y}$ instead of investigating whether the mean of the first population is larger than the mean of the second population $\mu_1 > \mu_2$. This type of confusion has been present in Excel for decades. Several versions in the nineties had in their "Data Analysis Toolpack" a help file called "Learn about the t-test: Two Sample Assuming Equal Variances Analyses". What you could learn was as follows. "This analysis tool performs a two-sample Student's t-test. This t-test form assumes that the means of both data sets are equal; it is referred to as a homoscedastic t-test. You can use t-tests to determine whether two sample means are equal". Apparently, when you have two datasets you can use the Data Analysis Toolpack in Excel for finding out whether \bar{x} equals \bar{y} . And you can do so at some alpha level, as follows. "Enter the confidence level for the test. This value must be in the range 0...1. The alpha level is a significance level related to the probability of having a type I error (rejecting a true hypothesis)". There is no clear distinction between a null and an alternative hypothesis (which is *the true hypothesis* to be rejected?) nor is there any reference to underlying populations. This type of fuzziness is disturbing. Attention to these problems has been drawn at several occasions, even in a publication (Callaert 1999). Change however is slow and confused. In Excel 2003 as well as in Excel 2007 it depends on the order in which you call for help. Press F1 (Help), type the phrase Data Analysis and click Search. Then click on Data Analysis and in the new window click on t-Test. The following text appears.

This analysis tool performs a two-sample student's t-test. This t-test form assumes that the two data sets came from distributions with the same variances. It is referred to as a homoscedastic t-test. You can use this t-test to determine whether the two samples are likely to have come from distributions with equal population means.
Hypothesized Mean Difference Enter the number that that you want for the shift in sample means. A value of 0 (zero) indicates that the sample means are hypothesized to be equal.
Alpha Enter the confidence level for the test. This value must be in the range 0...1. The alpha level is a significance level that is related to the probability of having a type I error (rejecting a true hypothesis).

But if you click on Formulas → More Functions → Statistical → TTEST → "Help on this function", then you can read about equality of *population means* together with a choice of using either a one-tailed or a two-tailed t-distribution.

Tails specifies the number of distribution tails. If tails = 1, TTEST uses the one-tailed distribution. If tails = 2, TTEST uses the two-tailed distribution.

Fathom

Never before I've worked with Fathom, so I only can give some first impressions by a novice (having downloaded a Fathom Evaluation Version 2.1). The fact that I was lost right from the start might be blamed on my inexperience. I think however that the rather abstract structure of Fathom working with "collections", "attributes",

“measures” and “statistical objects” is not obvious for beginning students. In contrast with this, Maxara and Biehler (2007) report on a study where Fathom was used systematically by their university students, apparently with success. I assume that those students’ first contact with Fathom was different from mine, since I clicked Help→Sample Documents→Statistics and started reading. I was quite amazed.

To start with, a clear notation could be helpful. The Fathom Documents use “mu”, “Mean”, “popMean”, “m”, “Avg”,... and “sigma”, “Std. dev.”, “popSD”, “s”, “sd”,... Why not stick to μ and σ for populations and to \bar{x} and s for sample results?

Furthermore, the notational distinction between a binomial model X (capital letter) and its x -values (small letter) should be applauded were it not that X is said to be a

binomialProbability (x, n, p, min, max)	This probability function computes the probability that $X = x$, where X is a random variable chosen from the set of possible values.
---	--

random variable chosen from the set of possible values.

The binomial model comes up several times but its discrete nature is seldom stressed, even in small samples. The “Polling Simulation” document wants to compare theory and experiment and uses `predictedProportion = binomialProbability (propYesForOnePoll*20, 20, 0.45)` resulting in a theoretical model where a lot of possible outcomes and their associated probabilities are missing. It is not because one has not seen 17 successes in a particular simulation (and hence not a proportion of $17/20=0.85$) that the predicted probability of a proportion of 0.85 doesn’t exist.

The Cells from Measures from Poll Table” enables us to compare theory and experiment numerically.

Cells from Measures from Poll Table

Cells from Measures from Poll Table

	propYesForOnePoll	S1	S2	predictedProportion
12	0.65	30	0.030	0.0000197
13	0.7	17	0.017	0.0149808
14	0.75	8	0.008	0.00490281
15	0.8	1	0.001	0.00125356

A further problem with this document lies in its histogram representation comparing the simulation results with the (also truncated of course) theoretical model. Repeating a poll of size 20 1000 times does not produce 1000 different outcomes. There still are only 21 different possible proportions. A bar graph comparing theoretical probabilities with experimental relative frequencies would make sense here since the chance model is discrete. By the way, try to let your students discover for themselves

the formula `Density of propYesForOnePoll = binomialProbability (round (20x), 20, 0.45) *20` for drawing such a histogram. Of course, the problem is much deeper and relates to the obsession of making curves fit histograms who themselves have to represent experiments with discrete outcomes. The “Normal” document for example shows a histogram of 100

random numbers from a normal population together with [quote]: “a plotted curve of a normal distribution with the same mean, standard deviation, and area as the histogram”. Yes, with the same area! Fortunately the example uses a histogram on a density scale. But there is no problem if one would use a histogram with frequencies. In the same document under number 3 of the “To do” list attention is drawn to the fact that the density then has to be multiplied by both the count and the bin width. If you do this, you find the figure on the right.

But `normalDensity(x, mean, stdDev) * count() * binWidth` is a model for what? It is a curve fitting the “frequency histogram” but it certainly isn’t a model for an underlying chance mechanism. These problems are not uncommon. In Schaeffer and Tabor (2008) one finds a similar figure. This time, a histogram has been drawn on a Relative Frequency scale and the density has only been multiplied by the bin width. The authors write: “The figure shows a simulated sampling distribution of sample proportions. This sampling distribution has a mean of 0.53 and a standard deviation of 0.05 and is nicely represented by the normal distribution (overlaid smooth curve) with that same mean and standard deviation”. But the top of a normal density $N(0.53; 0.05)$ is equal to 8, not to 0.16. So, what’s the name of a bell-shaped curve that (i) is nowhere negative and (ii) has an area under the curve equal to 0.02? Indeed, that’s the blue curve in that paper.

Fathom’s “Central limit Theorem” document has analogous problems. Wouldn’t it be nice to compare the histograms of the simulated sample means \bar{x} with the target model of \bar{X} ? That model is *normal* with *mean* $\mu = 1.5$ and with *standard deviation* $\sigma / \sqrt{n} = \sqrt{0.5} / \sqrt{n}$. The document instead uses the mean and standard deviation of the randomly generated set of 200 \bar{x} -values. Moreover, the collection called “Population” is not the population but contains the sample values, while the population itself is represented by a bimodal curve integrating out to 2 (yes, two).

CONCLUSION

Thinking in chance models might be too abstract for the young learner but at some level in the developmental process the more mature student might need more than “approximations by simulation” in order to fully understand the underlying reasoning

of statistical inference. At this point one needs a careful identification of all the involved entities, together with a clear notation, both in textbooks and software. It might be interesting for further research to investigate the impact of an unambiguous notation on the effectiveness of student's learning and understanding of statistics.

RECOMMENDED KNOWLEDGE OF PROBABILITY FOR SECONDARY MATHEMATICS TEACHERS

Irini Papaieronymou

Michigan State University, USA – PhD Candidate

PA College, Larnaca, Cyprus – Lecturer

Changes in school mathematics curricula in the last few decades have brought along an increase on the importance placed on probability (National Commission for Excellence in Education, 1983; National Council of Teachers of Mathematics, 2000). Since teachers' knowledge can have an impact on students' learning (Fennema & Franke, 1992), it is important that teachers have sufficient probability content and teaching knowledge. This paper identifies the suggested probability knowledge for secondary mathematics teachers through an examination of the recommendations from four professional organizations, namely the American Mathematical Society (AMS), the American Statistical Association (ASA), the Mathematical Association of America (MAA), and the National Council of Teachers of Mathematics (NCTM).

Keywords: teachers' knowledge, probability, professional recommendations

PROBABILITY CONTENT IN THE SECONDARY SCHOOL MATHEMATICS CURRICULUM

Since the late 1950s, there have been strong calls for an increase in the inclusion of probability in the US K-12 mathematics curriculum (NCSM, 1977; NCEE, 1983; NCTM, 2000). Probability has come to gain importance as a content area that students need to have experience with in order to be well-informed citizens since its study “can raise the level of sophistication at which a person interprets what he sees in ordinary life, in which theorems are scarce and uncertainty is everywhere” (Cambridge Conference on School Mathematics, 1963, p.70; as cited in Jones, 2004).

In 1963 a group of mathematicians and National Science Foundation (NSF) representatives published *Goals for School Mathematics* in which the importance of “some ‘feeling’ for probability” for all students was indicated (Jones, 1970, p. 291; as cited in Sorto, 2004). Following, the National Council of Supervisors of Mathematics (NCSM) defined probability as one of the basic skills that students should acquire (1977). In 1983, the National Commission for Excellence in Education (NCEE) published *A Nation at Risk*, a report aimed at pointing out the immediate need for reform in education, with the suggestion that high school graduates understand elementary probability and be able to apply it in everyday life.

More recently, the National Council for Teachers of Mathematics (NCTM) published the *Curriculum and Evaluation Standards for School Mathematics* (1989) in which it was recommended that in grades 5-8 students “explore situations by experimenting

and simulating probability models”, construct sample spaces in the attempt to determine probabilities of “realistic situations”, and appreciate the use of probability in the real world (1989, p. 109). Particular to grades 9-12, recommendations included the understanding of the difference between experimental and theoretical probabilities, theoretical and simulation techniques for computing probabilities, and interpreting discrete probability distributions (p. 171). In the mid to late 1990s the NCTM standards were revised resulting in the publication of *Principles and Standards for School Mathematics* (2000). Here, recommendations stated that

“middle-grades students should learn and use appropriate terminology and should be able to compute probabilities for simple compound events ... In high school, students should compute probabilities of compound events and understand conditional and independent events.” (NCTM, 2000, p. 51).

This increased attention on probability in school curricula is an indicator of how important it is that “teachers, mathematics educators, parents, and administrators, must provide their children and their students with alternative ways of approaching data and chance” (Shaughnessy, 2003, p. 223). Since “[T]here is perhaps no other branch of the mathematical sciences that is as important for *all* students, college bound or not, as probability and statistics” (Shaughnessy, 1992, p. 466, emphasis in original) and since misconceptions about probability are common among children, it is important that instruction allows students to confront their misconceptions and develop a deeper understanding of probability concepts (Garfield & Ahlgren, 1988; Konold, 1989; Shaughnessy, 2003). Since teachers’ knowledge can have an impact on students’ learning (Fennema & Franke, 1992), it is important that teachers be able to tackle these student difficulties and misconceptions on probability as they arise in mathematics classrooms. In order to be able to do so, teachers need to have sufficient probability content and teaching knowledge.

Teachers’ Knowledge of Probability

Although there have been calls for an increased attention on probability in the school curriculum, one of the problems encountered is the inadequate preparation of teachers in probability (Penas, 1987; CBMS, 2001). Many teachers have not encountered probability in their own K-12 mathematics courses and sometimes need convincing as to why they need to learn and teach probability topics (CBMS, 2001). Batanero et al. (2004) suggest that educators need to provide better initial training for teachers by offering courses at the college level specific to the didactics of probability. Such a course should include an introduction to the history of probability; information on statistics journals, associations, and conferences; the study of fundamental probability concepts; readings of literature on heuristics and biases in probability, as well as students’ difficulties and misconceptions in probability; identification of the educational theories and teaching approaches, assessment, teaching resources, and the use of technology; and examples of projects that can be used when teaching probability.

Teachers' Knowledge of Mathematics

Several scholars in the past three decades have provided insight into the definition of teachers' knowledge. In his work, Shulman (1986) provided a framework of teachers' knowledge which includes the following three categories: i) *subject matter content knowledge* which refers to “the amount and organization of knowledge per se in the mind of the teacher” as well as not only understanding *that* something is so but also *why* it is so and why it is important to the discipline (p. 9); ii) *pedagogical content knowledge* which refers to

“the most useful forms of representation of those ideas, the most powerful analogies, illustrations, examples, explanations, and demonstrations – in a word, the ways of representing and formulating the subject that make it comprehensible to others” (p. 9).

This category also includes knowledge of common conceptions/preconceptions that students have; and iii) *curricular knowledge* which includes knowledge about the

“full range of programs designed for the teaching of particular subjects and topics at a given level, the variety of instructional materials ..., and the set of characteristics that serve as both the indications and contraindications for the use of a particular curriculum or program materials in particular circumstances” (p. 10).

The difficulty faced by educators is how to blend the components of teacher knowledge so as to effectively prepare teachers to help all students to learn meaningfully.

FOCUS OF THE PAPER AND QUESTION

With the above issues under consideration, a study was carried out by the author in which US state and national mathematics standards for grades 6-12, secondary mathematics textbooks, and recommendations from professional organizations were analyzed in order to identify the content and teaching knowledge that secondary mathematics teachers need to have relative to the domain of probability. A report of the results relating to the probability topics that secondary mathematics teachers should know and be able to teach was presented at a previous conference (Papaieronymou, 2008), whereas this paper focuses on the teaching aspects of these probability topics and more specifically on the following question:

What are the aspects of teaching knowledge of probability that secondary mathematics teachers need to have as suggested by professional organizations?

For the purposes of addressing this question, only the recommendations from professional organizations were analyzed. The data sources specific to students (i.e. national and state standards for grades 6-12 and secondary mathematics textbooks) were not very informative since they did not directly address teachers' knowledge.

METHODS

Data Sources

In particular, *A Call for Change: Recommendations for the Mathematical Preparation of Teachers of Mathematics* (1991) published by the MAA, the *Professional Standards for Teaching Mathematics* (1991) published by the NCTM, *The Mathematical Education for Teachers* (CBMS, 2001) published by the AMS, and the *Guidelines for Assessment and Instruction in Statistics Education (GAISE) College Report* (Aliaga et al., 2005) published by the ASA were analyzed. The ASA report presents a list of goals for college students – not specifically prospective mathematics teachers – and recommendations for the teaching of introductory statistics courses.

Data Analysis

The number of recommendations from each professional organization was as follows:

Data Source	Number of Recommendations before multi-coding
AMS (2001)	27
ASA (2005)	9
MAA(1991)	17
NCTM(1991)	6
Total	59

Table 1: Number of recommendations from each organization before multi-coding

These 59 recommendations were categorized according to Shulman's (1986) framework of teacher knowledge with 8 recommendations being placed under more than one category. In deciding under which knowledge category to place each recommendation, the verbs appearing in the recommendation and their use in association with the probability concepts mentioned in the respective recommendation were considered. Some examples of recommendations that were placed under each of Shulman's categories are:

Recommendation	Knowledge Category
Mathematics teachers should be able to use permutation and combinatorial computations in problems arising from several areas, including geometry, algebra, and graph theory. They should also understand how counting techniques apply in the calculation of the probability of events. (MAA report, p. 36)	Subject-matter content knowledge
The fact that, under random sampling, the empirical probabilities	Pedagogical

actually converge to the theoretical (the law of large numbers) can be illustrated by technology (computer or graphing calculator) so that an understanding of probability as a long-run relative frequency is clearly established. (AMS report, p.116)	content knowledge
Precede computer simulations with physical explorations (e.g. die rolling, card shuffling) (ASA report)	Curricular knowledge
Other topics that should be introduced include fair games and expected value, odds, elementary counting techniques, conditional probability, and the use of an area model to represent probability geometrically (NCTM, 1991, p. 138)	Subject-matter and pedagogical content knowledge

Table 2: Examples of recommendations under Shulman's (1986) knowledge categories

In the last recommendation provided in Table 2 above, the use of the area model to represent probability implies pedagogical content knowledge since this type of knowledge includes the ways of *representing the subject*. The reference to topics of probability that should be introduced implies subject matter content knowledge; the topics refer to the *amount* of knowledge that teachers should have with respect to probability so as to be able to introduce these topics in their mathematics classrooms.

RESULTS

Once the 59 recommendations were categorized under Shulman's framework for teacher knowledge, with 8 recommendations being placed under two of the knowledge categories, the results were:

Data Source	Subject-matter content knowledge	Pedagogical content knowledge	Curricular knowledge	Total
AMS (2001)	22	5	1	28
ASA (2005)	7	1	1	9
MAA (1991)	13	6	2	21
NCTM (1991)	2	4	3	9
Total	44	16	7	67

Table 3: Number of recommendations under each of Shulman's (1986) categories

As can be seen from Table 3, about 66% (44 out of 67) of the recommendations from the four professional organizations relate to subject matter content knowledge, 24% (16 out of 67) of the recommendations refer to aspects of pedagogical content knowledge and 10% of the recommendations specify aspects of curricular knowledge that should be included in the preparation of secondary mathematics teachers.

The analysis also showed that the following topics were recommended by at least two of the organizations:

Common Topic	Professional Organizations in agreement
Combinatorics	AMS, MAA, NCTM
Experimental and Theoretical Probability	AMS, MAA, NCTM
Simulations	ASA, MAA, NCTM
Probability Distributions	AMS, MAA, NCTM
Hypothesis Testing	AMS, ASA, MAA
Conditional Probability	AMS, NCTM
Expected Value	AMS, NCTM
Probabilistic Misconceptions	AMS, NCTM
Uses/Misuses of Probability	AMS, MAA

Table 5: Probability topics recommended by at least two of the organizations

DISCUSSION

Given the small number (59) of recommendations overall across all four organizations specific to the area of probability and that 66% of the recommendations relate to subject matter content knowledge whereas 24% refer to pedagogical content knowledge and only 10% refer to curricular knowledge, the results imply that it is still unclear what exactly the pedagogical content knowledge and curricular content knowledge that secondary mathematics teachers need to have in the area of probability is.

A closer examination of the recommendations indicates that with respect to pedagogical content knowledge specific to probability, teachers need to acquire an awareness and ability to confront common probabilistic misconceptions and student difficulties relative to probability concepts (as suggested by the ASA, the MAA, and the NCTM). In addition, teachers need to be able to use technology to carry out simulations in order to illustrate probabilistic concepts (as recommended by all four of the professional organizations) and should also be able to use concrete objects such as dice, cards, and spinners to demonstrate probability concepts to students in the mathematics classroom (as suggested by the ASA and the NCTM). Furthermore, secondary mathematics teachers should be able to represent probabilities using various models such as the area model (as suggested by the NCTM).

Specific to curricular knowledge, secondary mathematics teachers should be aware of the various materials and programs that they can use to help students understand probability concepts. That is, they should be aware that they can use various computer programs such as Fathom and DataScope in their mathematics classrooms

when working with probability concepts (as suggested by the AMS) and they should know the power of simulation as a technique that can be used to solve probability problems (as recommended by the MAA and the NCTM).

As can be seen from Table 5, the four professional organizations place considerable emphasis on experimental versus theoretical probability and simulations. Secondary mathematics teachers need to be able to plan and conduct experiments and simulations (Aliaga et al., 2005; CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991; NCTM, 1991), distinguish between experimental and theoretical probability (Committee of the Mathematical Education of Teachers, 1991), determine experimental probabilities (CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991), use experimental and theoretical probabilities to formulate and solve probability problems (Committee of the Mathematical Education of Teachers, 1991), and use simulations to estimate the solution to problems of chance (Committee of the Mathematical Education of Teachers, 1991; NCTM, 1991). Secondary mathematics teachers should be able to provide a model which gives a theoretical probability that can be compared to experimental results, which in turn is essential when studying the concept of relative frequency (CBMS, 2001). In order to help students develop an understanding of probability as a long-run relative frequency, secondary mathematics teachers need to understand the law of large numbers and be able to illustrate it using simulations (CBMS, 2001).

With regards to theoretical probability, teachers should know about and be able to use both discrete and continuous probability distributions (NCTM, 1991), understand probability distributions (CBMS, 2001) and especially the normal distribution (CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991), as well as the binomial, poisson, and chi-square distributions (Committee of the Mathematical Education of Teachers, 1991). They should also be able to use simulations to study probability distributions (CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991) and demonstrate their properties (CBMS, 2001). Moreover, they should be introduced to fair games (NCTM, 1991) and understand expected value (CBMS, 2001).

Another topic among the recommendations from three of the four professional organizations is that of hypothesis testing. Secondary mathematics teachers should understand the concept of statistical significance including significance level and p-values, and that of confidence interval (Aliaga et al., 2005; Committee of the Mathematical Education of Teachers, 1991) including confidence level and margin of error (Aliaga et al., 2005).

Returning to the idea of theoretical probability, secondary mathematics teachers should be able to use counting techniques (NCTM, 1991) such as permutations and combinations to determine such (theoretical) probabilities (Committee of the Mathematical Education of Teachers, 1991). In addition, they should be exposed to

the applications of combinatorics (CBMS, 2001) including their use in calculating the probability of events (Committee of the Mathematical Education of Teachers, 1991). Secondary mathematics teachers should also understand and be able to calculate the probabilities of independent and dependent events (CBMS, 2001), compound events made up of independent and dependent events (CBMS, 2001) and also understand conditional probability (CBMS, 2001; NCTM, 1991). Various representations such as area models and tree diagrams should be used by teachers to aid students in better understanding compound events (CBMS, 2001; NCTM, 1991).

In addition, teachers should know about the uses of probability in many fields and its misuses in such sources as newspapers and magazines (CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991). Once experiments have been performed, teachers should be able to use probability to make decisions and predictions (CBMS, 2001; Committee of the Mathematical Education of Teachers, 1991).

An issue that arose as recommendations were being coded concerned the exact definition of the verbs that appeared in the documents. In many cases it was unclear as to what action or type of knowledge was expected of teachers based on the verb used since the meaning of the verb appearing in the report was unclear. Within the four documents of recommendations from the professional organizations, verbs appeared in different forms e.g. use, using, used or apply, applying, applied. Counting the different forms of a verb as one verb family gave rise to a total of 53 verb families being identified in the four reports. For example, consider the last recommendation on Table 2 which lists a set of probability topics that need to be ‘introduced’ in a mathematics classroom. The mere list of topics in this recommendation implies subject matter content knowledge. However, if the recommendation had established more clearly *how, in what order, what types of problems* should accompany these topics, and *how much emphasis* should be placed on each, the categorization might have been different. Let us also consider the verb family *understand* which had the highest frequency (29) in the four documents overall. In the mathematics education literature much has been written about the definition of this verb family. For example, Skemp (1976) makes a distinction between *relational understanding* (“knowing both what to do and why” (p.20)) and *instrumental understanding* (“rules without reasons” (p.20)). On the other hand, the National Research Council (2001) refers to *procedural understanding* and *conceptual understanding*. However, in the four reports examined in this study, it is not clearly indicated by the professional organizations which of these meanings the verb family *understand* carries when used in a recommendation. Such precise meanings are needed so as to accurately code the recommendations.

CONCLUSION

In recent decades, probability has come to gain importance as one of the content areas of school curricula in the United States. However, research on teachers’ knowledge in this content area is scarce. The identification of the knowledge of probability that

secondary mathematics teachers need to have in the form of content topics and their aspects of teaching is an essential tool that can be used in future research in this area. The analysis of recommendations on probability provided by professional organizations has revealed the importance of language in attempting to communicate to mathematics educators and teachers what is expected that they know and teach. As mentioned, 53 verb families were identified in the data sources. However, no clear definitions of these verbs, as related to the probability topics they accompanied, were provided by any of the sources leaving much to the interpretation of the researcher. Precise definitions of action verbs are needed in such documents to avoid possible errors in the coding of the recommendations and to help educators as they plan courses for prospective mathematics teachers.

Last, the analysis of the reports on recommendations for the preparation of secondary mathematics teachers by the AMS, ASA, MAA, and NCTM, revealed the inadequate number of such recommendations especially with regards to pedagogical content knowledge and curricular knowledge requirements specific to the area of probability at the secondary level. Given the increased attention of probability in school curricula, it is essential that professional organizations provide more extensive and detailed reports regarding the recommended skills in probability for future mathematics teachers. It would perhaps be most beneficial if professional organizations provide such a report collaboratively so that there is common agreement about the expectations of probabilistic knowledge of secondary mathematics teachers.

STATISTICAL GRAPHS PRODUCED BY PROSPECTIVE TEACHERS IN COMPARING TWO DISTRIBUTIONS

Carmen Batanero*, Pedro Arteaga*, Blanca Ruiz**

*Universidad de Granada

**Instituto Tecnológico y de Estudios Superiores, Monterrey, México

We analyse the graphs produced by 93 prospective primary school teachers in an open statistical project where they had to compare two statistical variables. We classify the graphs according its semiotic complexity and analyse the teachers' errors in selecting and building the graphs as well as their capacity for interpreting the graphs and getting a conclusion on the research question. Although about two thirds of participant produced a graph with enough semiotic complexity to get an adequate conclusion, half the graphs were either inadequate to the problem or incorrect. Only one third of participants were able to get a conclusion in relation to the research question.

Keywords: Statistical graphs, semiotic complexity, prospective teachers, assessment, competence.

INTRODUCTION

Graphical language is essential in organising and analysing data, since it is a tool for *transnumeration*, a basic component in statistical reasoning (Wild & Pfannkuch, 1999). Building and interpreting statistical graphs is also an important part of statistical literacy which is the union of two related competences: interpreting and critically evaluating statistically based information from a wide range of sources and formulating and communicating a reasoned opinion on such information. (Gal, 2002). Because recent curricular guidelines in Spain introduce statistics graph since the first year of primary school level and therefore, this research was oriented to assess prospective primary school teachers' graphical competence in order to use this information in improving the training of these teachers.

Understanding statistical graphs

In spite of its relevance, didactic research warn us that competence related to statistical graphs is not reached in compulsory education, since students make errors in scales (Li & Shen, 1992) or in building specific graphs (Pereira Mendoza & Mellor, 1990; Lee & Meletiou, 2003; Bakker, Biehler & Konold, 2004). Other authors define levels in graph understanding (Curcio, 1989; Gerber, Boulton-Lewis & Bruce, 1995; Friel, Curcio & Bright, 2001) that vary from a complete misunderstanding of the graph, going through reading isolated elements or being

able to compare elements to the ability to predict or expand to data that are not included in the graph. More recently, these levels were expanded to take into account the critical evaluation of information, once the student completely reads the graph (Aoyama, 2007):

1. *Rational/literal level.* Students correctly read the graph, interpolate, detect the tendencies and predict. They use the graph features to answer the question posed but they do neither criticise the information nor provide alternative explanations.
2. *Critical level:* Students read the graph, understand the context and evaluate the information reliability; but they are unable to think in alternative hypotheses that explain the disparity between a graph and a conclusion.
3. *Hypothetical level:* Students read the graphs, interpret and evaluate the information, and are able to create their own hypotheses and models.

Graphical Competence in Prospective Teachers

Recent research by Espinel, Bruno & Plasencia (2008) also highlight the scarce graphical competence in future primary school teachers, who make errors when building histograms or frequency polygons, or lack coherence between their building of a graph and their evaluation of tasks carried out by fictitious future students. When comparing the statistical literacy and reasoning of Spanish prospective teachers and American university students even when the tasks were hard for both groups, results were much poorer in the Spanish teachers, in particular when predicting the shape of a graph or reading histograms. Monteiro and Ainley (2007) studied the competence of Brazilian prospective teachers and found many of these teachers did not possess enough mathematical knowledge to read graphs taken from daily press. A possible explanation of all these difficulties is that the simplicity of graphical language is only apparent, since any graph is in fact a mathematical model. In producing a graph we summarize the data, going from the individual observations to the values of a statistical variable and the frequencies of these values. That is, we introduce the frequency distribution, a complex object that refers to the aggregate (population or sample) instead of referring to each particular individual and this object can be not grasped by the students.

THE STUDY

As stated in the introduction, the main goal in our research was to assess the graphical competence of prospective primary school teachers. A secondary aim was to classify the graphs produced by these teachers as regards its complexity. More specifically we analyse the graphs produced by 93 prospective teachers when

working in an open statistical project with the aim of providing information useful to teacher educators. These students had studied descriptive statistics (graphs, tables, averages, spread) the previous academic year (their first year of University) as well as in secondary school level. The data were collected along a classroom practice (Godino, Batanero, Roa & Wilhelmi, 2008) that was carried out in a Mathematics Education course (second year of University) directed to prospective teachers in the Faculty of Education, University of Granada. In this practice (2 hours long) we proposed prospective teachers a data analysis project. At the end of the session, participants were given a sheet with the data obtained in the classroom and were asked to individually produce a data analysis written report to answer the question set in the project. Participants were free to use any statistical graph or summary and work with computers if they wished. They were given a week to complete the reports that were collected and analysed.

The statistical project: “Check your intuitions about chance”

This project is part of a didactical unit designed to introduce the “information handling, chance and probability” content included in the upper level of primary education. Some aims are: a) showing the usefulness of statistics to check conjectures and analyse experimental data; b) checking intuitions about randomness and realising these intuitions are sometimes misleading. The sequence of activities in the project was as follows.

1. *Presenting the problem, initial instructions and collective discussion.* We started a discussion about intuitions and proposed that the future teachers carry out an experiment to decide whether they have good intuitions or not. The experiment consists of trying to write down apparent random results of flipping a coin 20 times (without really throwing the coin, just inventing the results) in such a way that other people would think the coin was flipped at random.
2. *Individual experiments and collecting data.* The future teachers tried the experiment themselves and invented an apparently random sequence (simulated throwing). They recorded their sequences using H for head and T for tail. Afterwards the future teachers were asked to flip a fair coin 20 times and write the results on the same recording sheet (real throwing).
3. *Classroom discussion, new questions and activities.* After the experiments were performed we started a discussion of possible strategies to compare the simulated and real random sequences. A first suggestion was to compare the number of heads and tails in the two sequences since we expect the average number of heads in a random sequence of 20 tosses to be about 10. The lecturer posed questions like: If the sequence is random, should we get exactly 10 heads and 10 tails? What if we get 11 heads and 9 tails? Do you think in this case the

sequence is not random? These questions introduced the idea of comparing the number of tails and heads in the real and simulated experiments for the whole class and then studying the similarities and differences.

4. At the end of the session the future teachers were given a copy of the data set for the whole group of students. This data set contained two statistical variables: number of heads for each of real and simulated sequences and for each student; n cases with these 2 variables each. As prospective teachers were divided in 3 groups, n varied (30-40 cases in each group). They were asked to complete the analysis at home and produce a report with a conclusion about the group intuitions concerning randomness. Students were able to use any statistical method or graph and should include the statistical analysis in the report.

RESULTS AND DISCUSSION

Once the students' written reports were collected, we made a qualitative analysis of these reports. By means of an inductive procedure we classified into different categories the graphs produced as a part of the analysis, the interpretations of graphs and the conclusions about the group intuitions. The classification of graphs took into account the type of graph, number of variables represented in the graph, and underlying mathematical objects as well as some theoretical ideas that we summarise below.

Font, Godino and D'Amore (2007) generalize the notion of *representation*, by taking from Eco the idea of semiotic function "*there is a semiotic function when an expression and a content are put in correspondence*" (Eco, 1979, p.83) and by taking into account an ontology of objects that intervene in mathematical practices: *problems, actions, concepts-definition, language properties and arguments*, any of which could be used as either expression or content in a semiotic function. In our project we propose a *problem* (comparing two distributions to decide about the intuitions in the set of students) and analyse the students' practices when solving the problem. More specifically we study the graphs produced by the students; these graphs involve a series of *actions, concepts-definitions* and *properties* that vary in different graphs. Consequently the semiotic functions underlying the building and interpretation of graphs, including putting in relation the graphs with the initial question by an argument also vary. We therefore should not consider the different graphs as equivalent representations of a same mathematical concept (the data distribution) but as different configurations of interrelated objects that interact with that distribution. Five students only computed some statistical summaries (mean, median or range) and did not produce graphs; we are not taking into account these students in our report. Using the ideas above we performed a semiotic analysis of

the different graphs produced by the other 88 students and defined different levels of semiotic complexity as follow:

L1. Representing only his/her individual results. Some students produced a graph to represent the data they obtained in his/her particular experiment, without considering their classmates' data. These graphs (e.g. a bar chart) represent the frequencies of heads and tails in the 20 throwing. Students in this level tried to answer the project question for only his /her own case (tried to assess whether his/her intuition was good); part of these students manifested a wrong conception of chance, in assuming a good intuition would imply that the simulated sequence would be identical to the real sequence in some characteristic, for example the number of heads. Since they represented the frequency of results in the individual experiment, in fact these students showed an intuitive idea of statistical variable and distribution; although they only considered the Bernoulli variable "result of throwing a coin" with two possible values: "1= head", 0= tail" and 20 repetitions of the experiment, instead of considering a Binomial distribution "number of heads in the 20 throwing" that have a wider range of values (1-20 with average equal to 10) and r repetitions of the experiments (r = number of students in the classroom).

L2. Representing the individual values for the number of heads. These students did neither group the similar values of the number of heads in the real nor in the simulated sequences. Instead, they represented the value (or values) obtained by each student in the classroom in the order the data were collected, so they did neither compute the frequency of the different values nor explicitly used the idea of distribution. The order of data in the X-axis was artificial, since it only indicated the arbitrary order in which the students were located in the classroom. In this category we got horizontal and vertical bar graphs, line graphs of one or the two variables that, even when did not solve the problem of comparison, at least showed the data variability. Other students produced graphs such as pie chart, or stocked bar charts, that were clearly inappropriate, since they did not allow visualizing the data variability.

L3. Producing graphs separate for each distribution. The student produced a frequency table for each of the two variables and from it constructed a graph or else directly represented the graph with each of the different values of the variable with its frequency. This mean that the students went from the data set to the statistical variable "number of heads in each sequence" and its distribution and used the ideas of frequencies and distribution. The order in the X-axis was the natural order in the real line. In case the students did not use the same scale in both graphs or used different graphs for the two distributions the comparison was harder. Examples of correct graphs in this category were bar graphs and frequency polygons. Students also produced incorrect graphs in this category such as histograms with incorrect

representation of intervals, bar graphs with axes exchanged (confusing the independent and dependent variable in the frequency distribution), representing the frequencies and variable values in an attached bar graph or representing variables that were not related.

L4. Producing a joint graph for the two distributions. The students formed the distributions for the two variables and represented them in a joint graph, which facilitated the comparison; the graph was more complex, since it represented two different variables. We found the following variety of correct graphs: attached bar chart; representing some common statistics (e.g. the mean or the mode) for the two variables in the same graph; line graphs or dot plots in the same framework. Example of incorrect graphs in this category were graphs presenting statistics that were not comparable (e.g. mean and variance in the same graphs) or the same statistics for variables that cannot be compared.

In Figure 1 we present an example of graphs produced in each category. Even when within each of these categories we observe a variety of graphs and configurations of mathematical objects it is evident a qualitative gap between each of the different levels. In Table 1 we present the distribution of students according the semiotic complexity of the graph, its correctness, the interpretation of the graph and the conclusion about intuitions.

Table 1. Results

	Correctness of the graph			Interpretation of graph			Conclusion on the intuitions			Total in the level
	1	2	3	1	2	3	1	2	3	
L1. Representing only the student data	1		1	1	1				2	2
L2. Representing individual results	10	1	4	4	10	1		3	12	15
L3. Separate graphs	15	17	14	15	15	16	1	12	33	46
L4. Joint graphs	14	6	5	9	11	5	1	7	17	25
Total	40	24	24	29	37	22	2	22	64	88

(1) Correct; (2) Partially correct; (3) Incorrect or no interpretation / conclusion

Figure 1. Examples of graphs in each different level of semiotic complexity

From a total of 93 students 88 (94,6%) produced some graphs when analysing the data, even if the instructions given to the student did not explicitly require that they constructed a graph. This fact suggests that students felt the need of building a graph and reached, by a transnumeration process some information that was not available in the raw data. Most students (52,2%) produced separate graphs for each variable (level 3), that were generally correct o partly correct (correct graph with different scales or different graph in each sample; not centring the rectangles in the histogram, or missing labels).

14 students in this level constructed a non-meaningful graph since they represented the product of values by frequencies, exchanged the frequencies and values of variables in the axes thus confusing the independent and dependent variable in the frequency distribution. 28,4% students worked at level 4, and produced only a joint graph for the two variables, although 6 of these graphs were partly correct and 5 incorrect (same reasons than those described in level 3). Few students only analysed their own data (level 1) and only 17% of participants studied the value got

by each student without forming the distribution. Consequently the concept of distribution seemed natural for the majority of students who used it to solve the task, although the instructions did not require this explicitly.

In general, these prospective teachers interpreted correctly or partially correctly the graphs in all the levels, reaching the Curcio's (1989) intermediate level (reading between the data) and the difficulty of interpretation of graphs increased with its semiotic complexity. However, an important part of students in our levels 3 and 4, even when they built correct graphs did not reached the "reading between the data" level, because either they did not interpret the graph either made only a partial interpretation. As regards the Aoyama's (2007) levels, the majority of prospective teachers only read the graphs produced at a rational/literal level, without being able of read the graphs at a critical or a hypothetical level. The teachers performed a mathematical comparison of the graphs but did not get a conclusion about the intuitions in the classroom (e.g. they correctly compared averages but did not comment what were the implications in relation to the students' intuitions). Only two students in the group reached the hypothetical level in reading the graphs, as they got the correct conclusion about group's intuition. These two students realised that the group have correct intuitions about the average number of heads but poor intuitions about the spread. Students were supposed to get this conclusion from comparing the averages and range in the variables in the simulated and real sequences distributions. At higher level statistical tests could also be used to support this conclusion that have been observed in previous research about people perception of randomness. 22 participants got a partial conclusion that the intuition as regards averages was good, as they were able to perceive difference or similitude in the averages, but they did not considered the results obtained in comparing spread of the variable (number of heads) in the two sequences. These students also work at the Aoyama's (2007) hypothetical level, although they did not considered spread in comparing the two distributions. Those working at levels 1 and 2 got few partly correct conclusions and none correct conclusion, so that these levels of complexity in the graph were not adequate to get a complete conclusion.

CONCLUSIONS

In the project posed the prospective teachers went through the different steps in the statistics method as described by Wild and Pfannkunch (1999) in their PPCAI cycle: setting a problem, refining the research questions, collecting and analysing data and obtaining some conclusions. They also practiced the process of modelling, since, beyond working with the statistics and random variables, they should interpret the results of working with the mathematical model in the problem context (whether the students' intuitions was good or not). This last step (relating the result

with the research question) was the most difficult for the students, who lacked familiarity with statistical projects and modelling activities. Since these activities are today recommended in the teaching of statistics since primary school level in Spain and are particularly adequate to carry out group and individual work as recommended in the Higher European Education Space we suggest they are particularly suitable for the training of teachers. Our research also suggest that building and interpreting graphs is a complex activity and confirm some of the difficulties described by Espinel, Bruno and Plasencia (2008) in the future teachers, in spite that they should transmit graphical language to their students and use it as a tool in their professional life. Improving the teaching of statistics in schools should start from the education of teachers that should take into account statistical graphs.

THE ROLE OF CONTEXT IN STOCHASTICS INSTRUCTION

Andreas Eichler

Universität Münster

This report focuses on a research project that combines two aspects of a stochastics curriculum related to teachers' classroom practice, and their students' stochastic knowledge and beliefs. Data were collected with questionnaires. The development of the questionnaires derived from results of a qualitative research project will be sketched. Afterwards, some results concerning the role of the context will be discussed.

Keywords: stochastics teachers, students' learning, beliefs, role of the context

INTRODUCTION

One central aim of the teaching of stochastics in school is to prepare students to deal with real stochastic situations in their lives (Jones, Langrall, & Mooney, 2007). This aim involves two goals, the students' comprehension of stochastic concepts, and the students' awareness that it is possible to use stochastics to cope with specific real situations. There is a wide consensus between researchers into stochastic education that to achieve these two goals, students must explore stochastic concepts on the basis of realistic situations instead of exploring solely pseudo realistic situations (cards, urns, dices) or learning stochastics in a formal and abstract way (e.g. Jones et al., 2007). While there is a consensus about the *role of the context* for the teaching and learning of stochastics, there is, however, still little insight into the daily teaching practice of "conventional" stochastics teachers. In this report, the results of a research project involving a quantitative survey concerning the classroom practice of German stochastics teachers will be discussed. The main focus is the role of the context based on the following aspect:

1. The teachers' beliefs about the goals of teaching stochastics,
2. the students' beliefs about the usefulness of stochastics, and
3. the impact of the teachers' beliefs on the students' beliefs.

The research project discussed in this report is part of a larger research project involving a qualitative designed investigation of stochastics teachers' classroom practices and the impact of the latter on students' learning (Eichler, 2008a; Eichler, 2007). The results of the qualitative part of the research that provides the basis for the quantitative survey will be sketched in the following.

RESULTS OF THE QUALITATIVE RESEARCH

The first step of the qualitative research comprised an interview study with eight stochastic teachers (Eichler, 2007a). This study yielded four types of (individual) statistics curricula that are similar concerning the content, but considerably differ

with regard to the teachers' objectives or beliefs. The distinction between the four types is characterised by differences of the teachers concerning two dimensions. The first dimension can be described with the dichotomous pairs of a static versus a dynamic view of mathematics or stochastics. The second dimension can be described with the orientation on formal mathematics versus mathematical applications. The four types of statistics teachers were characterised with reference to their main objectives as follows (Eichler, 2007a).

(dimension 2)	application	<i>Application preparers</i> : their central goal is to have students grasp the interplay between theory and applications. Students firstly must learn stochastic theory in order to cope with mathematical applications later.	<i>Every-day-life preparers</i> : their central goal is to develop stochastical methods in a process, the result of which will be both the ability to cope with real stochastic problems and the ability to criticise.
	formal	<i>Traditionalists</i> : their central goal is to establish a theoretical basis for stochastics. This involves algorithmic skills and insights into the abstract structure of mathematics, but it does not involve applications.	<i>Structuralists</i> : their central goal is to encourage students' understanding of the abstract system of mathematics (or stochastics) in a process of abstraction which begins with mathematical applications.
		static view of mathematics	dynamic view of mathematics

(dimension 1)

Figure 1: Four types of stochastics teachers

The second step of the qualitative research comprised the observation of the classroom practice of four teachers (Eichler, 2008a). One central result of this step of observation was that the instructional practice of the teachers provides strong evidence that they pursue their main objectives. Concerning the role of the context, the traditionalists and the every-day-life-preparers represent the extreme positions. The students of the traditionalists predominantly explore stochastical concepts on the basis of formal or pseudo realistic situations (cards, urns, dices). They seldom explore realistic situations. In contrast, realistic situations are crucial in the classroom practice of the every-day-life-preparers. Their students predominantly explore stochastical concepts on the basis of realistic situations or real problems, which arise, for instance, from articles of newspapers.

The third step of the qualitative research comprised an interview study with five students of each of the four teachers who were observed before. In this step the construct of statistical knowledge (Broers, 2006) and the distinction of declarative knowledge, procedural knowledge, and conceptual knowledge (Hiebert, & Carpenter, 1992) was used to describe the students' knowledge (Eichler 2008a). A central result of the third step of the qualitative research was that the students differ in their knowledge and beliefs. The differences consist between the students of one teacher, and between sets of students of different teachers. The students also differ concerning the role of the context. Thus, the students differ in the use of stochastic situations (formal, pseudo realistic or realistic) to explain stochastical concepts. Further, the

students differ considerably concerning their beliefs about stochastics and mathematics referring to their relevance for society and their relevance for the own life (Eichler, 2008a).

METHOD

In regard to the characterisation of the four types of teachers (figure 1), a questionnaire including four parts was developed. The first part concerns the instructional contents of stochastics courses. The other three parts of the questionnaire concern the teachers' objectives of statistics and mathematics instruction. In each of the latter three parts of the questionnaire the teachers were asked to rate typical statements of the teachers who represent one of the four types (from full agreement to no agreement, coded with 1 to 5). In these three parts respectively two statements of every type have to be rated.

The questionnaire for the students involves items concerning declarative knowledge and conceptual knowledge. Concerning their *declarative knowledge*, the students were asked to rate a list of 28 statistical concepts whether they: are not able to remember the statistical concept (coded with 0), are able to remember the statistical concept (coded with 1), are able to approximately explain a statistical concept (coded with 2), are able to exactly explain a statistical concept (coded with 3).

Concerning the conceptual knowledge, the students were asked to indicate interconnections into the consecutively numbered concepts (category *declarative knowledge*)

Four parts of the questionnaire comprise the role of the context. Thus, the students were asked to indicate

- stochastic situations of the classroom (category *application*).
- statistical applications along with related statistical concept (category *connections*).
- real situations (outside of the classroom), for which stochastics may be useful (category *benefit*).
- the benefit of stochastics for students' future life, the benefit of stochastics for the students' professional career. These two categories were linked with a single item, in which the students are asked to rate the relevance of stochastics for their lives from high relevance (coded with 5) to no relevance (coded with 1, category *relevance-life*, and category *relevance-profession*).

A random sample of 240 German secondary high schools was selected. These schools were asked to conduct the survey. 166 of these agreed. Two teachers' of each of these schools and three students per teacher with different statistical performance were asked to fill out the questionnaire (January to July 2007). The completed

questionnaires of 107 teachers and 315 students were analysed. The stochastics courses last between three and six month with three to five hours a week.

RESULTS CONCERNING THE TEACHERS

The statistics curriculum is dominated by the so called classical block of probability (see table 1).

Block	Topics and percent of teachers teaching the topic (n=107)
Classical block of probability	Frequencies (98%), Laplacean probability (97%), statistical probability (72%), probability tree (100%), Bernoulli experiment (99%), binomial distribution (100%), expected value (95%), standard deviation (95%)
Inferential statistics	Hypothesis testing (89%), confidence intervals (51%), Bayesian statistics (27%)
Conditional probability	Conditional probability (81%), (in)dependence (80%), theorem of Bayes (74%)
Distributions	Normal distribution (79%), hypergeometrical distribution (49%) Poisson distribution (49%)
Descriptive statistics	Frequencies (98%), mean (87%), spread (74%), median (52%), regression and correlation (16%)

Table 1: Percentage of teachers teaching different instructional content

Factor analysis concerning the objectives of the teachers' statistics curricula in the responses to questionnaires yield three interpretable factors (table 2) which include 15 of the 24 items referring to the objectives of the statistics curriculum. For each factor the number of items and the Cronbach's Alpha is shown in table 2.

Factor	Factor 1 (5 items, $\alpha = 0.689$)	Factor 2 (6 items, $\alpha = 0.725$)	Factor 3 (4 items, $\alpha = 0.779$)
Interpretation	Traditional curriculum, little reference to real data	Curriculum with high reference to real data	Curriculum with high reference to process

Table 2: Factors concerning the objectives the statistics curriculum

In the following the main focus is on the first two factors or rather on the teachers with a high acceptance to the items of one of these two factors. These items are shown in the following table. The items involve a statement of a teacher who represents one of the four types of stochastic teachers (figure 2). The type is indicated in the brackets (T: traditionalists; S: structuralists; A-P: application-preparers; E-P: every-day-life-preparers).

Factor 1	Factor 2
<ul style="list-style-type: none"> - The objective of teaching stochastics is to establish a theoretical foundation of stochastics (T). - Students must learn to deal successfully with abstract and formal systems (S). - Algorithmic skills constitute the basis of learning statistics or mathematics 	<ul style="list-style-type: none"> - The main goal of the teaching of stochastics is the students ability to understand decision-making processes in our society (E-P) - Students must explore stochastic concepts solely on the basis of real stochastic situations (E-P). - Students must learn to use stochastic or mathematical theory to be able to argue referring to real problems (A-P).

<p>(T).</p> <ul style="list-style-type: none"> - Students must be well prepared concerning final exams and studies (T). - Students must learn a precision in reasoning in order to deal successfully with abstract and formal mathematics (S). 	<ul style="list-style-type: none"> - Students must understand that stochastics or mathematics is part of the general ability of problem solving (E-P). - Students must learn to solve real problems either for their own or in a team (E-P). - Students solely will be motivated if they understand that stochastics or mathematics is applicable in the reality (A-P).
--	--

Table 3: List of the items included in factor 1 and factor 2.

The correlation coefficient between factor 1 and factor 2 is - 0,1. For the distinction between teachers with high acceptance to the items of one factor and low acceptance to the other, two clusters were defined by the medians concerning the value of the two factors. Cluster 1 includes those teachers with high acceptance to factor 1 and low acceptance to factor 2. Cluster 2 includes those teachers with high acceptance to factor 2 and low acceptance to factor 1. Cluster 1 includes 39 teachers, cluster 2 34 teachers.

Figure 2: Clusters of teachers concerning factor 1 and factor 2

RESULTS CONCERNING THE STUDENTS

Figure 3 shows the results concerning five categories:

1. the students' self estimated ability to explain the 28 different stochastic concepts (the students' declarative knowledge),
2. the number of connections between two different stochastic concepts as part of the students conceptual knowledge (for instance: if a student indicated the connection between the three concepts of expected value, variance and standard deviation, the number of possible connection is 3 over 2 or rather 3)
3. the number of stochastic situations of the classroom (*application*).
4. the number of pairs of applications and statistical concept (*connections*).
5. the number of real stochastic situations (*benefit*).

Due to the fact that different teachers indicated different numbers of stochastic concepts taught in the classes, figure 3 shows the results concerning the category *knowledge weighted*. For this category the students' self estimated knowledge is

divided by the number of concepts taught by the teachers. This category alludes to a restricted sample, which involves the set of completed questionnaires of one class (some of the completed questionnaires allude only to the teachers or only to the students).

Figure 3: Results concerning the students knowledge and beliefs (average and 95%-interval)

The interpretation (only for the averages) is as follows: The sum of the students' self-estimations concerning the 28 given stochastic concepts is in average about 39. In average, the students rate their knowledge about the stochastic concepts taught by their teachers with about 1,4. The students indicate more than 9 connections between different stochastic concepts, they indicate about 2,1 stochastic situations of the classroom and about 2 stochastic situations outside of the classroom. Finally, the students indicate in average about 1,9 connections of a stochastic situation and a specific stochastic concept.

Concerning the role of the context it is important whether the indicated stochastic situations to the categories application, benefit, and connections refer to realistic situations or pseudo realistic situations (the pseudo realistic situations include games of chance). Table 4 shows the distribution of the indicated stochastic situations (with the number of indications in brackets) for the first two categories:

Application		Benefit	
realistic situations (255)	pseudo realistic situations (385)	realistic situations (359)	pseudo realistic situations (270)
quality control (48)	game of chance (100)	economy (63)	game of chance (100)
forecasts (30)	lottery (91)	quality control (45)	lottery (78)
elections (28)	dice (66)	elections (39)	poker (13)
statistics (24)	urns (33)	statistics (37)	bets (18)
clinical diagnostic (23)	coins (23)	polls (32)	dice (14)
polls (16)	cards (15)	clinical diagnostic (26)	bingo (13)
economy (16)	poker (13)	further education (26)	
weather (11)	lots (10)	weather (17)	
		stock market (16)	
		insurance (12)	
other situations with less than 10 indications		other situations with less than 10 indications	

Table 4: Distribution of stochastic situations and number of indications in brackets

The stochastic situations are topics: the situation *economy* includes, for instance, market research, promotion and some more specific situations. Although some of the

stochastic situations were indicated for both categories, application and benefit, it is obvious that

- concerning the category benefit, the pseudo realistic situations are restricted to existing games of chance, and
- concerning the category application, the majority of situations refers to pseudo realistic situations.

Some of the indicated situations stem from typical tasks in German textbooks, in particular quality control, elections, and clinical diagnostic. Students predominantly use these three different situations connecting a stochastic situation with a specific stochastic concept. The students, however, more often use pseudo realistic situations for connecting a stochastic situation with a specific stochastic concept, and, in this case, predominantly dice, urns and lottery (see table 4).

Realistic situations (157)		Pseudo realistic situations (341)	
Situation	Connected stochastic concepts	Situation	Connected stochastic concepts
Quality control (85)	hypothesis testing (17), binomial distribution (6), confidence interval (5), Bernoulli experiment (4), conditional probability (4) normal distribution (3), expected value (2), spread (2), probability tree (1), combinatorics (1) 2 x 2 table (1)	Dice	Laplacean probability (36), Bernoulli experiment (14), probability tree (9) random experiment (7), expected value (5), binomial distribution (4) probability (2), statistical probability (2), normal distribution (2), hypothesis testing (1), variance (1) simulation (1), combinatorics (1)
Clinical diagnostic (33), elections (9)		Urns (79), lottery (53)	

Table 5: stochastic situations and related stochastic concepts

Obviously, students remember predominantly connections between pseudo realistic situations and specific stochastic concepts. Further, the variation of indicated stochastic situations concerning the category connections is much lesser than the variation of indicated situations concerning the categories application and benefit.

Although the students estimated their declarative knowledge by themselves, these estimations give evidence of the students' factual knowledge. Thus, the correlations between the students' declarative knowledge and other categories discussed above are shown in table 6:

	conceptual knowledge	Application		benefit		connections	
		realistic situations	pseudo realistic situations	realistic situations	pseudo realistic situations	realistic situations	pseudo realistic situations
declarative knowledge	0,418**	0,172**	-0,233**	0,277**	-0,181**	0,269**	-0,177**

Table 6: Correlations between students' declarative knowledge and 5 other categories

The correlations are predominately weak, although they are significant different from zero. However, the correlations as a whole give evidence that the students' self estimated declarative knowledge measure in some sense the students' flexibility of

dealing with statistical concepts. Further, there is evidence that the higher the students' flexibility of dealing with statistical concepts is, the higher their reference to realistic statistical situations is, and the lower the reference to pseudo realistic situations is.

TEACHERS – STUDENTS

To prove possible interrelations between the teachers' orientation concerning the goals of the stochastics instruction and the students' knowledge and beliefs, the sample must be restricted. This was necessary, because sometimes a teacher sends his completed questionnaire back but his students not, sometimes the students send their completed questionnaires back, but the teacher not. Two strategies were used for the following analysis. Firstly, the correlations between the factors, i.e. factor 1 and factor 2 (or rather the sum of ratings the teachers given to the items of the two factors), and the categories concerning the students (knowledge weighted, application, benefit, and connections). Secondly, the clusters of teachers defined above (figure 2) were used to split up the sample of the students. The averages of the two new samples concerning the categories knowledge weighted, application, benefit, and connections were compared by a t-test.

Figure 4: Students' weighted knowledge and students' procedural knowledge. f1F2: teachers, who have low acceptance to factor 1 and high acceptance to factor 2, F1f2: teachers, who have high acceptance to factor 1 and low acceptance to factor 2

Most parts of the analysis give no evidence of an interrelation between the teachers' orientation and the students' knowledge and beliefs. For instance, concerning the clusters of teachers, who have low acceptance to factor 1 (traditional curriculum) and high acceptance to factor 2 (curriculum with high reference to real data) or who have low acceptance to factor 2 and high acceptance to factor 1 (see figure 2), the distribution of the students' weighted knowledge and the students' ability to indicate connections between stochastical concepts (figure 4).

Although there are differences in detail, these differences are statistically not relevant. Thus, there is little or no evidence that a teacher's orientation towards a traditional curriculum (factor 1) or a curriculum that includes real data (factor 2) promote (or impede) students' learning in reference to the students' declarative knowledge, the students' conceptual knowledge, and the students' beliefs concerning the relevance of statistics except the category benefit. For this category t-test give some evidence that the students of teachers with high acceptance to factor 2 and low

acceptance to factor 1 use more often realistic situations than pseudo realistic situations to explain the relevance of stochastics for the society. However, the differences are not significant (table 7).

Benefit	Realistic situations (F1f2)	$\bar{x} = 1,14$	Pseudo realistic situations (F1f2)	$\bar{x} = 0,66$
	Realistic situations (F1f2)	$\bar{x} = 0,83$	Pseudo realistic situations (F1f2)	$\bar{x} = 1,00$
		$\alpha = 0,121$		$\alpha = 0,063$

Table 7: Difference of the students concerning the category benefit

In contrast to the low interrelations between the teachers' objectives concerning the statistics curriculum and their students' knowledge and the students' beliefs, there is stronger evidence that the amount of contents has an impact on the students' knowledge. So, the greater the number of statistical concepts taught by the teachers is, the lower the declarative knowledge of the students seems to be (Pearson's correlation coefficient $r = -0,43^{**}$).

CONCLUSION

The results of the quantitative survey concerning the curriculum of statistics teachers and the learning of students give evidence that:

- "The traditional way of teaching statistics, with its heavy emphasis on formal probability" (Broers, 2006, p.4) is still existent in German secondary high schools;
- the teachers' instructional contents are similar, but the teachers' objectives differ considerably;
- the quality of students' declarative knowledge affects their conceptual knowledge and their beliefs concerning the relevance of statistics;
- the students predominately indicate few realistic situations to explain both the relevance of stochastics for the society and connections between stochastic situations and specific stochastic concepts;
- the teachers' orientation towards a curriculum with high reference to real data seems to affect the students' ability to use realistic stochastic situations to explain the relevance for the society.

However, the latter interrelation between the teachers' orientation and the students' beliefs is weak. Above all, there is no evidence for the impact of the teachers' orientation and the students' knowledge and beliefs. The lack of statistical relevant interrelations between the teachers teaching and the students learning may be caused by the fact, that there are only small differences of the teachers' stochastics teaching with the emphasis on probability. It is possible that a stronger orientation to a data driven curriculum has a stronger impact of the students' knowledge and beliefs concerning the role of the context. Further it is possible, that the quantitative survey discussed in this report is not able to measure possible differences concerning the

students' knowledge and beliefs. There is some evidence that qualitative research can show differences in detail between students' of teachers who have different goals concerning the role of the context (see Eichler, 2008a).

However, the stochastics teachers' teaching is determined by the teachers' fundamental orientation, i.e. the teachers' system of objectives (or beliefs) concerning stochastics teaching. Pajares (1992) stated that it could be difficult to change the teachers' central beliefs. One approach to change these central beliefs may start by the teachers' conviction that a changed curriculum actually will promote students' stochastical knowledge. For this reason it would be desirable to have more research into the stochastics teachers' curricula, the students' stochastical knowledge and beliefs, and, in particular, the relations between stochastics teachers' curricula and the students' stochastical knowledge or beliefs.

DOES THE NATURE AND AMOUNT OF POSTERIOR INFORMATION AFFECT PRESCHOOLER'S INFERENCES

Z. Nikiforidou, J. Pange

Department of Early Childhood Education

University of Ioannina-Greece

Children as young as 5 have been found to possess basic notions of probability, in contradiction to the piagetian perspective. In the current pilot study, preschoolers (N=25) participated in a probability task of single events, with alterations in the given posterior information. Children took into account the new sets of information and responded differently in each condition, depending on the nature and the amount of information. Such findings stress the importance of designing probability tasks in accordance to the children's cognitive capacities and probabilistic understanding.

Key words: preschoolers, posterior probability, design of probability tasks.

INTRODUCTION

The development of probabilistic thinking is a topic of much interest during the last decades from many perspectives, i.e. mathematical, cognitive, and educational.

Early research carried out mainly by Piaget and Inhelder (1951) supported that children undergoing the pre-operational developmental stage (4-7 years old) have no intuitions of randomness and no conceptions of chance and probability. Under this traditional perspective, probabilistic concepts develop as complementary to logical operational structures which emerge in relation to age (Kreitler & Kreitler, 1986). At the age of 5, children cannot differentiate certain from random events.

On the other hand, Fischbein (1975) suggested that young children possess a particular intuition of chance and probability in the sense that they possess 'primary intuitions' which are 'cognitive acquisitions derived from the experience of the individual, without the need for any systematic instruction' (Fishcbein et al, 1971).

Based on this intuitive perspective, young children show a minimal understanding of randomness and can identify the most/least likely outcomes (Way, 2003). Preschoolers have been found to understand the probability of an event (Jones et al, 1997; Falk& Wilkening, 1998), to make use of random sampling and base rate information (Denison et al, 2007), to realize part-part comparisons in order to estimate probability (Spinillo, 2002), to make use of probabilistic evidence in order to infer about causal strength (Kushnir& Gopnik, 2005). Preschoolers are able to compute prior probabilities in order to predict an uncertain event.

In the current study preschoolers were tested onto whether they can take into account and manipulate posterior probability. Posterior probability is a revised probability that integrates new available information. What happens when children are asked to consider new specific information in order to make judgments about the outcome of a probabilistic task? According to a study carried out by Girotto & Gonzalez (2008), even kindergartners were found to be able to use posterior information in order to update their evaluations about random outcomes. Young children made optimal decisions while integrating new information into prior information of single events.

The general hypothesis is that preschoolers are expected to take into consideration the extra-posterior information while building-up their inferences. The nature and amount of information that characterizes each condition (base rate vs category) is expected to affect children's responses: the more precise information (condition 2 vs condition 1), the more accurate judgments.

METHODOLOGY

This pilot study took place in a public kindergarten in a town of Western Greece, in 2008. The random sample consisted of both girls and boys. In this study we did not consider age and gender effects due to the small sample. Participants (N=25), aged 5 to 6, were asked to make predictions in a two-stage procedure: at a first point they were asked to infer given *prior* information and then they were asked to infer again by taking into account new, available *posterior* information.

The probabilistic task consisted of animal cards that depicted ducks and mice. In every condition the sample space was invariably 8 and cards were distributed unequally in 2 identical boxes. Among the 8 cards there was one lucky-card that had a sticker on it. Once children found that particular card in the correct box, they gained a sticker themselves. The lucky animal in all cases was a duck -participants were aware of that from the beginning of the task- and consequently mice were used as 'noise'.

		1st stage of choice (based on prior information)	2nd stage of choice (based on posterior information)
1st condition: base rate		No info provided about the content.	Aware that one box has 6 animal-cards vs the other box with 2.
2nd condition: category		Aware that both boxes have 4 cards each.	Aware that the distributions are 3:1 and 1:3

Table 1: Design of the probabilistic task.

The design of the task (Table 1) comprised 2 conditions with differences in the nature and amount of information and 2 stages of provided information that affected participants' choice. In both conditions, participants began with information that didn't favor any box; both boxes had equal chances to carry the lucky-animal (level of probability, 50:50). Then, posterior information would provide additional evidence about in which box the lucky-duck might be.

In precise, in the 1st condition, children were given as prior information nothing, they were just asked to choose one box at random. As posterior information, they were informed that one particular box contained 6 whereas the other 2 cards.

In the 2nd condition, information was more detailed both in the prior and the posterior stages. In the beginning, preschoolers were aware that both boxes had 4 cards each, and after, they were given as posterior information each box's distributions of the sample spaces (3:1 vs 1:3).

Children participated in pairs in a separate room of the school. They were given instructions about the task and were motivated by the fact that they would win stickers. During the game, cards remained on the table reminding them the given information. At a 1st level, participants were asked to select orally the box they believed contained the lucky animal-card. As soon as they pointed to a box and before drawing a card of their choice, they were given new information orally by the experimenter about where the lucky card might be. Based on this new information, children either reconsidered their prior choice and switched box or made new predictions in order to succeed the desired outcome, i.e. the lucky –card. All participants carried out the 2 conditions in the same order.

Children recorded by themselves their final choices on specially designed sheets, independent of the actual outcome. These recorded sheets were used for further analysis.

RESULTS

Overall, children made correct predictions; they gave in total 36 correct answers out of 50. For the purposes of the current study, 'correct' is the answer that relates to the box with the higher probability of hiding the lucky animal. The predictions that related to the less probable box were scored as 'incorrect'. Such coding is used just for the analysis of the current results, as there is no such 'correct- incorrect' in probability tasks.

From the descriptive analysis (Table 2) it can be seen that in condition 1, children predicted the correct box by 60% and in condition 2 they responded correctly by 84%, in terms of selecting the more probable box.

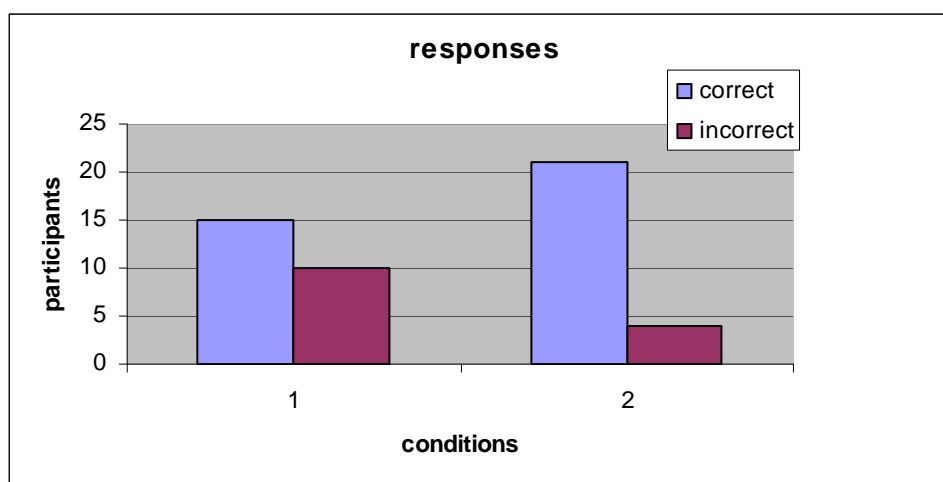

Table 2: Overall responses in cases 1&2.

The differences in the available information of each condition affected children's responses. Concerning the nature and the amount of information, it was found by the paired-sample t-test analysis concerning proportions, that there is a significant difference between conditions 1 and 2, $t(25) = 2.295$, $p < 0.05$. There is a significant difference between the means of the two conditions. This implies that children's inferences in tasks that relate to posterior probability get affected by the kind and the range of information provided as new.

DISCUSSION

The results of this pilot study support that preschoolers may participate in probabilistic tasks successfully and integrate any available information, while forming their inferences in more than one stage. These results comply with the findings of Girotto & Gonzalez (2008). Among these lines, young children correctly revise their decisions when given new sets of information about single, non-repeatable events.

The baseline for both conditions was that the sample space was 8 and the lucky animal was a duck. The amount of given information was more complex and detailed in condition 2 and was not of equivalent difficulty as in condition 1. Thus, in this 2nd condition preschoolers were found to be able to make more correct predictions in terms of choosing the more probable set of given information. Overall, children showed the capacity to consider and handle information while participating in a probabilistic task.

However, the limited sample considers an issue for further research. Another limitation that could be taken into account refers to the children's participation in pairs. If children conducted the task individually would they make the same predictions? Or do they get influenced by their classmates? In addition, more

conditions, randomization of the boxes, more variations in the given information (i.e. qualitative) and other stimuli such as cards with different themes or pictures could lead to different interpretations.

In this game, children made more correct predictions when given more detailed and precise information about the sample space (i.e. condition 2 vs condition 1). This has a methodological significance that should be considered while designing probabilistic tasks. Children express and develop probabilistic ideas, depending on the design of the given activity (Papaparistodemou & Noss 2004; Pratt, 2000). The nature and the amount of information are important factors that affect children's probabilistic thinking.

Opposed to the piagetian perspective, young children before the age of 7 can make inferences and handle more than 2 combinations in order to participate in probability tasks. Recent studies have shown that children as young as 4 demonstrate an understanding of probabilities and expected value, adjust preferences based upon probability, understand basic notions of probabilistic thinking (Acredolo et al, 1989; Schlottmann, 2001; Way, 2003; Nikiforidou & Pange, 2007) and possess specific concepts and skills associated with probabilistic reasoning (Langrall & Mooney, 2005).

Furthermore, preschoolers make use of additional information and reveal a capacity to proceed in posterior probabilities (Giroto & Gonzalez, 2008) or in a two-stage choice task. Future research has to focus in this direction; in setting all the factors that are cognitively equivalent to young children's probabilistic thinking. The types of random generators, the mathematical structure of sample space, the type of responses, the nature of comparison or estimation (Way, 2003), the sort and amount of given information should be taken into consideration while designing probability tasks for preschoolers, who are characterized by intuitive and non-formal thinking.

STUDENT'S CAUSAL EXPLANATIONS FOR DISTRIBUTION

Theodosia Prodromou¹ and Dave Pratt²

¹Vergina Lyceum, Cyprus; ²University of London, UK

This paper presents a case study of two students aged 14-15, as they attempt to make sense of distribution, adopting a range of causal meanings for the variation observed in the animated computer display and in the graphs generated by the simulation. The students' activity is analysed through dimensions of complex causality. The results indicate support for our conjecture that carefully designed computer simulations can offer new ways for harnessing causality to facilitate students' meaning-making for variation in distributions of data. In order to bridge the deterministic and the stochastic, the students transfer agency to specially designed active representations of distributional parameters, such as average and speed.

Keywords: causality, agency, stochastic thinking, variation, randomness, probability

VARIATION AND CAUSALITY

This research study builds on ideas which emerged from two research studies: 1) the seminal work of Piaget (1975, translated from original in 1951) and 2) Pratt's work (1998; 2000) as it attempts to clarify how students let go of determinism whilst at the same time re-apply such ideas in new ways to account for variation (Prodromou, 2008; Prodromou & Pratt, 2008).

Piaget and Inhelder (1951) reported how the organism fails in the first place to apply operational thinking to the task of constructing meanings for random mixtures, which were therefore unfathomable. Only much later, according to Piaget, the organism succeeds in inventing probability as a means of operationalising the stochastic. In contrast, students soon gain mastery over the deterministic, appreciating cause and effect at least in a basic manner, apparently lending itself more easily to operational thinking. Instead of interpreting Piaget's work as presenting an impregnable divide between the stochastic and the deterministic, at least until a late stage of development, we began to wonder whether the divide was a manifestation of conventional technologies and whether digital technology might provide a means by which the deterministic might be harnessed to support new ways of thinking about the stochastic.

In Pratt's work (for example, 2000, 2002), students aged 11 years explored computer-based mini-simulations of everyday random generators, such as coins, spinners and dice. These simulations provided functionality beyond that which would be experienced in everyday life. For example, the students were able to change the workings of the simulation and so explore their ways of thinking about randomness. Gradually, the students articulated the heuristic that "the more times you throw the dice, the more even is its pie chart". We detect in this statement a sense that the number of throws *determined* the appearance of the pie chart. Similar causal

statements were made about other aspects of the system, such as the effect of changing the workings of the simulation.

Pratt referred to these causal heuristics as *situated abstractions* (Noss and Hoyles, 1996), internal meanings for making sense of phenomena that capture the abstracted nature of the meaning, expressed in language tied to the situation. Pratt and Noss (2002) have further elaborated on the nature of situated abstractions as part of a model for the micro-evolution of mathematical knowledge.

We believe Pratt has made a *prima facie* case that, in certain conditions, possibly deeply connected to the potential of technologically-based environments, students can construct stochastic meanings out of causality. In this study, we examine this possibility further by building a digital simulation to provide a *window* on students' *thinking-in-change* (Noss & Hoyles, 1996) about average and spread as parameters within a distribution.

First though, we must be more specific about what we mean by causality. In fact, causality can be seen at a variety of levels (Grotzer and Perkins, 2000; Perkins and Grotzer, 2000). Grotzer and Perkins have proposed a taxonomy or a classification scheme that attempts to organise increasing complexity of causal explanation. The taxonomy comprises causal explanations organised in four dimensions along which causal complexity is characterized:

Mechanism includes the most superficial causal explanations, appealing to the most general of phenomena, or to token agents, perhaps “luck”, “destiny” or “god’s will” in the case of stochastic. Within this dimension we begin also to see inferences of underlying mechanisms.

Interaction pattern begins with simple cause and effect explanations but extends to complex relational causality, involving the co-existence of two or more interdependent factors, possibly with feedback mechanisms. For example, agent A affects agent B but feedback from agent B then affects agent A.

Probabilistic Causality relates to the use of uncertainty in modelling causal relationships. Often apparently deterministic systems hide uncertainty in a chaotic complexity. Thus, does the cup which rests on the table express the equilibrium of underlying static forces? Or should we seek explanation by reference to the chaotic dynamic motion of the sub-atomic particles that constitute the table and the cup? Conversely, we choose to explain phenomena in terms of probability to avoid reference to deep layers of underlying causality. Thus, we might choose to model the outcome from the throw of a dice in terms of probability, rather than by reference to multiple and interacting forces, such as the strength of the throw, the weight of the dice and the friction at the surface.

Agency describes those explanations that recognise that causality is distributed across many elements. Such explanations might use ideas of emergence. For example, we

might consider a theoretical distribution as a pattern that emerges from the many pieces of data.

We wished to explore what sorts of computer-based tools might provide us with a window on the use of these differing levels of causal complexity to make sense of distribution, as generated within a computer simulation. We set out to design a virtual environment that supported students in attributing agency to the emergent shape of the distribution while they were discriminating and moving smoothly between data as a series of random outcomes at the micro level, and the shape of distribution as an emergent phenomenon at the macro level.

In that respect, we conjectured that the computer simulation environment could enable students:

- at the micro level to use their understanding of causality whilst at the same time begin to recognise its limitations in explaining local variation, and
- at the macro level to see parameters such as average and spread as causal agents, impacting on the shape of distribution, whilst nevertheless not completely defining the distribution.

METHOD

Approach and tasks. The approach of this research study falls into the design research methodology (Cobb et al., 2003) resulting in the *BasketBall* simulation as depicted below (Fig 1). The animation of the basketball player was controlled by

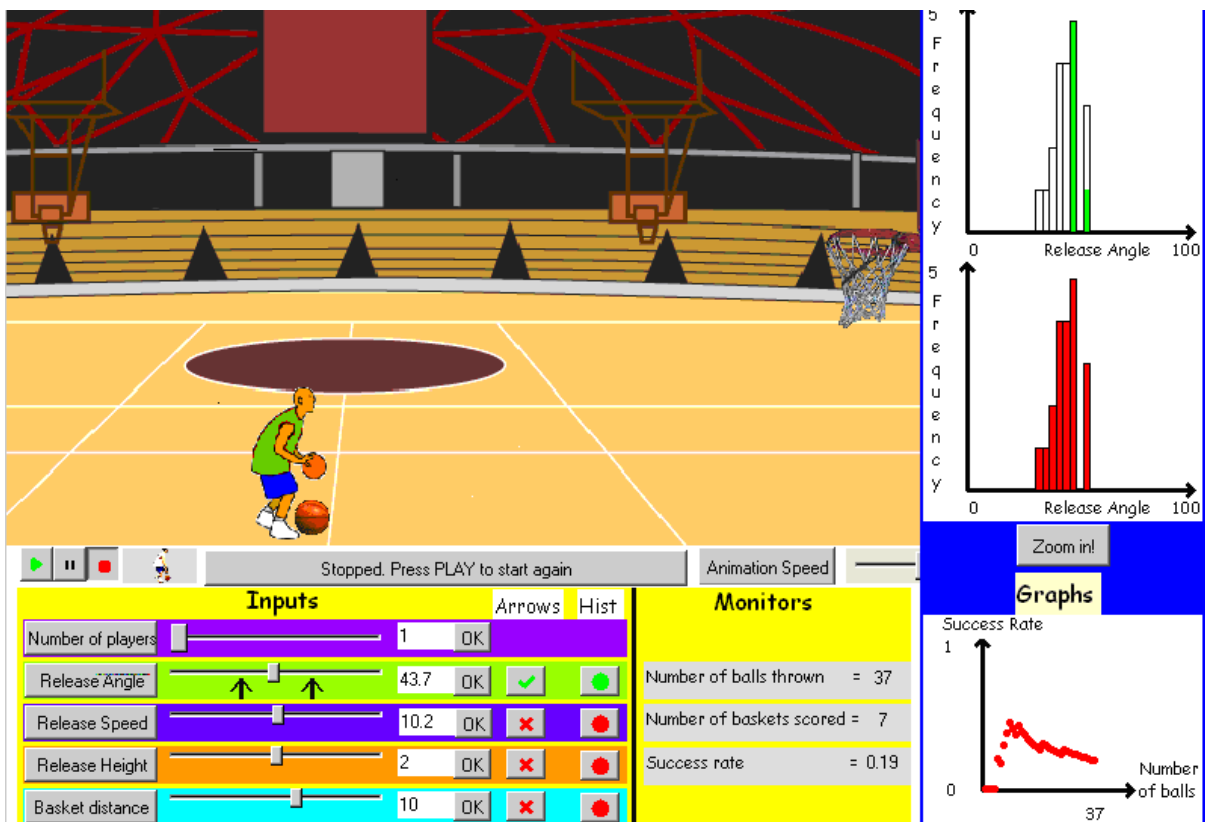

Fig 1: The interface of the *BasketBall* simulation.

varying the handles on the sliders of the release angle, speed, height and distance or by entering the data directly. Once the play button has been pressed, the player continues to throw with the given parameters until the pause or stop button is pressed. The trace of the ball can be switched off. Feedback is made available from the Monitors and Graphs panes. When the arrows button has been switched on, two arrows appear from both sides of the handle on the slider (Fig 2), in which case the value of the parameter is chosen from a distribution of values, centred on the handle of the slider. The students are able to vary these arrows to increase or decrease the spread of the values of the parameter around that centre. The microworld also allowed the students to explore various types of graphs relating the values of the parameters to frequencies and frequencies of success. The students have access to a linegraph of the success rate as well as a histogram of the frequency of successful throws or throws in general against release angle (or release speed, or height, or distance). Initially, the students were challenged to throw successfully the ball into the basket. When the parameters were determined, the histograms of the frequency of successful throws against release angle (or release speed, or height, or distance) appeared as a single bar columns.

Once the preliminary task was completed, some discussion about the realism of the simulation followed, which normally introduced notions such as skill-level, the use of the ‘arrows’ buttons and the appearance of the histograms. When bias had been introduced to the throws, the graphs appeared as histograms. The subsequent task for the students was to model a real but not perfect basketball player (one who was not successful on *every* throw).

Fig 2: The value of the parameter was selected from a distribution of values, centred on the position of a slider.

Participants. The simulation was used by eight pairs of students in a UK secondary school. It was assumed that the simulation would be used only by students ranging in age from fourteen to fifteen years because a tight focus on the students’ intuitions of the distributions indicated that the age of 14-15 years old was mainly ripe for conceptual change in this domain. Another important advantage of working with students of this age was curriculum-based. In the UK National curriculum (DfES, 2000) students of this age are expected to know how to graph data using histograms, dotplots and boxplots, and compare distributions and make inferences, using the shapes of distributions and measures of average and range. Students of this age,

therefore, encounter distribution as a collection of data, either given or generated through experiments and surveys.

In this paper, we concentrate on the work carried out by two students, Ethan and Emma (aged 14-15 years), as they engaged with modelling a real but not perfect basketball player. These students had already experienced moving either or both of the arrows, generating values that corresponded to distributions with different spread and bias. The first author was a participant observer during this process. She frequently intervened in order to probe the reasons or intuitions that might lie behind participants' actions.

Data collection and analysis. The data collected included audio recording of the students' voices, video recording of the screen output on the computer, and the first author's[2] field notes. The analysis was one of progressive focussing (Robson, 1993). At the first stage, the recordings were simply transcribed and screenshots were incorporated as necessary to make sense of the transcription. Subsequently, the first author turned the transcript into a plain account. At the third stage, an interpretative account was written by the first author and discussions about the validity of those interpretations with the second author followed, making therefore an account of the data before accounting *for* the activity (Mason, 1994).

FINDINGS

The case of Ethan and Emma provides an illustration of students' typical causal explanations for the observed variation. The two hour session with Ethan and Emma demonstrates how the two students mobilized combinations of different tools to create explanations of variation.

Having already found how to make a successful basket, in the following extract, Ethan and Emma were first introduced to the arrows and they had spent a little time looking at the effect on the animation:

- 1 Re[1]: What do you think these arrows do?
- 2 Et: ...Do they change the angle and the height?
- 3 Em: It's just changed the angle, so we will get better results, so we can see.
- 4 Re: What do you mean by 'better'?
- 5 Em: Because each result is different on the graph (Fig 3).
- 6 Re: Why are they better?
- 7 Em: Because they much more like realistic.

By looking at the animation, Ethan had recognized that the arrows were causing changes in the throws made by the Basketball player (line 2). Emma refers to the changes in the graph (line 5), and seems to acknowledge that it is more realistic for the basketball player to throw at varying angles (line 7).

A few minutes later however, Emma deliberated upon the role of the arrows in determining the choice of angle:

Fig 3: Emma seems to be referring not only to the different values of the angles which were chosen by the basketball player, but also appears to refer to the graph of success rate.

- 8 Re: What do you think the arrows are for?
- 9 Em: Is it... where the two arrows are, every time he throws is going to be the distance between that arrow (the arrow to the left of the vertical bar on the slider) and that arrow (the arrow to the right of the vertical bar on the slider)...
- 10 Re: Do you mean the angle?
- 11 Em: Yeah ... the angle ... You can only throw from here to there (pointing to the two arrows). You cannot go any place outside the two arrows.

Emma seemed to be conjecturing that the angle was chosen from between the two arrows (lines 9 and 11), though she still had offered no sense for the mechanism by which the choice was made.

For several minutes, the students experimented with the arrows, at which point their attention was re-focused on the variation which could be perceived through the histograms:

- 12 Re: Tell me what do you think your graphs will look like. Do you expect these graphs to have one bar, two bars, three bars, or four bars?
- 13 Em: ...about three bars.
- 14 Re: So, it will not be only one bar? Why?
- 15 Em: Because he is throwing at different angles... so... he is not throwing at the same angle all the times, so there would be more than one bar.

Emma asserted that variation in the throwing angles would result in additional bars in the histogram (line 15), and soon went further to predict that “the wider apart the arrows around the handle, the more bars there would be in the histogram”. Although, as can be seen, Emma tended to lead the discussion, Ethan was also comfortable at this point that variation could be perceived in the player’s throws and through the frequency histograms.

Their thinking about the relationship between the gap in the arrows and the number of bars was tested further a few minutes later when the bars were moved very far apart:

- 16 Re: Would there be more or less bars on the histograms?
- 17 Em: Because he can throw any distance between those two arrows... We haven’t given him a fixed angle to throw it at, so they would not be

the same every time. It will be different... because the arrows give him more of a choice... because the computer like assigns any angle at random between those two arrows... it records it in the graph.

For the first time, Emma referred to a random mechanism operating to make the choice from the gap between the arrows (line 16). She referred also to the interactions between a group of agents (arrows, basketball player, computer), which somehow cooperated to accomplish variation in the distribution.

So far, the discussion had centred on the connection between the gap in the arrows and the variation as seen in the animation or in the graphs. Later, the discussion switched to whether the score was successfully made or not. In the following extract, the handle is positioned on an angle which would successfully throw the ball into the basket and Emma and Ethan know this to be the case. They considered the effect of the arrows on success:

- 18 Em: Yeah... because when we put the arrows closer together, so it doesn't have enough choice, like... He can only pick between those two arrows for the release angle... so, he gets a better chance of... to score.
- 19 Et: As he's got the release angle inside... that space so... so got to choose that release angle that is scored...
- 20 Re: Which is inside ...?
- 21 Em: 63.3... and 76.3... he can only choose... a release angle between those two numbers.

Emma and Ethan both seemed to grasp that a small gap reduced the possibilities for failing to throw a successful basket (lines 17 and 18).

DISCUSSION

As an expert observing Emma and Ethan's activity, it is not difficult to recognise the connection between the arrows and the statistical notion of spread. Such an expert might see the distance between the arrows as a measure of spread. In fact, the data that is actually generated might portray spreads greater or less than that predicted by the gap between the arrows. In this sense the gap between the arrows operationalises the spread parameter of an underlying theoretical distribution, whereas what the students observe is a set of data generated randomly from that distribution.

The above protocol illustrates, through the case of Emma and Ethan, the use of causal explanations, at differing levels of causal complexity, to make sense of variation as it is depicted in the simulated animation of a basketball player and in graphical feedback. These explanations do not take the form of formal robust theory-oriented statements but rather they emerge more as tentative, situated, conjectural utterances, though as the exploration continues the utterances carry more authority and assurance and begin to sound more like conclusions than conjectures.

In Table 1, we list seven observed situated abstractions, based on the body of evidence, which the above protocol typifies:

Ref	Characterisation of situated abstraction	Line
SA1	“the arrows affect the angle that the basketball player throws the ball”	2
SA2	“the arrows affect the graph”	5
SA3	“angles are chosen from between the arrows”	15
SA4	“the wider apart the arrows around the handle, the more bars there would be in the histogram”	15
SA5	“the computer assigns any angle at random between the arrows and records it in the graph”	16
SA6	“The computer assigns a random value from the gap between the arrows for the basketball player to throw the ball”	17
SA7	“the closer together the arrows, the more is that chance to score”	18

Table 1: Examples of situated abstractions

The situated abstraction, SA1, reflects an awareness that the arrows have a causal affect on the variation in throws by the animated basketball player. SA2 similarly recognises a causal effect on the graph. Both these situated abstractions seem to operate at the mechanism level in the Grotzer and Perkins taxonomy. There appears at this stage to be little appreciation of further underlying levels of causal complexity though these begin to emerge later. Situated abstractions, SA3 and SA4, show an increased focus on mechanism as Emma and Ethan strive to make sense of how the arrows affect the player’s actions and the appearance of the graphs.

Situated abstraction, SA5, portrays the relationship not as purely deterministic but as including a random element. This introduction of uncertainty seems to represent a move from the mechanism level to probabilistic causality in the terminology of Grotzer and Perkins. Emma and Ethan do not have a sophisticated understanding of probability and so they do not progress deeply into this level but they do seek out, as articulated in both SA5 and SA6, explanations that accept a probabilistic language as a means of coping with a possible multitude of unknown factors. Of course, this move may have been all the easier to make because randomness is something they perhaps regularly experience on computers through, for example, playing computer games. In SA7, Emma and Ethan recognise, even with their ongoing probabilistic language, combinations of agents, as predicted in the interaction pattern level in the Grotzer and Perkins taxonomy. Emma and Ethan envisage a transference of agency from the computer to the arrows and then to the Basketball player. We note that we have previously reported a similar transference of agency from the student itself to the arrows (Prodromou, 2008; Prodromou & Pratt, 2006).

CONCLUSION

The facility to transfer agency seems to be a crucial move in making connections between the causal and the stochastic (from our perspective on the student's psychological state) and in harnessing the deterministic (from the perspective of designing for the student's abstraction). Indeed, by providing handles, arrows and a basketball player, together with feedback on "their actions" (and here we intentionally give these things agency), we set up the possibility that distribution might be seen as generated by the agents. Technological tools, therefore, may have been especially significant in supporting the construction of stochastic meanings out of causality and that in this sense they may provide a route towards operationalising the stochastic in the absence of formal operations.

We believe that such a view of distribution is consistent with the expert position in which a theoretical distribution is sometimes viewed as a generative model, for example sending out a signal *determined* by the average parameter and noise *determined* by the spread parameter. Such a position accepts that the deterministic view of distribution is useful within limitations. Simulations such as basketball might provide opportunities for students to begin to appreciate that expert position.

Even though we have referred regularly to agents, the reader may have noticed that nothing has actually been said about the final level in the Grotzer and Perkins taxonomy, that of agency in which causality is distributed across many agents. In fact, we intend to report elsewhere on students' attempts to make connections from the distribution of data to the theoretical distribution, a direction which demanded an emergent perspective from the students.

When students view variation as an accomplishment of a combination of agents, they think about distribution in terms of a relational model. Their expressions move along the underlying causality dimension towards considering that the simulated *BasketBall* is a context perturbed by a random mechanism. Students' accounts began gradually to address dimensions of probabilistic causality, such as noisy systems, chancy systems. Students were able to view the activities in the *BasketBall* context as noisy processes dependent on a variety of intervening variables. Those accounts were themselves preceded by students' understanding of mediating causality, where predominant causal agents, such as the arrows, and neglected agents of lower saliency in the context, such as the basketball player and the computer, mediate the effect of one agent to another in order to cause variation in the setting (Interaction pattern).

NOTES

1. 'Re' refers to the first named author (Dr. Theodosia Prodromou).
2. The data were collected for the first author's doctoral thesis.

GREEK STUDENTS' ABILITY IN PROBABILITY PROBLEM SOLVING

Sofia Anastasiadou

University of Western Macedonia

This study aims to contribute to the understanding of the approaches students develop and use in solving probabilistic tasks and to examine which approach is more correlated with students' ability in probability problem solving. Participants were students from the 12th grade. Implicative statistical analysis was performed to evaluate the relation between students' approach and their ability to solve problems. Results provided support for students' intention to use the algebraic approach and avoid Venn's diagrams. Students who were able to use the coordinated approach by using multiple representations had better results in problem solving. In addition the results suggest the flexibility in multiple representations is a trivial predictor of probabilistic problem solving.

Keywords: Probability, problem solving, 12th grade students, representations.

INTRODUCTION

There is an increasing recognition that statistical and probabilistic concepts are among the most important unifying ideas in mathematics. Statistical concepts form the single most important idea in all mathematics, in terms of understanding the subject as well as for using it for exploring other topics. The reasons to include probability and statistics teaching refer to the usefulness of statistics and probability for daily life, its instrumental role in other disciplines, the need for a basic stochastic knowledge in many professions and its role in developing a critical reasoning (Gal, 2002).

The understanding of probabilistic and statistical concept does not appear to be easy, given the diversity of representations associated with this concept, and the difficulties presented in the processes of articulating the appropriate systems of representation involved in probabilistic and statistical problem solving (SPS) (Anastasiadou, 2007).

Probability is difficult to teach for various reasons, including disparity between intuition and conceptual development even as regards apparently elementary concepts (Chadjipadelis and Gastaris, 1995). Since an education that only focuses on technical skills is unlikely to help teachers overcome their erroneous beliefs, it is important to find new ways to teach probability to them, while at the same time bridging their content knowledge and their pedagogical content knowledge (Batanero et al, 2005).

There is general consensus in the mathematics education community that teachers need a deep and meaningful understanding of any mathematical content they teach (Chadjipadelis, 2003). Biehler (1990) suggests that teachers require meta-knowledge

about probabilities and statistics, including a historical, philosophical, cultural and epistemological perspective on statistics and its relations to other domains of science.

In primary and secondary school levels, probability and statistics is part of the mathematics curriculum and primary school teachers and mathematics teachers frequently lack specific preparation in statistics education (Anastasiadou and Gagatsis, 2007; Chadjipadelis, 2003). According to Batanero et al., (Batanero et al, 2005) probability is increasingly taking part in the school mathematics curriculum; yet most teachers have little experience with probability and share with their students a variety of probabilistic misconceptions. The understanding of probabilistic concepts has been a main concern of statistics education that is an important focus of interest for the International Statistical Institute and of the International Association for Statistical Education.

In the field of statistics learning and instruction, representations play an important role as an aid for supporting reflection and as a means in communicating statistical ideas. Furthermore the NCTM's Principles and Standards for School Mathematics (2000) document include a new process standard that addresses representations and stress the importance of the use of multiple representations in statistical learning. In addition, an important educational objective in statistics is for pupils to identify and use efficiently various forms of representation of the same mathematical concept and move flexibly from one system of representation of the concept to another.

A representation is defined as any configuration of characters, images, concrete objects etc., that can symbolize or "represent" something else (Confrey & Smith, 1991, Goldin, 1998). Representations have been classified into two interrelated classes: external and internal (Goldin, 1998). Internal representations refer to mental images corresponding to internal formulations that we construct of reality. External representations concern the external symbolic organizations representing externally a certain mathematical reality. In this study the term "representations" is interpreted as the "external" tools used for representing statistical ideas such as tables and graphs (Confrey & Smith, 1991). The need for a variety of semiotic representations in the teaching and learning of probabilities is usually explained through reference to the cost of processing, the limited representation affordances for each domain of symbolism and the ability to transfer knowledge from one representation to another (Duval, 1987). By a translation process, we mean the psychological processes involving the moving from one mode of representation to another (Janvier, 1987). Several researchers in the last two decades addressed the critical problem of translation between and within representations, and emphasized the importance of moving among multiple representations and connecting them (Gagatsis & Elia, 2004; Goldin, 1998; Yerushalmy, 1997). Different representations referring to the same concept complement each other and all these together contribute to a global understanding of it (Gagatsis & Siakalli, 2004). Duval

(2002) claimed that the conversion of a mathematical concept from one representation to another is a presupposition for successful problem solving. A person who can easily transfer this knowledge from one structural system of the mind to another is more likely to be successful in problem solving by using a plurality of solution strategies and regulation processes of the system for handling cognitive difficulties. Kaput (1987) suggest that the concept of representation involves the following five components: a representational entity, the entity that it represents, particular aspects of the representation entity, the particular aspects of the entity that it represents that form the representation and finally the correspondence between the two entities. According to the above definition, the representation is considered a mental symbol or concept, which represents a concrete material symbol. It takes the place of another element and obtains more capabilities than the object itself. Many studies identified the difficulties that arise in the conversion from one mode of representation of a mathematical concept to another. They revealed students inconsistencies when dealing with relative tasks that differ in a certain feature, i.e. mode of representation. This incoherent behavior was addressed as one of the basic features of the phenomenon of compartmentalization, which may affect mathematics learning in a negative way (Gagatsis & Elia & Mousoulidis, 2006). According to Duval (Duval, 2002), the phenomenon of compartmentalization reveals a cognitive difficulty that arises from the need to accomplish flexible and competent conversion back and forth between different kinds of mathematical representations.

In Greece, the introduction of Statistics in the mathematics textbook of primary schools took place at the end of nineties. The teaching of fundamental statistical concepts was assigned to primary school teachers who are responsible for teaching all the curriculum subjects in the primary level. (Anastasiadou, 2007). The emphasis on statistics and probability in curricula varies, often according to knowledge and feelings of the teacher.

Although that many researches have been done in relation to study of the of the representations role in mathematical understanding and learning, there only a few that explore students' performance in using multiple representations of statistical and probability concepts with emphasis on the effects exerted on performance and on the relations among the various conversion abilities from one representation to another.

The purpose in this study is to contribute to the statistics education research community understands of approach students build up and use in solving statistical tasks and to examine which approach is more associated with students' ability in solving statistical concepts. A main question of this study referred to the approach primary school students use in order to solve simple probability tasks. It is important to know whether students are flexible in using algebraic, graphical and verbal representations in probabilistic problems. Most of the students used an algebraic approach in order to solve the simple probabilistic tasks. This study intends to shed light on the role of different modes of representation on the understanding of some basic probabilistic concepts. This study

investigated pre-service teachers' performance, in two aspects of probabilistic understanding: the flexibility in multiple representations and the problem solving ability.

METHOD

Participants- Data analysis-Tasks

The sample of the study involved 132 12th grade students from secondary schools in different regions of Thessaloniki (Western Thessaloniki, Eastern Thessaloniki, Central Thessaloniki) in Greece. These regions were selected because of their diversity in size and population. In Greek secondary education only students of the 12th grade are taught basic concepts of probability theory.

For the analysis of the collected data the similarity statistical method (Lerman, 1981) was conducted using a computer software called C.H.I.C. (Classification Hiérarchique, Implicative et Cohésitive) (Bodin, Coutourier & Gras, 2000). This method of analysis determines the similarity connections of the variables. In particular, the similarity analysis is a classification method which aims to identify in a set V of variables, thicker and thicker partitions of V , established in an ascending manner. These partitions, when fit together, are represented in a hierarchically constructed diagram (tree) using a similarity statistical criterion among the variables. The similarity is defined by the cross-comparison between a group V of the variables and a group E of the individuals (or objects). This kind of analysis allows for the researcher to study and interpret in terms of typology and decreasing similarity, clusters of variables which are established at particular levels of the diagram and can be opposed to others, in the same levels. It should be noted that statistical similarities do not necessarily imply logical or cognitive similarities. The red horizontal lines represent significant relations of similarity.

The test consisted of 12 tasks of two "equivalent" problems in difficulty from the mathematical point of view. In particular, the tasks concerned concepts of the probability theory such as probability, Venn's diagrams, events and probability problems.

Right and wrong or no answers were scored as 1 and 0, respectively. Students' responses to the tasks comprise the variables of the study which were codified by an uppercase V (variable concerns Venn's diagrams) or P (probability problem), η R (concept definition, e.g. event), followed by the number indicating the exercise number. Following is the letter that signifies the type of initial representation (e.g. r =representation, t =table, g =graphic, v =verbal) and, lastly, comes the letter that signifies the type of final representation.

For example the first and second tasks are the following ones: Task 1. Given two events A and B of a chance experiment and with the help of set theory we have the following event $A' \cap B'$. Present with a Venn diagram this event ($V1sg$). Task 2. Given two events A and B of a chance experiment and with the help of set theory we have the following

event $(A \cap B) \cup (A \cap B')$. Express the verbal representation of this event (V2sv).

RESULTS

Descriptive results

Table 1 presents the success rates of third, fifth and sixth grade indigenous students and immigrants in all types of conversions.

Tasks	Type of translation	12 th grade success rate of students (%)	Tasks	Type of translation	12 th grade success rate of students (%)
V1sg	Symbolic - Graphic	52.8%	P7va	Verbal - Algebraic	32.6%
V2sv	Symbolic - Verbal	51.6%	P8vg	Verbal - Graphic	28.3%
V3gs	Graphic - Symbolic	34.5%	P9vs	Verbal - Symbolic	22.6%
V4gv	Graphic - Verbal	30.7%	P10vv	Verbal - Verbal	27.5%
V5vg	Verbal - Graphic	46.2%	R11vv	Verbal - Verbal	23.1%
V6vs	Verbal - Symbolic	48.6%	R12vs	Verbal - Symbolic	22.9%

Table 1: Success rates of indigenous students and immigrants in the tasks

Similarity diagram of students' responses to the two tests

The similarity diagram in this study concern the data 11th grade and allow for the arrangement of students' responses ((V1sg), (V2sv), (V3gs), (V4gv), (V5vg), (V6vs), (P7va), (P8vg), (P9vs), (P10vv), (R11vv), (R12vs), to the tasks into groups according to their homogeneity.

Two clusters (Cluster A and B) of variables are identified in the similarity diagram of 11th grade students' responses as shown in Figure 1. Cluster A involves three pairs of variables V1sg-V2sv, V3gs-V4gv, V5vg-V6vs in Cluster A and concerns events representations with the aid of Venn diagrams. Cluster B involves three pairs of variables R11vv- R12vs, P7va-P8vg, P9vs-P10vv and involves variables relating to probability problem solving. This grouping suggests that students dealt similarly with the conversions involving probability problems.

The structure of the diagram reveals a cognitive difficulty that arises from the need to accomplish flexible and competent conversion back and forth between different kinds of probabilistic representations. Thus, this particular structure of the diagram indicates a

compartmentalization of the tasks of the tests. Students approached in a completely distinct way the tasks which involved the use of Venn's diagrams and the probability problems. Therefore, possible instructive activities would focus on the identification of the two different groups. The strongest similarity (almost 1) occurs between variables (V3gs-V4gv) (Figure 1) that were the most difficult for the students of 12th grade (Table 1). Furthermore the similarity (V1sg-V2sv, V3gs-V4gv) is also important (0.923).

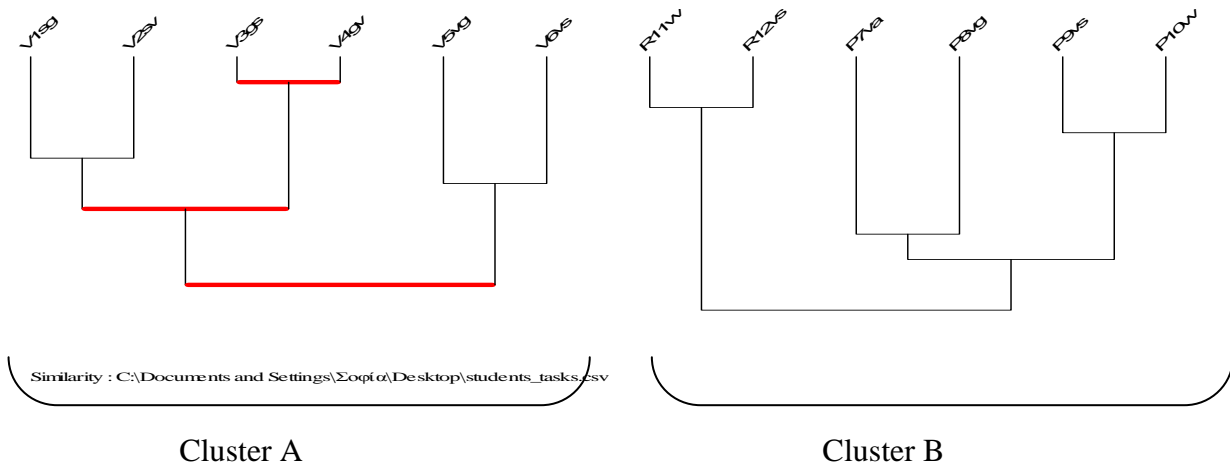

Figure 1: **Similarity Diagram**

CONCLUSIONS RESULTS

Representations enable students to interpret situations and to comprehend the relations embedded in probabilistic problems. Thus, we consider representations to be extremely important with respect to cognitive processes in developing probabilistic concepts. The main contribution of the present study is the identification of secondary students' abilities to handle various representations and to translate among representations related to the same probabilistic relationship. Our findings provide a strong case for the role of different modes of representation on 12th grade students' performance to tasks on basic statistical concepts such as frequency. At the same time they enable a developmental interpretation of students' difficulties in relation to representations of Venn diagrams. Lack of connections among different modes of representations in the similarity diagram indicates the difficulty in handling two or more representations in probabilistic tasks. This incompetence is the main feature of the phenomenon of compartmentalization in representations, which was detected in students of both grades. This inconsistent behavior can be seen as an indication of students' conception that different representations of the same concept are completely distinct and autonomous mathematical objects and not just different ways of expressing the meaning of a particular notion. An alternative explanation for the difficulty in transferring knowledge

could be the emphasis on stating with representations and defining transfer as connecting those representations. Perhaps links that were more powerful and meaningful for the students would have led to a space of the utility of the statistical and probability construct (Ainley and Pratt, 2002). Transfer might then be achieved by recognizing new situations which are consistent with the same meaning. In addition the lack of transfer may be attributed to the students' lack of preparation: time to discuss, interact and work on related tasks.

Probability instruction needs to encourage pupils' involvement in activities including translations between different modes of representation. Even more educators should focus on reasons that we use a specific representation or another of the same probability concept. As a result, students will be able to overcome the compartmentalization difficulties and develop their flexibility in understanding and using a concept within various contexts or modes of representation and in moving from one mode of representation to another. Moreover there is a strong need for teachers to understand what it is that students know about stochastic and offer them experiences of probability before theoretical perspectives are introduced.

It seems that there is a need for further investigation into the subject with the inclusion of a more extended qualitative and quantitative analysis. In the future, it is interesting to compare the strategies and modes of representations students used in order to solve the problems. Besides, longitudinal performance investigation in the multiple representation flexibility tasks for secondary students should be carried out.

ALGEBRAIC THINKING AND MATHEMATICS EDUCATION

Janet Ainley^a, Giorgio T. Bagni^b, Lisa Hefendehl–Hebeker^c, Jean–Baptiste Lagrange^d

^aUniversity of Leicester, ^bUniversity of Udine,

^cUniversity of Duisburg–Essen, ^dUniversity of Lyon

In CERME–6 Working Group “Algebraic Thinking” we continued the work done in previous CERME conferences, both by following the discussions raised and by pointing out unanswered questions (Puig, Ainley, Arcavi & Bagni, 2007).

More particularly, in CERME–6, Working Group “Algebraic Thinking” was concerned with further discussion on historical, epistemological, and semiotic perspectives in research in the teaching and learning of algebra. The role of artifacts, technological or not, was also considered in this perspective. In general, Working Group “Algebraic Thinking” was interested in proposing to address the issue of the actual impact of research on curriculum design and development, and on practice.

In order to allow a detailed discussion of the contributions, we decided to split the working group into two subgroups:

- the subgroup A (co–ordinated by Lisa Hefendehl–Hebeker) included some contributions mainly focused on cognitive aspects. The Authors were W.F. Castro and J.D. Godino; M.–C. Croset; A. Cusi; J.–P. Drouhard; C. Fernández and S. Llinares; B. Gómez and C. Buhlea; M. Hoch and T. Dreyfus; J. Hodgen, D. Kuchemann, M. Brown and R. Coe; R. Oldenburg; I. Papadopoulos and M. Iatridou; F. Siebel and A. Fischer; I. Sinitsky and B.–S. Ilany; E. Söbbeke and C. Böttinger; A.M. Wille.
- the subgroup B (co–ordinated by Janet Ainley) included some contributions mainly focused on pedagogical aspects. The Authors were O. Akkus and E. Cakiroglu; M. Ayalon and R. Even; G.T. Bagni; A.B. Fyhn; S. Gerhard; M. Haspekian and E. Bruillard; I. Jones; J.–B. Lagrange and T.K. Minh; C. Marchini, A. Cockburn, P. Parslow–Williams and P. Vighi; M. Panizza; R.A. Rinvold, and A. Lorange; E. Robotti, G. Chiappini and J. Trgalova.

Posters presentations by R. Berrincha and J. Saraiva, Ç. Kiliç and A. Özdaş, B.M. Kinach, A. Matos, C. Monteiro and H. Pinto, A.I. Silvestre, I. Vale, T. Pimentel produced important contributions to our discussion.

In the following file, contributions are organised according to the alphabetic order of the corresponding authors.

GENERAL REFLECTIONS

The invention of the symbolic language of algebra influenced the development of mathematics in all domains. Symbolic language is used throughout all mathematics:

for instance, there is no possible calculus or analysis without solving inequalities, structures (groups, rings, ...) are used to describe all parts of mathematics (Drouhard, 2009). This must be taken into account when considering early algebra.

Historically, algebra results from what evolution scientists call co-evolution. This co-evolution involves: first an art, then a science of resolution of numerical problems; first informal representation systems, then formal registers (semiotic representation systems); first a science of numbers, then a science of structures (Drouhard, 2009). So today algebra is a science of resolution of numerical problems, a family of semiotic systems (linguistic or not), and a science of numbers and structures.

In a passage of his *Questions Concerning Certain Faculties Claimed for Man*, Charles S. Peirce (1839–1914) suggests that it is impossible to “think without signs” (Peirce, 1868/1991, p. 49). In a Peircean perspective, algebraic language is based upon iconicity. Let us quote Peirce (1931–1958, 2.279, *MS 787*):

Particularly deserving of notice are icons in which the likeness is aided by conventional rules. Thus, an algebraic formula is an icon, rendered such by the rules of commutation, association, and distribution of the symbols [...]. For a great distinguishing property of the icon is that by direct observation of it other truths concerning its object can be discovered than those which suffice to determine its construction.

Two remarks must be taken into account. Firstly, every sign “contains” all the components of Peircean classification, although one of them (e.g. iconicity) is predominant. For instance, algebra is not characterised by the presence or absence of letters: algebra is characterised by the existence of a semiotic representational system, a system which allows us to solve numerical problems and to express number properties. So algebra is not but has got a language (Drouhard, Panizza, Puig, & Radford, 2006).

Secondly, Peirce’s semiotics hardly explains the complexity of sign-based human thought processes and the manner in which they relate to their corresponding historical settings (Douek, forthcoming). The historical dimension of cognition and its cultural subbasement (see Bradford & Brown, 2005; D’Ambrosio, 2006) are a fundamental theme in recent sociocultural perspectives where cognition is conceptualized as “a cultural and historically constituted form of reflection and action embedded in social praxes and mediated by language, interaction, signs and artifacts” (Radford, 2008, p. 11). Sociocultural perspectives lead to both new conceptions of cognition and new views about knowledge and the cognizing subject: algebraic thinking can be framed into the mentioned perspective.

Algebraic language must be described by linguistic terms (“syntax”, “semantics”). In terms of semantics, the power of algebra lies in the capability to judiciously “forget the meaning”. From an educational viewpoint, it is worth noting that students must at the same time master the languages (natural and symbolic), their respective syntax and semantics and the semiotic aspects of these languages, and be flexible, so be able

to work both with meaningless and meaningful expressions (see remarks in Puig, Ainley, Arcavi & Bagni, 2007).

COGNITIVE ASPECTS

As regards cognitive aspects (subgroup A), it is worth noting that the tension between the possibility of formal manipulation and the necessity of semantic understanding, which is typical for algebraic activities, causes particular cognitive demands for the learners. There are many partial abilities which should be learned and grow together to an interrelated system. Mental acts and ways of thinking (Harel, 2008) which are essential for algebraic thinking have to be activated on different layers:

- *Structuring*: The symbolic language of algebra is a tool to conceive arithmetical structures, and as a semiotic system it has a structure of its own. Comprehensive learning of algebra and successful manipulation of its language deserves “structure sense” in different respects.
- *Generalizing*: Generalizing belongs to the essence of algebra. It means to grasp something typical, which all cases under consideration have in common. Variables are tools to express indeterminacy and generality. To describe a sequence of geometrical patterns by a formula and to find a common form of a set of formulas (for example quadratic equations) are activities on different stages of generalization.
- *Representing*: The representation system of algebra in its final stage is symbolic and formal, that means, it allows context-free manipulation. This makes it difficult to grasp for learners, but for experts it gains a new kind of meaning and richness in itself.

Many contributions showed that there are previous stages in the development of these ways of thinking, which should be cultivated in the learning process. Such activities might help to reduce the “cognitive gap” between arithmetic and algebra:

- *Structuring and generalizing*: For example pre-service primary teachers experience structuring and thus develop “algebraic awareness” when they analyze, describe and continue patterns and structures in geometric and algebraic contexts. A fruitful interplay between arithmetic and geometric visual approaches can also be experienced on later stages.
- *Representing*: L. Radford demonstrated in his plenary address that alphanumeric symbolism is not the only way to express algebraic thinking. He pointed out that there is a conceptual zone before, where algebraic thinking is contextual and embodied in the corporeality of actions, gestures, signs and artefacts.

Nevertheless such approaches to teaching algebra have their own problems.

PEDAGOGICAL ASPECTS

In considering pedagogical approaches to teaching algebra (subgroup B) there is a potential tension between the need to focus on structure independently of context (for

example to develop understandings of equality, equivalence), and the uses of context as ways to make structure visible (for example by means of metaphor, metonymy, allegory, artefacts, narratives, ...). Teachers and pupils may be attending to different aspects of the activity: while the teacher is looking through a context such as a visual pattern in order to see generality, pupils may be looking at the stages of construction of the particular pattern.

Different perceptions of the nature of algebraic activity may become apparent when considering the role of, and need for, proof. Similarly, alternative perceptions of the nature of tools, artefacts and representations emerge from close study of the conversations in classrooms. This presents real challenges for teachers in their interactions with learners, and of their interventions in activities.

A continuing challenge is the design of tasks which may motivate a real need for algebraic thinking. There is clearly no single ‘best’ approach to algebra; many good approaches can support each other. It is important to interrogate each approach to identify what it may offer and for whom. The design of such tasks must take account of the rich variety which may be covered by the phrase ‘algebraic thinking’ and the ways in which such thinking may be expressed. Rather than focussing on differences between arithmetic and algebraic thinking, it may be powerful to see this as a continuum, or parallel development, rather than as a dichotomy. Generalisation may be embodied through gesture, including virtual gestures on a computer screen, or expressed through natural language as well as through symbolism. Variable is an algebraic idea that children must understand on their way to learning symbolic generalisation because it allows thinking about change, generalisation and structure. It is an idea which may be introduced and expressed in many ways: the design challenge is to find ways to engage learners in the real need for, and power of, algebra.

THE EFFECTS OF MULTIPLE REPRESENTATIONS-BASED INSTRUCTION ON SEVENTH GRADE STUDENTS' ALGEBRA PERFORMANCE

Oylum Akkus¹ and Erdinc Cakiroglu²

The purpose of this study was to investigate the effects of multiple representation-based instruction on seventh grade students' algebra performance. The study was conducted on four seventh grade classes from two public schools lasting eight weeks. For assessing algebra performance, three instruments called translations among representations skill test, objective based achievement test, and Chelsea diagnostic algebra test were used. The analyses were conducted by using multivariate covariance statistical model. The results pointed out that multiple representation-based instruction had a significant effect on students' algebra performance compared to the conventional teaching. In addition to this, students from experimental groups found this way of teaching fruitful.

INTRODUCTION

Various meanings can be given to the concept of “representation” in connection with the teaching and learning of mathematics. Seeger, Voight, & Werschescio (1998) summarized some of those definitions in very general terms as follows: “...representation is any kind of mental state with a specific content, a mental reproduction of a former mental state, a picture, symbol, or sign, symbolic tool one has to learn their language, a something “in place of” something else”.

Multiple representations can be generally defined as providing the same information in more than one form of external mathematical representation by Goldin and Shteingold (2001). The usage of multiple representations in mathematical learning was investigated in depth by Janvier who defined it “understanding” as a cumulative process mainly based upon the capacity of dealing with an “ever-enriching” set of representations (Janvier, 1987, p. 67). There are two important key terms in a theory of representation that are; “to mean or to signify, as they are used to express the link existing between external representation (signifier) and internal representation (signified)” (Janvier, Girardon, & Morand, 1993, p. 81). External representations were defined as “acts stimuli on the senses or embodiments of ideas and concepts”, whereas internal representations are regarded as “cognitive or mental models, schemas, concepts, conceptions, and mental objects” which are illusive and not directly observed (Janvier, et. al., 1993, p. 81).

Another approach to the theory of multiple representations which is called Lesh Multiple Representations Translations Model (LMRTM) has been suggested by Lesh (1979). His theory draws the theoretical framework of this study since he improved a

¹ Assist. Prof. Dr., Hacettepe University, Elementary Mathematics Education Division, Ankara, Turkey

² Assist. Prof. Dr., Middle East Technical University, Elementary Mathematics Education Division, Ankara, Turkey

model involving translations among representational modes and transformation within one representational mode. According to Lesh, Post and Behr (1987), representations are crucial for understanding mathematical concepts. They defined representation as “external (and therefore observable) embodiments of students’ internal conceptualizations” (Lesh, et al. 1987, p. 34). This model suggests that if a student understands a mathematical idea she or he should have the ability of making translations between and within modes of representations. According to this view, a good problem solver should be able to “sufficiently flexible” in using variety of representational systems. He claimed further, “As a student’s concept of a given idea evolves, the related underlying transformation/translation networks become more complex; and teachers who are successful at teaching these ideas often do so by reversing this evolutionary process; that is, teachers simplify, concretize, particularize, illustrate, and paraphrase these ideas, and imbed them in familiar situations” (p. 36).

A MULTIPLE REPRESENTATIONS TRANSLATION MODEL

After reviewing a number of theories about multiple representations, this study emphasizes investigating particularly students’ ability to use the given representational mode for solving problems, and to make translations among the representational modes. A multiple representational translations model combined from the models belonging to Lesh and Janvier would seem to be perfect modeling for this research study. The five distinct representational modes; namely, manipulatives, real-world situations, written symbols, spoken symbols, and pictures or diagrams in LMRTM were directly included in the model of this study. Some of those representational modes were named differently referring the Janvier Representational Translation Model (JRTM). Instead of “written symbols” from LMRTM, wording of “formulas” from JRTM was included in this study. Besides in lieu of the combination of “situations, pictures, and verbal descriptions”, the researcher decided to use those representational modes separately. Therefore instead of “situations, pictures, and verbal descriptions” in JRTM, “manipulatives,” “pictures or diagrams,” and “spoken symbols” were taken from LMRTM. “Tables” and “graphs” were taken separately from JRTM. Janvier’s Representation Translation Process was revised in light of the Lesh (1979) ideas as appeared in Table 1.

Table 1: The combined model of Lesh and Janvier for translations among representation modes

From \ To	Spoken Symbols	Tables	Graphs	Formulas (Equations)	Manipulatives	Real Life Situations	Pictures
Spoken Symbols	–	Measuring	Sketching	Abstracting	Acting out	Acting out	Drawing

Real Life Situations	Describing	Exemplifying	Plotting	Modeling, Abstracting	Particularizing	–	Modeling
Pictures or Diagrams	Describing	Describing	Sketching	Abstracting	Constructing	Situationalizing	–

SIGNIFICANCE OF THE STUDY

The issue of what instructional approaches should be used in algebra classes does not have a single and clear answer. No matter which instructional approach is used, the primary goal of mathematics instruction should be to help students in forming conceptual understanding. Janvier (1987) mentioned that if teachers enrich their algebra classrooms by placing multiple representations, the students can more efficiently make connections between the meaning of algebraic concepts and the way of representing them, therefore they simply “go for the meaning, beware of the syntax” which results in conceptual understanding.

The improvement of mathematical understanding and representational thinking of students require flexible use of multiple representations and the interaction of external and internal representations (Pape & Tchoshanov, 2001). Since making meaningful translations in representational modes plays a crucial role in acquisition of mathematical concepts and there are still unanswered questions about the instructional outcomes of using multiple representations, we believe that it would be worth to investigate the multiple representations in this respect.

Since this study focuses on the effects of multiple representation-based environments in mathematics classroom, its results should help mathematics educators who seek alternative pedagogical instructions in classroom settings. Furthermore, if a teacher is aware of his/her students’ understanding of the multiple representations and what kind of learning is supported by multiple representation-based environments, s/he can better choose and utilize appropriate type of methods, manipulatives, or activities to meet the needs of students. Moreover, providing students with a multiple representation-based algebra instruction would promote a conceptual shift to thinking algebraically. Therefore, receiving such kind of instruction makes students more competent in the area of algebra.

RESEARCH QUESTION

The purpose of this study is to examine the effects of a treatment based on multiple representations on seventh grade students’ performance in algebra, and this study attempted to answer the following research question;

“What are the effects of the multiple representations-based instruction compared to conventional teaching method on seventh grade students’ algebra performance when students’ gender, mathematics grade of previous semester (MGPS), age, prior algebra level are controlled?”

METHOD

The research question was examined through a quasi-experimental research design since this study did not include the use of random assignment of participants to both experimental and control groups. The target population of this study consists of all seventh grade students from public schools in Çankaya district in Turkey. There were 103 public schools in this region. However, two schools from this district were determined as the accessible population. There were 2 seventh grade classes in School A, and 7 in School B. One experimental and one control group were selected from both schools. There were 15 girls and 13 boys in experimental group and 16 girls and 13 boys in control group taken from School A. On the other hand, the experimental group from School B consists of 17 girls and 21 boys and in the control group the number of girls and boys were equal, that is 18. The participants in this study ranged in age from 11 years to 14 years old.

INSTRUMENTS

To assess algebra performance, three distinct instruments namely Algebra Achievement Test (AAT), Translations among Representations Skill Test (TRST), and Chelsea Diagnostic Algebra Test (CDAT) were used. The rationale of using combined instruments is to perceive algebraic learning in a multi dimensional way. It includes procedural, conceptual, and translational knowledge and skills in its nature (Lesh, Landau & Hamilton, 1983). By utilizing three instrument it was aimed to assess algebraic learning within its all dimensions and each instrument was tried to assess different aspect of algebra learnings. It can be claimed that when a student gets higher scores from three instruments s/he can be called as successful in algebra since getting high score means that s/he can use procedural algebra knowledge in problem solving, understand algebra conceptually, and also make simple translations among representations.

Among three instruments Algebra Achievement Test (AAT) was administered to analyze students’ computation skills in algebra intensively. 10 essay type questions were used in this instrument which combines traditional school algebra test items including symbolic manipulations and computations in algebra. The items which are related with the procedural skills in school algebra are criterion-referenced tasks addressing key learning goals specified in the Mathematics Curriculum for Elementary Schools, published by Turkish Ministry of National Education (MEB, 2002). The required time for this instrument was 30 minutes. The internal reliability value of Cronbach alpha was calculated as .90. To score the students’ responses to each question in AAT four-point rubric was used. The highest point of 4 indicated a complete understanding of underlying mathematical concepts and procedures while the lowest point of 0 was

given for irrelevant or no responses. The minimum and maximum possible scores from the test items are 0 and 40 points, respectively. Students who got scores above mean score of the group was accounted as high achievers.

Another instrument for assessing students' algebra performance was the Translations among Representations Skill Test (TRST). The purpose of this test was to obtain data about students' abilities in making translations among different representational modes. TRST contains 15 open-ended items which were designed to measure skills of translation among representations, use of certain representations, and creating new representations. The items in TRST required a translation from one representation type to another, such as from tabular representation to graphical one. In the last two items all type of representations were required to solve the problem. Duration of the test was 40 minutes. It was scored by using a three-point holistic scoring rubric. The highest point of 3 was awarded for responses showing that the problem was solved correctly and that the appropriate translations among representations were used. The lowest point of 0 indicated if the response is completely wrong or immaterial to the. The possible minimum score was 0, and the possible maximum score was 36. The internal reliability estimate of TRST was found to be .79 by calculating the Cronbach alpha coefficient.

The last instrument was Chelsea Diagnostic Algebra Test (CDAT) which was developed by the Concepts in Secondary Mathematics and Science Team (Hart, Brown, Kerslake, Küchemann, & Ruddock, 1985) to determine 13-15 years old children's algebraic thinking levels. This test was designed to measure the conceptual knowledge of elementary algebra. In CDAT there are six different categories of interpreting and using the "letter". Apart from these six categories, four levels of algebra understanding were developed with respect to the children's responses and the items themselves. In Level 4, children can deal with the items that require specific unknowns and which have a complex structure (Hart, et al., 1989) and they can be accounted as successful in algebra. The students answered the items in this test approximately in 60 minutes. The discrimination power of the items ranged from 0.20 to 0.60. Reliability measure as based on KR-20 coefficient was found to be 0.93. There were 53 items in the adapted version of CDAT. The possible minimum and maximum scores were 0 and 53 respectively. Besides, CDAT was used as a pretest to find out experimental and control group students' conceptual algebraic knowledge before the intervention. It was considered that seventh grade students' algebra knowledge coming from their previous mathematics background might affect the experiment therefore CDAT as pretest was also taken to MANCOVA statistical model as a profounding variable.

TREATMENT BASED ON MULTIPLE REPRESENTATIONS

For this study, the instructional design for experimental groups consists of daily lesson plans in which several activities took place. There were 21 activities which were involved in the lesson plans of the instructional unit in order to aid in teaching of a unit of algebra. All 21 lesson plans which had distinct contexts and problem situa-

tions were developed in order to reflect the procedure of translations among representations, transformations within a specified representation, usage of any representational mode in dealing with algebraic situation. In particular, students were required to learn constructing the multiple representations of algebraic situations, including expressing them in tables, graphs, and symbols. Instead of teaching these representation skills in isolation, it was anchored within meaningful thematic situations. Instead of direct instruction in how to construct and use mathematical representations in algebra, students were only guided in the activities to explore different representations and to develop their understanding of each one. In experimental groups students were frequently given tasks that require them to make translations among different representations. This approach was used to present and develop concepts from verbal, algebraic, graphical, and tabular standpoints. To illustrate, for instance, a concept first introduced a numerically intuitive approach in which tables were used to collect and work on data. Then a verbal representation was used to verbally complement the relationship among numbers in the tabular representation. Finally, a transition was made to the algebraic representation. The usage of multiple representations varied for each activity presented in this treatment. For instance, for the topic of equations, first the tabular representation then the verbal representation were constructed; however, for conceptualizing the concept of graph, first, the algebraic representation, and then the other representations were used.

The actualization of treatment can be illustrated in one activity namely; “*Inequalities*”. In this activity students were responsible to find out the main characteristics of inequalities using the tabular representation. At the beginning the activity sheets were given to the students, and then they examined the activity. They filled the given table by required numbers, and then the translation from one representation to another came. For this, the daily life situations and the algebraic representational modes were selected. Students were required to give one daily life example to the inequality of “ $x-3 < 7$ ”. Students’ examples were like;

“There are x number of teachers in one school, then 3 of them are appointed to another school, and the number of the remaining teachers was less than 7”.

“Let us say that the number of the desks in our class was x , we get rid of 3 of them, then there are less than 7 desks in our class”.

After getting students translations among representations, all of them were discussed in class. It is compulsory for the students to keep the activity sheets in the folder that the researcher gave them, since they did all the works on those papers. They were also responsible to bring their folder to the class every mathematics lesson.

In the treatment, particularly the translations among representational modes were stressed and valued by the researcher. In conventional algebra teaching, however, translation among representations might occur only when the students are required to draw a graph. In this case, instead of constructing a table to represent the given equation, they only identified two points where the line pass through. Then, by the help

of this information, a graph could be drawn. However, the multiple representations-based instruction emphasizes the translations from variety of representational modes to the other modes. Therefore, students could have the opportunity to notice that one mathematical concept can be represented in several ways and these ways can be complementary to understand this concept. The same task of drawing the graph of a linear equation is taken in a way that, students analyze the equation through daily life situations, plain language, tables, and graphs. In that sense, drawing the graph of an equation is not an end but it is a means of interpreting the existing mathematical situation. The treatment lasted eight-weeks. Each week experimental groups received four lesson hours, with each session lasting 40 minutes.

RESULTS

To test the null hypothesis related to the research question, the statistical technique of Multiple Analysis of Covariance (MANCOVA) was used for comparing the mean scores of control and experimental groups separately on the AAT, TRST, and CDAT. MANCOVA was carried out by putting experimental groups together as a one experimental group and control groups as one control group as well (Cohen & Cohen, 1983).

Initial descriptive analysis revealed that the experimental groups had the higher scores on all the instruments compared to the control groups. Before conducting MANCOVA the assumptions called normality, multicollinearity, homogeneity of regression, equality of variances, and independency of observations were verified (Green, Salkind, & Akey, 2003).

The MANCOVA results revealed that, there was a significant effect of two methods of teaching on the population means of the collective dependent variables of seventh grade students' scores on the AAT, TRST, and CDAT after controlling their age, the MGPS, and PRECDAT scores. 37% of the total variance of MANCOVA model for the collective dependent variables of the AAT, TRST, and CDAT was explained by group membership of the participants. Using the Wilks' Lambda test, significant main effects were detected between the groups experimental group and control group ($\lambda = .63$, $p = .000$). Therefore, the results of this study were of practical significance. The significant finding of a group effect from MANCOVA, allowed further statistical analysis to be done in order to determine the exact nature of significant differences found in main effect. Therefore univariate analyses of covariance (ANCOVA) were carried out on each dependent variable in order to test the effect of the group membership. From the analyses, it can be stated that, multiple representation based instruction has a significant effect on the dependent variable scores of CDAT [$F(1,125) = 38.005$, $p = .000$], TRST [$F(1,125) = 25.942$, $p = .000$], and AAT [$F(1,125) = 18.271$, $p = .000$]. Furthermore, for the observed treatment effects, it was obvious that the values of eta squared for the scores of the CDAT, TRST, and AAT were .233, .172, and .128 respectively which are equal to the medium effect size. This explains 23% of the variance in CDAT, 17% of the variance in TRST, and 13% of the variance in AAT related with the treatment. Power for the scores of the CDAT, TRST, and AAT

were found as 1.00, .92, and .78 respectively. Step-down analysis was carried out as significant MANCOVA follow up analysis. By the help of this analysis, the unique importance of dependent variables which were found as significant in the MANCOVA analysis was investigated. Since there are three significant dependent variables namely, CDAT, TRST, and AAT, three step-down analyses were conducted. By doing so, any possible variance overlap among the dependent variables was planned to be detected. According to these results, the effect of multiple representation-based instruction had still significant effect on each dependent variable.

DISCUSSION

This research study has documented that, compared to conventional instruction, multiple representations-based instruction did make a significant influence on the algebra performance of seventh grade students. There might be various reasons to this result. Visualization of algebraic objects, connections among algebraic ideas, and the improvement of translational abilities in algebra problem solving (Lesh, Post, & Behr, 1987) can be counted as what multiple representations-based instruction provide for students. By the help of this instruction, students avoid memorization in algebra learning, and understand concepts meaningfully. As suggested in Swafford and Langrall's (2000) study; multiple representations-based instruction promotes conceptual understanding of algebra and makes students conceptualize algebraic objects. The results of this study are supported in the literature by numerous studies. One of them is Brenner's (1995) and her colleagues study. They conducted only 20 days multiple representations unit including variables and algebraic problem solving. After treatment they implemented four instruments related to algebra learning to the seventh and eight graders. Significant difference was found between experimental and control group of students in favor of the students in experimental groups. The findings of this study are also consistent with the findings of previous studies (Ozgun-Koca, 2001; Pitts, 2003) that provided evidence for the effectiveness of multiple representations-based instruction in engaging students in meaningful algebra learning. Additionally, in Herman's (2002) study similar results were found. It was stated that after multiple representation based instruction in college algebra course, students were better able to establish connections between varieties of representational modes.

This study confirmed the need for considering other kinds of representations, such as; representations used in graphic calculator and computer programs or representations that students create and unique for them. As it was suggested by Ozgun-Koca (2001), computer-based applications can be used to provide linked and semi-linked representations, and graphical form of representations. These applications can make students to abstract mathematical concepts from virtual world. Besides, allowing students to create their own representations for solving algebra problems makes them more creative and flexible in mathematics (Piez & Voxman, 1997). In this study it was observed that, students were mainly restricted by four types of representations which are tabular, graphical, algebraic, and verbal. This can be due to the activities or re-

researcher's emphasize on those representation types. However, students should be given an opportunity that they can use representations that they invent or create. Moreover, it can be suggested that future research can focus on teachers and teaching strategies in algebra classrooms. All of the data for this study was collected from students. Future research could combine data from students and their teachers, because teachers have also impact on shaping students' representation preferences. What teaching strategies and representation types are used within algebra classrooms by teachers and how those representations are conceptualized by the students seems to be worthwhile to investigate.

According to the researcher, mathematics educators ought to recognize making establishment between concepts for the mathematics instruction for all students. Nowadays, many attempts can be observed to improve mathematics instruction. Multiple representation-based instruction for conceptual algebra understanding is just the one that the researcher implemented and appreciated the benefits of using this method. Giving opportunity to new instructional methods like multiple representation based instruction in mathematics classrooms enables students better mathematics learner. As Klein (2003) implied; *'Learning to create and interpret representations using specific media such as texts, graphics, and even videotapes are themselves curricular goals for many teachers and students'* (p. 49). As a three-year experienced mathematics teacher before, the researcher could say that in traditional mathematics classroom, there is a need to encourage students to think more deeply on mathematical concepts, to intrinsically motivate for learning, to make students appreciate the nature of mathematics by getting rid of rote memorization, and to avoid overemphasizing mathematical rules and algorithms. In fact, new instructional methodologies like multiple representation-based instruction can address this need.

OFFERING PROOF IDEAS IN AN ALGEBRA LESSON IN DIFFERENT CLASSES AND BY DIFFERENT TEACHERS

Michal Ayalon and Ruhama Even

The Weizmann Institute of Science, Israel

This paper analyzes the ways proof ideas in an algebra lesson were offered to students (1) by two different teachers, and (2) in two different classes taught by the same teacher. The findings show differences between the two teachers, and between the two classes taught by the same teacher, regarding the proof ideas made available to learn in the lesson.

Keywords: Proof ideas, algebra, classroom, curriculum, teacher.

INTRODUCTION

Research suggests that getting students to understand what a mathematical proof is and the role that proofs play in mathematics is not an easy task (de Villiers, 1990; Dreyfus & Hadas, 1996; Harel & Sowder, 2007). However, most of the research on proof focuses on the individual student's cognition and knowledge. There is an absence of studies that focus on the complexity of teaching and learning proof in the classroom (Mariotti, 2006), and on the role of the content and sequencing of the curriculum on the quality of teaching proof (Holyes, 1997; Stylianides; 2007). Moreover, research related to proof is commonly conducted in the context of geometry, and examination of proof in algebra is sparse. This study addresses this shortcoming of current research. Its aim is to examine the enactment of a written algebra lesson, which centers on determining and justifying equivalence and non-equivalence of algebraic expressions. The study focuses on ways important proof ideas were offered to students, the extent to which they were explicit in the lessons, and the contributions of the teacher and the students to their development. Two of these ideas are general: refutation by a counter example as mathematically valid, and supportive examples for a universal statement as mathematically invalid – two ideas that are difficult for students (e.g., Balacheff, 1991; Fischbein & Kedem, 1982; Jahnke, 2008). Another idea is algebra specific: the use of properties and axioms in proving that two algebraic expressions are equivalent as mathematically valid.

Recent research suggests that different teachers enact the same curriculum materials in different ways (Manouchehri & Goodman, 2000), and that the same curriculum materials may be enacted differently in different classes taught by the same teacher (Eisenmann & Even, in press). Thus, we chose to focus here on the ways the proof ideas in the algebra lesson were offered to students (1) by different teachers, and (2) in different classes taught by the same teacher. This study is part of the research program *Same Teacher – Different Classes* (Even, 2008) that compares teaching and learning mathematics in different classes taught by the same teacher as well as classes taught by different teachers. Various aspects are examined, with the aim of gaining

insights about the interactions between mathematics teachers, curriculum and classrooms.

PROOF IDEAS IN THE WRITTEN LESSON

The lesson appears in a 7th grade mathematics curriculum program developed in Israel in the 1990s (Robinson & Taizi, 1997). The curriculum program used by the teachers in this study is intended for heterogeneous classes and includes many of the characteristics common nowadays in contemporary curricula. One of its main characteristics is that students are to work co-operatively in small groups for much of the class time, investigating algebraic problems situations. Following small group work, the curriculum materials suggest a structured whole class discussion aimed at advancing students' mathematical understanding and conceptual knowledge. The curriculum materials include suggestions on enactment, including detailed plans for 45-minute lessons.

The lesson "Are they equivalent?", which is the focus of this paper, is the 6th lesson in the written materials. Prior to this lesson, equivalent expressions were introduced as representing "the same story", e.g., the number of matches needed to construct a train of r wagons. The use of properties of real numbers (e.g., the distributive property) was mentioned briefly as a tool for moving from one expression to an equivalent one, but it was not yet presented explicitly as a tool for proving the equivalency of two given expressions.

Based on an analysis of the textbook and the teacher guiding, three proof-related ideas were found as being explicit in this lesson:

Idea 1: Substitution that results in different values proves that two expressions are not equivalent (a specific case of refutation by a counter example as mathematically valid).

Idea 2: Substitution cannot be used to prove that two given algebraic expressions are equivalent³ (a specific case of supportive examples for a universal statement as mathematically invalid).

Idea 3. It addresses the problem that emerges from idea 2: the use of properties in the manipulative processes is a mathematically valid method for proving that two expressions are equivalent.

The lesson is planned to start with small group work aiming at an initial construction of Ideas 1 and 2. Students are given several pairs of expressions; some equivalent and some not. They are asked to substitute in them different numbers and to cross out pairs of expressions that are not equivalent. After each substitution they are asked whether they can tell for certain that the remaining pairs of expressions are equiva-

³ Students were not familiar at that stage with the properties of linear expressions.

lent. Finally, students are instructed to write pairs of expressions, so that for each number substituted, they will get the same result.

Then small group work continues, asking students to write equivalent expressions for given expressions. The aim is to direct students' attention to the use of properties in relation to equivalence of algebraic expressions, which is relevant to idea 3.

The whole class work returns to idea 1, and moves, through idea 2, to idea 3, aiming at consolidating these ideas, by discussing questions, such as: How can one determine that expressions are not equivalent? that expressions are equivalent? By substituting numbers? If so, how many numbers are sufficient to substitute? If not, what method is suitable? Finally, the teacher guide recommends that the teacher demonstrate the use of properties for checking equivalence, and together with the students implement this method on several pairs of expressions in order to check their equivalency.

Ideas 1, 2, and 3 are connected to three other ideas, none of which appears explicitly in the first six lessons in the written materials:

Idea 4 justifies Idea 2: There may exist a number that was not substituted yet, but its substitution in the two given expressions would result in different values, thus showing non-equivalence.

Idea 5 justifies Idea 3: The use of properties of real numbers in the manipulative processes guarantees that any substitution in two expressions will result in the same value, thus showing equivalence.

Idea 6 is the underpinning for Ideas 1, 2, and 3, as well as for Ideas 4 and 5. It defines equivalent algebraic expressions: Two algebraic expressions are equivalent if the substitution of any number in the two expressions results in the same value.

Figure 1: Connections among the proof-related ideas in the lesson

Ideas 4 and 6 are implicit in the written lesson, and Idea 5 does not exist.

METHODOLOGY

The primary data source include video and audio tapes of the enactment of the written lesson in four classes, each from a different school (i.e., four different schools). One teacher, Sarah, taught two of the classes, S1 and S2; another teacher, Rebecca, taught the other two classes, R1 and R2 (pseudonyms). The talk during the entire class work

was transcribed. The transcripts were segmented according to focus on the six ideas, yielding 3-4 more or less chronological parts in each class. Next, the collective discourse in the classroom was analyzed by examining the contributions of the teacher and the students to the development of the proof ideas in each enacted lesson. We compared how the teachers structured and handled the proof ideas in each lesson, and what was available to learn in different classes of the same teacher and in the classes of the two teachers.

PROOF IDEAS IN THE ENACTED LESSONS

Idea 1

In line with the written curriculum materials, the whole class work in all four classes included an overt treatment of Idea 1. However, contrary to the recommendations in the written materials, in none of the classes did the whole class work begin with the question, how can one determine whether algebraic expressions are not equivalent. Instead, the students performed substitutions in pairs of algebraic expressions from Problem 1 because the teacher requested them to do so, and not as a way of addressing a problem. When the substitutions resulted in different values, the classes concluded that the two expressions were not equivalent. In all four classes, it was the teacher who eventually presented Idea 1 explicitly, attending only to the specific context of non-equivalence of expressions, with no reference to the general idea of refutation by using a counter example as mathematically valid.

Idea 2

After working on non-equivalence, the four classes proceeded to work on equivalence of algebraic expressions. In both of her classes Sarah presented Idea 2, that substitution cannot be used to prove that two given algebraic expressions are equivalent. She explicitly incorporated in the presentation of this idea its underlying justification (which does not appear explicitly in the written materials) that possibly there exists a number that was not yet substituted, but its substitution in the two given expressions would result in different values (idea 4). For example, Sarah said in class S1:

We saw that with substitution, it is always possible that there is a number that I will substitute, and it will not fit. We can substitute ten numbers that would fit, and suddenly we will substitute one number that will not fit, and then the expressions are not equivalent... We have to find some way other than substitution, which will help us determine whether expressions are equivalent.

Contrary to the recommendations in the written materials, the students in Sarah's classes did not participate in constructing Idea 2 in class. Sarah merely presented it as motivation for finding a method to show equivalence, and immediately proceeded to work on using properties in the manipulative processes as a means to prove equivalence (Idea 3).

The idea that substitution cannot be used to prove that two given algebraic expressions are equivalent was dealt with differently in Rebecca's classes. In general, in both classes Rebecca pressed on finding a method that works, rather than evaluating the method of substitution, which does not work. However, the issue of substitution continued to be raised. In class R1, following the students' suggestion, the initial focus was on rejecting substitution because of the inability to perform substitution of all required numbers (an infinite number), as the following excerpt illustrates:

Rebecca: When will I be sure that these three [points to the pairs on the board] are indeed equivalent? That each pair is equivalent? When will I be sure?

S: When you check all the numbers.

...

S: There is an infinite number of numbers so you will never finish.

Rebecca: So I am not going to substitute infinite numbers. I need to find some other trick.

Idea 2, that supportive examples (i.e., substitution) could not be used to prove a universal statement (i.e., that two given algebraic expressions are equivalent), was not dealt with in class R1. Rather, it seemed to be taken as shared. Repeatedly, after substituting numbers in pairs of expressions and receiving the same value, the class concluded that the pairs appeared to be equivalent but that it was impossible to know for certain. For example,

Rebecca: OK, we are told to check another number, four.

S: Right.

Rebecca: You checked four. What did you get?

S: That they are equivalent.

Rebecca: I got the same result, right?

S: Yes, right.

S: All is well so far.

By stating, "I got the same result" following the statement "they are equivalent" Rebecca signaled that they did not yet know whether the latter claim was correct. Students then agreed, "All is well *so far* (emphasis added)". Later in the lesson, a similar conversation took place,

Rebecca: So, does it mean that they are equivalent?

S: Yes.

S: Yes. Ah, no, not necessarily.

Rebecca: Why? Do you have a counter example?

S: We don't know that they are equivalent.

Still, there was no explicit rejection of substitution for proving equivalence, as a specific case of supportive examples for a universal statement as mathematically invalid. Instead, Rebecca changed the focus of the activity to looking for a connection be-

tween the two algebraic expressions in each pair, as a transitional move towards Idea 3.

In contrast with class R1, class R2 embraced the idea that substitution is a valid means of determining equivalence of algebraic expressions. Unlike R1, where after several substitutions that resulted in the same value, students claimed that they still could not conclude that the two expressions were equivalent, in similar situations R2 students claimed that the expressions were equivalent because all the numbers they substituted resulted in identical numerical answers. This happened even after Rebecca offered idea 4, that there may be a number, which was not yet substituted, but its substitution in the two given expressions would result in different values. For example,

Rebecca: So, what do you say, what should I do, check all the numbers; maybe there is a number that won't fit here?

S: No [interrupts the teacher]

Rebecca: Or will it always fit?

S: Always.

...

Rebecca: Why are they equivalent? Why do I say that these are equivalent...?

S: Because we checked at least thirty.

Rebecca: We didn't check thirty, but I am asking: Why are these equivalent, in your opinion?

...

S: Because we checked.

Rebecca: Because you checked, but we said that maybe there is one number that you did not check.

S: But we checked almost all the [inaudible].

Eventually, Rebecca changed the focus of the activity to looking for algebraic expressions that are equivalent to given expressions, aiming at Idea 3. Thus, unlike Sarah, who used the brief mention of Idea 2 (and 4) as a motivational transition from Idea 1 to Idea 3, in R2, Rebecca did not motivate the search for a method different from substitution.

Idea 3

Led by Sarah, in line with the written materials, S1 and S2 searched for properties that show that the expressions produced when working on Problem 1 (S1), or given in Problem 3 (S2), were equivalent. Sarah then stated that the use of properties is the way to show equivalence, not substitution. When introducing Idea 3 in S2, Sarah explicitly connected with Ideas 5 and 6, which underpin and justify Idea 3. However, no such connections were made then in S1. Only later on, in her concluding remarks in S1, when summarizing both ways of proving equivalence and non-equivalence of expressions, did Sarah explicitly propose Idea 6.

Class R1 started to work on Idea 3 by searching for connections between pairs of expressions from Problem 1 that remained as potentially consisting of equivalent ex-

pressions. The class then quickly embraced the discovery that by using properties, it was possible to move from one expression to another, by indicating equivalence. Rebecca then introduced explicitly Idea 3. However, in R1, like in S1, no connections were made then to Ideas 5 and 6. Nevertheless, Idea 6 was introduced explicitly at the beginning of the lesson, when a student asked for the meaning of equivalence expressions.

Class R2 had a different starting point than R1 for treating Idea 3 because the students were confident that based on the substitutions they performed they could infer that the remaining pairs of expressions from Problem 1 were equivalent. Rebecca then slightly deviated from the written materials' suggestions and asked the students to find new expressions that would be equivalent to the given ones. Eventually, R2 embraced the idea that equivalence can be determined by manipulating the form of expressions, using properties. In R2, too, no connections were made with Ideas 5 and 6. Moreover, Idea 6 was not proposed at all.

Figure 2 depicts the teaching sequences of the proof-related ideas as offered during the whole class work, in the written materials, as well as in the four classes.

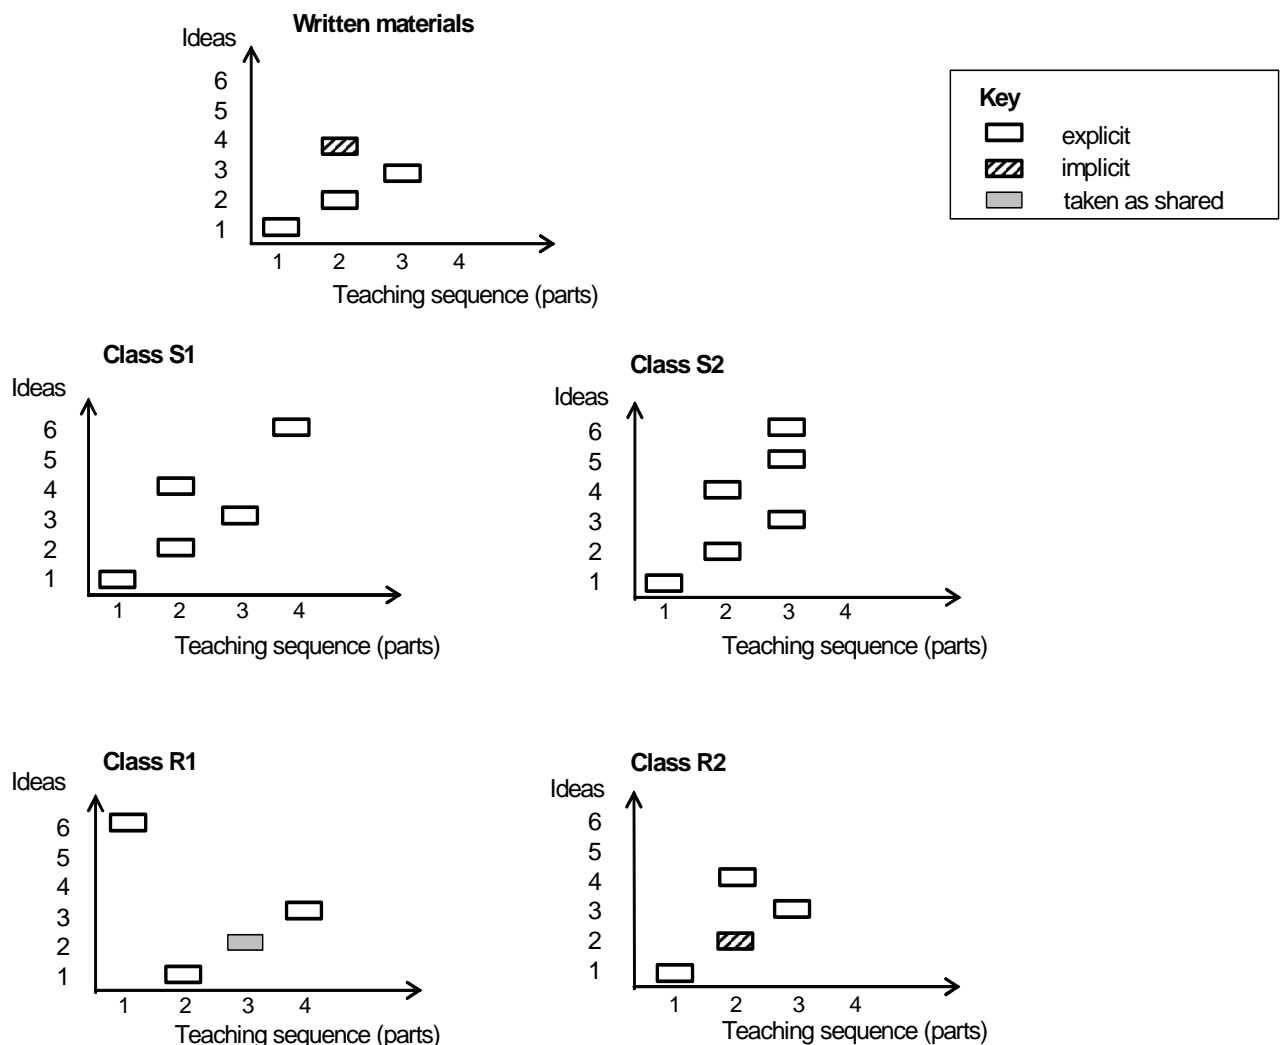

Figure 2: Teaching sequences of the proof-related ideas, as offered in the whole class work, in the written materials, as well as in the classes

The figure clearly demonstrates that Sarah was the only one who explicitly proposed the sequence of the three proof-related ideas (1, 2, and 3) that were explicit in the written lesson, whereas Rebecca explicitly proposed only Ideas 1 and 3. Moreover, any connections between these three ideas and the other three ideas (4, 5, and 6), which did not appear explicitly in the written lesson, were made only in Sarah's classes: Idea 2 was connected to its underlying justification, Idea 4 in both of Sarah's classes, whereas Idea 3 was connected to its underlying support by Ideas 5 and 6 in S2 only. Nevertheless, Idea 4 was offered by Rebecca in R2 with no explicit connection to Idea 2, and Idea 6 was offered in S1 (at the end of the lesson) and in R1 (at the beginning of the lesson), with no explicit connections to the other ideas.

FINAL REMARKS

Sarah and Rebecca taught the written lesson “Are they equivalent?” using the same written materials, which included a detailed lesson plan. Thus, it is not surprising that the mathematical problems enacted in class were similar in all four classes. However, the ways the proof ideas in the lesson were offered to students differed to some degree from what was recommended in the written materials. There were also differences between the two teachers, and between the two classes of the same teacher, in what was available to learn in the lesson. One of the main differences is related to offering Idea 2. This idea is central in the written materials. However, Sarah only briefly mentioned it in her classes, just as a transition to Idea 3. In R1 this idea was taken as shared, never made explicit, as was the case in R2, which strongly embraced the opposite idea. Another central idea in the written materials is Idea 3. The way that the written materials deal with Idea 3, without making Ideas 5 and 6 explicit, seemed to make teaching it a challenge. Eventually, each teacher handled this idea somewhat differently in each of her two classes.

These differences seem to be related to differences in teaching approaches. Sarah tended to make clear presentations of important ideas. Rebecca hardly made presentations, but instead, attempted to probe students, expecting them to explicate these ideas. Thus, some ideas were never made explicit, in one class more than the other, because of differences in students' mathematical behaviour and performance.

These initial findings illustrate the complexity of the interactions among teachers, curriculum and classrooms (Even, 2008). Rebecca faced serious challenges in her attempts to make students genuine participants in the construction of mathematical ideas, as was recommended in the written materials – more so in one of her classes – challenges that lie at the meeting point of the specific teacher, specific curriculum and

specific class. Sarah, who chose to make clear presentations of the mathematical ideas, faced different challenges, even though she used the same materials.

The mere fact that different teachers offer mathematics to learners in different ways, even when using the same written materials, is not entirely surprising, and has been documented by empirical research (e.g., Manouchehri & Goodman, 2000). Nonetheless, the nature of the differences is important because what people know is defined by ways of learning, teaching, and classroom interactions, as documented by Boaler (1997). Consequently, Sara'h and Rebecca's students were offered somewhat different proof-related ideas that are central in algebra and in mathematics in general, and that are known as not being easy for students. Furthermore, when instead of focusing solely on the comparison between teachers, different classes taught by the same teacher were also compared, important information was revealed about the interactions among curriculum, teachers and classrooms.

RAFAEL BOMBELLI'S ALGEBRA (1572) AND A NEW MATHEMATICAL "OBJECT": A SEMIOTIC ANALYSIS

Giorgio T. Bagni

Department of Mathematics and Computer Science, University of Udine (Italy)

In the theoretical framework based upon the ontosemiotic approach to representations, some reflections by Radford, and taking into account Peirce's semiotic perspective, I proposed to a group of 15–18 years–old pupils an example from the treatise entitled Algebra (1572) by Rafael Bombelli. I conclude that the historical analysis can provide insights in how to approach some mathematical concepts and to comprehend some features of the semiotic chain.

INTRODUCTION

In this paper I shall examine a traditional topic of the curriculum of High School and of undergraduate Mathematics that can be approached by historical references. The introduction of imaginary numbers is an important step of the mathematical curriculum. It is interesting to note that, in the Middle School, pupils are frequently reminded of the impossibility of calculating the square root of negative numbers. Then pupils themselves are asked to accept the presence of a new mathematical object, " $\sqrt{-1}$ ", named i , and of course this can cause confusion in students' minds. This situation can be a source of discomfort for some students, who use mathematical objects previously considered illicit and "wrong". The habit (forced by previous educational experiences) of using only real numbers and the (new) possibility of using complex numbers are conflicting elements.

Although the focus of this paper is not primarily on the analysis of empirical data, I shall consider an educational approach based upon an historical reference that can help us to overcome these difficulties. More particularly, I shall consider the semiotic aspects of the development of the new mathematical objects introduced (imaginary numbers) and I shall ask: can we find an element from which the semiotic chain is originated? Can we relate the early development of the semiotic chain to the objectualization of the solving procedure of an equation?

THEORETICAL FRAMEWORK

Radford describes "an approach based on artefacts, that is, concrete objects out of which the algebraic *tekhnē* and the conceptualization of its theoretical objects arose. [...] They were taken as *signs* in a Vygotskian sense" (Radford, 2002, § 2.2). In this paper I shall not consider concrete objects. Nevertheless Radford's remark about the importance of "signs in a Vygotskian sense" can be considered as a starting point of my research.

When we consider a sign, we make reference to an object, and in the case of mathematical objects, to a concept. However my approach does not deal only with "con-

cepts”. Font, Godino and D’Amore (2007, p. 14) state that although “to understand representation in terms of semiotic function, as a relation between an expression and a content established by ‘someone’, has the advantage of not segregating the object from its representation, [...] in the onto–semiotic approach [...] the type of relations between expression and content can be varied, not only be representational, *e.g.*, ‘is associated with’; ‘is part of’; ‘is the cause of/reason for’. This way of understanding the semiotic function enables us great flexibility, not to restrict ourselves to understanding ‘representation’ as being only an object (generally linguistic) that is in place of another, which is usually the way in which representation seems to us mainly to be understood in mathematics education”.

In my research I shall consider the ontosemiotic approach to mathematics cognition. It “assumes socio-epistemic relativity for mathematical knowledge since knowledge is considered to be indissolubly linked to the activity in which the subject is involved and is dependent on the cultural institution and the social context of which it forms part” (Font, Godino & D’Amore, 2007, p. 9, Radford, 1997).

My framework is also linked with some considerations about semiotic aspects, based upon a Peircean approach (although, for instance, the relationship between Vygotsky and Peirce is not trivial: Seeger, 2005). According to Peirce we cannot “think without signs”, and signs consist of three inter–related parts: an object, a proper sign (*representamen*), and an interpretant (in Peirce’s theory sign is used for both the triad “object, sign, interpretant” and the representamen, in late works). Peirce considered either the immediate object represented by a sign, or the dynamic object, progressively originated in the semiotic process. As a matter of fact, an interpretant can be considered as a new sign (*unlimited semiosis*). The limit of this process is the *ultimate logical interpretant* and it is not a real sign, which would induce a new interpretant. It is an *habit–change* (“meaning by a habit–change a modification of a person’s tendencies toward action, resulting from previous experiences or from previous exertions of his will or acts, or from a complexus of both kinds of cause”: Peirce, 1931–1958, § 5.475. I shall cite paragraphs in Peirce’s work).

The sign determines an interpretant by using some features of the way the sign signifies its object to generate and shape our understanding. Peirce associates signs with cognition, and objects (“mathematical objects” will be considered as “objectualized procedures”: Sfard, 1991, Giusti, 1999) “determine” their signs, so the cognitive nature of the object influences the nature of the sign. If the constraints of successful signification require that the sign reflects some qualitative features of the object, then the sign is an *icon*; if they require that the sign utilizes some physical connection between it and its object, then the sign is an *index*; if they require that the sign utilizes conventions or laws that connect it with its object, then it is a *symbol*.

According to Peirce, the formulas of our modern algebra are icons, i.e. signs which are mappings of that which they represent (Peirce, 1931–1958, § 2.279). Nevertheless pure icons, according to Peirce himself (1931–1958, § 1.157), only appear in think-

ing, if ever. Pure icons, pure indexes, and pure symbols are not actual signs. In fact, every sign “contains” all the components of Peircean classification, although one of them is predominant. So our algebraic expressions are *complex icons* (Bakker & Hoffmann, 2005). Moreover, it is worth noting that a sign in itself is not an icon, index or symbol. From the educational viewpoint, the identification of signs is not just a question of classifying a sign as *e.g.* an icon, but it is a question of showing their cognitive import (Bagni, 2006).

Frequently Peirce underlined the importance of iconicity. He argued (1931–1958, § 3.363) that “deduction consists in constructing an icon or diagram the relations of whose parts shall present a complete analogy with those of the parts of the object of reasoning, of experimenting upon this image in the imagination, and of observing the result so as to discover unnoticed and hidden relations among the parts”. (Peirce distinguished three kinds of icons: images, metaphor, and diagrams). According to Radford (forthcoming), since the epistemological role of “diagrammatic thinking” rests in making apparent some hidden relations, it relates to actions of *objectification*, and a diagram can be considered a *semiotic means of objectification*.

HISTORY OF MATHEMATICS AND IMAGINARY NUMBERS

History of mathematics can inform the didactical presentation of topics (although the very different social and cultural contexts do not allow us to state that ontogenesis recapitulates phylogenesis: Radford, 1997). Let us consider the resolution of cubic equations according to G. Cardan (1501–1576) and to N. Fontana (Tartaglia, 1500–1557). R. Bombelli (1526–1573), too, is one of the protagonists of history of algebra. His masterwork is *Algebra* (1572), where we find some cubic equations, and sometimes their resolution makes it necessary to consider imaginary numbers.

The resolution of the equation $x^3 = 15x+4$ leads to the sum of radicals $x = \sqrt[3]{2+11i} + \sqrt[3]{2-11i}$ where $2+11i = (2+i)^3$ and $2-11i = (2-i)^3$. So a (real) solution of the equation is $x = (2+i)+(2-i) = 4$. In the following image (Fig. 1) I propose the original resolution on p. 294 of Bombelli’s *Algebra*.

$$x^3 = 15x+4$$

$$[x^3 = px+q]$$

$$(4/2)^2 - (15/3)^3 = -121$$

$$[(q/2)^2 - (p/3)^3 = -121]$$

$$x = \sqrt[3]{2+11i} + \sqrt[3]{2-11i}$$

$$x = (2+i) + (2-i) = 4$$

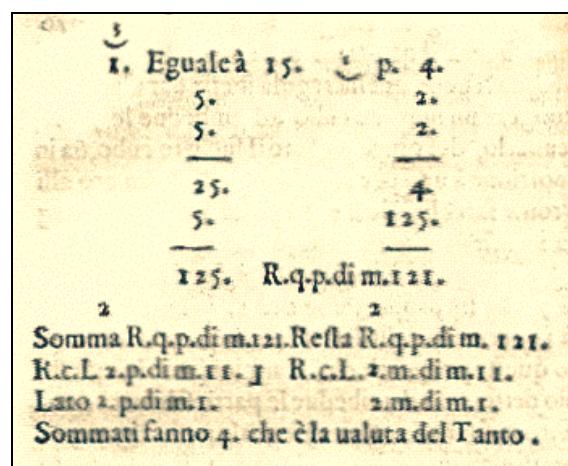

Fig.1

Bombelli justified his procedure using the two-dimensional and three-dimensional geometrical constructions (1966, pp. 296 and 298, Fig. 2 and Fig. 3 respectively). (Space limitations prevent a detailed discussion of these. The reader is referred to Bombelli: Bombelli, 1966).

Fig. 1

From the educational point of view, Bombelli's resolution can help our pupils to accept imaginary numbers. As a matter of fact, its effectivity supports Bombelli's rules for *pdm* and *mdm* ("più di meno" and "meno di meno" respectively, today written as i and $-i$). In the image see the original "rules" as listed on p. 169 of Bombelli's *Algebra*, Fig. 4).

Fig. 2

Fig. 3

IMAGINARY NUMBERS FROM HISTORY TO DIDACTICS

It is worth noting that the introduction of imaginary numbers, historically, did not take place in the context of *quadratic* equations, as in $x^2 = -1$. It took place by the resolution of *cubic* equations, whose consideration can be advantageous. Their resolution, sometimes, does not take place entirely in the set of real numbers, but one of their results is always real. A substitution of $x = 4$ in the equation above ($4^3 = 15 \cdot 4 + 4$) is possible in the set of real numbers. In the quadratic equation, the role of i and of $-i$ seems very important. As a matter of fact results themselves are not real, so their acceptance needs the knowledge of imaginary numbers.

Let us briefly summarize the results of an empirical research. In a first stage I examined 97 3rd and 4th year High School students (Italian *Liceo scientifico*, pupils aged 16–17 and 17–18 years, respectively). In all the classes, at the time of the test, pupils knew the resolution of quadratic and of biquadratic equations, but they did *not* know

imaginary numbers. Responding to a question about the statement $x^2+1 = 0 \Rightarrow x = \pm i$ only 2% accepted the resolution (92% refused it; 6% did not answer). A subsequent question proposed the following as a resolution of the cubic equation $x^3-15x-4 = 0 \Rightarrow x = \sqrt[3]{2+11i} + \sqrt[3]{2-11i} \Rightarrow x = (2+i) + (2-i) = 4$. This resolution was accepted by 54% of the pupils (35% refused it; 11% did not answer).

So imaginary numbers *in the passages* of the resolution of an equation, but *not* in its result, are frequently accepted by pupils (the *didactical contract* ascribes great importance to the result). Under the same conditions, a similar test was then administered to 52 students of the same age group, where the equations were presented in the reverse order (Bagni, 2000): 41% accepted the solution of the cubic equation (25% rejected it and 34% did not answer). Immediately after that, the solution of the quadratic equation was accepted by 18% of the students, with only 66% rejecting it (16% did not answer).

These data suggest that teaching a subject using insights from its historical development may help students to acquire a better understanding of it.

THE SEMIOSIC CHAIN

As previously noticed, this focus of this paper is not the detailed presentation of this experimental data (see, Bagni, 2000). Rather I shall consider some features of students' approach, making reference, in doing so, to Peirce's *unlimited semiosis*. As highlighted in section 2, every step of the interpretative process produces a new "interpretant n " that can be considered the "sign $n+1$ " linked with the object (considered in the sense of an objectualized procedure, following Sfard, 1991, and Giusti, 1999, p. 26). However we must ask ourselves: what about the very first sign to be associated to our object?

Our mathematical object (in this case, a procedure to solve an equation) would be represented by a first "sign". In fact, "absence" itself can be considered as a sign. Peirce (1931–1958, § 5.480) made reference to "a strong, but more or less vague, sense of need" leading to «the *first logical interpretants* of the phenomena that suggest them, and which, as suggesting them, are signs, of which they are the (really conjectural) interpretants». So I suppose that this kind of absence can be the starting point of the semiotic process.

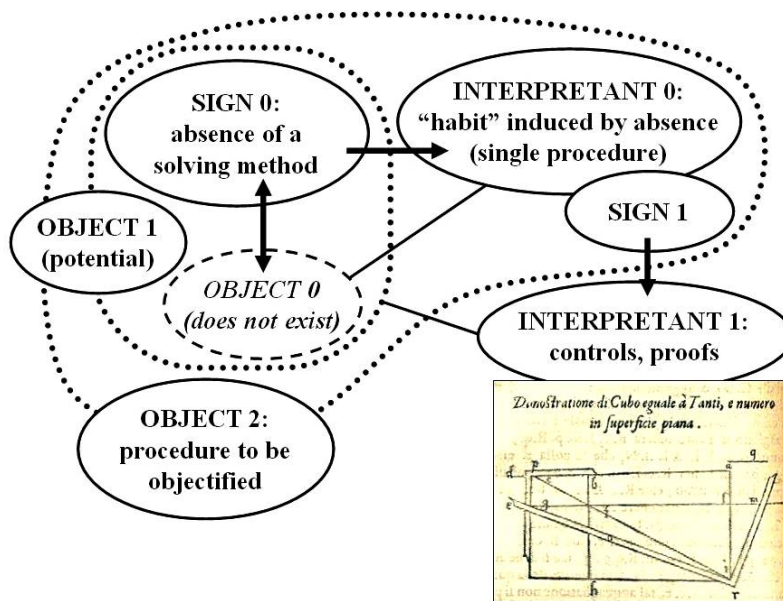

From an educational viewpoint this is influenced by important elements, e.g. the theory in which we are working, the persons (students, teacher), the social and cultural context. Of course by that I do not mean that there is a unique historical trajectory for every "mathematical object". Nevertheless this starting point can be described as a complexus of "object–sign–interpretant" without a particular "chronological" order. It can be considered a *habit* linked to the absence of a procedure, or, better, *a procedure to be objectualized*. So the situation is characterized by some intuitive sensations, and by the influence of social, cultural, traditional elements. Later, with the emergence of formal aspects, our object will become more "rigorous" (making refer-

ence, of course, to the conception of rigor in an historical and cultural context – the rigor for Bombelli and the rigor for modern mathematicians are different). These stages are educationally important.

According to an ontosemiotic approach, knowledge is linked to the activity in which the subject is involved and it depends on the cultural institution and the context (Font, Godino & D'Amore, 2007, Radford, 1997). In the case considered, pupils have the perception of an absence, referred to the strategy to be followed, namely the procedure to be objectualized. Historical references gave them the opportunity to consider a situation, and the context is characterized by the “game to be played” (the resolution of an equation) at the very beginning of our experience. We cannot make reference to a semiotic function related to an object to be represented. The “object” will be considered just later, on the basis of the solving strategy. A real strategy is actually absent, and only a “potential object” is connected to the possibility to find out an effective procedure in order to play the (single) game considered.

In Bombelli's work the iconicity has a major role, and this aspect can be relevant to students approach (further research can be devoted to this issue). Educationally speaking, in this stage the effectiveness of the procedure is fundamental. There is not a real mathematical object to be considered, nevertheless pupils have a “game to be played”, and this can be considered as a sign (sign 1). Now controls and proofs are needed, and geometrical constructions can be considered as an interpretant (interpretant 1). So the possibility to provide a first “structure” to the strategy (e.g. the consideration of standard actions) makes it to become a procedure to be objectualized.

Both from the historical viewpoint (let us remember the aforementioned Bombelli's geometrical constructions) and from an educational viewpoint (with reference to the substitution of the result, $x = 4$, in the given equation, $x^3 - 15x - 4 = 0$ so $4^3 - 15 \cdot 4 - 4 = 0$), a first objectualization can be pointed out. The experience considered do not allow to state that pupils reach a complete objectualization. In the following picture, the interpretant 2 is related to an objectualized procedure and it is referred to the "rules" listed by Bombelli (as noticed, only some students accepted them).

Later, the strategy will become an autonomous object and its transparency (in the sense of Meira, 1998) will be important from the educational point of view. It will not be linked to a single situation and it will be applied to different cases (Sfard, 1991). This stage can be characterized by the emergence of a *schema* of action (Rabardel, 1995).

According to Font, Godino and D'Amore (2007, p. 14), “what there is, is a complex system of practices in which each one of the different object/representation pairs (without segregation) permits a subset of practices of the set of practices that are considered as the meaning of the object”. The starting point of the semiotic chain can hardly be considered in the sense of semiotic function. It can be considered as a first practice that will be followed by other practices in order to constitute the meaning of the object.

FINAL REFLECTIONS

In my opinion the importance of an ontosemiotic approach to representations can be highlighted by a Peircean (or post-Peircean) perspective giving sense to the starting point of the semiotic chain. The analysis of this stage of the semiotic chain can help us to comprehend both our pupils' modes of learning and the essence of mathematical objects themselves.

Nevertheless, from a cognitive viewpoint, the question is not only to show how a process becomes an object. The main problem is to understand how signs become meaningfully manipulated by the students, through social semiotic processes. It is also important to notice that Peircean semiotics seems not completely suited to account for the complexity of human processes in problem-solving procedures. In fact, we do not go always from sign to sign, but more properly from complexes of signs to complexes of signs (and usually they are signs of different sort: gestures, speech, written languages, diagrams, artifacts, and so on).

According to L. Radford and H. Empey, «mathematical objects are not pre-existing entities but rather conceptual objects generated in the course of human activity». It is worth noting that “that mathematics is much more than just a form of knowledge production – an exercise in theorization. If it is true that individuals create mathematics, it is no less true that, in turn, mathematics affects the way individuals are, live and think about themselves and others” (p. 250). As a matter of fact, a strategy to be objectualized can influence pupils' approaches both to mathematical tasks and to different (non-mathematical) activities: “within this line of thought, in the most general terms, mathematical objects are intellectual or cognitive tools that allow us to reflect upon and act in the world” (p. 250). These remarks lead us to reflect about the importance of “mathematical objects” and of their representations. They were conceived by mathematicians in the history, they are reprised and re-invented by our pupils today. So they affected – and, nowadays, affect – “all of society and not only those who practice it in a professional way” (p. 251).

COGNITIVE CONFIGURATIONS OF PRE-SERVICE TEACHERS WHEN SOLVING AN ARITHMETIC-ALGEBRAIC PROBLEM

Walter F. Castro. *University of Antioquia. Colombia*

Juan D. Godino. *University of Granada. Spain*

The objective of this paper is to describe the cognitive configurations exhibited by the students when solving word problems which could be solved using arithmetic-algebraic methods. The configurations will be described in terms of theoretic elements provided by the onto-semiotic approach to mathematics knowledge and instruction.

Key words: elementary algebraic reasoning, cognitive configurations, primary teachers, didactic reflection.

INTRODUCTION

A number of researchers recommend the incorporation of elementary algebraic reasoning at different levels of primary education (e.g., Booth, 1988). Carraher and Schliemann (2007) state that algebra at the primary school is not simply a subset of the high school syllabus; rather, it is a rich sub-domain of mathematics education with its own approaches and problems to research.

The introduction of student primary teachers to elementary algebraic reasoning is a long and complex process (Van Dooren, Verschaffel and Onghema, 2003). It is considered that primary teachers should be able to recognize and to foster the algebraic reasoning manifested spontaneously by their students (Carraher and Schlieman, 2007). Therefore, research about fostering elementary algebraic reasoning in student teachers is of great relevance to initial teacher education (Borko et al, 2005).

On this research domain there are two questions posed by Carraher and Schliemann (2007, p.675): ‘can young students really deal with algebra?’ and, ‘can elementary school teachers teach algebra?’. Some researchers have tackled the second question. For example, Schmidt and Bernarz (1997) detail student teachers’ resistance and conflicts in the passage from arithmetic reasoning to algebraic reasoning. Similar findings are reported by Van Dooren et al. (2003).

Our purpose is to present the initial findings of a student teachers educational proposal on mathematics reasoning. The proposal offers opportunities to student teachers to develop didactic analysis knowledge (Godino, J. D., Rivas, M., Castro, W. F. y Konic, P, 2008) that could aid student teachers to recognize and to foster elementary algebraic reasoning in their pupils.

We focus the attention on the notion of cognitive configuration introduced by the “onto-semiotic approach”, OSA, (Godino, Batanero, and Roa, 2005; Godino, Batanero, and Font, 2007) to characterize the mathematic knowledge that is mobi-

lized in order to solve an arithmetic-algebraic problem. We consider that this notion offers a wider view of the construct of strategy by considering the conceptual, propositional, argumentative, representational and situational aspects of knowledge alongside the traditional procedural approach.

INSTITUTIONAL CONTEXT AND METHODOLOGY

The research has been carried out with a sample of 94 primary student teachers enrolled in a mathematics method course at University of Granada, Spain. The course aims to develop mathematical knowledge as well as didactical reflection. It is to mention that algebra as such was not studied in the course. During the course several mathematical problems that could be solved using elementary algebraic reasoning were given to students. In this paper we analyze the students' solutions to one of these problems which were given during a test.

A ball is thrown from an unknown altitude; it bounces up to one fifth of the altitude it was thrown from. If after three rebounds the ball reaches an altitude of 6 cm, a) What is the altitude it fell from the first time?, b) Explains the resolution using algebraic notation.

The problem belongs to a category of very well studied word problems. However, within the framework of this course, we are specifically interested in the arithmetic and algebraic solutions provided spontaneously by students.

EPISTEMIC ANALYSIS OF THE PROBLEM⁴

The OSA focuses on five dimensions in analysing the objects and meanings used in solving a mathematical problem: linguistic objects, concepts, properties, procedures and arguments. In what follows we analyse the problem using OSA⁵. This analysis has two purposes for the teacher educator: to explore the objects and meanings put into effect during the solution of the problem, and to identify eventual meaning conflicts and to foresee difficulties and errors that could emerge in students' solutions to similar problems.

The word problem is stated in terms of linguistic elements, which refer to quantities, magnitudes and relationships between them. These can be expressed in arithmetic or algebraic terms.

The statement "*A ball is thrown from an unknown altitude*" refers both to a real experience and to the unknown value of a quantity. Next it enounces a condition "*it bounces up to one fifth of the altitude it was thrown from*" that establishes the numeric relationship, invariant during the bouncing, between the altitude the ball falls from and the altitude to which it bounces, expressed by the fraction $1/5$.

⁴ To see an example of such analysis, we refer the readers to the work of Godino et al. (2008).

⁵ A priori analysis of the solution to the problem done by an expert.

The statement “*If after three rebounds the ball reaches an altitude of 6 cm*” establishes that the numeric relationship is compounded three times with itself, fraction of fraction. Additionally it assigns a value to the last altitude.

Finally the statement, “*What is the altitude it fell from the first time?*” establishes the quantity that must be identified in terms of the given information in the problem wording.

The linguistic terms refer to mathematic concepts (e.g., fraction, equality, unknown, operation), whose meanings, properties and procedures are related argumentatively in a complex way and favors or inhibits the solution to the problem.

It is worth to mention that both the eventual arithmetic and algebraic solutions place the primary entities in different configurations. For instance, in an arithmetic solution, if it is assumed that 6 is the fifth of an unknown quantity, then we can find the unknown quantity by multiplying for five, inverting the fractioning operation used initially. However, in an algebraic solution, it is not necessary to use either this property or the associated concept. The unknown quantity is multiplied, three times, by $1/5$ and this is equated to 6. Subsequently the unknown is isolated using a procedure that frames the solution in terms of multiplication/division.

COGNITIVE ANALYSIS OF THE STUDENTS’ SOLUTIONS

In what follows we will describe our typology of cognitive configurations evident in the solutions produced by the students. In each case, we identify the mathematical objects and meanings used by the students in representing their solutions.

*Algebraic configurations*⁶

Algebraic solutions are those where the use of unknowns is clearly manifested. The types of algebraic solutions are: use of unknown, assigning tags to equations, use of three unknowns, and additive relationships.

ALC1⁷: Use of unknown. On this type of procedure the unknown appears explicitly written and it is isolated. The students have attributed meaning to the linguistic objects “a bounce” and “*If after three rebounds*”, and have represented such linguistic elements in procedural objects, this can be deduced from the actions carried out on fractions, on relationships established and expressed by the equal sign and, finally, on isolating the unknown.

ALC2: Assigning tags. Students explicitly associate each rebound with an equation. They use a process made of three steps: initially identify the unknown “*altitude the ball fell from*” which is named x , later name the equation corresponding the first bounce as “*first rebound*”, and so two times more, up to the point where they write the equation that corresponds to the third bounce, and name it “*third rebound*”, equate to six and obtain the sought value.

⁶ See Godino et al. 2008.)

⁷ The code ALC and ARC stands for algebraic and arithmetic configurations, respectively.

Every solution on this category is correct. It seems that students control the alleged difficulty that rises when dealing with unknowns by assigning a tag that lets them to isolate each rebound, represented linguistically, and at the same time allocated it in the problem context. On this type of solution the students have isolated the linguistic object “*it bounces up to one fifth of the altitude it was thrown from*”, and have identified it as an operative invariant in the whole process and have given it a procedural role expressed by multiplying by one fifth.

The procedural and linguistic objects are materialized argumentatively through the appropriate use of the equality in its relational meaning and by means of numerical operations and properties that are carried out on the equation with the purpose of isolating the unknown.

ALC3: Use of three unknowns. Students use three unknowns, each one of them associated to the unknown’s numerical values corresponding to each bounce. Then they propose an equation and they execute a nested replacement of variables, from the expression corresponding to the last one up to the expression corresponding to the first bounce, and they proceed to isolate the unknown.

The problem is tackled by means of a procedure that breaks up it in three moments; the first and the second are represented by an equation with two unknowns, and the third, by an equation with one unknown. The mastering of linguistic elements that describe the relationships is predominant on this procedure.

The possible meaning conflicts on the description of the problem are overcome by assigning a semiotic function, whose antecedent corresponds to each and every bounce, and the consequent is a relationship, expressed as an equation.

On this procedure the students operate “with” and “on” the unknown (Tall, 20001) and spontaneously use the transitive property of equality (Filloy, Rojano and Solares, 2004).

It is observed, on this solution strategy, the use of procedures on two levels, the first that involves the “process” of dividing the problem in three parts, and the second, the use of properties and procedures, in the usual manner as mathematical procedures are used. This type of solution is illustrated on Figure 1.⁸

⁸ A translation is provided

a is the initial height from which the ball is thrown. Each bounce a , b , 6 cm is $\frac{1}{5}$ of the previous bounce. We isolated the first equation in order to substitute it in the others.

$$6 = \frac{1}{5} \text{ of } c = \frac{c}{5}; \quad c = 6.5 = 30; \quad 30 = \frac{1}{5} \text{ of } b = \frac{b}{5}; \quad b = 30.5 = 150$$

$$150 = \frac{1}{5} \text{ of } a = \frac{a}{5}; \quad a = 150.5 = 750, \text{ the initial height } 750 \text{ cm}$$

Figure 1. Use of three unknowns (ALC3)

CAL4: Additive relationships. On this type of solution, the students use an unknown and produce expressions and equations that relate arithmetic data by means of additive expressions. Some students wrote expressions (not equations) to represent the problem. The operative invariant “one fifth” appears multiplying the unknown that is operated, additively with the numbers three and six but without establishing a relationship expressed by an equation. In some cases the fragility of knowledge about properties of rational numbers is manifested.

In some other solutions it can be seen that some relationships are proposed among the numerical values “three” and “six”, where “one fifth” multiplies the unknown, the students identify the presence of an unknown and recover the numbers out of the problem wording, however they do not related them in any way.

Arithmetic configurations

Arithmetic solutions were classified as those where only arithmetic operations are used without any reference to unknowns. The types of arithmetic solutions identified are: Reverse multiplication, multiplicative relationship, additive relationship, and rule of three.

ARC1: Reverse multiplication. The solution procedure consists of inverting the operation: it is known that the altitude to which the ball bounces is one fifth of the altitude it was thrown from, as 6 is the last altitude, therefore the previous altitude is 6×5 and the previous altitude to the last one is $6 \times 5 \times 5$. Finally the altitude the ball was thrown from is: $6 \times 5 \times 5 \times 5$.

Students using ARC1 exhibit competence and fluency in the use of the multiplication operation in the context of known quantities. It is of note that this aspect of “operation sense” underlies algebraic thinking Slavit (1999, p.256).

On this category are located the right arithmetic answers given by the students. The only meaning conflict found on some answers is considering four bounces instead of three. Figure 2 illustrates this type of solution.

1er bote - 150 cm
 2º bote - 30 cm
 3er bote - 6 cm x 5

$$\begin{array}{r}
 150 \\
 \times 5 \\
 \hline
 750 \text{ cm}
 \end{array}$$

La pelota se lanzó desde 750 cm

③ ↑ 6 cm = 1/5 de ② ↑ 30 cm = 1/3 de ① ↑ 150 cm = 1/5 de (PI) ↓ 750 cm

Figure 2. Reverse multiplication (ARC1)⁹

ARC2: Arbitrary use of multiplication. Students focus their attention simply on the numbers contained in the problem: 6, 3 and 5, and the solution they offer is an arbitrary combination of multiplicative operations among these three numbers. The students appear to construct their solution without paying any attention either to the conditions on numbers or to relationships among them. According to Garolafo (1992), these students do not exhibit a “numeric approach”, because they do not display strategies neither to decide which operations to use nor to assess a plan to solve the problem.

It is deduced from the students’ solutions that they have not comprehended the meaning, in operative terms, of the linguistic objects “*first*”, “*second*” and “*third*” bounce, nor in relational terms of “*If after three rebounds the ball reaches an altitude of 6 cm*”. The students are incapable of expressing numerically the relationships present in the problem.

The two approaches to rational numbers duplicator/partition and stretcher/shrinker (Behr, et. al. 1997) are stressed on this strategy due to the fact that 6 cm is not identified as the last bounce, corresponding to one fifth of a quantity that can be found by multiplying for five, inverting the operation initially implemented, fractioning by five. The operative actions corresponding to adding up fractions are carried out correctly even though it seems to be a lack of meaning that students attach to the numbers and operations between them.

ARC3: Arbitrary use of addition. As with ARC2, the students only pay attention to numeric data, and simply add up the numbers, in some cases, without appearing to establish *any* relationship among them. It seems that students have assumed that the problem has an additive structure, where the length of the bounces are added up and the data 6cm, corresponds to the sum of the altitudes of the three bounces.

The meaning conflicts are located in the linguistic elements corresponding to “*first*”, “*second*” and “*third*” bounce, as well as, to the statement “*one fifth of*”, which is interpreted only in its numeric dimension. It seems that the relationships among the numbers and expressed linguistically in the problem wording are superfluous to students.

⁹ The translation for the Spanish in the graph is: 1) Ball was thrown from 750 cm; 2) Bote stands for bounce

ARC4: Rule of three. The students establish a proportionality relation between the number three, that corresponds to the bounces and 6cm, then formulate the question: what is the altitude corresponding to one bounce? The meaning conflicts on this category are much more profound. It seems that students have associated the data format presentation and the problem wording to the archetypal format of proportionality problems that are solved through the so called “rule of three”.

On this type of solution the students carry out the change of type of register procedure that lets them to produce meaning in numerical terms but with no link to the problem. It seems that problem complexity compels students to veer towards more familiar grounds and to perform arithmetic operations (Herscovics & Linchevski, 1994).

A discussion of results

The last three types of arithmetic solutions (ARC2, ARC3 and ARC4) are characterized by a wrong meaning assignment to linguistic objects. Understanding the statement of a word problem requires recognition of the existence of dependence among meaning corresponding to elementary entities. Anghileri (1995) suggests that the close relationship between real settings and the procedures used to solve problems characterized the initial states in learning mathematics. The students have not succeeded in writing a numerical “argument” that links different objects appearing during the resolution process.

The difficulties in representing the problem arithmetically or algebraically are evident from the analogy between ALC4 and ARC3. Nonetheless the meanings and the ways they are related differ essentially. Along with each type of resolution it has been shown that the problem structure raises a number of interpretative challenges, and how the solutions correspond to particular configurations of primary entities, where these facilitate or hinder the arithmetic or algebraic problem representations. The mathematic objects invoked in the problem are the same but the meanings, the relationships among them and the meaning conflicts are diverse to students.

To Filloy, Rojano and Puig (2007), “the mode of thought- be arithmetic or algebraic- appears to be determined by the type of ‘ relational calculation’ that underlies the problem structure” (p.216). We consider that the relational calculation can be expressed and objectified in terms of primary entities, which could be useful for the teachers to recognize both the mathematic tasks complexity and the variety of mathematical reasoning leading to the solution.

RESULTS SUMMARY

Table 1 gives a detailed breakdown of the number and proportion of each type of algebraic and arithmetic solution.

Types of algebraic solutions	ALC1	ALC2	ALC3	ALC4	Correct/incorrect
Number of students	25	17	5	11	37/58
Types of arithmetic solutions	ARC1	ARC2	ARC3	ARC4	10/23
Number of Students	4	14	3	2	
Do not answer	13				

Table 1: Type of configuration and number of students in each one

It can be seen that the number of algebraic solutions as the number of right solutions outnumbered the corresponding arithmetic solutions. The proportion between right solutions and solutions of each type is bigger for the case of algebraic solutions.

Even though students are asked to provide an algebraic solution in the second problem's item, they could have provided an arithmetic solution in the first problem item as well. Given that algebra was not studied during the course, it is worth noting the students' algebraic preference.

IMPLICATIONS FOR STUDENT TEACHER TRAINING

A finding of this research is that the algebraic methods used by the students to solve the problem outnumber in quantity and in effectivity the arithmetic strategies. Just a small number of students choose to solve the problem by means of a right arithmetic strategy in contrast to the findings reported by Nathan and Koedinger (2000). Another finding is the apparent disarticulation among the linguistic, conceptual and procedural elements in the cognitive configurations exhibited by the students, who do not manage to elaborate an "argument" leading to a problem solution.

We consider that teacher's activity not only concerns with planning mathematic tasks but also with the promotion and recognition of the meaning present in the students' solutions, where the primary entities are articulated. Recognizing the entities involved students' solutions could help teachers guide their didactic actions.

Therefore it is important to make teachers conscious of the network of objects, meanings and configurations that are put into effect during the mathematics problems solutions to help identifying the meaning conflicts manifested by pupils and therefore, to give answers to those conflicts in the classroom context. As a consequence, it is convenient to use the cognitive-epistemic analysis (Godino et al. 2008) in initial teacher training programs.

Some researchers have contended that teacher's competence to understand and to use the mathematic knowledge adapting it to students' achievements is important (Ball, 1990; Wilson, Shulman and Richert, 1987). More recently Hill, Rowan and Ball

(2005) found that content knowledge is related meaningfully to students' achievements.

We conclude with the observation about the arithmetic strategies that we have discussed above. Our study suggests that algebraic thinking underlies successful problem solutions. We believe that a focus on elementary algebraic reasoning can aid teachers in enabling their pupils to more fully understand the arithmetic domain.

TRANSFORMATION RULES: A CROSS-DOMAIN DIFFICULTY

Croset Marie-Caroline

UJF, Leibniz-MeTAH, Grenoble, France, Marie-Caroline.Croset@imag.fr

The learning of a symbolic system such as algebra relies on the learning of the use of transformation rules. The implementation of rules in a CAS (Computer Algebra System) for students' modelling has pointed out some questions that are at the junction of three research fields: informatics, mathematics and didactics. Each of these communities has its own perception of algebraic objects, founded on models or practices. The implementation of objects that live in school has questioned object reliability. In this paper, a parallel is proposed between difficulties of informatics implementation of transformation rules and novices' difficulties.

Keywords: algebraic calculations, rules, informatics implementation, students' difficulties.

An important part of school algebra rests on algebraic calculations, what Kieran calls the “transformational activity”, which she distinguishes from the generational and global activities (Kieran, 2001). This activity focuses on changing the form of an expression or an equation in order to *maintain equivalence*. This includes, for instance, collecting like terms, factoring and expanding expressions. These are algorithmic tasks like the transformation of $(5 + x)x + 10 + 2x$ into $(5 + x)(x + 2)$. The conservation of equivalence relies on *correct rules* that allow substituting expressions by others. These rules will be called “transformation rules” in this paper. They are supported by the laws of the polynomial ring –commutative law, distributive law and so on. Rules produce objects of a particularly interesting form. Their use is guided by what the desired expression has to look like: reduced polynomial expression or factored polynomial expression. Bellard et al. (2005) call them the constituent rules of mathematic theory: “these rules constitute the base of the [transformational] activity, govern the motion and predetermine the permitted actions”. Such mathematical rules are supposed to be accurate and self-sufficient.

Nevertheless, Durand-Guerrier and Herault (2006) stress the fact that rules are objects the usage of which is not so obvious: “the rule is not only a way to learn but it is also an object which has to be learned”. It is, in fact, impossible to present a rule alone to students. Rules have to be transposed, adapted and as such lose a part of their accuracy. The implicit notions of rules are compensated by a necessary didactical contract (Brousseau, 1997): “it is an illusion to believe that one can produce the meaning in the mind of someone by indirect ways through the rule and examples” (Wittgenstein, Ambrose, & Macdonald, 1979). Durand-Guerrier and Herault (op.cit.) also point out the illusion to think that the use of a rule is plain, such as “rails that would guide un-faillingly and in advance the way to be followed”. Actually, it is an interpretation that allows these implicit details between the rule and its application to be overcome. But what are exactly the notions underlying the learning of a transformation rule?

Our research is in line with the identification of systematic errors that students commit when solving transformational exercises. A library of correct and incorrect transformation rules has been built for that purpose and an automatic diagnosis mechanism has been implanted in order to associate a sequence of applied rules to student's transformation (Chaachoua, Croset, Bouhineau, Bittar, Nicaud, 2008). The implementation of these rules has raised questions about the kind of representation of a transformation rule. Automating the process forces the researcher to clarify some implicit mechanisms for the expert: how does a rule work? In which way does it work? How is it matched? It has led to three crucial points about implantation difficulties:

- The reading direction of a rule;
- The notion of sub-expression;
- The generic status of a rule.

Each of these points is discussed in the next sections. We propose, in addition, to link these three points to three classical difficulties which novices may experience when doing transformational activities: the difficulty of understanding the symmetric aspect of the equal sign (see e.g. (Kieran, 1981)); the difficulty of the structural aspect of an algebraic expression (see e.g. (Sfard, 1991)) and the difficulty of applying a general rule to a particular case (see e.g. (Durand-Guerrier, Herault, 2006, p. 144)).

The choices made to raise difficulties in programming may shed light an improvement of the teaching of algebraic rules and may overcome students' problems. Indeed, the reading direction of a rule is essential for a deductive reasoning, the notion of sub-expression allows matching correctly a rule and the generic status of a rule is the power of algebra.

1. REPRESENTATION, READING DIRECTIONS AND REASONING PROCESS

Transformation rules can be represented by two kinds of writings: equality or implication. Both present advantages and have good reasons to be used. Yet, we will see that rules as implication form are interesting in that it highlights the reasoning process in the transformation activity.

Rules as equality, used in school

The first representation –a rule as an equality– is the usual one used in school. Rules can be called by different names in the textbooks: proposition, property, identity, equality and sometimes even theorem (Bellard et al., 2005). Whatever their name, rules are often coming in the form of equality. For example, the distributive law is presented as:

$$k(a + b) = ka + kb, \text{ where } k, a \text{ and } b \text{ are real.} \quad (Eq1)$$

There is a double meaning of the equal sign: that of “identity” or that of “relation”. In transformation rules, the equal sign is of course used as “identity”, whereas in equations, the equal sign is used rather as “relation”. This well-known duality is a real dif-

difficulty for students. Presenting rules as identity can, on the one hand, be interesting to get students used to and, on the other hand, provoke confusion.

Such representations are declarative rather than procedural: this form of identity has no explicit reading direction since the equal sign has a double way: from left to right and vice versa. A learning of the way to use such a rule has to be taught. Whereas the process-product has been many times denounced (Davis, 1975) and that special exercises are proposed to students in order to grasp the equivalence notion, here is a case where the equality has to be used in one of the two ways. In fact, textbooks sense that, most of the time, it is necessary to distinguish the two ways by proposing two identities: not only (*Eq1*), which is used to expand expressions but also “ $ka + kb = k(a + b)$ ” to factor. This kind of presentation requires a specific work to become operative: associate a reading direction to the equality for application, according to the aim.

Rules as implication, used in informatics

The second representation –a rule as an implication– is the one used in informatics. One calls “implication” what Durand-Guerrier, Le Berre, Pontille, & Reynaud-Feurly (2000) call “formal implicative”, representation used in geometry:

$$\forall x \in \mathfrak{R}, P(x) \Rightarrow Q(x).$$

Implemented rules are represented as *oriented* mechanisms, also called “rewrite rules” (Dershowitz & Jouannaud, 1990): $A \rightarrow B$, where A is *rewritten* in B . The object A produces the object B and B can not produce A unless an other rule $B \rightarrow A$ is considered. For example, the rules:

$$k(a + b) \rightarrow ka + kb \text{ (R1) is used to expand,}$$

$$ka + kb \rightarrow k(a + b) \text{ (R2) is used to factor.}$$

It is rather a necessity in computing modeling to represent rules as oriented ones than a choice. Indeed, it is not really possible to implement rules as identity. If a single rule is implemented both for expanding and for factoring, there will be some loop and ending problems. For example, with the single rule (*Eq1*), the expression “ $3(x + 4)$ ” would be transformed into “ $3x + 12$ ”, then into “ $3(x + 4)$ ” and so on.

Even if it is a necessity, this kind of representation is interesting because its reading direction is explicit: given a real or a polynomial expression under the form “ $ab + ac$ ”, where “ a ”, “ b ” and “ c ” are reals or polynomials, it can be rewritten into “ $a(b + c)$ ”. One can suppose that the use of rules as implication is easier because of its procedural aspect. The kind of representation has an impact on its use easiness, as we will show in the next section.

Impact of the reasoning process

Although geometry is a special introduction field for proof, the latter is not a prerogative of geometry. The “deep structure” (Duval, 1995) of the transformational activities can be presented as a ternary organisation proposed by Duval. A premise (here, a certain expression), a proposition (a transformation rule) and a conclusion (an other expression), as shown in Figure 1, constitute a deduction step. These steps follow on, the conclusion of the current step becoming the premise of the next one. Using Duval’s classification (Duval, 1990), the algebraic calculation is formed by *deductive reasoning of steps explicitly concatenated in reference to a transformation rule*. Thereof, this activity can be viewed as a process of demonstration:

“Demonstration would be defined to be, a method of showing the agreement of remote ideas by a train of intermediate ideas, each agreeing with that next it; or, in other words, a method of tracing the connection between certain principles and a conclusion, by a series of intermediate and identical propositions, each proposition being converted into its next, by changing the combination of signs that represent it, into another shown to be equivalent to it” (Woodhouse, 1801)

Figure 1: Deduction steps.

Representing rules as implications could allow the user to follow this reasoning process explicitly, as shown in Figure 2.

Figure 2: Example of the reasoning process in algebra. The level of making explicit a demonstration and the granularity of a deductive step evolves with the level of the student. Here, for example, we have omitted to explicit the commutative law. As Arsac notes: “any demonstration is shortened from another demonstration” (Arsac, 2004).

Splitting an identity into two implications conceals the fact that rules are equivalent but clarifies the *way of application* and, above all, it allows following the Duval’s structure of a deduction step. This is the *modus ponens* mode: “if p , then q , now p ,

then q ". The representation form of a rule has an impact on its use easiness but it lets the difficulty to know to which object the rule can be applied.

2. MATCHING AND SUB-EXPRESSIONS NOTION

An unrefined syntactic unification between the premise of a rule and a part of an expression does not produce an algebraic behaviour. With an unrefined unification, a rule as $x + x \rightarrow 2x$ would transform " $5x + x$ " into " $5 2x$ ", which has no sense (what is the operator between "5" and "2"?) nor the expected result. This is a well-known mistake committed by students: substitute an expression by another by working only on a syntax level and taking no account of semantics. Mastering substitution needs knowing the notion of what a *sub-expression of an expression* is.

The definition of an expression from the rewrite rule theory of Dershowitz (1990), in which rules are applied on *sub-objects*, underlines the notion of sub-expression, thanks to its recursive definition. Let us consider a set of symbols of terminal objects (e.g., integers), a set of symbols of variables (e.g., $\{x, y, z\}$), and a set of symbols of operators (e.g., $+$, $-$, \times , \wedge , sqrt , $=$, $<$, and, or, not). An *algebraic expression* is a finite construction obtained from the following recursive definition:

- a symbol of terminal object
- or a symbol of variable
- or a symbol of operator applied to arguments which:
 - are algebraic expressions,
 - are in the correct number (correct arity [1]),
 - and have correct types [2].

With this definition, matching a rule R to an expression E would consist of finding a sub-expression E_1 of E , replacing E_1 in E by the expression that produces R . For example, in " $5x + x$ ", the algebraic (sub) expressions are " $5x$ ", " x " (two times), " 5 " and " $5x + x$ ". The expression " $x + x$ " is not a sub-expression of " $5x + x$ ". To deal with this problem, the internal representation of expressions in computer algebra systems (CAS) is a tree representation, in which the structure of the expression is explicit, as shown in Figure 3.

Figure 3: Tree representation of the expression $5x + x$.

The necessity of the tree representation appears also in school curricula. Although school approach of expressions is foremost syntactic -algebraic expressions are defined as “writings including one or more letters”-, new French curricula encourage making students work on tree representations. As they claim, tree representation allows pointing out the structural aspect of an expression as defined by Kieran:

“The term *structural* refers, on the other hand, to a different set of operations that are carried out, not on numbers, but on algebraic expressions. [...] the objects that are operated on are the algebraic expressions, not some numerical instantiations. The operations that are carried out are not computational. Furthermore, the results are yet algebraic expressions.” (Kieran, 1991)

This structure notion is essential to deal with matching difficulties. It enables understanding why such rule like $k(a+b) \rightarrow ka+kb$ (*RI*) can be applied on sub-expressions of expressions such as $3+4(x+1)$. Nevertheless, is it sufficient to understand that this rule can be applied also on expressions such as $4x^2(x+1)$ or $4x^2(x+1+x^2)$? Either in informatics or at school, we will see that most of the time, one needs to precise as many rules as there are cases.

3. GENERIC STATUS OF RULES

The third idea which emerges of rules implementation turns on the generic status of a rule: how a rule such as (*Eq1*) or (*RI*) can be sufficient to apply to the expressions “ $7(3+x)$ ”, “ $-7(3+x)$ ”, or even “ $7(3+x+x^2)$ ”? How to deal with the matching of “ $a+b$ ” with “ $3+x+x^2$ ”? It is, with no doubt, the principal difficulty for novice users of rules: the application of a general rule to a particular case. It is, in fact, the same in informatics. Although the two first points –reading direction & matching problems– have been easily resolved in informatics, it has not been the same for this third problem.

The entry by rewriting rules –and thus a syntactic presentation– leads to some new problems. Let us study again the case of (*RI*). For experts, it is not really this rule that is used but much more the single distributive law. With this last one, experts can expand any product of polynomials. In informatics, one needs rules to be implemented and so, the exact structure of an expression has to be specified. For (*RI*) implementation, “ k ”, for example, has to be defined: is “ k ” a real, a product such as a monomial or a sum? It is not possible to just say “given a polynomial k ”. Indeed, to transform “ k ”, its structure has to be specified. For example, if “ k ” is negative, the sign of the entire expression is changed. The main operator of the expression becomes “minus” and not “times”: the entire internal tree representation is changed, as shown in Figure 4. The same difficulty is found when “ $a+b$ ” is a sum of three terms: it can change the mechanism of the implementation of the rule. Without genericity, one needs to distinguish cases like “ $k(a+b)$ ” from “ $k(a+b+c)$ ”. To deal with that, the concept

of distributive law has been implemented. Let us consider two lists and an operator, the distributive rule can be written as:

$$(a_1, a_2, \dots, a_n) \Delta (b_1, b_2, \dots, b_n) \rightarrow (a_1 \Delta b_1, a_1 \Delta b_2, \dots, a_1 \Delta b_n, a_2 \Delta b_1, a_2 \Delta b_2, \dots, a_n \Delta b_n).$$

We do not have to specify the length “ n ” of the lists.

Figure 4: The single change of the real 7 into -7 changes the entire structure of the tree representation of the expression. On the left, the expression $7(5+x)$; on the right, the expression $-7(5+x)$.

Another example is very representative of this problem: the rule of monomials addition, which can be written as $ax + bx \rightarrow (a \oplus b)x$, where \oplus is the calculated sum operator. Such rule is not so easy to implement. If we ask the premise to be a sum of two products, this rule will not apply to expressions such as “ $ax + x$ ” because “ x ” is a single argument and not a product: an automatic mechanism does not recognize “ x ” as the product of “1” and “ x ”. To deal with this problem, some concepts have been implemented like the *monomial concept*. We have implemented the added fact that a monomial can be either a product of a real and a variable –of explicit degree or not– or a single variable –of explicit degree or not. Thus, expressions such as “ $4x^5$ ”, “ $4x$ ”, “ x^1 ” or “ x ” are read as monomials, and the rule $ax + bx \rightarrow (a \oplus b)x$ can be easily implemented: one needs just to specify that the premise has to be a sum of two monomials.

The same problem occurs at school: the polynomial notion is not taught in France [3]. The variable “ k ” from the rule (*Eq1*) is then defined as a real, so are “ a ” and “ b ”. Understanding that “ a ” can be itself a sum, or even a sum with variables, requires a real work. How do French textbooks deal with this problem?

To answer this question, we have used the concept of praxeologies from the Chevallard’s anthropological theory of didactics. Let us remain that Chevallard proposes to describe any human activity by a quadruplet which enables an activity to be cut in types of task, which can be solved by techniques –a way of doing–, which can be explained by a rational discourse, “logos” (Chevallard, 2007) [4]. Our work in progress (Croset, 2009) shows that French textbooks distinguish three types of task for expanding expressions:

$$“k(a + b)”, “k(a - b)” \text{ and } “(a + b)(c + d)”.$$

Cases like “ $-(a + b)$ ” or “ $+(a + b)$ ” are discussed in another part of textbooks (“how to remove brackets?”). Some textbooks propose even more distinctions: they discern also “ $(a + b)k$ ” and “ $(a - b)k$ ”.

On the one hand, it seems that textbooks decide to specify many cases although all these tasks are explained by a single “logos”: the distributive law. The fact that textbooks need to precise many cases points out the well-known difficulties of students to apply a general rule to particular cases. On the other hand, all possible cases cannot be specified. Textbooks do not specify types of tasks as “ $k(a + b + c)$ ” or “ $k(a + b)(c + d)$ ”. Understanding the structure of the expression is supposed to be sufficient to deal with all these forms. Nevertheless, we have not found such work and reflection about the generality of rules. Only a few textbooks precise links between the three types of task described above. Explanations such as using $k(a + b) \rightarrow ka + kb$ to expand “ $(a + b)(c + d)$ ” are not common. Neither are presented the iteration concept to expand “ $k(a + b)(c + d)$ ” whereas our work (ibid.) shows that students’ mistakes occur specially in this sub-type of task.

The second problematic example about monomials revealed by the computing implementation occurs also in students’ difficulties: recognizing “ x ” as a monomial is not an easy task for a novice. A novice’s common mistake is precisely to transform “ $ax + x$ ” into “ ax ” because of the lack of the explicit coefficient “1” ahead of the “ x ”: when “ a ” is added to “nothing”, it remains “ a ” [5]. The concept of monomial is not taught currently in French curriculum. We speak about “like terms” but few textbooks precise that “ x ”, “ $1x$ ”, and “ x^1 ” are “like terms” which can be collected.

The force of algebra lies in the writings generic status. Its interest is lost if all cases are presented. To avoid that, a specific work on concepts such as distributive law or monomial could be proposed to novices, just like it has been done for the computing implementation.

4. CONCLUSION

The learning of the transformational activity cannot be restricted to memorizing rules. This requires a specific work about the application of rules. Our research focusing on automatic student modelling has brought to light three important difficulties concerning the application of transformation rules, which have been compared with similar novices’ difficulties: knowing that a rule has a reading direction allows students to follow a reasoning process when they transform algebraic expressions; knowing the structure of an expression permits a correct matching; finally, having a good perception of the generic status of rules allows students to apply a general rule to a particular case. All these elements are necessary conditions for learning the algebraic symbolic system. Our paper has described the parallel between informatics implementation difficulties and the ones met by novices. One can wonder if the way to deal with the first ones could be used to deal with the second ones.

Regarding these three points, rules have been looked at from a technical point of view. Another point of view would be considering what experts' criteria are to control their transformations: substitute numerical values to equivalent expressions in order to verify the equivalence; in other words, being aware that equivalent expressions denote the same object. Similarly, another interesting point of view is to explore how to *choose* the appropriate rule. We have seen that a rule is general but the choice of a rule is crucial to obtain the form that one needs. The *raison d'être* of a rule, the strategic process and elements that guide an expert in choosing this particular rule, and not another one, have not been discussed here, despite the fact that informatics is also interested in such questions. We can expect that a parallel would be again possible between novices' strategic difficulties and the implementation ones.

NOTES

1. The arity of an operation is the number of arguments or operands that the operation takes. For example, addition is an operation of arity 2, sqrt is an operation of arity 1.
2. For example the expression " $\sqrt{5x=3}$ " has not a correct type.
3. A recent study has compared the algebra learning in France and in Vietnam (Nguyen, 2006). It shows that algebraic expressions found in French textbooks rely on the notion of polynomial function whereas the ones that can be found in Vietnamese textbooks rely on the polynomial notion.
4. The reference (Chevallard, 2007) is not the best one for the notion of praxeology but it presents the advantage of being written in English. French reader can see also (Bosch & Chevallard, 1999).
5. Haspekian (2005) proposes another explanation to this mistake: the difficult notion of neutrality of the multiplicative law. We think that, in our context, the mistake is more relative to a visual lack.

INTERRELATION BETWEEN ANTICIPATING THOUGHT AND INTERPRETATIVE ASPECTS IN THE USE OF ALGEBRAIC LANGUAGE FOR THE CONSTRUCTION OF PROOFS

Annalisa Cusi

Dipartimento di Matematica - Università di Modena & Reggio

Abstract. *This work is part of a wide-ranging long-term project aimed at fostering students' acquisition of symbol sense (Arcavi, 1994) through teaching experiments on proof in elementary number theory (ENT). In this paper I present some excerpts of students discussions while working in small groups on activities of proof construction. My analysis of these transcripts is aimed at highlighting the incidence of anticipating thoughts and of the flexibility in the coordination between different conceptual frames and different registers of representation in the development of proof in ENT. In particular, I singled out four main sources of interpretative blocks, highlighting the strict interrelation between anticipating thought and students' difficulties in the interpretation of the algebraic expressions they produce.*

1. INTRODUCTION

Many research studies support an approach to algebraic language related to the development of reasoning. Arcavi (1994), for example, claims that, in addition to stimulating students' abilities in the manipulation of algebraic expressions, teachers should make them see the value of algebra as an instrument for understanding, introducing them to algebraic symbolism from the beginning of their studies through specific activities that encourage an appreciation of the value and power of symbols. A central aspect in Arcavi's approach to algebraic language is, in fact, the concept of symbol sense. The author chooses to characterize symbol sense highlighting, through meaningful examples, the attitudes to stimulate in students to promote an appropriate vision of algebra. Particular attitudes that he names include: the ability to know when to use symbols in the process of finding a solution to a problem and, conversely, when to abandon the use of symbols and to use alternative (better) tools; the ability to see symbols as sense holders (in particular to regard equivalent symbolic expressions not as mere results, but as possible sources of new meanings); the ability to appreciate the elegance, the conciseness, the communicability and the power of symbols to represent and prove relationships. Many researchers share a similar vision of the approach to the teaching of algebra. Among them, Bell (1996), states, in particular, that it is necessary to favour the use of algebraic language as a tool for representing relationships, and to explore aspects of these relationships by developing those manipulative abilities that could help in the transformation of symbolic expressions into different forms. This idea is strictly connected with Bell's description of "the essential algebraic cycle" as an alternation of three main typologies of algebraic activity: representing, manipulating and interpreting. Similar observations are also found in Wheeler (1996), who asserts the importance of ensuring that students acquire the fundamental awareness that algebraic tools "open the way" to the discovery and (sometimes) crea-

tion of new objects. Kieran (2004) also stresses the importance of devoting much more time to those activities for which algebra is used as a tool but which are not exclusively to algebra (global/meta-level activities according to Kieran's distinctions) because they could help students developing transformational skills in a natural way since meaning supports manipulations. Proof is certainly one of the main activities through which helping students develop a mature conception of algebra. I adopt Wheeler's idea that activities of proof construction through algebraic language could constitute "a counterbalance to all the automating and routinizing that tends to dominate the scene". I believe that activities of proof in ENT would both provide students with the opportunities they need to progress gradually from argumentation to proof (Selden and Selden, 2002)) and help them to appreciate the value of algebraic language as a tool for the codification and solving of situations that are difficult to manage through natural language only (Malara, 2002).

I agree with Zazkis, Campbell (2006) who state that "the idea of introducing learners to a formal proof via number theoretical statements awaits implementation and the pros and cons of such implementation await detailed investigations" (p.10). In order both to investigate these aspects and to foster the diffusion of activities of proof in ENT in school, aiming at making student appreciate the value and power of algebraic language, I am working with upper secondary school students (10th grade) [1]. I planned and experimented a path for the introduction of proofs in ENT. The path was articulated through small-groups activities (some groups were audio-recorded), followed by collective discussions (audio-recorded) on the results of the small-group activities. In order to foster a widespread participation during group activities, I decided to work with homogeneous (according to competencies and motivations) small groups. In this work I will dwell on a central moment in the path: the small-groups' work aimed at constructing the proof of some conjectures they produced starting from numerical explorations. In particular I will present the main results of the analysis of group discussions when students were trying to prove one of the conjectures.

2. THEORETICAL FRAMEWORK WHICH SUPPORT MY ANALYSIS OF STUDENTS' DISCUSSIONS

Many different competencies are required of a student who has to face proof problems in ENT. In particular, he/she has to: (a) know the meaning of the mathematical terms in the problem text and interpret them correctly by reference to it; (b) translate correctly from verbal to algebraic language; (c) be able to interpret the results of the transformations operated on the algebraic expressions in relation to the examined situation; and (d) control the consequences of his/her assumptions. I identified a set of theoretical references that are both appropriate to the analysis of the transcripts of group discussions dealing with proofs and in tune with the view of algebra that I am trying to promote. The main reference in my research is the work by Arzarello, Bazzini and Chiappini (2001). The authors propose a model for teaching algebra as a *game of interpretation* and highlight the need for the promotion of algebra as an efficient

tool for thinking. An awareness of the power of the algebraic language can be developed only once the student has mastered the handling of some key-aspects that arise in the development of algebraic reasoning. In particular, the authors highlight the use of *conceptual frames* defined as an “organized set of notions, which suggests how to reason, manipulate formulas, anticipate results while coping with a problem”, and *changes from a frame to another* and from a knowledge domain to another as fundamental steps in the activation of the interpretative processes. According to the authors, a good command in symbolic manipulation is related to the quality and the quantity of anticipating thoughts which the subject is able to carry out in relation to the effects produced by a certain syntactic transformation on the initial form of the expression. Boero (2001) also argues that *anticipation* is a key-element in producing thought through processes of transformation. The author defines anticipating as “imagining the consequences of some choices operated on algebraic expressions and/or on the variables, and/or through the formalization process”. In order to operate an efficient transformation, the subject needs to be able to foresee some aspects of the final shape of the object to be transformed in relation to the target. Arzarello *et Al.* stress that the ability to produce anticipations strictly depends on changes in the frame considered in order to interpret the shape of the expression.

Another theoretical reference that I take as fundamental for analyzing students’ management of meaning in algebra is the concept of *representation register* proposed by Duval (2006). The author defines representation registers those semiotic systems “that permit a transformation of representations”. Among them, he includes both natural and algebraic language. Duval asserts that a critical aspect in the development of learning in mathematics is the ability to change from one representation register to another because such a change both allows for the modification of transformations that can be applied to the object’s representation, and makes other properties of the object more explicit. According to the author, real comprehension in mathematics occurs only through the coordination of at least two different representation registers. He analyzes the functions performed by different possible typologies of transformations, distinguishing between *treatments* (“transformations of representations that happen within the same register”) and *conversions* (“transformations of representation that consist of changing a register without changing the objects being denoted”) and highlighting both the fundamental role of each of these typologies of transformations and the intertwining between them.

In order to clarify how this set of theoretical references could help in analysing the role played by algebraic language in the construction of proofs (or attempts of proof) in ENT, the next paragraph will be devoted to the *a priori* analysis of the problem on which the working group activities, examined in this paper, were focused.

3. A PROBLEM AND ITS A PRIORI ANALYSIS

The problem, on which this paper is centred, is the following: “Write down a two digit number. Write down the number that you get when you invert the digits. Write

down the difference between the two numbers (the greater minus the lesser). Repeat this procedure with other two digit numbers. What kind of regularity can you observe? Try to prove what you state”.

The regularity to be observed is that the difference between the two numbers is always a multiple of 9; precisely it is the product between 9 and the difference between the digits of the chosen number. The proof requires the polynomial representation of each number: since a number of two digits m and n can be written as $10m+n$, where $m>n$, the difference can be represented as $10m+n-(10n+m)$. Through simple syntactical transformations it is possible to turn the initial expression into a form that makes the required property explicit: $10m+n-(10n+m)=9m-9n=9(m-n)$. The initial conceptual frames to which the statement of the problem refers are ‘difference between numbers’ and ‘two digits numbers’. It can be assumed, therefore, that the student will not automatically choose the ‘polynomial notation’ frame to represent the problem (some students might apply the ‘positional representation of a number’ frame and then get stuck). The reference to the ‘divisibility’ frame, which allows them to foresee the desired final shape of the expression after correct treatments (i.e. $9 \cdot k$, where k is a natural number), seems to be less problematic but possible blocks in the treatments to perform on the initially constructed polynomial expression can be ascribed to interpretative difficulties, which are strictly related to students' inability to correctly anticipate the final shape of the considered expression (it is necessary to recognize the transformation that leads to an expression that can be easily interpreted in the final frame ‘divisibility’). Finally, some observations about possible students' behaviours could be proposed. Many students could end their numerical explorations after having observed that the difference between the two numbers is always a multiple of 9, without recognizing the relationship that exists between the two digits of the first number and the difference between the two numbers (i.e. the considered difference is the product between 9 and the difference between the digits of the chosen number). Consequently, the analysis of the final expression could provide another index of students' interpretative abilities, in that access to the new meanings it embodies depends on those abilities.

4. RESEARCH HYPOTHESIS AND AIMS

My hypothesis is that the production of good proofs in ENT depends upon the management of three main components: (a) the appropriate application of frames and coordination between different frames; (b) the application of appropriate anticipating thoughts; and (c) the coordination between algebraic and verbal registers (on both translational and interpretative levels).

The aim of this paper is to investigate the role played, in students' proving processes, by the three components I singled out and the mutual relationships between them. In this work I will present a sample of prototype-productions [2] helpful to highlight that the lack or unsuccessfully application of one of these components leads to failure

and/or blocks of various types. In particular, I will highlight the interrelation between anticipating thought and interpretative blocks.

5. RESEARCH METHODOLOGY

Theoretical models I used helped us identify some interpretative keys for the analysis of protocols of students' discussion while working in small groups. My analysis focused on the following: (1) The conceptual frames chosen to interpret and transform algebraic expressions and the coordination between different frames; (2) The application of anticipating thoughts; and (3) The conversions and treatments applied and the coordination between verbal and algebraic registers.

My choice of analyzing small groups' discussions is motivated by the conviction that only when students are involved in a communication it is really possible for us to produce an in-depth analysis of the coordination between verbal and algebraic register. Moreover I believe that the analysis of the sole written protocols is not enough to highlight students' actual interpretations of algebraic expressions they construct. The need to communicate their reasoning to others forces students not only to verbally make what they are writing explicit, but also to explain both the objectives of the transformations they carry out and their interpretation of results.

6. THE ANALYSIS OF PROTOTYPE-PRODUCTIONS

In this paragraph I will present two examples of prototype-protocols of discussions, chosen because they highlight how students' interaction allows to identify the reasons of erroneous conversions and the difficulties in the interpretation of expressions.

6.1 Example 1:

The following example is characterized by the application of an initial suitable frame, not associated to an adequate conversion and a correct interpretation of the produced expressions.

After having considered many numerical examples, students A, C and N conclude that the considered difference is always a multiple of 9. The following dialog represents the proving phase.

27 C: Let us do with letters.

28 N: It is more complicated.

29 C: It will be $10x$... plus ...

30 A: ...plus y (*they write $10x+y$*) [3]

31 C: If we invert the digits, it will be $y+10x$

32 A: and now ... we have to do the difference

33 C: (*She writes and reads*) $10x+y$... minus ... (*she writes $y+10x$*) it becomes $10x+y-y-10x$

34 N: I think there is a mistake because the result is zero ... they cancel each other out.

We are not able to prove it.

35 C: We have $10x+y$ and it represents the number ... Then we have to ...

36 A: (*She reads*) 'when you invert the digits' ...

37 C: It is the same of having 1 and ... It is as if we take it on this side, so y should be take on the other side... however, if we take 10 on this side, it will be left a ...

38 A-N-C: one!

39 C: So it is not $10x$. I think it is x ... So it would become $10x+y-(y+x)$. The two y cancel each other out, so they will be left $10x-x$. Exactly $9x$! We were able to prove it! ...

40 C: ... (*C. is looking to the numerical examples*) But here I can see something more, I think. I can see that, practically, this is ... Look what I noticed (*she is looking at the differences 86-68, 92-29, 76-67, 52-25*) ... if you subtract the two tens, 8-6, you have only to consider the product between 9 and the difference between the two tens: 9 times 2 is 18; 7-6 is 1, 9 times 1 is 9; 5-2 is 3, 9 times 3 is 27.

41 A: We have to write it down. I would have never noticed it!

42 C: (*she dictates*) It is always a multiple of 9 and we can observe that the result of the subtraction ... you have to subtract the two tens and to multiply the result by 9... Do you know how I thought of it? Because I saw $9x$ and I said "it is a multiple" because there is 9 times x . Then I said "but ... what is x ? x is the tens!". Then I tried to do x minus x .

43 A+N: Good!

This protocol can be subdivided in three key-moments: (1) *Initial conversion and first treatments* (lines 27-33); (2) *Identification of a problem, modification of the conversion and new treatments* (lines 34-39); (3) *Attempt of interpretation of the obtained expression and refinement of the conjecture* (lines 40-43).

Initially C carries out a *first erroneous conversion* (line 31), translating this concept through the expression $y+10x$. While students correctly interpret the natural language term "invert" when they work on numerical examples in order to formulate the conjecture, when they have to carry out a conversion into algebraic register, the concept "exchanging the place" is translated through the pure exchange of the order of the monomials which constitute the polynomial $10x+y$, dispelling serious difficulties in coordinating the 'positional notation' and 'polynomial notation' frames and lack in the internalization of the last. The difference (zero) they obtain starting from this erroneous conversion lead them to detect the inaccuracy of their initial conversion and to look for a new correct one. They detect a mistake in having supposed that $10x$ should represent the units digit, so they decide to correct this mistake, substituting x instead of $10x$, but they do not consequently modify the representation of y as tens-digit. Therefore, writing the polynomial as $y+x$, they carry out again an incorrect conversion. Probably because of the prevailing of the anticipating thought they carry out (expecting a multiple of 9, they only concentrate on the factor 9 when they look at the expression $9x$), once they obtain $9x$ as the difference between the two numbers, they do not immediately subject the new result to a careful interpretation. Only afterwards C interpret x as the tens-digit of the initial number and decide to investigate the considered examples in order to refine their conjecture. C concentrates on the tens-digits of the two numbers (x and y in the correct representation) and observes, starting from examples, that the result is obtained multiplying 9 by the difference between those digits. This observation, however, does not help her in critically interpreting the ex-

pression $9x$. In her final intervention, she even tries to translate into algebraic language, through the expression $x-x$, the difference between the two tens, but she is not able to ‘grasp’ the gap between the algebraic representation she proposes and her verbal considerations.

6.2 Example 2

In the following transcripts we can highlight what kind of difficulties students meet when appropriate application of the initial conceptual frame and conversions are not supported by anticipating thoughts and by a semantic control.

The three students G, B and A decide to work separately on the conjecture: while A and G analyze numerical examples only, B works on the algebraic formalization of the difference to be considered. Without speaking with her friends, B is able to perform the correct conversion, representing the considered difference with $10x+y-(10y+x)$. Afterwards she performs correct treatments on this expression, obtaining $9(x-y)$, and she decides to illustrate her result to A and G.

19 B: I obtained this thing ... Why 9? 9 is 9! 9 is odd! Is it possible that the result is always an odd number?

20 A: No. Consider 20! The difference is 18!

21 G: I sincerely can't find a regularity ...

22 B: I could only find that the result is 9 multiplied by $x-y$, but ... why is 9 here? There is 9 only because there is 10!

23 G: Let's try with 28 ... $82-28$... the result is 54! So ... What have these numbers in common???

24 B: I found it!! I found it!! If I choose 65 and 56, the difference is 9. In the algebraic case the result is 9 multiplied by $(x-y)$!

25 G: Please, explain it!

26 B: Because, independently from the initial number, the difference is always 9.

27 G: No! Consider 82 and 28!

28 B: What a pity! I liked this observation! ... Wait a moment ... here (*she refers to the examples she chose*) we pass from a ten to the next ten. I found it! Only if we start from a number whose digits are consecutive, the difference is 9!!! 34 and 43 ... All the numbers have consecutive digits!

29 G: It is true! 54 e 45!

30 B: 12, 23, ... Do you understand? 1 and 2 are consecutive numbers.

32 A: 14 and 41? 15 and 51?

33 B: No! The two digits must be consecutive! When they are consecutive, the difference is always 9!

34 A: So ... what does it happen?

35 B: I don't know ... It happens that the difference between the numbers is 9. If you look at the algebraic case ... Can you see that it is always 9 multiplied by something?

36 A: Only if the digits are consecutive the difference is 9?

37 B: I don't know why ...

38 G: But ... I think that the distance between the numbers is not the only reason ...

(silence)

39 B: ... It is always a multiple of 9!!!

40 A: In what sense?

41 B: Let's try! 52-25! The result is 27!

42 A: Also if we choose 15 and 51 ...the result is 36!

43 B: They are all multiple of 9! Can you see that every case is the same?! Tell me other numerical examples!

44 A: 51-15 is 36

45 G: 52-25 is 27

46 B: 21-12 is 9, which is a multiple of 9!

47 G: So we can observe that the result is always a multiple of 9.

This excerpt could be subdivided in two key-moments: (1) *Attempt to interpret the expression produced during an 'algebraic exploration' of the problem situation* (lines 19-38); and (2) *Formulation of the conjecture* (lines 39-47).

Students' choice to proceed separately turns out to be not effective. In fact, while the analysis of numerical examples does not help A and G in formulating a conjecture, the total absence of anticipating thoughts about the objective of the algebraic manipulations B operates blocks her interpretation of the obtained expression $9(x-y)$. In fact, B initially tries to guess the correct interpretation of the expression as the representation of an odd number (line 19). When this interpretation is refuted by a counterexample proposed by A (line 20), B decides to refer to numerical examples in order to meaningfully look at the obtained expression. The choice of the numerical examples she considers (only numbers whose digits are consecutive) suggests her that the difference is always 9 (line 24). Now the presence of an anticipating thought (the difference is 9) negatively influences B's interpretation of the expression $9(x-y)$. When, again, G proposes a counterexample against B's conjecture (line 27), she does not try to re-interpret the expression and limits herself to look at numerical examples to understand what are the conditions under which the regularity she first observed (the difference is 9) is valid (lines 28 and 30). Although her correct observation about the interrelation between the digits of the initial number and the difference between the two numbers, again B is not able to correctly re-interpret the expression $9(x-y)$, focusing on the role assumed by the factor $(x-y)$ (lines 35 and 37). B's troubled conquest of an only partial interpretation of the expression $9(x-y)$ and her necessity to refer to numerical examples to understand what she obtained testify that, if algebraic manipulations are not guided by an objective, significant interpretations are blocked. An evidence of this problematical aspect is the fact that, paradoxically, the working group activity ends with the formulation of a conjecture.

7. CONCLUSIONS

The analysis I presented in the previous paragraph allows to offer some conclusions with respect to the role played by the three components I identified and the mutual relationships between them. The first protocol highlights the strict correlation between lack of flexibility in coordinating different frames, difficulties in carrying out

conversions from verbal to algebraic register and lack of interpretative games in the analysis of the expressions produced. Moreover, it testifies how such correlation causes failures in the production of proofs in ENT. In fact, the three students display rigidity in their use of frames and an incapability of simultaneously manage different frames. Such rigidity makes them produce partial or incomplete interpretations of the constructed expressions, so they are not alerted about the non-acceptability of their proof. The second protocol testifies the strict interrelation between anticipating thoughts, the activation of conceptual frames and the subsequent interpretations of the produced expressions: since the conversion and the treatments operated by B are not oriented by an anticipating thought, the activation of a proper conceptual frame and a correct interpretation of the final expression are blocked. Moreover, this protocol represents a good example of results produced by the strict interrelation between *blind manipulations* (i.e. produced without an objective) and blocks in the interpretative processes. The rigidities highlighted in the analyzed protocols are shared by other protocols (not presented here because of space limitations), to which different problems could be add, such as: (a) blocks related to the activation of an incorrect initial frame of reference; (b) blocks in the treatments and in the interpretative processes due to an inability to foresee the expression to be attained by the activation of the correct final frame; (c) difficulties in the choice of the treatments to be operated caused by the absence of anticipating thoughts.

These observations helped us in singling out an initial classification of interpretative blocks in relation to causes that have produced them. Summarizing, I identified *interpretative blocks associated to*: a) *difficulties in simultaneously managing different frames* (example 1, line 42); b) *total absence of anticipating thoughts* (example 2, line 19); c) *activation of erroneous anticipating thoughts* (example 2, lines 24-26); d) *activation of a predominant (partial) anticipating thought* (example 1, line 39; example 2, lines 39-43). This classification let us highlight, in particular, the fundamental role played by anticipating thoughts during these kind of activities, thanks to the strict interrelation between them and students' difficulties in the interpretation of the algebraic expressions they produce.

In conclusion, my analysis of students' discussions during small group activities turned out to be an effective methodological instrument to verify my hypothesis on the importance of the key-components I singled out for the analysis of proof productions in ENT.

The results of this analysis will be a starting point for the next step of my research. I am convinced that the only way to make this approach to algebraic language really effective is to help teachers act as fundamental models in guiding their students toward the acquisition of the essential competencies that can help them overcoming difficulties and blocks identified in this work and developing awareness of the central role played by algebraic language as a reasoning tool. Therefore I will focus my research on the role played by the teacher during class activities in order to highlight the attitudes of an aware teacher, the choices he makes and the effects of his/her ap-

proach on students, from the point of view of both awareness shown and competencies acquired.

NOTES

1. The study was conducted in some classes (10th grade) of a *Liceo Socio-Psico-Pedagogico*, which is an upper secondary school originally aimed at educating future primary school teachers.
2. The term “prototype-production” is here used with the meaning of “representative of a category of productions of the same kind”.
3. The difficulties I hypothesised in the identification of the initial frame are not highlighted by this protocol because students have faced the problem of the representation of two and three-digit numbers in a previous activity.

EPISTEMOGRAPHY AND ALGEBRA

Jean-Philippe Drouhard¹⁰

University of Nice

(IREM de Nice, IUFM Célestin Freinet, UMR P3 “ADEF”)

We propose to address the problem of how to know students’ knowledge in an entirely new approach called “epistemography” which is, roughly, an attempt to describe the structure of this knowledge. We claim that what is to be known is made of five tightly interrelated organised systems: the mathematical universe, the system of semio-linguistic representations, the instruments, the rules of the mathematical game, and the identifiers.

Keywords: epistemography, algebra, semiotics, language, subparadigm.

One of the most commonly shared principle of didactics of mathematics is that teaching must ground on students' previous knowledge. Therefore we researchers (and teachers too!) need to know what students know and what they are supposed to know.

But the point is that knowing what students are supposed to know is less easy to do than it appears at a first glance, particularly when they shift from primary studies to secondary studies and when there are frequent curricular changes in the primary studies. In this case, secondary teachers cannot rely on remembering their primary school time; reading curricular documents is not very helpful, neither discussing with primary teachers. The problem is the lack of a common language, or better said, that the common language is not accurate enough. Saying that “students know the sense of operations” or that they are able to solve “simple word problems” is far too fuzzy and superficial.

We propose to address this problem (how to know students’ knowledge) in an entirely new approach called “epistemography” which is, roughly, an attempt to describe the structure of this knowledge.

Epistemography is based on an attempt to generalise and conceptualise findings about knowledge we made mainly during previous researches on algebraic thinking. According with many authors we found that semiotic and linguistic knowledge plays a central role in Algebraic Thinking. And we faced the following question: to what extent is this knowledge, *mathematical*? Letters and symbols are not mathematical objects in the same way that numbers or sets or functions are¹¹; but on the other hand they are equally necessary to do mathematics.

¹⁰ JPDrouhard@gmail.com

¹¹ More precisely, digits, letters, symbols and expressions made with them form a “language”. Languages are mathematically described by the “Language Theory” (a part of Mathematical Logic, shared with computer science).

Epistemography is a description of the structure of what the subjects have to know in order to actually do mathematics (and not just to pretend to do mathematics!). We chose to call this theory “epistemography” because it is about knowledge (“epistemo-”) but, unlike epistemology, not in a historical perspective: rather, epistemography is a kind of geography of knowledge.

We claim that what is to be known is made of five tightly interrelated organised systems: the mathematical universe, the system of semio-linguistic representations, the instruments, the rules of the mathematical game, and the identifiers. We will now present in detail these five knowledge systems. Due to the lack of space this presentation is a quite schematic and abstract one; a much more detailed and discussed presentation of epistemography is to be written.

THE MATHEMATICAL UNIVERSE

To solve some algebraic problems, you must know that the product of two negative numbers is positive. You can believe that negative numbers are real numbers, or just “imaginary” ones; whatever philosophical option you take, if you want to do mathematics, you need to have some knowledge about something. We call a “mathematical object” this “something”, and the Mathematical Universe the system made up of these mathematical objects (e.g. numbers), their relations (e. g. rational numbers are real numbers) and properties (e. g. the product of two negative numbers is positive). Usually, objects of the mathematical universe may be described as individuals (like the number 20) or classes (the even numbers).

SEMIO-LINGUISTIC REPRESENTATIONS SYSTEM

How to avoid, however, considering as belonging to the mathematical universe, objects or properties whose nature is totally different? We must, actually, distinguish carefully (mathematical) objects (like the number 20) from their (semiolinguistic¹²) representations (like the string of characters “20” made of a “2” and a “0”, but also “XX” made of two “X” or “::: :::” made of twenty dots). This distinction –and its consequences– is essential and has been stressed by many authors (Drouhard & Teppo, 2004, Duval, 1995, 2000, 2006, Ernest, 2006, Kirshner, 1989, Radford, 2006, Bagni, 2007 amongst many others). Misunderstanding or neglecting this distinction may lead to quite severe consequences on mathematics learning and teaching studies. Hence our claim is that, besides knowledge about objects of mathematical universe, students must have some (at least practical) knowledge of the very complex and heterogeneous, and often hidden, system of semio-linguistic representations.

But, how can we decide if a given property is mathematical or semio-linguistic? There is a practical criterion: mathematic properties may be called “representation-free”: they remain true whatever representation system is used. For example, the irra-

12 “semio-” means “related to signs” and “linguistic”, “related to language”; see further.

tionality of $\sqrt{2}$ does not depend on how integers, square roots or fractions are written. Actually the Greeks' notations of the first proof had nothing in common with ours (in particular they did not use any symbolic writing). Semiotic properties, on the contrary, rely on representational conventions. The property that in order to write $1/3$ you need an infinite number of (decimal) digits is true – in base ten only; it is false in base three (“ $0,1$ ”: zero unit and one third) or, as in the Babylonian system, in base sixty: \llcorner : two times ten sixtieths.

Mathematical language

What are the characteristics of the semio-linguistic system? First of all, the “mathematical language” (in a loose sense) is a written one¹³. Mathematical semio-linguistic *units* are written texts. Following and extending Laborde's ideas (1990), written mathematical texts are heterogeneous, made of natural language sentences, symbolic writings, diagrams and tables, graphs and illustrations. Their organisation follows what we call the fruit cake analogy, the natural language being the dough and the symbolic writings, diagrams, graphs and illustrations being the fruit pieces. To describe rigorously such a complex structure is far from easy.

Linguistic system

Students' ability to understand natural language mathematical texts (the “dough”) is linguistic by nature. Mathematical natural language (we call it the “mathematicians jargon”) is mostly the natural language itself; but Laborde (1982) showed there are some differences (unusual syntactic constructions like “Let x be a number...”) between the jargon and the mother-tongue, difficult to interpret by students.

Symbolic writings (like “ $b^2 - 4ac > 0$ ”) make up a language, too (Brown & Drouhard, 2004, Drouhard et al, 2006), which is far more complex and different from mother-tongue than it appears at first sight; detailed and accurate descriptions of this language can be found in Kirshner (1987) and Drouhard (1992). Students must learn this language and its syntax¹⁴ – which allows symbolic manipulation (Bell, 1996): the actual mathematic language, ruled by a rigid syntax, permits to perform operations on the symbolic expressions rather than on (mental or graphic) representations.

The present mathematical language is also characterised by a complex but precise semantics. Semantics (the science of the meaning) is the set of rules and procedures which allows interpreting expressions, in other words which allows relating expressions to mathematical objects.

The most accurate description of this semantics (how symbolic writings refer to mathematical objects and properties) is based on G. Frege's ideas (Drouhard, 1995).

13 which puts upside down the usual relationship between oral speech and written texts

14 the syntax is the part of the grammar which deals with the rules that relate one to another the elements of a language. (Syntax says that a parenthesis must be close once opened...

G. Frege's key concepts are "denotation" (which can be a numerical value (in the case of "20"), a numerical function (in the case of " $x+1$ "), a truth value (in the case of " $1 > 20$ ") or a boolean function (" $x+1 > 20$ "), according to the type of symbolic writing)¹⁵, and "sense" (the way denotation is given). The linguistic nature of students' difficulties with symbolic writings is often underestimated, or confused with conceptual difficulties.

Semiotic system

Let's give an example of a semiotic problem in algebra. How to represent an infinite series of decimals? Imagine I ask you what the properties of the number 0,666... are. When multiplied by 3 it gives 2? No. Actually I had in mind the number 1999/3000. And yes, I cheated: I broke the representational rule of decimals, which is a semiotic rule (on how to interpret elements like "...") about linguistic objects (the numeric expressions).

There are more than one approach to mathematics semiotics, which were fully presented in the special issue N° 134 (2003) of *Educational Studies in Mathematics*. Duval dedicated his lifelong work to an extensive and coherent theory of semiotics of mathematics education. Three key concepts are the semiotic representation registers, the treatments (within a register) and the conversions (between different registers). Other researchers (see amongst others Otte, 2006) are investigating how to interpret mathematics education using the terms of the founder of semiotics, Charles S. Peirce (1991): the three types of signs –index, icon, symbol– and, maybe more interesting, the three types of inferences –induction, abduction, deduction).

An entire communication paper would not suffice to present even a small part of the outcomes of semiotics for the study of algebraic thinking. Hence we called "semio-linguistic" the mathematics representation system. Therefore students must handle both aspects of this representation system, the linguistic as well as the semiotic one, and the complex interaction between them.

INSTRUMENTS

Up to now we have seen that to do mathematics, students must not only know objects and how to represent them: now we will see that they need also to know how to use instruments (Rabardel & VÉrillon, 1995) to operate on the representations of objects.

However, unlike object/representation opposition, instruments are not characterised by their nature (mathematical objects can also be tools, as noted by Douady, 1986) but instead by their use. Students, then, must learn what these instruments are and how to use them. Given that instruments are only characterised by their use, it is possible to propose a typology, based on their nature: material instruments (like rulers or

15 The AlNuSet software, developed by Giampaolo Chiappini allows (in a totally original way) a dynamic view of the denotation of algebraic expressions.

compasses, see Bagni, 2007), conceptual instruments (mathematical properties, like theorems), semiotic instruments (manipulations on semiotic representations) – this idea appears in L. S. Vygotsky, 1986); eventually one may consider “meta” instruments like strategies and, more generally, meta-rules.

THE RULES OF THE MATHEMATICAL GAME

We have seen that students must know what mathematical objects are and their properties, how to represent them and how to use instruments. Is this sufficient to do mathematics? Not at all: using a given instrument to operate on a given representation may be, or not, legitimate (even if done properly). For instance, to solve some numerical problems, some procedures are arithmetical (and are not legitimate in algebra) and other are algebraic (and are not legitimate in arithmetics).

Therefore algebra is not just a question of objects, representations and tools, but also of rules, which are saying what the actions are that we *may* or *may not* do amongst the actions we *can* do. Algebra is not a game in the same sense that chess is a game, but, like chess, algebra does have rules. These rules, moreover, are changing with passing times: the present way of doing differs from, say, the Renaissance Italian way of doing algebra. L. Wittgenstein (the “second Wittgenstein”, the author of the *Philosophical Remarks*, or *On Certainty*, 1986) is an invaluable guide to clarify the extremely complex relationship between objects, signs, practices and rules. (Ernest, 1994, Bagni, 2006).

SUBPARADIGMS

Some rules (in particular logic) are universal for all mathematics. But other rules are related to a certain domain of mathematics. A square number is always positive, except when studying complex numbers. We call these domains “subparadigms”, which are analogous Kuhn’s paradigms, but less vast, and commensurable between them). This notion of subparadigm allows us to understand the shift from arithmetics to algebra. Semantics (and instrumental value) of the “=” sign change, thus objects (the equalities, the expression with letters) also change. The semiotic systems, although looking quite the same (“ $2+1 = 3$ ” and “ $2+x = 3$ ”), are different in fact.

IDENTIFYING KNOWLEDGE

A last type of knowledge allows us to identify (or recognise) if what we do is mathematical or not, and to identify to what domain of mathematics it belongs. When a student writes something that superficially looks like algebra but actually is wrong or meaningless, the teacher might say: “This is *not* algebra”; and if later the student succeeds in writing a meaningful and correct algebraic text, the teacher might comment: “*This is* algebra”. With these statements, the teacher speaks about the student’s text but also about algebra; he is actually teaching the student *what* is algebra – and what

is not¹⁶ (Sackur et al., 2005). We call this Identifying Knowledge; it is also that which allows us to recognise whether a mathematical problem is arithmetical or algebraic, and to choose the appropriate instruments to solve it (without certainty: this kind of knowledge is more abductive than deductive, see Panizza, 2005).

THE LAYERED DESCRIPTION

As said above, epistemography is not the theory of everything (or, better said, of every kind of knowledge)! Firstly, we only consider here the part of knowledge which is specific to mathematics; this leaves aside nonspecific knowledge, related with the use of (oral and written) natural language or with general reasoning capabilities. “Mathematical activities”, however, remains too vague to allow a precise description. Then, by analogy with the Internet reference model, which is a layered abstract description for the very complex communications and computer network protocol design, we propose a layered description of students’ mathematical activities.

The five descriptive layers of students’ mathematical activities are:

1. the School Layer (what are the students’ rights and duties, why and how to work in the classrooms and at home, what kind of participation is expected by the teacher etc.). This is what french-speaking researchers like Sirota (1993) or Perrenoud (1994) call ““being a student” as a job”¹⁷. A great number of students’ difficulties may be analysed in terms of the school layer: when they don’t want to learn, or don’t know how to, for instance.
2. The Maths Classroom Layer (how to do maths in the classrooms and at home, what kind of participation is expected by the maths teacher and what is the math teacher supposed to do, etc.). This part of the students’ activities is ruled by what Brousseau (1997) calls the *didactical contract* (see also Sarrazy, 1995, for an extensive survey of this notion). Many students’ difficulties can be analysed in terms of didactical contract, as it was brilliantly done by Brousseau (*ibid*) and followers.
3. The Modelling Layer, which is the description of, for instance, how students change a word problem into a mathematical problem, or even how they change a mathematical problem (i. e. expressed in mathematical terms) into an other problem which they can solve with their mathematical tools. A whole field of mathematics education is devoted to the modelling part of the students’ mathematical activities (see for instance Lesh and Doerr, 2002).

16 which would be almost impossible to do with an explicit discourse within this context: definition or characterization of mathematics are epistemological statements, not mathematical statements

17 unfortunately, according to Dessus (2004) this concept is almost non-existent in English-speaking sociology of education studies.

4. The Discursive Layer, which is the description of students' reasoning on mathematical objects. This reasoning may be expressed by a discourse (like "if x is greater than -3 then $x+3$ is positive and therefore..."), hence the name of this description layer¹⁸. In France, Duval (2006) is a main contributor in this domain, which is closely related to researches on argumentation (see for instance Yackel and Cobb, 1997) and on proofs (see for instance Gila Hanna, 2000).
5. The deepest, Symbolic Manipulation Layer, describes how students operate on symbolic forms to yield other symbolic forms which represent the solutions of the problem. In the case of algebraic thinking, not too many authors (see for instance Bell, 1996 or Brown & Drouhard, 2003) stress on that – mainly because on the contrary it is often overemphasized by textbooks and teachers.

It is important to notice that what is layered is the description, not the student's activity. It is very similar to what happens in linguistics: the language's description is split in phonetics, syntax, semantics, pragmatics etc. but the subject's act of speech, on the contrary, is of a whole.

CONCLUSION

A way to cope with the problem of identifying students' mathematical knowledge has long been to focus on students' solving abilities and this can explain the prominent role which has been given to assessment throughout the world. However, many mathematics educators remain reluctant to reduce assessment criteria to solving abilities. Our point is that solving abilities are not so relevant clues on what students know and what they are supposed to know. On the one hand, the student's failure in achieving a task does not give much information on what his or her deficiencies or misconceptions are. On the other hand, the student's success may just show his or her technical abilities, but we cannot be sure that s/he understood conceptually.

Then, how can we determine what students know and are supposed to know? We claim that epistemography can provide accurate answers to this question.

SÁMI CULTURE AND ALGEBRA IN THE CURRICULUM

Anne Birgitte Fyhn

University of Tromsø, Norway

Abstract: The Sámi culture's richness of patterns and structures give rise to the question whether an implementation of Sámi culture in the teaching of algebra might improve this teaching for the Sámi pupils. The Sámi have their curriculum but Sámi culture does not seem to be implemented in its algebra syllabus. Mathematical archaeology with respect to metonymy upon the Sámi cultural elements duodji and joik indicate possibilities for the teaching of algebra. But a remaining question is the Sámi mathematics teachers' view of the situation and of the suggested possibilities. The paper aims to prepare for empirical studies which focus on the Sámi mathematics teachers' mathematical archaeology upon their own cultural elements, as a basis for the teaching of algebra.

Key words: algebra; curriculum; mathematical archaeology; patterns; Sámi

BACKGROUND AND RESEARCH QUESTIONS

The Sámi are an indigenous people of the arctic who live in the northern part of Norway, Sweden and Finland, and in the Kola Peninsula of Russia (Kuhmunen, 2006). In 1990 Norway ratified the ILO Convention No. 169 concerning indigenous and tribal peoples in independent countries, and after this the Sámi in Norway got their curriculum (KUF, 1997). In the three latest national curricula, the Norwegian Ministry of Education has worked out special Sámi syllabuses for several subjects, but not for mathematics. One quite common interpretation of the curriculum is that the teaching of algebra should be the same for pupils in the Sámi core area in Northern Norway as for any pupil in our capital Oslo in the south. A quite different interpretation is that the Sámi should have their syllabus in mathematics.

This paper constitutes parts of a basis for a project which intends to research the possibilities of a Sámi algebra syllabus. The idea is that one researcher and one group of Sámi mathematics teachers together design and develop a teaching of algebra based upon Sámi cultural expressions. One lower secondary school in the Sámi core area wants to join a meeting where this project is introduced. The aim of this paper is to obtain important basis material for this important meeting. The basis material includes a) an analysis of the present situation regarding the teaching of algebra for Sámi pupils, and b) an analysis of some Sámi cultural expressions with respect to possibilities for a teaching of algebra. This leads to the two research questions of this study: 1: How is Sámi culture implemented in the algebra part of the national mathematics syllabus for lower secondary school? 2: If there are any (algebraic) structures to be found in Sámi cultural expressions, then how may these structures emerge?

THEORETICAL FRAMEWORK

Algebra

According to Lakoff & Núñez' (2000, p. 110), "Algebra is the study of mathematical form or "structure"". According to the latest TIMSS framework (Mullis et. al., 2007) algebra consists of patterns, algebraic expressions, equations/formulas and functions. Barton (1999) describes mathematics as a system of quantities, relations and space. His term "relations" is interpreted to be wider than just algebra. Fyhn (2000) uses the metaphor "pattern" similar to Lakoff & Núñez' (2000) "structure". Lakoff & Núñez (ibid.) focus on the terms "essence" and "structure" in their approach to algebra,

Algebra is about essence. It makes use of the same metaphor for essence that Plato did – namely, Essence is form. ...Algebra is the study of mathematical form or "structure". Since form (as the Greek philosophers assumed) is taken to be abstract, algebra is about abstract structure. (ibid., p. 110)

The analyses in this paper use the term algebra as by Lakoff & Núñez (ibid.).

Aesthetical Expressions as Basis for the Teaching of Algebra

Fyhn (2000) searched for and analysed relations between pupils' participation in different leisure time activities and their score in some TIMSS mathematics tasks from 1995 and 1998. The pupils were categorised according to their participation in different leisure time activities, activities which they performed at least once a week. The results pointed out some common features for the categories "creative-crafts-girls", girls who participate in activities that concern drawing or handicraft, and the "musicians", pupils who play an instrument. The creative-crafts-girls' mean test score was below the mean score, while the musicians scored high above the mean. Geometry was expected to be a domain where the creative-crafts-girls had their highest score, but their score in geometry turned out to be rather low. Actually these girls' highest scores were on tasks which tested the pupils' understanding of patterns. The musicians turned out to have a test score profile that to a large extent was parallel to the creative-crafts-girls' (ibid.). This gave raise to the idea of a teaching of algebra that is based on the pupils' understanding of patterns.

Symmetry is an important part of the two latest Norwegian mathematics syllabuses for primary school (KUF, 1996; KD, 2006b). But the approach to symmetry is limited to be via geometry. Norway give less priority to algebra in school, and algebra is the domain where the Norwegian pupils have their lowest score in the TIMSS (Trends in International Mathematics and Science Studies) (Grønmo, Bergem, Nyléhn & Onstad, 2008). This opens for new ways of teaching of algebra. Due to the Sámi culture's apparently richness of patterns and structures, a good implementation of Sámi culture in the mathematics subject syllabus might lead to an improved teaching of algebra for Sámi pupils. Before any approaches can be done towards the design of new approaches to school algebra, there is a need for investigating how and to what extent structures and patterns from Sámi culture are integrated in the mathematics syllabus.

Parts of this investigation will take place in cooperation with the teachers; the rest will take place in this paper. In addition the apparently richness of structures and patterns in Sámi cultural expressions need to be confirmed and described before they can be treated as a basis for the teaching of algebra.

Mathematical Archaeology

Mathematics can be integrated into an activity to such a degree that it disappears for both the pupils and the teachers. According to Skovsmose (1994, p. 94) “Mathematics has to be recognised and named, that is the task of a mathematical archaeology.” It makes a difference whether the teaching is built upon situations that contain possibilities for application of mathematics or just for descriptive purposes. Many sorts of descriptive uses of mathematics can be possible as well as appropriate through mathematical archaeology; mathematics can be treated as an emerging subject (ibid., p. 90). It is important to a project, which contains mathematics as an implicit element, to spend some time on mathematical archaeology. The reason is: “If it is important to draw attention to the fact that mathematics is part of our daily life, then it also becomes important to provide children with a means for identifying and expressing this phenomenon” (ibid., p. 95). If there exists any algebra in the Sámi culture, it has to be implicit and hidden. A result of a mathematical archaeology may be that such algebra is recognised, named and described. A description of such algebraic structures may lead to an increased consciousness about possibilities for the teaching of algebra.

METHOD

The first research question will be answered by a) a survey of the development of the Sámi Curriculum in general and analyses of the treatment of algebra in it, b) a survey of the mathematics textbooks for Sámi pupils and analyses of their treatment of algebra, and c) analyses of the treatment of algebra in the national tests for Sámi pupils in mathematics and Sámi language. The second research question concerns the emergence of mathematics from elements in the Sámi culture. The research question will be enlightened by performing mathematical archaeology (Skovsmose, 1994) upon *duodji* and *joik*. *Duodji* is the name of Sámi craft, handicraft and art (KD, 2006a), while *joik* is the old Sámi folk music (Graff, 2001). The emergence of mathematics is categorised into three different levels; 1: recognition, 2: naming and 3: description.

ANALYSES

The Sámi Curriculum

The Sámi’s right to take care of and develop their language and culture has not always been accepted in Norway. The *norwegianisation* (assimilation) of the Sámi has been extensive and long-lasting (Minde, 2005). The norwegianisation also has led to a disparagement of Sámi culture, and this gives reasons to believe that there are few tracks of Sámi culture to be found in the Norwegian curriculum. In 1989 the Ministry of Education published the Sámi syllabuses (KUD, 1989) as a special supplementary

booklet to the national curriculum for the compulsory school. The intention was to adapt the traditional syllabuses to the Sámi culture and the Sámi surroundings. Some subjects got their own syllabus, but mathematics did not. The 1997 national curriculum (KUF, 1996a; KUF, 1996b) included a special Sámi curriculum (KUF, 1997). The mathematics syllabus was identical with the Norwegian one except for the illustrations.

The national curriculum of 2007 (KD, 2006a) includes a special Sámi syllabus for seven subjects, but not for mathematics. Reasons for a particular Sámi mathematics syllabus are that the Sámi and the Norwegian numerals are structured differently (Nickel, 1994), and that the traditional Sámi measuring units are based on body measures and not on the SI-system (Jannok-Nutti, 2007). For the pupils who learn Sámi as their first language, Sámi units of measurement and mathematical methods are treated as Basic Skills in mathematics, as an integrated part of the subject Sámi language (KD, 2006c). And “skills in mathematics require understanding of form, system and composition” (ibid., p. 3). According to Lakoff & Núñez (2000), this is algebra. But according to the curriculum, this is part of the syllabus in Sámi language. For the pupils who learn Sámi as their second or third language, basic skills in mathematics mean general concept development, reasoning and problem solving as well as the understanding of quantities, amounts, calculations and measurements (KD, 2006a). For these pupils the syllabus has no aims regarding their understanding of form, system and composition.

In the Norwegian national curriculum (KD, 2006b), the subject area “numbers and algebra” for the lower secondary school is presented this way

The main subject area numbers and algebra focuses on developing an understanding of numbers and insight into how numbers and processing numbers are part of systems and patterns... Algebra in school generalises calculation with numbers by representing numbers with letters or other symbols. This makes it possible to describe and analyse patterns and relationships. Algebra is also used in connection with the main subject areas geometry and functions. (ibid., p. 2)

As for the pupils who learn Sámi as their first language at school, the understanding of form, system and composition may be integrated with descriptions and analyses of patterns and relationships in the mathematics lessons. But this message is only implicit in the curriculum. Thus an interesting question is whether the Sámi culture is integrated in the teaching of algebra for the Sámi pupils.

Textbooks

The Sámi mathematics textbooks are Norwegian textbooks translated into Sámi language. The Norwegian Directorate for Education and Training (Udir, 2004) presents two mathematics textbooks in Sámi language for lower secondary school; one of them is approved for the curriculum of 1997, and the other one is Finnish. For economic reasons Norway offer the lower secondary school pupils no Sámi mathematics

textbooks which are approved for our latest curriculum. However, these pupils have their right to get appropriate books: The United Nations' Declaration on the Rights of Indigenous Peoples Article 14 claims that "Indigenous peoples have the right to establish and control their educational systems and institutions providing education in their own languages, in a manner appropriate to their cultural methods of teaching and learning" (UN, 2007, p. 6). The Sámi parliament, the Sámediggi, is an elected representative assembly for the Sámi in Norway (Kuhmunen, 2006). The Sámediggi's Youth Committee underlines the importance of getting Sámi textbooks. They sent an open letter to the Norwegian Minister of Education where they demand that the Ministry carry out necessary actions in order to improve the school-days for Sámi children (Nystø Ráhka, 2008). The textbook situation for Sámi pupils is far from satisfactory. Thus it is not any surprise that no attention is paid towards including Sámi culture in the algebra paragraphs in the existing textbooks.

National Tests

From 2003 Norwegian pupils have taken part in national tests as part of a national system for quality assessment (KD, 2003). From 2007 the mathematics tests were replaced by tests in mathematics as a basic skill in every subject. One result of this is that algebra is no longer part of the tests. The tests are translated from Norwegian to Sámi language; the Sámi pupils are offered no special tasks. The Ministry of Education and Research have decided that pupils who have Sámi as their first or second language will be tested in mathematics as a basic skill in this subject (KD, 2007c; KD, 2008). The Norwegian Directorate for Education and Training will carry out the translations of the mathematics tests into the three Sámi languages (ibid.). The national tests in mathematics as a basic skill do not reflect the pupils' achievement of any goals which are particular for the Sámi curriculum, and the algebra goals for the Norwegian pupils are neither reflected in these tests.

Duodji and Joik

The ornamentations in Sámi handicraft, *duodji*, and the Sámi folk music, *joik*, are both rich on structures and patterns. This claim is based upon the doctoral dissertations of Dunfjeld (2001) and Graff (2001). According to Dunfjeld (2001) the Sámi people's understanding of their own ornamentation differs from the pure formal understanding of ornamentation that we find in Western Europe. Thus she introduced the term "Tjaalehtjimmie" which has a meaning beyond pure decoration; "it is composed by signs, ornamentals and symbols which together may give meaning" (ibid., p. 102, my translation). For example may the meaning of the triangular engraving be decided from its localisation and orientation related to other symbols in a composition like in figure 1.

Figure 1. How the triangular engraving may symbolise personal pronouns in first and second person, and in singular and dual (Parts of figure from Dunfjeld, 2001, p. 109)

In duodji there are several more or less advanced plaited patterns. Fyhn (2006) describes hair plaiting by first splitting the hair into three equal parts. Plaiting can be further described by numerous repetitions of “take the right part and cross it over the mid-part. Then take the left part and cross it over the mid part”. The right part, whichever it is, can refer to all of the three parts of the hair, and so is for the mid part and the left part as well. This is what we understand with conceptual metonymy (Lakoff & Núñez, 2000), and this exists outside mathematics.

This everyday conceptual metonymy ...plays a major role in mathematical thinking: It allows us to go from concrete (case by case) arithmetic to general algebraic thinking... This everyday cognitive mechanism allows us to state general laws like “ $x + y = y + x$ ”, which says that adding a number y to another number x yields the same result as adding x to y . It is this metonymic mechanism that makes the discipline of algebra possible, by allowing us to reason about numbers or other entities without knowing which particular entities we are talking about. (ibid, p. 74-75)

According to the curriculum the Sámi ornamentations are geometry (KD, 2006a). Dunfjeld (2001) denotes these structures as geometry, too, and she refers definite to figures as triangles, rhomboids, squares and rectangles. Her mathematical archaeology is at level two; naming. When she refers to the organisation of the geometrical figures and the patterns they shape, she does not denote it as mathematics anymore. Fyhn’s (2006) description of ornamentation as metonymy is mathematical archaeology at level three, description.

Graff (2001) claims that researchers have focused on joik from different perspectives: as text, as melodies and rhythms, and as communication. To “joik” a person means to perform a particular joik which is dedicated to this person; the joik is an expression with a meaning (ibid.). The pitch constitutes an analogy for conceptual metonymy in music, when two or more people sing together. The structure of the song is given on beforehand; independent of what particular pitch to use. Graff (ibid.) points out, among other things, that the melodic motive in joik is based upon melodic patterns which in turn might have different shapes. The structuring of the joiks which he investigated, show that a rhythmic motive might be repeated throughout the complete joik (ibid.). Algebra is the study of mathematical form or “structure” (Lakoff & Núñez, 2000), and joik is just a way of expression that like other music is built up by

given structures. According to the curriculum, the understanding of how different patterns and structures influence artistic and musical expressions is part of mathematical skills in the subject music (KD, 2006a). Graff's (2001) term "rhythmic motive" is the name of a structure and could be denoted as mathematical archaeology at level two. He gives thorough descriptions of the structures as well, and he uses words like "ascending –descending melody line (inverted U-form)" (ibid., p. 210, my translation) and "transposition" (ibid., p. 214, my translation). But there is no mathematics connected to the names and the descriptions of these structures. The structures that constitute a basis for duodji ornamentations and for joiks may be identified and described by mathematical terms. The process in which algebra is emerging from these aesthetic expressions can be carried out as mathematical archaeology (Skovsmose, 1994) at three levels. But because joik as well as duodji express more than just aesthetics and structure, the meaning aspect need to be focused and enlightened.

CONCLUSION

The Sámi curriculum (KD, 2006a) offers a special Sámi syllabus for several subjects, but not for mathematics. "The understanding of form, system and composition" is part of the syllabus for Sámi as first language. Together with "descriptions and analyses of patterns and relationships" from the algebra syllabus, this opens for an integration of elements from the Sámi culture in the mathematics lessons. But that depends on whether the Sámi mathematics teachers are aware of and agree to these possibilities, and how the Sámi language teachers approach "form, system and composition" in their lessons. Due to the norwegianisation (Minde, 2005) there are reasons to believe that the teachers are not aware of the possibilities of integrating elements from their culture in the teaching of algebra.

The United Nations' Declaration on the Rights of Indigenous Peoples (UN, 2007), states that the Sámi lower secondary school pupils have their right to get appropriate mathematics textbooks in their own language. There are Sámi versions of Norwegian textbooks for primary school and for some of the grades in lower secondary school, but many of these books are based on a lapsed curriculum. And no special attention is paid towards including Sámi culture in the algebra parts of these textbooks. The lack of Sámi mathematics textbooks results in extra work for the teachers. Sámi pupils are offered translated versions of the Norwegian national tests in mathematics as a basic skill in every subject. The fact that these tests do not concern any algebra is an example of how Norway gives less priority to algebra in school. The national tests neither reflect the pupils' achievement of any goal in the Sámi curriculum. Aesthetic expressions may become a resource in the teaching of algebra: According to the Sámi curriculum (KD, 2006a) the relations between aesthetics and geometry are elements in the work with duodji decorations, while the music syllabus focus on the understanding of different patterns and structures. No connection between aesthetics and algebra is found in the Sámi curriculum.

One question for the further research is whether and to what extent the Sámi mathematics teachers find the project relevant and worthwhile taking part in. One more question is how metonymies might function in bridging the gap between Sámi cultural discourses and the algebra teaching discourse. The term “discourse“, is here used as by Foucault (2004, p. 53), “...discursive practice is a place in which... objects is formed and deformed.” These questions are closely interwoven and the further development of the project depends on the meeting between the researcher and the teachers. Maybe the teachers really want to join the project. But one other outcome is that the teachers dislike the ideas of creating an algebra teaching based upon Sámi cultural expressions. Another outcome might be that the teachers give priority to other parts of mathematics than algebra at the moment. A third possible outcome is that the teachers want to take part in the project, but that metonymies turn out to be less useful than they seem at the moment.

PROBLEM SOLVING WITHOUT NUMBERS AN EARLY APPROACH TO ALGEBRA

Sandra Gerhard, *University of Frankfurt am Main*

Abstract: *This paper reports a research project that aims at finding a good approach to school algebra using magnitudes and measurement. Thereby we not only focus on the way algebra can be taught effectively but also at on when in student's mathematical education a geometric and measuring approach can be successful. For this purpose we provide a theoretical framework and modify an early algebra program developed for first-graders to implement it in different age-levels.*

Key Words: *Algebraic Symbolizing, Early Algebra, Cognitive Gap, Measurement*

INTRODUCTION

In Germany, as in many other countries, algebra is taught as generalized arithmetic (see e.g. Lins & Kaput, 2004) after a long term arithmetical education. Reasons can be found on the one hand in the historical development of algebra as a medium for solving advanced arithmetical problems, on the other hand in the Piagetian stages of cognitive development. According to Piaget's theory children achieve the formal operational stage – and therewith the capability for abstract reasoning - not before the age of eleven (Piaget & Inhelder, 1972). It is however not self-evident that all aspects of algebraic thinking require achievement of the full formal operational stage.

Linchevski (2001) talks about a “cognitive gap”, which characterizes “these steps in the pupil's learning experience where without a teaching intervention [...] he or she would not make a certain step” (Linchevski, 2001, p. 144), and this is independent of the Piagetian stages.

If one reinterprets the cognitive gap in terms of Vygotski's zone of proximal development (Vygotski, 1987), the cognitive gap marks not only the difference between what a learner can achieve without help and what a learner *cannot* achieve *without* help, but what a learner *can* achieve *with* help: in this case developing algebraic skills.

THEORETICAL FRAMEWORK AND RESEARCH QUESTIONS

Early Algebra

The idea of teaching algebra in earlier grades beyond a preparatory pre-algebraic way is most welcome as one can see in several early algebra projects (see Carraher & Schliemann, 2007). A reason for the popularity of early algebra is that the problems that students have with school algebra is likely to be based mostly on long experience of arithmetic classes without algebraic contents (see McNeil, 2004). This leads us to a first question:

1. Are there coherences between students' arithmetical skills and their effective approach to algebra?

From Carraher and Schliemann's (2007) review of the seven most common difficulties middle and high school students have with algebra (Carraher & Schliemann, 2007, p. 670) we can extract at least two main ideas that are demanded in arithmetic but are no longer desired while dealing with algebra. These are on the one hand the belief that the equal sign only represents an unidirectional operator that produces an output on the right side from the input on the left side, and on the other hand a focus on finding particular answers.

Algebraic symbolizing

Regardless of whether it is taught as regular school algebra in grade 7 or as early algebra in an earlier grade, if algebra is to be taught at school we have to think about what school algebra is meant to be. School algebra is taught as dealing with algebraic symbols, terms and equations, but often without context. This is accompanied by the problem, that students do not see the point in algebraic symbolizing.

“The lesson from history has implications for teaching in the sense that the potential of dominating algebraic syntax will not be appreciated by students until they have experienced the limits of the scope of their previous knowledge and skills and start using the basic elements of algebraic syntax.” (Rojano, 1996, p. 62)

Van Amerom proposes that “algebra learning and teaching should be based on problem situations leading to symbolizing instead of starting with a ready-made symbolic language.” (van Amerom, 2002, p. 10)

An alternative to conventional algebraic symbolizing is to allow the students to develop their own sign system when solving algebraic problems. But the algebraic syntax, as we know it and the way it is used worldwide, is a sophisticated tool for communicating about algebraic problems, and thus the understanding of and the ability to use and manipulate conventional algebraic symbolism is an important goal of algebra education (see Dörfler, 2008).

Summarizing, on one hand there is a negative correlation between students' advanced arithmetical skills and their effective approach to algebra. On the other hand there is the need to teach algebraic syntax in an environment that brings students to the limit of their mathematical abilities. This leads us to the conclusion that if algebra and algebraic syntax can in fact be taught in early grades successfully then it should indeed be taught in these early grades for the following reasons.

First of all, an earlier approach to algebra offers a lot more mathematical exercises that children can understand but cannot solve with the mathematical knowledge they've achieved up to then. At the same time the emphasis on arithmetic is reduced, which may decrease a habituation effect to arithmetic. Apart from that, lower achiev-

ers in arithmetic may profit from an early approach to algebra and algebraic syntax can support their algebraic thinking strategies.

The MeasureUp- Program

An unconventional way of teaching school algebra is taken by the MeasureUp-Program (Dougherty & Slovin, 2004) which combines early algebra with a fast introduction to common algebraic symbolization, at an early stage in primary school even before numbers are introduced. MeasureUp is based on a teaching experiment from the 60s implemented by Davydov (1975), a Wygotskian student. Within this teaching experiment the students develop abstract algebraic thinking by comparing magnitudes, like length, area, volume, etc. of concrete objects. The comparison of magnitudes is written down firstly with the help of signs of different sizes and finally with letter inequations and equations. The teaching of numbers follows only when the students can handle the algebraic syntax of elementary linear equations properly.

Our main concern is with the idea of introducing the abstract use and manipulation of the algebraic symbol system by concrete comparison of the magnitudes excluding numbers. We want to find out if this concept, which we will call the MeasureUp-Concept, will work for primary school children even though they have already have been introduced to numbers and arithmetic. This leads us to the following question.

2. Does the MeasureUp-Concept give German primary school-children a “good” approach to algebra and algebraic symbolism?

To answer this question we concentrate on two basic ideas of algebra, expressing magnitudes and their relations in letters and detaching the thinking from the concrete context.

The various aspects of letter variables range from letters as specific unknown over letters as generalized numbers to letters as changing quantity (see e.g. Küchemann, 1978). In our very first approach we have not seen it as important which of these aspects the children were working with. We are primarily interested in the question of whether the children are really seeing the letters as numbers and not developing the misconception of seeing letters as objects. As it is not intended to focus the children on magnitudes as numbers we have to differentiate the two categories letter as magnitude and letter as object. Bertalan (2008) claims, that a geometric approach supports the (mis)conception of letters as objects.

Within the intervention the children are working with concrete objects whose different magnitudes are compared. We want to know if the children are able to detach their thinking from the concrete material and if they are able to deal with word problems that do not refer to concrete material.

When to teach algebra and algebraic syntax?

Our focus of interest lies in the Measure Up-Concept, the introduction of abstract use and manipulation of the algebraic symbol system by concrete comparison of the

magnitudes excluding numbers, which is only a small but important part of the MeasureUp-Program. Because the MeasureUp-Program starts with the first grade it is reasonable to arrange our first observations at this age-level.

However, there are several widespread reasons, why algebraic syntax without numbers should *not* be taught in primary school, including curricular issues and the argument that this is too far away from a primary school students' everyday use of mathematics and thus should not be subject of mathematic lessons. With these reasons in mind, we come to another question of interest:

3. Does the Measure Up-Concept work in high school grades lower than grade 7 in the sense that none of the difficulties named above appear.

METHODOLOGY

Our research is based on the paradigm of design based research (DBR), which “blends empirical educational research with the theory-driven design of learning environment” (The Design-Based Research Collective, 2003, p. 1). It contains two main goals which have to be well-connected. These are on the one hand designing learning environments, on the other hand developing theories of learning. DBR happens in multiple cycles of design, implementation, analysis and redesign. The following investigation marks the first completed cycle of design, implementation and analysis. Later we will state conclusions for redesign.

As the starting point for the intervention we chose the MeasureUp-Program which we modified for our purpose. As variables are not part of primary school curricula, we have been looking for a school that enables us to teach the MeasureUp-Concept. We found that a Montessori primary school class with mixed age-groups would fit best for our first investigation. The self directed activity of children in a Montessori class allows us a flexible intervention alongside the regular class.

Implementing the MeasureUp-concept in a Montessori class made it necessary to develop material that children can work with on their own. So we developed exercise books which contain the introduction and comparison of magnitudes not only of Montessori but also other concrete materials, the setting up of equations and inequations, the so-called statements, and transforming inequations in equations, including transitivity and commutativity.

Example 1:

Compare

1. Take boxes I, II and III
2. Name the volumes of the boxes.
3. Compare the volumes of boxes I and II, write a line-segment and a statement.
4. Compare the volumes of boxes II and III, write a line-segment and a

statement.

5. Which statement can you write down for the volumes of boxes I and III without comparing the volumes?

The last exercise book contains word problems that do not refer to concrete material and word problems that contain numbers.

Example 2:

Word problems

A street has length A . Julia has already walked length B . How far does she still have to go?

A street has length L . Tim has already walked 200 m. How far does he still have to go?

A street has length 845 m. Hans has already walked 220 m. How far does he still have to go?

To address the question of whether there are coherences between students' arithmetical skills and their effective approach to algebra, we had to collect data about the arithmetical knowledge of the children. Thus every student attended the half-standardized interview ElementarMathematisches BasisInterview (EMBI, basis interview on elementary mathematics,) before the intervention (Peter-Koop et al, 2007). Thus we are able to compare high achievers with low achievers.

Then we introduced the exercise books to the children and allowed them to work with them during their free activity time. With some students or student groups we made appointments which gave us the opportunity to videotape the students while they were working with their exercise books and explaining their work to an interviewer. This happened within the principles of the Montessori school which means: students join voluntarily, the intervention will take part in an individual atmosphere and mistakes are not to be corrected. The work will consider the individual stage of development and, if required, the exercises will be extended or modified. So the interviewer held a double role as interviewer and teacher. Then we transcribed the videos and conducted a series of qualitative content analyses. To answer our first question

1. Are there coherences between students' arithmetical skills and their effective approach to algebra?

we have been coding in regard to the following topics:

- The students' possible belief that the equal sign only represents a unidirectional operator that produces an output on the right side from the input on the left side.
- The students' focus on finding particular (i.e. numerical) answers.

These we used as categories for our content analysis. Then we compared the findings of a, according to the EMBI, lower achiever with findings of a higher achiever.

To answer our second question

2. Does the MeasureUp-Concept give German primary school-children a “good” approach to algebra and algebraic symbolism?

we concentrated on the ideas of expressing magnitudes in letters and detaching the thinking from the concrete context. We did a qualitative content analysis with the two categories letter as number and letter as object. Also we did a qualitative content analysis on the children’s work with concrete material and also on the situations where children are solving word problem which does not refer on material (Example 2). For the latter we did not use pre-set categories, but generated them inductively.

For answering the third question,

3. Does the MeasureUp-Concept work in lower high school grades than grade 7 in the sense that none of the difficulties named above appear.

we are planning further cycles of design, implementation, analysis and redesign in a 5th grade of a German high school.

OBSERVATIONS ON STUDENTS’ ACTIVITIES

The design of the study only allowed us a focus on a small number of students. So our following interpretations are based on two case studies, Jay and Elli, which have been chosen for following reasons. Both students, a boy and a girl, are 3rd graders and will leave the class in the following year to join grade 4-6.

As showed by the EMBI, Jay is good at counting and handles interpreting and sorting of numbers beyond 1000 easily. He shows multiple strategies in addition, subtraction and multiplication and is able to solve division problems in an abstract way. Elli is also good at counting, but not as good as Jay and she is able to interpret and sort three-digit numbers. She is solving addition and multiplication problems through counting and needs proper material for solving multiplication and division problems. So we can call Jay a higher achiever and Elli a lower achiever. This is important for our first question, whether success in algebra class depends on arithmetic skills.

The analyses of both the transcripts and the exercise books showed that there is no dominance of the belief that the equal sign only represents a unidirectional operator that produces an output on the right side from the input on the left side. Jay and Elli both wrote and completed several equations of the form $D+B=A$ and $D=A-B$, without accounting for the direction of the equation. The transcripts also did not show any sign of preference or confusion about writing the equations the one or other way.

We had a different result when analyzing the focus on particular answers. We take a look at how Elli and Jay dealt with Example 2 (see above).

Jay: ...how far does she still have to go?

- Teacher: Right, you have said...
- Jay: D. *J wants to write down D, but the teacher stops him.*
- Teacher: Wait, can you write an equation?
- Jay: What's that?
- Teacher: A statement, with equal signs and plus and minus.
- Jay: Err, D plus B equals A.
- Teacher: Yes, right, you can write that down. *J writes it down.*
- Jay: Yes, but first of all I can write down D. *J writes down D and underlines it.*

Here we can see that Jay is looking for a particular answer. He names the length that still has to be travelled with D and wants to write it down as answer. The intervention of the teacher reminds him, that he can find a statement that shows how he can get length D with length A and B. Certainly, because of the early intervention of the teacher, we do not know if Jay would have written a statement without prompting. As we can see, he has no difficulties in finding the equation $D+B=A$ and later on he will have no problems with transforming the equation into $D=A-B$. But for him, both equations do not belong to the solution. In his exercise book we can find both equations in a subsidiary position. By contrast he insists in writing down and underlining D “first of all” right behind the word problem. The underlining is an indicator that for Jay D is the particular answer of the word problem but the equations are not.

Elli handles the word problem differently. At first she has problems with understanding the question and after the encouragement of the teacher she draws the street and attaches the given information. Then she suggests different statements that are however not solution-orientated. With some help by the teacher she finally writes down the statement $S=A-B$.

The following transcript shows that generally Elli feels comfortable with using letters.

- Elli: A street has length 845 meters.
- Teacher: Hm.
- Elli: Is the length M. Hans already walked 200 meters. How far does he still have to go?
- Teacher: Hm.
- Elli: I want to do that with letters.
- Teacher: You want to do that with letters? Ok. Which letters do you want?
- Elli: N and M.

By contrast Jay again is eager to calculate the solution and notes “that’s easier”.

If we interpret the observed situation, while keeping the research question in our mind, we explicitly have to differentiate algebraic thinking from using algebraic syntax. Elli’s difficulty with the last word problem that prompts the wish to use letters is a sign of her low achievement in arithmetic. We can also see her difficulties with algebraic thinking and algebraic syntax, but nevertheless Elli is expecting benefit from using algebraic syntax. Jay on the contrary has no difficulties with solving the word problems because he realizes their algebraic structure. He does not use the algebraic

syntax, but this is not because he cannot use it. We have seen that he can easily find a proper statement and is able to manipulate the equation. We conjecture he does not use algebraic syntax because the word problems are easy for him and he is focussing upon an answer where the approach is a minor matter.

We do not suspect that lower achievers in arithmetic will be likely to have fewer difficulties with algebraic thinking and using and manipulating algebraic syntax than higher achievers. But they may be more open for the use of algebraic syntax while working on word problems, because they expect a benefit for solving word problems and therewith are more accessible for the use of algebraic syntax.

As we have seen students at that age-level can work easily with letters as denotation.

For a “good” approach to algebra we need to know whether they name the object or the magnitude. By viewing the transcripts we found evidence for both letter as object and letter as magnitude. But we also observed a third category as is seen in the following transcript.

Teacher: Which letter stands for example for this length? *The teacher shows a grey stick.*

Jay: Err, the lowest, the lowest letter of all, which...ah...which is the lowest one?
Jay is sorting the letter-cards

Jay: So we call the small grey ones U. This is an U.

Teacher: So, then you can name all.

Jay: A is always the biggest one.

Jay is naming “the small grey ones”. Thus he is naming not only one object, but a class of objects with the same attributes. But he is naming the objects and not the magnitudes. Although the letter U names an object, the size of the object is still contained in the letter, because it is “the lowest” letter and the grey sticks have the lowest length. There is no lower letter than U because the letters V - Z are not available on letter-cards. Furthermore we can see that there is also a highest letter, the letter A which names “always the biggest one”. Elli shows a different but similar performance when she has to compare the width of two stripes which have same width but different length.

Elli: Do you have an U?

Teacher: I do.

Elli: Like Urs? And a D like Donatella?

Teacher: A D like Donatella? Ok.

Elli: My mother. An U and a D like my mum.

Teacher: There’s the D, look. So, you can already write that down. Here is.... which has the width U?

Elli: Dad is bigger.

Like Jay, Elli includes the size of the object in the letter. For that purpose she refers to the size of family members. But Elli is focusing on what differentiates the objects and not on what is being compared. So she is choosing the letters while focusing on

the length and not the width. Therefore she picks two letters that refer to two family members which different length, U for her “bigger” dad and D for her smaller mum.

Beside the categories letter as object and letter as magnitude we can summarize the above observation under the category letter as object with a certain size. This leads to new questions of interest. Does a geometric approach to algebra support the idea of a letter as object with a certain size instead of letter as object and letter as magnitude? And if so, is it to be seen as positive or negative for a “good” approach to algebraic thinking and/or algebraic syntax?

Finally we take a look at the word problems of Example 2 again, to find out how Jay and Elli handle problems that do not refer to concrete materials but to imagined objects, in this case a street. Both were offered the opportunity to use paper strips or sticks to represent the street or to draw the street. For solving the second word problem, which mixes letters with numbers, Eli drew a street, while Jay used paper strips. The following observation was made as Elli was working on the word problem.

Teacher: So, a street has length N , Tim already walked 200 meters.

Elli: Then he still has to go 400 meters.

With Jay we can make a similar observation.

Jay: ...that is length L . *J displays a different paper strip.*

Teacher: That is length L ? Ok.

Jay: 200 meters, how big is a man, that big, then, I think, these are about 200 meters.

Teacher: Ok.

Jay: And this small edge here, that goes here, are the remaining...?

Teacher: Meters. How do you call the remaining meters?

Jay: 50 meters?

Both understand the offered material not as aid for visualising the real street but as a scaled down model version of the street. They can't detach themselves from the concrete material thus they are not able to solve this word problem without assistance.

PERSPECTIVE

In regard to our questions the evaluation of the exercise books and the transcripts did not provide as conclusive results as we had hoped for. In particular looking at how the students perceive the letters brought up new questions. These questions have to be considered in our redesign. We also have to work more closely on the abilities of the children. We have seen that Jay did not use the algebraic syntax in some cases because he did not require it. As a main goal of the intervention is to adapt the use of algebraic syntax, we have to modify these particular exercises so that we can adapt them easily and flexibly at the abilities of the students. Furthermore we decided to move the question of the ability to detach the thinking from the concrete context to the projected intervention in grade 5. There we also will try to gain more clarity if a long term arithmetic education gets in the way of an effective approach to algebra.

THE AMBIGUITY OF THE SIGN $\sqrt{\quad}$ ¹⁹

Gómez, Bernardo & Buhlea, Carmen

Departamento de Didáctica de las Matemáticas. Universitat de València

In this paper an educational problem is discussed deriving from the ambiguity of the radical sign, $\sqrt{\quad}$, produced by its shift in meaning when passing from arithmetic to algebra. This problem is concerned with understanding difficulties that are linked to a particular tradition of teaching in which the radical sign is introduced by means of the square root notion. As a conclusion it indicates that any teaching proposal should take into account the distinction between root and radical.

Key words: roots, radicals, meaning, textbook

INTRODUCTION: The problem under investigation

The ambiguity of the sign $\sqrt{\quad}$ as a consequence of the change in its meaning when passing from arithmetic to algebra often goes unnoticed by teachers and textbook authors. This lack of perception may be the cause of certain cognitive conflicts experienced by teachers and students.

This work takes its cue from one of these conflicts. It is a conflict expressed by a Spanish secondary school mathematics teacher called Patricia, on attempting to understand the definition of equivalent radicals. She states that the equality $\sqrt[4]{3^2} = \sqrt[3]{3}$ cannot be true, since in the expression on the left the index of the root is even, so that it has two opposing roots, two solutions, whereas in the expression on the right the index is odd so it only has one root, which means that the two expressions have a different number of roots.

The conflict expressed by Patricia leads to the difficulties and controversies related to the values, properties and rules of radicals, which are the ultimate aim of this work.

Examples of that, are the students opinion about the statement $\sqrt{25} = \pm 25$. (Roach, Gibson and Weber, 2004), the value of $(-8)^{1/3} = -2$ (Even and Tirosh, 1995; Goel and Robillard, 1997; Tirosh and Even, 1997), and the rule for multiplying imaginary numbers (Martínez, 2007).

THEORETICAL FOUNDATIONS

To support the work carried out, a theoretical approach has been adopted that has three fundamental references.

1. One of these looks at the cognitive side, taking into account the need to reconceptualise signs that change meaning when passing from arithmetic to algebra (Kieran, 2006, p. 13).

¹⁹ This research was supported in part by a grant from the Spanish MEC.. Ref.: SEJ2005-06697/EDUC.

This happens with the sign $\sqrt{\quad}$ which changes meaning, since it either indicates an operation, as happens in $\sqrt{4}$, or indicates the main root of this operation, as happens in the solution to the equation $x^2 - a = 0 \rightarrow x = \pm\sqrt{a}$.

There are examples of this double meaning to be found in the teaching tradition that appears in textbooks by such influential authors as Euler.

Euler considered that:

150. (...) the square root of any number always has two values, one positive and the other negative; that $\sqrt{4}$, for example, is both +2 y -2, and that, in general, we may take $-\sqrt{a}$ as well as $+\sqrt{a}$ for the square root of a (...). (Euler, 1770, p. 44)

In Euler's text the $\sqrt{\quad}$ sign is used ambiguously. In $\sqrt{4}$ it is perceived as an indicated operation (finding the square root of 4) and it is associated to the set of two results, in this case +2 and - 2. In $+\sqrt{a}$ it is perceived as a result of the aforementioned process and designates one of the two roots of a .

This duality of meaning starts in arithmetic when introducing the $\sqrt{\quad}$ sign in order to indicate an operation in an abbreviated way, *the fifth elementary operation*²⁰. In arithmetic this number can be found and it is unique. Thus, for example, the square root of 4 is 2, which is written $\sqrt{4} = 2$.

Things change in algebra, since the square root of a ($a > 0$) cannot be calculated, so that to indicate its value the expression \sqrt{a} is introduced, which no longer represents an indicated operation but a result.

3. The second reference looks at the formal component. The mathematicians have decided to assign to the radical expression, \sqrt{x} , $x \geq 0$, only one value, one of the roots of x , the root no negative, the one that they name principal root. With this restriction, the right thing is to write $\sqrt{4} = 2$, not $\sqrt{4} = \pm 2$.

We agree to denote by \sqrt{a} the positive square root and call it simply the square root of a . Thus $\sqrt{4}$ is equal to and not -2, even though $(-2)^2=4$ (Lang, 1974. p. 10).

With this decision, the mathematical problem of the ambiguity of the radical sign disappears, but not the didactic problem. Students do not learn only what they are told; much of students' learning occurs when they attempt to make sense of the mathematical situations that they encounter (Roach, et al. 2004). To help students to make sense of the formal definition there are several options:

A) To avoid contradictions. If $\sqrt{4} = \pm 2$, then $\sqrt{4} + \sqrt{4} = (\pm 2) + (\pm 2) = \{-4, 0, +4\}$; $\sqrt{4} - \sqrt{4} = (\pm 2) - (\pm 2) = \{-4, 0, +4\}$ and $\sqrt{4} + \sqrt{4} = \sqrt{-4} + \sqrt{-4}$

²⁰ This consists of given a number, find another which when multiplied by itself gives the first.

B) To satisfy the requirements for the definition of operation of exponentiation to rational exponents. This definition should not depend on the representatives of numbers involved in the operation. We want $a^r = a^{\frac{m}{n}} = \sqrt[n]{a^m} = a^{\frac{km}{kn}} = \sqrt[kn]{a^{km}}$ (see Tirosh, & Even, 1997, p. 327). Nevertheless, if $\sqrt{4} = \pm 2$, then $\sqrt[6]{3^2} \neq \sqrt[3]{3}$. And, in general, $\sqrt[kn]{a^{km}} \neq \sqrt[n]{a^m}$, when kn is even and n is odd,

C) To satisfy the requirements for functions. The basic arithmetic operations addition and multiplication by a number different from zero establish bijective functions: $x \rightarrow x+a$, $x \rightarrow x \cdot a$, $a \neq 0$. These functions have unique inverse functions corresponding to the inverse operations. But, an operation like: $x \rightarrow x^2$ does not establish an injective function; because $x^2 = (-x)^2$. Consequently, the function $x \rightarrow x^2$ has to be confined to one of its branches to be inverted, $x \geq 0$. In the same way the inverse operation, $x \rightarrow \sqrt{x}$, has to be confined to positive domain, and range, in order to be unique.

2. The third reference takes on a psychological point of view, taking into account the dual operational/structural nature of mathematical conceptions and their role in the formation of concepts, indicated by Sfard (1991).

Sfard (1991) supports this theory with the fact that a mathematical entity can be seen as an object and a process. Treating a mathematical notion as an object leads to a type of conception called structural, whereas interpreting a notion as a process implies a conception called operational.

For Sfard, the ability to see a mathematical entity as an object and a process is indispensable for a deep understanding of mathematics, such that the “concept formation implies that certain mathematical notions should be regarded as fully developed only if they can be conceived both operationally and structurally” (p. 23).

It is worth pointing out that when referring to the role of operational and structural conceptions, Sfard conjectures that when a person gets acquainted with a new mathematical notion, the operational conception is usually the first to develop, whereas the structural conception follows a long and difficult process that needs external interventions (of a teacher, of a textbook), and may therefore be highly dependent on a kind of stimulus (of teaching method) which has been used (p. 17).

Pointing out that, the investigation on the conceptualization of the radical sign should be held in a revision of manuals and textbooks.

OBJECTIVES

Once the general problem to be studied has been pointed out, as well as the theoretical references, it is necessary to specify the general aims that are to guide the investigation's design and methodology:

1. To determine the characteristic aspects of teaching the radical sign, just as they are shown in textbooks today.

2. To diagnose mathematical knowledge with respect to the radical sign that some secondary school teachers have.
3. To explain teachers' possible conceptual and operational difficulties.

PATRICIA'S CONFLICT

The aims are linked to Patricia's conflict. Patricia is a high school mathematics teacher (in Spanish public education) and a student in a post-graduate programme. She presented the following conflict to her professor:

In the textbook, the concept of equivalent radicals is defined as follows: "Two radicals are equivalent if they have the same roots" (and so I had learned). On the other hand, simplifying a radical by dividing the index of the radical and the exponent of the radicand by the same number, results (in theory) in a radical equivalent to the first. However, in a case like the sixth root of three squared, the cube root of three is obtained. As the index of the first radicand is an even number, two solutions exist (one being the opposite of the other) but in the second case, the index is an odd number and therefore there is a single root. Therefore, it cannot be said that these two radicals have strictly the same roots. So, are they equivalent?

Patricia says:

(A) Two radicals are equivalent if they have the same roots.

Also Patricia makes reference to the following equivalency:

$$(E) \quad \sqrt[nk]{a^k} = \sqrt[n]{a}, k, n \in \mathbb{N}^*, n \geq 2, a \geq 0.$$

Applying the equivalency (E), Patricia obtains that: $\sqrt[6]{3^2} = \sqrt[3]{3}$. However, to her the sixth root of three squared has two opposed roots, "two solutions", as the index is an even number and the cube root of three has a single root as the index is an odd number, which means that the two expressions do not have the same number of roots and so according to (A) they would not be equivalent.

Hypothesis in relation to this conflict

In order to try to explain the causes of conceptual and operative difficulties that give rise to Patricia's conflict, the following hypothesis has been formulated:

(H₁) The lack of perception of the difference between the operational and structural conceptions of the radical sign that Patricia expresses is the cause of her conflict.

(H₂) This lack of perception is a product of a traditional teaching proposal, which does not pay attention to the need to re-conceptualise the $\sqrt{\quad}$ sign when passing from arithmetic to algebra.

(H₃) In an alternative teaching proposal, where the meanings of root and radical are formulated, the conflict expressed by Patricia is not expected.

METHODOLOGY

To verify the solidity of the hypotheses an exploratory study was carried out, as a step prior to a more rigorous inquiry in terms of methodology, still to be carried out.

This exploration is based on a revision of current and representative textbooks of two alternative proposed ways of teaching: the Spanish one, which introduces the radical sign in arithmetic, and the Rumanian one, which introduces it in algebra. The revision of textbooks is has been complemented by a questionnaire followed by an interview with two representative individuals, Patricia (Spanish) and Iulian (Rumanian), two typical high school mathematics teachers.

With the revision of textbooks an attempt has been made to identify characteristic features in the teaching of roots and radicals in Spanish and Rumanian textbooks, and to identify comments that may favour the ambiguity of the $\sqrt{\quad}$ sign, and Patricia's conflict.

The questionnaire

The questionnaire consists of a paper and pencil test which included four tasks. The first one is based on the teaching proposal given in the Spanish textbooks. In the task it is considered, as in Euler's text, that the square root of any positive number has two solutions, one positive and another negative. However, to represent this set of results the symbolic form $\sqrt{4} = \pm 2$ is used as well as the rhetorical form: "the solution is double, positive and negative". The intention of this task was to know if the difference is perceived between the structural and operational conception. The task is:

In the class of 9th grade, after introducing the theme of the roots and radicals, the students were asked to calculate the square root of four.

One student wrote $\sqrt{4} = \pm 2$, justifying thus:

"As the radicand is positive and the root's index is even, then the solution is double, positive and negative".

Is this correct?

Task 1

The interview's design took into account the answers produced by Patricia and Iulian to task 1. If the answer was "No", then the interviewee was asked to justify why and if it was "Yes", then they were given the second task with the aim of bringing in a cognitive conflict, in order to study the students' reaction

The second task is based on substituting $\sqrt{4}$ for ± 2 in a context of calculation. With this the aim was to put the affirmative answer to the task 1 into conflict.

If $\sqrt{4} = \pm 2$ then complete:

$$\sqrt{4} + \sqrt{4} = (\pm 2) + (\pm 2) = \dots$$

$$\sqrt{4} - \sqrt{4} = (\pm 2) - (\pm 2) = \dots$$

Explain the answer.

Task 2

A third task is based on the restriction of the property of radicals in the case where k is an even number and $a < 0$, which requires the intervention of the module.

$$(P) \quad \sqrt[n]{a^k} = \begin{cases} \sqrt[n]{a}, & k, n \in \mathbb{N}, n \geq 2, a \geq 0 \\ \sqrt[n]{|a|}, & k, n \in \mathbb{N}, k - \text{even}, n \geq 2, a < 0 \\ \sqrt[n]{a}, & k, n \in \mathbb{N}, k - \text{odd}, n \geq 2, n - \text{odd}, a < 0. \end{cases}$$

Here, the intention was to confirm that the interviewee was taking into account the radical's formal definition, in a traditional problematic case. The hypothetic situation that is present is the following:

In a class of 10th grade, after introducing the radicals theme, the students were asked to simplify:

$$\sqrt[6]{(-8)^2}$$

One student wrote: $\sqrt[6]{(-8)^2} = \sqrt[2 \cdot 3]{(-8)^2} = \sqrt[3]{-8} = -2$

and said: "I have applied the following rule: $\sqrt[n]{a^{mk}} = \sqrt[n]{a^m}$. Is this correct?"

Task 3

If the answer to the task was "No", then the interviewee was asked to justify why and if it was "Yes", then the fourth task was given with the aim of introducing a cognitive conflict, in order to study the student's reaction.

Task 4 imposes the strategy for calculating $\sqrt[6]{(-8)^2}$ that leads to a different result from -2. With this, the intention was to put the affirmative answer given previously to the task 3 into conflict, in order to again study the reaction of the interviewee.

If you consider:

$$\sqrt[6]{(-8)^2} = \sqrt[2 \cdot 3]{(-8)^2} = \sqrt[3]{-8} = -2$$

then complete:

$$\sqrt[6]{(-8)^2} = \sqrt[6]{64} = \dots$$

Task 4

RESULTS OF TEXTBOOKS REVIEW

1. In the Spanish textbooks reviewed the sign $\sqrt{\quad}$ is used to express the reverse operation of taking a number to the power of two (Figure 1):

Calculating the square root is the reverse operation of calculating the power of a square:

$$b^2 = a \leftrightarrow \sqrt{a} = b.$$

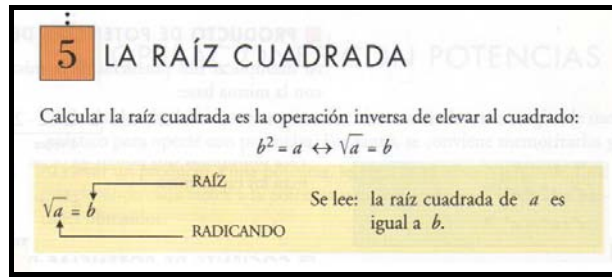

Figure 1. 1^o Secondary (7th grade), Anaya 2006, p. 52

The expression that has the $\sqrt{\quad}$ sign is called a radical, that is to say the operation shown, and not the main root of said operation (Figure 2).

It is called the n^{th} root of a number a , and is written $\sqrt[n]{a}$, where a number b meets the following condition: $\sqrt[n]{a} = b$ and $b^n = a$

$\sqrt[n]{a}$ is called radical; a , radicand, and n , the root's index.

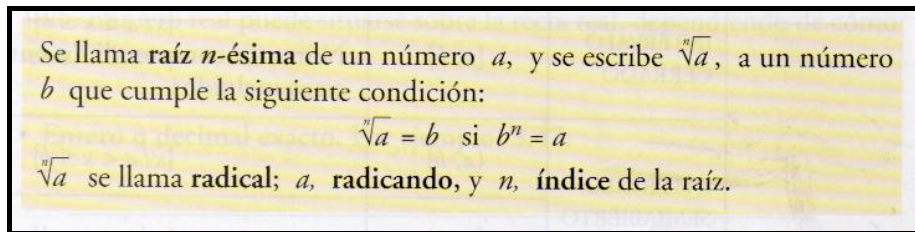

Figure 2. 4^o Secondary (10th grade), Anaya, 2006 b, p. 32

As a consequence it is considered that a radical has roots and that its number depends on the index of the radicand's sign (Figure 3).

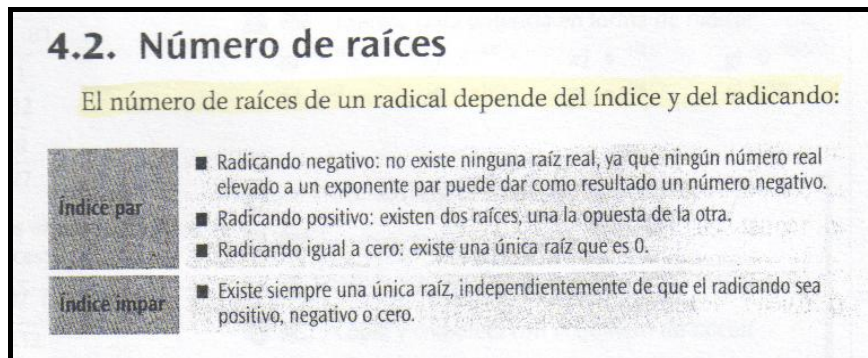

Figure 3. 3rd Secondary (9th grade), Oxford, U. P., 2007, p.32

So, equalities appear written as $\sqrt{36} = \pm 6$ (Figure 4).

Figure 4. 3rd Secondary (9th grade), S. M., 2003, P. 36

The properties of the radicals are stated without mentioning their field of validity. So it is not taken into account that $\sqrt{a^2} = |a|, \forall a \in \mathbf{R}$ (Figure 5).

Figure 5. 4^o Secondary (10th grade), Anaya, 2006 b, p. 36

2. In the Rumanian textbooks reviewed, the sign $\sqrt{}$ is associated with the radical notion. The radical with an index two of a positive number a is defined as the positive solution of the equation $x^2 = a$ and is denoted by \sqrt{a} . (Figure 6)

Figure 6. 10th grade, Fair Parteners, 2005, p. 13

It is taken into account that $\sqrt{a^2} = |a|, \forall a \in \mathbf{R}$, and the domain of validity of the radical's properties is specified. (Figure 7)

Figure 7. 10th grade, Fair Parteners, 2005, P. 13

FINDINGS AND CONCLUSIONS

As for the first objective, the review of textbooks shows that there are substantial differences in dealing with the $\sqrt{\quad}$ sign. Specifically, it can be said that in the Spanish textbooks studied, the conception associated with this sign is operational, whereas in Rumanian texts it is structural.

As regards the second objective, Patricia and Iulian's mathematical knowledge with respect to the radical sign shows significant differences.

In tasks 1 and 2, Patricia identifies $\sqrt{4}$ with the set of two solutions (2 and -2), and does not see the radical as the positive root when the index is even. In the interview, to emphasize this in task 2, she indicated that in reality there are not two solutions, but there are contexts in which it is replaced by +2 and others in which it is replaced by -2.

Iulian does not agree with $\sqrt{4} = \pm 2$, arguing that the radical of an even index of a positive number belongs to the interval $(0, \infty)$ and specifies that, in any context $\sqrt{4}$ represents a number, that is, the positive square root of 4.

In task 3 and 4, Patricia does not take into account that $\sqrt{a^2} = |a|, \forall a \in \mathbf{R}$. On the other hand Iulian correctly applies the restriction of the property of radicals and he realizes the error that the hypothetical student commits.

In conclusion, it can be said that Patricia has procedural knowledge of the $\sqrt{\quad}$ sign, whereas Iulian has structural knowledge, and that these conceptions are consistent with what is shown in the textbooks studied.

As for the third objective, this part of the work was restricted to Patricia's conflict, the answers to the questionnaire and the interviews that provide indications suggesting the validity of the hypotheses.

(H₁), Patricia does not distinguish between operational and structural use of radical sign.

(H₂), the review of Spanish texts evidences that the teaching proposal reflects the ambiguity of the radical sign, used in the expression $\sqrt{4} = \pm 2$, and does not use the formal definition of radicals, so that it is plausible to think that they encourage the appearance of Patricia's conflict.

(H₃), in the revised Rumanian texts, the formal definition of the radical sign is observed, so that it is possible to think that they support Iulian's way of acting, which does not encounter the conflict that Patricia expresses.

Finally, the important educational implication that should be pointed out is that in any educational proposal that aims to avoid conflicts such as the one expressed by

Patricia, the formal definition of radical must be considered, and it must be guaranteed that students understand the reasons for this definition.

BEHIND STUDENTS' SPREADSHEET COMPETENCIES: THEIR ACHIEVEMENT IN ALGEBRA? A CASE STUDY IN A FRENCH VOCATIONAL SCHOOL

Mariam Haspekian, Eric Bruillard

DIDREM (Université de Cergy), STEF (ENS Cachan, INRP)

Research on the use of spreadsheet in mathematics education usually points out its potentialities in the learning of algebra. The link between spreadsheet and algebra is thus often seen in the direction “spreadsheet for algebra”. This paper follows the opposite direction, i.e. “algebra for spreadsheet”, by questioning the role of algebra in students’ spreadsheet competencies. It reports a case study, based on computer tests, in the framework of a French research project studying students’ spreadsheet uses and competencies. The results of the test show algebra raising out again, playing a role behind students’ achievements and actions with spreadsheets. Algebra, Spreadsheet competences, Computer tests

INTRODUCTION

What role can technology play in mathematics education? Usually, didactic research approaches ICT questions through this direction, i.e. “technology for mathematics”. This is the case for many studies on spreadsheets which consider this latter as a good tool to help pupils understanding algebraic concepts.

Here, we take the opposite direction: “what about algebra for spreadsheet?” by questioning the role algebra plays in students’ mastery of spreadsheets. This issue comes from the analyses of experimentations in the context of *DidaTab*, a French research project studying students’ spreadsheet competencies. To identify the basic competencies students have acquired, the *DidaTab* project realised tests of competencies in several classes. In the analyses of the results, the relation with algebra stands out again, raising issues on the relations between students’ achievements and actions with this kind of software and their mastery of algebra.

In the first part, we give a quick description of the *DidaTab* project. The second part focuses on relationships between spreadsheets and mathematics learning. Then, to get a more concrete view of spreadsheet mastery problems, we detail the results of a computer test administrated to 17 y.o. students in a vocational marketing school. The results of this test put in perspective students achievements, actions, and software interaction understanding, with their knowledge (or their lack of) in algebra.

THE DIDATAB PROJECT

According to educational authorities of many countries, ICT has to be used in classrooms. In the case of secondary education, all countries have established detailed recommendations (Eurydice, 2004, p. 24). In general, using ICT to enhance subject knowledge or learning correct use of a word processor or a spreadsheet are part of the objectives at lower secondary level. But, if ICT seems to be included in prescribed curricula, we only have very few data about effective practices in classrooms and ICT

competencies of students. Some data from PISA 2003 (Eurydice, 2005) provides interesting results (for example, that less than half of students are familiar with using a spreadsheet to plot a graph) but rely on declarative statements. We don't know whether students under or over estimate their competencies. To get a more comprehensive picture, we considered that it was not fruitful to take into account ICT as a whole, and decided to focus on specific software. Spreadsheets, prescribed in French curricula for ten years now, were a good indicator of ICT mastery. What do students learn about spreadsheets? Which basic competencies do they have acquired at the end of their schooling?

DidaTab (didactics of spreadsheet^[1]) was a three year project (2005-2007) founded by the French ministry of research and dedicated to study personal and classroom uses of spreadsheets in French context. The methodology combined questionnaires, interviews (students and teachers), classroom observations, computer tests, content analysis of official curriculum texts, websites and resources, and some comparative studies with other countries (Belgium, Greece, Italy) have been made. As results (Blondel & Bruillard, 2006), we have an almost complete cartography of spreadsheets uses in the French secondary education, including an overview of personal uses, and we began to describe kinds of genealogy of uses, according to subject matters (e.g. mathematics, technology, social sciences, experimental sciences...). But we have not yet built a theoretical framework to explain spreadsheets uses and competencies of students. Some of these competencies relate to knowledge of mathematical nature, especially algebraic one. In a next part, we discuss this particular relation between spreadsheets and mathematics.

SPREADSHEET AND MATHEMATICS COMPLEX RELATIONSHIPS

In the title of this section, we play on the word “mathematics” to relate two points: mathematics as a school subject, this questions the place of spreadsheet within syllabus, or mathematics as knowledge that spreadsheets may bring into play, this questions the place of mathematics within the spreadsheet objects.

Spreadsheets within mathematics syllabus

Spreadsheets have been introduced at many different teaching levels and courses of the French Educational system. Part of the mathematics syllabus since 1997, first in middle school (grade 6 to 9) then in high school (grade 10 to 12), their place varies according to the school streams, as mathematics education appears under different aims. Two main tendencies can be distinguished, each of them promoting a different use of spreadsheets.

In the scientific streams, mathematics is a very theoretical discipline also used to select students. In this “abstract” approach of mathematics, spreadsheets appear as a

^[1] In French, spreadsheet is “tableur”. See <http://www.stef.ens-cachan.fr/didatab/en/index.html> for other information and results in English about *DidaTab* project

tool to serve the learning of mathematical concepts. Then spreadsheets' role is to support and enhance learning.

In some other streams, as vocational or literary, mathematics is considered as a more experimental subject oriented towards everyday life problems. This objective favours the use of different kinds of software such as spreadsheets, which allow a more concrete approach of mathematics opened on its everyday applications.

First vision leads to a very small place for working spreadsheet competencies. Moreover, as we will elaborate in the next section, using spreadsheet to enhance mathematical learning is "double-faced" as far as spreadsheet is not neutral on mathematical concepts. Second vision opens a larger place for building some spreadsheet competencies. In these streams, a hypothesis would be that students' difficulties in mathematics could be counterbalanced by some instrumental abilities and some mastery of this software^[2]. But the situation is not as simple because of the specific relationships existing between spreadsheet and mathematics: spreadsheet mastery requiring mathematical knowledge.

Mathematics within spreadsheet objects

ICT use in mathematics education is a question among the more general problematic of technology use in human activity, studied in the field of cognitive ergonomics. A theory of instrumentation (Vérillon & Rabardel, 1995); developed in this field, provides a frame to tackle the problematic of the learning in complex technological environments. In this frame, an instrument is not *given* but *built* by the subject (Vérillon and Rabardel, 1995) through a progressive individual *instrumental genesis*. This genesis, is not *neutral*, instruments have impact on the *conceptualisation*. This idea of non neutral «mediation» between subject and tools provides a way to report on the strong imbrications that exist, and have always existed, between mathematics and the instruments of the mathematical work. It led to an instrumental approach in didactics that has been used in several researches on symbolic calculators (CAS) in mathematics education (Artigue 2001, Lagrange 1999, Drijvers 2000, Guin, Ruthven & Trouche 2005). What about spreadsheets?

Some "computer" objects, characteristics of spreadsheets, do not strictly correspond to mathematical knowledge transposed in a computer environment, even not to a computer transposition of school knowledge, but are *however linked with* mathematics. The basic principle of spreadsheet, which consists in connecting cells between themselves by "formula", gives an example of these objects, linking spreadsheet to the domain of algebra. Such a particular relation with mathematics is precisely the reason why many research in didactics from different countries (Ainley (1999); Arzarello et al. (2001); Capponi (2000); Dettori et al. (1995) or Rojano and Sutherland (1997)) give spreadsheets a role in the learning of algebra. at elementary stages, iden-

^[2] For instance, in the literary stream, a place is given to concrete aspects of mathematics and this is precisely a stream where spreadsheets take an important part in the mathematics syllabus.

tifying them as tools of arithmetic-algebraic nature. Haspekian (2005a), having adopted an instrumental approach, showed that in spite of an apparent simplicity of use, it is not so evident for teachers to take benefit from these characteristics. The tool generates some complexity: spreadsheets transform the objects of learning and the strategies of resolution by creating new action modalities, new objects, and by modifying the usual ones (as variable, unknown, formula or equation...). Here are some examples.

In a paper and pencil environment, variables in formulae are written by means of symbols (a letter generally for the school levels concerned here). This variable ‘letter’ relates to a set of possible values (numerical here) and exists in reference to this set. In spreadsheet, let us take for example the formula for square numbers. The Fig.1 shows a cell argument A2 and a cell B2 where the formula was edited, referring to this cell argument.

	A	B
1		
2	5	=A2^2

Figure 1 A2 is the cell argument; B2 calculates the square of the value in A2

Here again the variable is written with symbols (those of the spreadsheet language) and exists, as with paper and pencil, in reference to a set of possible values. But this referent set (abstract or materialised by a particular value, e.g. 5 in Fig.1) appears here through an intermediary, the cell argument A2, which is both:

- an abstract, general reference: it represents the variable (indeed, the formula does refer to it, making it play the role of variable);
- a particular concrete reference: here, it is a number (in case nothing is edited, some spreadsheets attribute the value 0);
- a geographic reference (it is a spatial address on the sheet);
- a material reference (as a compartment of the grid, it can be seen as a box)

So, where in paper and pencil environment, we stick a set of values, a cell argument overlaps here, embarking with it, besides the abstract/ general representation, three other representations without any equivalent in paper and pencil (Fig.2).

Figure 2: The “cell variable”

Other examples of the changes due to spreadsheets are given in Haspekian 2005a.

From an institutional point of view, these changes have different impact following the different way chosen to introduce algebra. As the recent ICMI study showed (Stacey et al., 2004), different aspects of algebra can be focused on: as a tool of generalisation, a tool of modelling, or a tool to solve arithmetical, geometrical or everyday life

problems through what is called since Descartes, the « analytical method ». Following the case, different mathematics is brought forward: variables, formulae and functions on one hand, unknowns, equations and inequations on the other hand. In the French school culture, it is traditionally the analytic way that is chosen, the resolution, though equation solving, of various problems appears as emblematic of pupils introduction to algebra. Table 3 gives a quick insight of the distance between the algebraic culture in the French secondary education and the algebraic world carried out by spreadsheets.

"Values" of algebra	In paper pencil environment	In spreadsheet environment
Objects	unknowns, equations	variable, formulae
Pragmatic potential	tool of resolution of problems (sometimes tool of proof)	tool of generalization
Process of resolution	"algorithmic" process, application of algebraic rules	arithmetical process of trial and refinement
Nature of solutions	exact solutions	exact or approached solutions

Table 3: distance between different "algebraic worlds"

More generally, the mathematical culture sustained by spreadsheets is an « experimental » one: approximations, conjectures, graphical and numerical resolutions, implementing everyday life/ concrete problems, statistics... Thus, this vision fits with the aim of mathematics in particular streams of the French Education, especially where students not very good at mathematics are supposed to use spreadsheet with stronger objectives. It is thus interesting to investigate with students of non scientific streams and test them at the last year of their schooling (grade 12).

As we will see next, the computer test confirms the complex relation between spreadsheet and mathematics. Algebraic aspects; especially the use of cell-variables in formulae, stand out again as one of students' main difficulties with the tool.

STUDENTS' SPREADSHEET COMPETENCES: A CASE STUDY

We report here the example of a one hour computer test administrated in 2005 in a class of 13 students of vocational school^[3] (17 year old) preparing a marketing diploma. After presenting the objectives and a brief description of the test, we first give an overview of the general results and then an analysis on the algebraic aspects that these results lead to focus on.

Objectives and description of the test

For this part of the *DidaTab* project, the objective was to assess students' spreadsheet competences in a computer test. In order to design such tests, a first step consisted in the identification of basic spreadsheet skills, that have been actually organised in five categories (see below), then the definition of some general and simple tasks corre-

^[3] This school is identified as rather difficult in the sense that students have behavioural difficulties and social problems.

sponding to each ability, and finally the construction of a database of skills, questions and tasks (for more details on this step of the project, and especially on the design of the tests, see Tort and Blondel, 2007).

From the database we selected 24 exercises relevant to the school year of the students and covering all categories of skills. Then, the students' mathematics teacher chose 11 exercises from this list according to the competences she assumed that her students have. With regard to the classification, the 11 exercises are divided in the following way:

1. "Cells and Sheets Editing" (3 were selected)
2. "Writing of formulae" (4 were selected)
3. "Translating data into graphs" (1 was selected)
4. "Managing data tables" (2 were selected)
5. "Modelling" (1 was selected)

The tasks were proposed in the computer test with increasing order of difficulty, in a spreadsheet file. Students had to answer directly within the tool and record their work at the end of the test. The collected data are constituted by these file records, observation and the complete recording of the actions for one of the students.

An overview of the results

Among the five categories of skills, clear differences between basic skills linked to superficial manipulations (not requiring knowledge of the contents) and abilities requiring deeper knowledge appear.

The best rates of success for the 13 students, concern cell formatting: italic (10), bold (11), date format (9). The results decrease then as the tasks require more understanding of spreadsheets objects. Some tasks requiring deeper knowledge of spreadsheet functionalities have been moderately achieved: recopying a format (6), sorting out data (6), or representing data with a graph by choosing the best type of representation (4). Finally, more specific knowledge as the conditional format (0) or specific displays either of numerical data (fractional format: 1) either of graphics (displaying labels on the X axis: 2) seem rather unknown from these students.

All exercises of the formulae category are part of the competences that have been failed in. Actually, the success rates for the four tasks of this category are the lowest of the test, varying from 0 to 2 good answers for each item: Writing a formula to calculate the AVERAGE of a line of data in adjacent cells (2), Writing a formula calculating a subtraction (0), a product (0), a division (0), Writing and copying down a formula using relative and absolute references (0, only 1 student answered: he gave a number...), Writing a conditional formula (using the IF function) (0).

Three main issues can be raised from these observations:

- 1) The inadequacies between the skills we thought students have and their actual level of competence. Students' abilities were clearly lower than expected.
- 2) The teacher tended as well to overestimate the skills of her students. The exercises she has chosen were globally too difficult.

3) The very bad results concerning the formulae category raise the question of spreadsheet's relation to algebra. Obviously, the formulae, the copying of formulae, the use of relative/absolute references as variables in formulae and the conditional formulae appear in students' results, as the less achieved competences.

In the next section we analyse this last point in more details.

Algebraic aspects in students' achievements

Competences just mentioned are all linked with algebraic knowledge of students, their understanding of the concepts of variable and formula. These results join other research in didactics of mathematics (Capponi, 2000, or Dettori & al. 2001). For Capponi, benefiting from spreadsheet potentialities requires from the user the understanding of some algebraic knowledge such as the notion of formula, and students' difficulties with spreadsheets show their needs in this domain: the work remains at the numeric level (data tables, numbers, operations) without reaching the level of an algebraic treatment (dynamic sheet of calculations, formulae).

About formulae

Looking further the tasks of the formulae category, we note that sometimes, not only the correct formula had not been found, but not even wrong formulae have been tried. Some students edit, instead of formulae, the corresponding arithmetic operations, some others edit directly the results they calculate by hand, but most of them do not answer anything. Another surprising point concerns the calculus of the average: we did not find any formula such as $(A5+B5 + \dots + N5)/ 14$ or equivalents and only 2 students achieved the calculus of this average.

Observation during the test brings out some more elements. One of the students who succeeded in the average used the AVERAGE functionality (and seemed yet surprised to have directly the response). This can seem paradoxical, but to calculate the average of the given numbers, he directly used the function "AVERAGE" provided by spreadsheet; the references to the adequate cells are then automatically made. The student has to calculate an average, he has an "average" function (as a key of calculator), and he uses it without controlling more what this feature produces. The use of "AVERAGE" can thus mask its lack of understanding of what is really a formula in spreadsheet and the way it can be used. We have the same observation for the other student who used the average function. Finally, in the whole test, we did not find any other formula at all except these automatic formulae as average or sum. And the very surprising result that is coming to light with these analyses is that no student used a single relative reference in the entire test! According to us, this is precisely linked to the problem of the cell variable. Very few students used formulae which send back automatically the cell references^[4] (such as SUM or AVERAGE) and not even a sin-

^[4] The spreadsheet used in this experiment is Microsoft Excel. The interface provides buttons that you can directly activate and obtain the writing of a formula including cell references

gle student was able to write a formula which requires finding and entering the cell variable.

About the cell variable

The use of cells as variable in a formula seems more difficult than the use of formulae itself. In tasks which require a formula which does not automatically send back the cells references, either students do not find any formula or they use again an “automatic” formulae (AVERAGE or SUM) even when these functions have nothing to do with the task! For example, a correct answer to a task was a formula with a multiplication and one student has written the following formula: “=SUM (C12*10)”. SUM is here totally useless and used in a non standard way. The student invoked the function and turned the usual argument automatically written by the software (“=SUM (C12)” in this case) into a multiplication. By using this automatic formula, he did not enter himself the cell reference in the formula.

We have exactly the same phenomenon in another task: 2 students used SUM in both columns although the answer has nothing to do with a sum. One of them, after using the function SUM transformed the separating sign ":" in the syntax of this function into a subtraction (and the result is then correct)! All the others had not answered or had put either an operation or directly the numerical result instead of a formula. Once again, the use of cells as variables in a formula seems to be problematic, the type of functions as SUM or AVERAGE being apparently the only type of formula those students manage.

The problem of the cell-variable is also revealed by the use of the recopy. Here again, a deeper analyse of the answers of the whole class shows that it is not so much the fill handle that raises problem than copying downwards formulae. The recopy becomes problematic when it puts at stake some cells references which have to be incremented. This principle of the spreadsheet functioning, which is one of its most basic interesting feature, but which has an algebraic nature (the recopied cell playing the role of variable in the formula and the spreadsheet keeping the structure of the formula during the recopy), seems not to be understood by students. Results concerning recopy are quite different whether the recopy does concern cell-variables (copying a formulae with references: 0) or not (as copying down a date: 6).

In conclusion, it seems clear that these students do not master the ability of self editing a cell-variable in a formula or the way the recopy affects the cell references.

DISCUSSION AND PERSPECTIVES

The computer test reveals difficulties of grade 12 students, not so much in surface manipulation skills, but in their lack of understanding of algebraic concepts. Using a formula in a spreadsheet requires having understood the concept of "variable" in the spreadsheet (the cell argument in the formula). Using a recopy of a formula requires seeing the increment of the references produced by the recopy as a means for the spreadsheet to preserve the algebraic structure of the formula along the copy. The

syntactic writing varies in every line but the algebraic structure is preserved. These types of knowledge were analyzed as algebraic competences which constitute a difficulty for students at the pre-algebraic level (Capponi, 2000, Haspekian 2005b).

In an exploratory study with younger students (grade 7), which consisted of a first approach to algebra through the use of spreadsheet, Haspekian (2005) found similar results. The students were asked to write, interpret or transform formulae. The observations have shown that the technique of using a formula and copying it down was the competence the longest to acquire and created most difficulties to the students. The difficulties were the following ones:

- comprehension of formulae (some remained in a use of arithmetical level of the spreadsheet);
- use of the fill handle, in particular at the beginning. But even afterward, when they experienced it several times, they had difficulty in appropriating it and its use was not systematic.

The experiment in vocational high school shows that students of grade 12 have the same difficulties as regard to these algebraic concepts embarked in the tool. It would be interesting to make paper-pencil test on their level in algebra to validate this hypothesis.

Another interesting point is the question of the modalities of spreadsheet learning. In the experiment of Haspekian (2005b), half of the students had followed a training course about spreadsheet (hands-on work) some months before the experiment. In particular they had seen formulae and recopy of formulae, and the teacher of this course had asserted that these students would have no difficulty with the tasks of the experiment. The results showed that they had the same difficulties and took the same time to answer the exercises that the other half of the students, those who had never used spreadsheet previously. Our computer test points out the same difficulties.

It is also interesting to compare with students of other professional fields or students of general fields. In *DidaTab*, another computer test has been administrated in a class of literary stream. Results show that students have less difficulty with recopy and formulae but have much more difficulties with manipulation skills. Yet in France, this stream is the general stream where spreadsheets use is the most strongly prescribed by curriculum... Certainly, as mentioned in part II, spreadsheets change too much the traditional mathematics that live in the general streams, teachers do not seriously enough take into account spreadsheet learning (not enough time devoted to spreadsheet learning, lack of structured training sessions, etc.) in these general streams, and many students are not able to manage important spreadsheet features. This result is confirmed by many interviews of students in the *DidaTab* project. Thus, our small experiment with 12th graders gives a rather different picture from general discourses about students great competencies. It seems that intrinsic difficulties of spreadsheet concepts are not sufficiently taken into account in mathematics education, even in the school streams where mathematics objectives and views are connected to every day

life. In conclusion, students of professional fields who are mostly supposed to use spreadsheet due to their school profile are unfortunately those who are precisely blocked by their difficulties in algebra, and students of general streams with a better level in mathematics are those who will not “meet” spreadsheets enough because of the specificity of their stream...

To go further, it would be interesting to deepen the research with more computer tests in different levels and settings, and try to define thus kinds of students trajectories of uses.

DEVELOPING KATY'S ALGEBRAIC STRUCTURE SENSE

Maureen Hoch

Center for Educational Technology,
Tel Aviv

Efrata College, Jerusalem

Tommy Dreyfus

Tel Aviv University

In this paper we follow one student through a sequence of tasks and describe our observations of how her algebraic structure sense develops.

Key words: algebraic structure sense, high school algebra

INTRODUCTION

In this paper we take a close look at how one Israeli 11th grade high school student (age 16) performed during a series of teaching interviews designed to develop algebraic *structure sense*.

The term *structure sense* was coined by Linchevski and Livneh (1999). Subsequently the idea was developed and refined by Hoch and Dreyfus (2006) who arrived at the following definition.

Students are said to display structure sense for high school algebra if they can:

- Recognise a familiar structure in its simplest form.
- Deal with a compound term as a single entity, and through an appropriate substitution recognise a familiar structure in a more complex form.
- Choose appropriate manipulations to make best use of a structure.

See Hoch (2007) for a full definition and examples.

In an earlier paper (Hoch & Dreyfus, 2007) we showed how, through a simple intervention, students acquired the ability to recognise and exploit the properties of algebraic expressions possessing the structure $a^2 - b^2$. We described what is structural about $a^2 - b^2$, and showed how a student can learn to recognise structure. Hoch (2003) discussed and analysed structure in high school algebra, considering grammatical form (Esty, 1992), analogies to numerical structure (Linchevski & Livneh, 1999) and hierarchies (Sfard & Linchevski, 1994), culminating in a description of algebraic structure in terms of shape and order. In this research we took a similar approach, relating to any algebraic expression or equation as possessing structure, which has external and internal components. External components include shape and appearance. Internal components are determined by relationships and connections between quantities, operations, and other structures.

We designed a series of tasks with the aim of facilitating the improvement of structure sense. The tasks were deliberately devoid of any context other than the structural and technical, because the students had shown themselves unable to use certain algebraic techniques in different contexts, a phenomenon also noted by Wenger (1987). If a meaningful context had been chosen, then the issue of whether the students were familiar with the context and how well they understood it would have had to be considered.

The tasks were based on five structures that Israeli students meet in high school: $a^2 - b^2$; $a^2 + 2ab + b^2$; $ab + ac + ad$; $ax + b = 0$; and $ax^2 + bx + c = 0$. Hoch and Dreyfus (2006) identified students' difficulties with these structures. The creation of the tasks was based on the first author's analysis of structure sense and supported by her teaching experience. She placed emphasis on verbalising about mathematical concepts. In order to speak about a mathematical concept (or object), students must be able to deal with the result of some process without having to think about the process itself. The process is performed on a familiar object and then the result becomes another object (Sfard, 1991; Sfard & Linchevski, 1994). For example, in exercise 3 below the term $3xy$ is the result of the process of multiplying three elements. The student is required to relate to this result as an entity, in order to find its value.

In one task, the aim is to familiarise the student with equations that could be considered to have linear or quadratic structure when a product is related to as the variable. The student is presented with the following exercises in sequence:

1. Find xy : $8xy + 15 = 0$.
2. Find xy : $8x^2y^2 + 6xy - 9 = 0$.
3. Find $3xy$: $17xy - 25 = 13 + xy$.
4. Find $2xy$: $34xy - 4x^2y^2 = 10xy - 13$.
5. Find x : $17x^2 - 45 = 0$.

The student is asked to say which structure each equation possesses, to make up similar equations, and in some cases to devise efficient ways of solving them. The fifth equation is obviously quadratic, but the student is asked whether it could be considered to have a different structure if the instruction was "Find x^2 ".

In another task the student is required to describe each of the five structures listed above in words, and make up expressions or equations similar to those shown. The idea here is that the need to explain a structure in words causes the student to think more carefully about it. Gray, Pinto, Pitta, and Tall (1999) considered the use of language a powerful method of dealing with complexity. The student is asked to create expressions or equations that might be difficult for a friend to recognise. The rationale for this is that the act of creating more examples deepens the personal relationship with the structure. Rissland (1991) and others (e.g., Bills et al., 2006) said that generating examples is an important cognitive activity and that the ability to generate examples as needed is a cognitive tool of experts, often lacking in novices.

TEACHING INTERVIEWS

A series of three teaching interviews was designed, comprising tasks including the ones described above, with the purpose of improving students' structure sense. A pre-test measuring structure sense was administered to two 11th grade classes of intermediate to advanced students. Ten students who performed badly on the pre-test were chosen to participate in individual sessions of approximately 45 minutes each, over a period of up to two weeks. Throughout the sessions the researcher encouraged the students to verbalise about what they were thinking and doing, with emphasis placed on the correct naming of each algebraic entity and structure. A post-test was administered individually in a separate session a few days after the third session, and several months later a delayed post-test was administered.

All ten students displayed considerable improvements in structure sense, as measured by the immediate post-test. These improvements were maintained over time, to varying extents. We chose to report on Katy because she displayed the highest level of retention of learned abilities, and also because she was enthusiastic and highly verbal. On the pre-test Katy displayed technical skills such as opening parentheses, collecting like terms, and factoring trinomials. However her structure sense was poor—she was unable to factor an expression without first converting it into an equation and could not recognise a common factor. We will present here some excerpts from Katy's interviews. The excerpts are presented in chronological order: excerpt 1 is from the first session, excerpts 2 and 3 are from the second session, and excerpts 4 and 5 are from the third session.

EXCERPT 1: DIFFERENCE OF SQUARES

Katy displayed difficulties in factoring $49 - y^2$ as $(7 - y)(7 + y)$, and only reluctantly agreed that the expressions $x^2 - 16$ and $49 - y^2$ belong in the same structure group. When asked to give a general formula for the expressions in this group, she first suggested the formula $a^2 - b$. She observed that $49 - y^2$ confused her, "because for me the 'squared' is always plus". With a little help she arrived at the formula $a^2 - b^2$. However she was confused when asked to give a name to the structure represented by $a^2 - b^2$. The following extract is typical of students' difficulties when trying to explain mathematical concepts in words. (K = Katy; I = interviewer)

K The expression is made up of ...

I How did you decide that these belong together? [Points to $x^2 - 16$ and $49 - y^2$]. What characterises them?

K That squared minus that squared. Of the first degree.

This is an example of careless use of terminology. Earlier Katy had described linear equations as being of the first degree, yet here she assigns this name also to a quadratic expression, despite the fact that she first mentioned the squared terms.

I You called them $a^2 - b^2$.

K Ah. So ... eh ... how to give it a name?

- I Um , a description.
 K Can I call it $a^2 - b^2$?
 I Yes.
 K Is that a name?
 I No, that's a formula. You have a number squared minus a number squared. What do we call the result of a number minus a number?
 K A ratio?
 I No, that's a number divided by a number.
 K Difference?
 I That's right. So we can call this the difference of two squares.
 K Ah, I understand, the difference of two squares.

Many of the students were unable to name the result of subtraction without heavy prompting.

EXCERPT 2: COMMON FACTOR

In the pre-test Katy failed to answer any of the questions that required extracting a common factor. In the first session different types of factoring were mentioned, though not practised, including extracting a common factor. Subsequently, in the second session Katy had no problem factoring the expression $36axy - 16aby$. She was able to relate to the common factor $4ay$ as a single entity. However the expression $16x + 40xy + 50x^2$ presented her with more of a challenge. She rewrote it as $50x^2 + 40xy + 16x = 0$, and extracted a common factor to get $x(50x + 40y + 16) = 0$.

- I Why did you write “equals zero”? I don't see an equation.
 K [Scores out “equals zero”.] I can't do anything else.
 I You extracted a common factor. I don't think you extracted the greatest common factor.
 K Ah. Two. [Writes: $2x(25x + 20y + 8)$.]
 I Fine, but why did you change the order?
 K It's just simpler for me to have the x squared at the beginning.

The above extract illustrates Katy's diffidence about what she can “do” with an expression, although she knows what to do with an equation. It mirrors her performance on the pre-test. She does not, probably cannot, justify her preference for having “the x squared at the beginning” other than that she feels it is simpler. This preference was shared by other students, and perhaps reflects the manner in which textbooks and teachers present quadratic expressions. Although Katy succeeded in factoring the expression, she did not relate to $2x$ as an entity—she extracted first x , then 2.

EXCERPT 3: EQUATIONS

When it came to equations, Katy was overconfident, making some instant decisions that were not always correct. She was asked to copy each equation under its structure (quadratic or linear). Here is her response to $(2x^2 - x)^2 + 2(2x^2 - x) - 35 = 0$.

K Wow. This also doesn't belong here (pointing to $ax^2 + bx + c = 0$) but

I If it doesn't belong, don't write it there.

K No, it does belong, if we use t, where t is 2x squared

I Why?

K Because there will be x to the third.

I Yes, I agree you need to use a substitution, what will your t be?

K 2x squared.

Here followed a brief discussion about the viability of such a substitution.

K [Thinks] Then I'll get an equation with t equals x and tx squared and t squared. x to the third can be t squared.

I How would you solve such an equation?

K Eh ...

I I don't know either. Can you think of a different way?

K [Thinks]

I Continue with the idea of t.

K Oh I didn't look. 2x squared minus x is t.

Substituting t in place of a compound variable in an equation is taught in 10th grade and using it without regard for the appropriateness of the substitution is typical of many students. The fact that Katy said "I didn't look" rather than "I didn't see" suggests that she is self-reflecting and aware of what she should have done.

Katy very quickly classified $(x^2 + 3x)^2 = 2x^2 + 6x + 15$ as having structure $ax^2 + bx + c = 0$. The interviewer asked her to write down the appropriate quadratic equation.

K The quadratic equation? The equation ...

I Let's see. What will t be?

K Eh. [Writes $(x^2 + 3x)^2 = 2x^2 + 6x + 15$] To open and solve?

I How would you solve it?

K [Writes $x^4 + 6x^3$]

Eventually Katy was led to make the appropriate substitution. It seems that her original perception of the equation's structure was based on a guess, probably provoked by the fact that the term in parentheses is squared, or perhaps by looking only at the right hand side of the equation.

EXCERPT 4: NAMING A STRUCTURE

After Katy factored $(x + 3)^4 - (x - 3)^4$ correctly the interviewer pointed out that most students found that extremely difficult, and asked Katy why she thought that might be.

- K Because of the fourth power? They didn't identify ...
- I Uhm.
- K They didn't see the structure.
- I But there was this expression x to the fourth minus y to the fourth that nearly everyone succeeded in factoring. [Writes $x^4 - y^4$].
- K Because, in my eyes, it's different. Simply, that's clear [points to $x^4 - y^4$] and that's not [points to $(x + 3)^4 - (x - 3)^4$].
- I And now, with new eyes?
- K That's also clear [points to $(x + 3)^4 - (x - 3)^4$].
- I Are they different?
- K Yes, because of the words.
- I What?
- K Because in my head I see "difference of squares".

This extract clearly shows that being able to think about structure and give it a name helped Katy identify it.

EXCERPT 5: EXEMPLIFYING

Table 1 shows Katy's responses when asked to describe each structure in words and create more examples. Katy only managed to give the name of each structure (note that she said common denominator instead of common factor, a mistake made by many students) rather than a more wordy explanation. This, too, was typical of all the students. She displayed enthusiasm over the task of creating new examples, and made an effort to produce something out of the ordinary.

Table 1 Verbalising and exemplifying

Structure	Explanations	New examples
$a^2 + 2ab + b^2$	It's sum squared	1. $(3 + 2x)^2 + 6(3 + 2x) + 9$ 2. $(4x^2 + 12x + 9)^2 + 6(3 + 2x) + 9$
$a^2 - b^2$	Difference of squares	3. $z^2x^2 - 9$ 4. $x^2(3x + 2)^2 - 64$
$ab + ac + ad$	Common denominator	5. $(x + 2)y + (x^2 + 5x + 6) + (x + 2)(x + 5)$
$ax + b = 0$	Eh ... linear equation	6. $2(2x + 4)^2 - 9 = (4x^2 + 16 + 16x) + 5$ Find $(2x + 4)^2$
$ax^2 + bx + c = 0$	Quadratic equation	7. $9x^2y^2 + 6xy + 2 = 0$ 8. $9x^2y^2 + 6xy + 4 = 0$ 9. Solve for $(x^2 + 2x)^2$ $(x^2 + 2x)^4 + (3x^2 + 6x)^2 + 9 = 0$ 10. $(x^2 + 2x)^4 + 3(x^2 + 2x)^2 + 9 = 0$ 11. $(3x + 2)^6 + 9 = (3x + 2)^3$

Katy wrote example 1 and, when asked to write another one even more difficult, adapted it to get example 2, commenting, “I would never be able to solve that”. The interviewer asked her why she thought these examples might be difficult for other students.

K Because when you come to an exercise, you don't look at the general structure, unless it is really obvious to the eye.

I Uhuh, okay.

K And because ... I wouldn't get it. I would have to figure out how the 9 got there, in order to extract $3 + 2x$.

It seems that here Katy was talking about how she behaved before the teaching interviews.

In between writing examples 3 and 4 Katy said, “Just a minute, something more complicated? Now this was the one I really didn't understand the most, now it seems the simplest, it's impossible to make it more difficult.” We consider this a testimony to her structure sense development.

Katy changed example 7 into example 8 because she thought that the former had no solution while the latter had a solution. She seemed surprised to be informed that it was perfectly permissible to write a quadratic equation with no real solution. “Oh,” she laughed, “I didn't know.” In fact she should have known, since in class she had learned to analyse quadratic equations, and in fact mentioned this kind of analysis at the end of the first session. This is an example of how Katy has compartmentalised her knowledge.

Katy corrected example 9 to example 10. She stated, “I meant this. Like $x^2 + 3x + 9$ ”.

At the end of the session the interviewer commented on how well Katy had done, and asked her if she had been practising.

K [Laughs] The penny dropped.

I How did the penny drop? Do you think you could tell me?

K I don't know. But at least three times in class I found myself using this.

I Yes? I am very pleased.

K I said to myself, here are connections, suddenly I recognised a structure.

Katy's self-reflection and enthusiasm were a foreshadowing of her performance in the post-tests.

POST-TESTS

In the immediate post-test, Katy answered all the items correctly. After the test she commented that she felt it had taken her too long because of, “The common factor. I don't think about that. I will have to think about the common factor.” (Note that this time she said factor, not denominator.) When asked to account for her excellent performance:

K Do you know what helped me the most? It's the order; three different things. Everything I see I categorize. And in addition it helps – how it sounds, subtraction of squares, that's ... like ... Now that we're doing trigo, that appears a lot, a lot, a lot a lot, in identities.

I And you think of the ...?

K Today, there were three exercises, like, I work ahead with two boys, and I see that I'm three exercises ahead of them, and I stop to look what they've got stuck on, and I see that they're stuck on the subtraction of squares, and I said, but it's obvious what to do.

In the delayed post-test, several months later, Katy answered almost all the items correctly. Overall, Katy's structure sense improved considerably, and this improvement was sustained over time. Although the improvements in structure sense of the other participating students were less than that of Katy, their improvements also stood the test of time, providing evidence for the efficacy of the teaching interviews.

DISCUSSION

A close look at Katy's transcripts reveals that she displayed much typical behaviour: confusion between expression and equation, denominator and factor, ratio and difference; tendency to change the formulation of quadratic expressions; difficulty with verbalizing. She showed a clear improvement in structure sense from session to session, yet there is no instance that pinpoints the actual learning process. However, naming a structure helped her to use it, and she actually said that she succeeded "because of the words" that she sees in her head. Naming the structure is an important part of learning it – the name is part of the definition. One of the roles of a definition is to introduce a concept and convey its characterising properties. Another is to create a uniformity that allows easier communication of mathematical ideas (Borasi, 1992; Zaslavsky & Shir, 2005). A known concept or object can be given a definition by describing a few characteristic properties (De Villiers, 1998; Shir & Zaslavsky, 2001).

In conclusion, there is evidence that learning has taken place. Since there is no way of pointing to any one incident of knowledge acquirement, it can be surmised that the learning occurred as a process over time.

After the first post-test Katy said, "I think you should tell the teachers to do this with all the students. It would help them so much. Really." Of course, one-on-one intervention is not possible in a classroom situation, so the tasks would have to be adapted to make them suitable for group work, and yet enable the teacher to intervene when necessary. These tasks were designed as a form of remediation, to be used with 11th grade students who were assumed to be familiar with the algebraic structures. This raises the question whether it would be more effective if students' attention were drawn to structure at a much earlier stage, perhaps even before they practised using the formulae. Answering this question requires further research.

Further research is also required to answer other questions arising when attempting to develop students' structure sense. For example, can the teaching interviews be adapted for whole class activities? At what stage in the learning of algebra would this kind of intervention be most appropriate? Could the improved structure sense manifest itself in other subject areas, with other structures? The improvements in structure sense were maintained over a period of a few months. What would a longitudinal study show?

CHILDREN'S UNDERSTANDINGS OF ALGEBRA 30 YEARS ON: WHAT HAS CHANGED?

Jeremy Hodgen*, Dietmar Kuchemann*, Margaret Brown* & Robert Coe**

King's College London (*) & University of Durham (**)

In this paper, we outline the design and method of the research project Increasing Student Competence and Confidence in Algebra and Multiplicative Structures (ICCAMS). Phase 1 consists of a large-scale survey of attainment in algebra and multiplicative reasoning, using test items developed during the 1970s for the Concepts in Secondary Mathematics and Science (CSMS) study (Hart, 1981). This will enable a comparison of the current attainment of students aged 11-14 with that of 30 years ago. Phase 2 consists of a collaborative research study with 8 teachers extending the investigation to classroom / group settings and examining how formative assessment can be used to improve attainment. Although the focus of this paper is on reporting the research design, some early analysis of data from the initial survey data from 2008 (n = 2400) is reported.

INTRODUCTION

Over the past 30 years, there has been a great deal of work directed at, first, understanding children's difficulties in mathematics and, second, examining ways of tackling these difficulties. Yet, there is no clear evidence that that this work has had a significant effect in terms of improving either attainment or engagement in mathematics. Indeed, children continue to have considerable difficulties with algebra and multiplicative reasoning in particular (e.g., Brown, Brown & Bibby, 2008; Wiliam et al., 1999). In this paper, we describe the project Increasing Student Competence and Confidence in Algebra and Multiplicative Structures (ICCAMS), a research study designed to address these problems.

ICCAMS is a 4-year research project involving a research team from King's College London and Durham University together with eight teacher-researchers from four schools. The project consists of a large-scale survey of 11-14 years olds' understandings of algebra and multiplicative reasoning in England followed by a collaborative research study with the teacher-researchers extending the investigation to classroom / group settings and examining how formative assessment can be used to improve attainment and attitudes. Although the project is in its early stages, we report some initial tentative results later in this paper. These initial results compare children's current understandings with a similar survey, the Concepts in Secondary Mathematics and Science (CSMS) study (Hart, 1981), which was conducted 30 years ago. When completed, the full results will enable us to examine what gains, if any, have been made over the intervening period. The Phase 2 findings will extend the results to children's understandings in group and classroom settings.

BACKGROUND

Mathematics education in the UK²¹ is facing a crisis; insufficient students are choosing to continue studying mathematics post-16, whilst university teachers and others point to falling standards in the subject (CBI, 2006; Smith, 2004). There is considerable research in the UK addressing reasons for non-participation in mathematics - students stop studying mathematics because they experience it as difficult, abstract, boring and irrelevant (e.g., Osborne et al., 1997). The most recent findings relating to 16 year-olds (Brown, Brown & Bibby, 2008) suggest that students' attainment and attitudes are strongly inter-related. A major factor is that even relatively successful students perceive that they have failed at the subject and lack confidence in their ability to cope with it at more advanced levels, especially in comparison to the perceived 'clever core' of fellow-students. When pressed about the reasons for their feelings of failure, students suggest that they do not understand parts of what they have been taught; this commonly relates to algebra and to aspects of multiplicative reasoning (e.g. percentages, and ratio) and its applications (e.g. in trigonometry). Students' negative attitudes commonly relate to the predominance of routine and formal work on algebra and multiplicative reasoning. Performance in these topics has been shown to be particularly weak in England relative to other countries (e.g. Mullis et al., 2004). Yet algebra and multiplicative reasoning are both essential for further study in mathematics, in science & engineering (as well as health and medicine, economics, etc.) and for mathematical literacy in the workplace and elsewhere (e.g., CBI, 2006).

The original CSMS study was conducted 30 years ago. The study made a very significant empirical and theoretical contribution to the documentation of children's understandings and misconceptions in school mathematics (e.g., Booth, 1984; Hart, 1981). In the intervening period, there have been various large-scale national initiatives directed at improving mathematics teaching and raising attainment: e.g., the National Curriculum, National Testing at age 7, 11 and 14, the National Numeracy Strategy and the Secondary Strategy²². Many of these initiatives have drawn directly on the CSMS study. During this period examination results have shown steady and substantial rises in attainment: e.g., the proportion of students achieving level 5 or above in Key Stage 3 (KS3)²³ tests has risen from 56% in 1996 to 76% in 2006 and the proportion of students achieving grade C or above at GCSE has risen from 45% in 1992 to 54% in 2006. However, independent measures of attainment suggest that that these rises may be due more to "teaching to the test" rather than to increases in genu-

²¹ This crisis in mathematics education is not confined to the UK. It is also a concern in the US and elsewhere in Europe.

²² These initiatives are particular to England. However, similar initiatives relating to testing (and accountability) and to national curricular are evident elsewhere in the world.

²³ In England, compulsory secondary school consists of two Key Stages: KS3 (11-14 years) and KS4 (14-16 years). In 2008, and for more than a decade previously, 14 year olds took a 'high stakes' test at the end of KS3, although this assessment has been abandoned for 2009 and future KS3 assessment arrangements are currently under review. GCSE (General Certificate in Secondary Education) is the examination taken at age 16, the end of compulsory schooling. Almost all 16 year olds in England take GCSE mathematics.

ine mathematical understanding. Replication results from the science strand of the CSMS study (using a test on volume and density) suggest that students' understanding of some mathematical ideas as well as the related science concepts has declined (Shayer et al., 2007). Studies at the primary level indicate that any increases in attainment due to the introduction of the National Numeracy Strategy have been at best modest (Brown, Askew, Hodgen et al., 2003; Tymms, 2004). Results from the Leverhulme Numeracy Research Programme suggest that any increase in attainment at Year 6 is followed by a reduction in attainment at Year 7 (Hodgen & Brown, 2007). Further, Williams et al. (2007) find that, following this dip at Year 7, there is a plateau in attainment across Key Stage 3.

AN ALTERNATIVE APPROACH: FORMATIVE ASSESSMENT?

National initiatives in mathematics education in England have largely focused on specifying what mathematics should be taught (e.g., the National Curriculum), how mathematics should be taught (e.g., the Secondary Strategy) and summatively assessing what mathematics has been learnt (e.g., National Tests). However, research suggests that a much more effective approach to increasing attainment and engagement would be formative and diagnostic assessment: the tailoring of teaching to students' learning needs (Black & Wiliam, 1998). In an extensive meta-analysis study Hattie (1999) found that interventions involving feedback are more effective than any other educational intervention, with an effect size of 1.13. Further, Wiliam (2007) calculates that, for the achieved effect size, the cost of formative assessment is lower than for other comparative educational interventions. Yet, whilst there has been a great deal of activity nationally and internationally in formative assessment, there is also considerable evidence that teachers have substantial difficulties implementing these ideas (Bell, 1993). These difficulties in implementation relate to three issues. First, formative assessment has largely been described generically rather than in subject-specific terms (Watson, 2006). Second, formative assessment has been poorly described theoretically and pedagogically (Black & Wiliam, 2006). Third, teachers' ability to use formative assessment in mathematics is limited by their knowledge about key ideas, and the likely patterns of progression in student learning. Thus if teachers focus on teaching mathematical procedures they may find it difficult to see what is causing problems for students in mastering and applying these, and though aware of the importance of questioning, they may not know what questions they should ask (Hodgen, 2007).

THE NEED FOR A COLLABORATIVE APPROACH TO DISSEMINATION

Much of both the research and the implementation of initiatives in these areas of mathematics have been "done to" teachers, which may in part explain the limited influence in schools. Leach et al. (2006) found that research evidence cannot simply be presented to teachers; research findings need to be "re-worked" as teaching materials. However this process of re-working, or recontextualisation, is not straightforward

(Ruthven, 2002). We hypothesise that in order for change to occur teachers must have greater insight into the problems of student understandings and attitudes, a profound understanding of fundamental mathematics (Ma, 1999), and understanding of how available resources relate to student understandings and underlying mathematical ideas. These approaches have been tried before in e.g. diagnostic teaching experiments – also based on the CSMS research - and have proven success (Bell, 1993; Swan 2006). Existing experience of collaborative research methods (e.g., Black & Wiliam, 2003) suggests that disseminating these approaches more widely and implementing them in ordinary classrooms is more likely to be successful if these approaches have been grounded in teachers' practices.

THE RESEARCH STUDY

ICCAMS is investigating engagement and achievement by focusing on the two topics at KS3 that are central to the current mathematics curriculum: algebra, and multiplicative reasoning. These topics are also fundamental to further study in mathematics and other numerate disciplines (e.g., science, engineering, economics²⁴, etc.) The study will focus on KS3, because this is where students first meet algebra and more abstract multiplicative reasoning, and where attitudes begin to deteriorate (Mullis et al., 2004). There is also evidence of a plateau in student achievement at KS3 (Williams et al., 2007).

Phase 1: The large-scale survey of algebra and multiplicative reasoning 11-14

In Phase 1, we are conducting a large-scale survey of attainment in algebra and multiplicative reasoning and attitude to mathematics, involving both cross-sectional and longitudinal elements. This will use test items first developed during the 1970s as part of the CSMS study (Hart, 1981). Based on a representative sample of schools and students in England, the survey will provide a comprehensive and detailed analysis of current student attainment in algebra and multiplicative reasoning. It will provide up-to-date information on student understandings of basic ideas in the areas of algebra and multiplicative reasoning enabling us to plot where changes have occurred since the original study. It will extend the CSMS study by linking understanding of concepts and student progression to student attitudes, to teaching, and to demographic factors. Analysis is being conducted using a variety of techniques, extending those used in the original CSMS study with Rasch and other techniques.

The full survey will consist of both cross-sectional (n=6000) and longitudinal (n=600) samples identified using the MidYIS database (Tymms & Coe, 2003). Three original CSMS tests (Ratio, Algebra, Decimals) will be administered with some additional items relating to fractions (drawn from the CSMS Fractions test) and spread-

²⁴ ICCAMS is funded by the Economic and Social Research Council in the UK as part of a wider initiative aimed at identifying ways to participation in Science, Technology, Engineering and Mathematics disciplines.

sheet items. Piloting indicated that only minor updating of language and contexts was required.

The test items range from very basic to sophisticated, allowing broad stages of attainment in each topic to be reported, but also each item, or linked group of items, is diagnostic in order to inform teachers about one aspect of student understanding.

Phase 2: The collaborative research study investigating formative assessment

In Phase 2, we are conducting a collaborative research study with teachers, which will indicate how they can best use a formative assessment focus within these curriculum areas to improve student confidence and competence, and thus participation, engagement and attainment. In this phase, we adopt a design research methodology (Cobb et al., 2003). Central to our approach will be the analysis of children's difficulties from both teaching and research perspectives.

Initially teachers will be supported in interpreting and acting upon the survey results of their students; later they will use classroom-based formative assessment based on the frameworks for learning provided by the tests, and assessment for learning approaches. They will also draw on research-informed approaches to the teaching of these curriculum areas. This study will, first, examine how teachers can make use of existing resources and initiatives to respond to students' learning needs, and, second, develop and evaluate an intervention designed to enable a wider group of teachers with much less support to do this. In the final year of the study, the approach will be implemented and evaluated with a further group of teachers and classes.

The Phase 1 findings will provide up-to-date information on student understandings of basic ideas in the areas of algebra and multiplicative reasoning to inform the teachers and teacher-researchers in Phase 2 both about their own students and about where they lie relative to the general population.

A central question for Phase 2 is how the generic approach of formative assessment can be adapted to the particular needs of mathematics teaching and learning. This will be done in several ways. First, the diagnostic results for individual students assessed against the learning and progression framework developed by CSMS will guide teachers in planning appropriate work for students and in further formative assessment. The CSMS tests were carefully designed over the 5-year project starting with diagnostic interviews in order to focus on student progression in understanding of key concepts such as variable and rational number. (See below for a fuller description of the Algebra test.) Second, we will identify and link existing teaching resources into the developmental and diagnostic learning structure provided by CSMS, building on and extending our existing work in this area which is underpinned by a combination of Piagetian and Vygotskian theories (Adhami, et al., 1995; Brown, 1992). There is extensive research evidence relating to the teaching and learning of both algebra and multiplicative reasoning that can inform this intervention (e.g. Bednarz et al., 1996; Sutherland et al., 2000; Ainley et al., 2006), but these research findings and resources

have only made a limited impact on teaching practices in classrooms. The solution lies not in designing yet another resource for the teaching of algebra and multiplicative reasoning, but in supporting the judicious use and interpretation of existing resources by teachers (Askew, 1996). Third, we will develop our existing work in this area (Hodgen & Wiliam, 2006).

THE WORK TO DATE AND EARLY ANALYSIS

In June 2008, tests were administered to a sample of around 3000 students in each of Years 7, 8 and 9²⁵. Approximately 2000 of these students took the Algebra test. The full cross-sectional sample will be completed in Summer 2009 when a further subsample of around 2000 students will be tested. We report here on the early analysis of this data. We note that these early results should be treated with caution. In particular, the current sample of students appears to be slightly higher attaining than the general population in England. This early analysis suggests that student attainment in algebra at age 14 is broadly similar to that of 30 years ago, although the patterns across the attainment range and in earlier years are more complex.

Students' understandings of letters

We now focus on just four linked items due to space constraints: 9a-d, illustrated in Figure 1. These items have been chosen to give a flavour of the test.

The CSMS algebra test was carefully designed over the 5-year project starting with diagnostic interviews. The original test consisted of 51 items. Of these 51 items, 30 were found to perform consistently across the sample and were reported in the form of a hierarchy (Booth, 1981; Küchemann, 1981). The test items range from the basic to the sophisticated allowing broad stages of attainment to be reported, but also each item, or linked group of items, is diagnostic in order to inform teachers about one aspect of student understanding. The focus of the test was on generalised arithmetic, and in particular it looked at different ways in which pronumerals can be interpreted (Collis, 1975). Items were devised to bring out these six categories (Küchemann, 1981):

Letter evaluated, Letter not used, Letter as object, Letter as specific unknown, Letter as generalised number, and Letter as variable.

The four items, 9a-d, were amongst the consistently performing items that formed part of the original hierarchy. Item 9a, at Level 1 in the hierarchy, and items, 9b and c, at Level 2, can be solved without having to operate on the letters as unknowns; the letters can be treated as objects (i.e., the name of the various sides of the figures). Items 9b and c additionally require the explicit use of some mathematical syntax. Item 9d, at Level 3, was designed to test whether students would readily 'accept the lack of closure' (Collis, 1972) of the expression $2n$, where the given letter, n , has to be treated as at least a specific unknown. The proportions of 14 year old students an-

²⁵ Key Stage 3 is made up of three academic years: Y7 (age 11-12), Y8 (age 12-13) and Y9 (age 13-14).

swering these items correctly in 1976 reflect this variation in difficulty: 94% for 9a; 68% for 9b; 64% for 9c; 38% for 9d.

The item facilities for 1976 and 2008 are presented graphically in Figure 1. This suggests that the *pattern* of progression is similar in 1976 and 2008: an initial relatively steep rise is followed by a much smaller rise subsequently. However, although the initial steep rise now appears to take place a year earlier, this initial advantage is not sustained and by age 14 students' attainment appears similar in 1976 and 2008. The results for item 9a are more of an anomaly: this relatively easy item appears to be more difficult now than in 1976.

Figure 1: Items 9a-d. Facilities for items in both 2008 [continuous] and 1976 [dotted] for Year 7 to Year 10 (ages 11-14). In 2008 data were not collected for Year 10; in 1976 data were not collected for Year 7.

DISCUSSION

In comparison to 30 years ago, in England, formal algebra is taught to all students earlier. This is partly as a consequence of the introduction of a National Curriculum. The initial results of the study reported here suggest that, whilst this practice confers an initial advantage to students, this increased attainment may not be sustained. Our early analysis suggests that, by age 14, current performance in algebra is broadly similar to that of students in 1976. Moreover, it is worth noting again that the sample of students tested in 2008 is in general a relatively high attaining group. Hence, the data presented here suggest that increases in examination performance are not matched by increased conceptual understanding and, thus, add weight to the research reported earlier in this paper.

PRESENTING EQUALITY STATEMENTS AS DIAGRAMS

Ian Jones

University of Warwick

I describe a diagrammatic computer-based task designed to foster engagement with arithmetic equality statements of the forms $a+b=c$, $a+b=b+a$, and $c=a+b$. I report on six trials with pairs of 9 and 10 year old pupils, highlighting how they talked about distinctive statement forms and used these distinctions to discuss strategies when working towards the task goals. These findings stand in contrast to how pupils typically view and talk about equality statements as reported in the literature.

INTRODUCTION

The design of tasks that engage pupils with mathematical ideas in an open and exploratory manner presents a significant challenge. Constructionism offers a vision of mathematics learning in which learners explore, modify and create mathematical artefacts on a computer screen (Turkle, Papert and Harel 1991). The term “microworld” (Edwards, 1998) is often used to describe software that supports learners “discovering” mathematical rules through experimentation, mental reflection and discussion. The intention is to engage learners with mathematical ideas in a way that is meaningful to them. However, this can be difficult when the conventions of formal notation are the intended domain of learning because they are not so readily meaningful to learners. A way forward is offered by diagrammatic task designs in which learners explore, modify and create *notational* artefacts (Dörlfer 2006). This paper reports on trials with a diagrammatic computer-based task designed to engage primary children with arithmetic equality statements.

CHILDREN’S CONCEPTIONS OF EQUALITY STATEMENTS

In typical primary classrooms, arithmetical equality statements are presented and talked about as commands to work out a result. This leads most children to expect a term comprising numerals and operator signs on the left of the equals sign, and a single numerical result on the right (Behr, Erlwanger and Nichols 1976; Dickson 1989). This expectation can prove stubborn (McNeil and Alibali 2005), and lead to difficulties with equation solving (Knuth, Stephens, McNeil and Alibali 2006).

Presenting young children with a variety of statement forms leads to more flexible thinking about mathematical notation (Baroody and Ginsburg 1983; Li, Ding, Capraro and Capraro 2008). Interventionist studies have focussed on the careful selection of statements that appeal to structural readings, as in $50+50=99+1$, $7+7+9=14+9$, $246+14= _+246$ and so on (Carpenter and Levi 2000; Molina, Castro and Mason 2008; Sáenz-Ludlow and Walgamuth 1998). The intention is that pupils can notice and exploit arithmetic principles in order to assess or establish numerical balance, without the need to generate results. Such interventions produce encouraging

findings, but the long term impacts remain an open question (Dörfler 2008; Tall 2001).

Figure 1: Screenshot from the computer-based task

A DIAGRAMMATIC APPROACH

An alternative to presenting statements as isolated questions of balance is offered by Dörfler's (2006) "diagrammatic" approach. The essence of diagrammatic notating tasks is learners manipulating conventional representations ("inscriptions") in an open, exploratory manner. This renders mathematical notating an empirical and creative activity, based in seeing potential actions (i.e. transformations). Generalisation can arise from noticing both visual patterns and patterns of repeated actions. As such, diagrammatic tasks offer learners an investigative, concrete notating activity that stimulates discussion, congruent with constructionist approaches. Note that "diagram" is being used here more loosely than everyday associations with "drawings" rather than "writings" would suggest. In another sense, however, it is more restrictive, referring only to those "inscriptions" that form precise mathematical structures with grounded rules for making transformations. From a diagrammatic perspective, arithmetic statements can be presented in parallel, forming relational systems akin to simultaneous equations (e.g. Figure 1). Numerals and their transformations, rather than numbers and arithmetic principles, are the intended "objects of the [learners'] activity" (p.100).

When pupils exploit shortcuts to establish the equivalence of presented statements they do engage in activities that are to some extent diagrammatic. Their attention is on the structural relationships of numerals, rather than computed results, and this can stimulate rich discussion (Carraher, Schliemann, Brizuela and Earnest 2006). However, such designs exclusively promote an "is the same as" meaning of the equals sign due to the task goal of establishing equivalence. There is no appeal to a "can be exchanged for" meaning, which is central to the nature of reversible equivalence relations (Collis 1975), and supports the transforming aspect of diagrammatic notating tasks.

The tasks used in the studies reported here presented pupils with sets of equality statements ("diagrams") on a computer screen. A screenshot from the task is shown in Figure 1 (an online example of the software is available at go.warwick.ac.uk/ep-edrfae/software). Each statement stands in isolation, but, as with an algebraic equation, can also combine with others in a collective, relational system. The task goal is to transform the term in the box at the top-left of the screen, $20+53$, into a single nu-

meral using the provided statements. For example, we might start by selecting $53=3+50$ and using it to transform the boxed term into $20+3+50$, then use $3 + 50 = 50 + 3$ to transform it into $20+50+3$, and so on until 73 appears in the box.

The tasks offer learners new ways to view and talk about statements. Working through notational diagrams (such as Figure 1) requires looking for matches of numerals across statements and the boxed term in order to determine where substitutions can be made, and this is quite distinct from viewing statements as isolated questions of numerical balance. Observing and predicting transformational effects ($20+53 \rightarrow 20+3+50$ and so on), when a statement is selected and visually matched notation is clicked, promotes making distinctions of statements by form. Notably, $a+b=b+a$ can be seen as commuting the inscriptions a and b ; and $c=a+b$ can be seen as partitioning the inscription c . If pupils articulate such distinctions when working towards the task goal this would stand in contrast to children's left-to-right computational readings of statements reported widely in the literature.

I report on six trials drawn from three studies. In each trial pupils were set a sequence of diagrams to solve, similar to that shown in Figure 1. These studies varied in the specific research questions addressed and the diagrams presented. The intention here is to present common and contrasting findings from across the trials (for a detailed discussion of the first two studies see Jones 2007, 2008).

METHOD

The method used was paired trialling and qualitative analysis for evidence of talking about mathematical ideas in novel ways (Noss and Hoyles 1996). Pairs of 9 and 10 year old pupils were presented with sequences of notational diagrams comprising statements of the forms $a+b=c$, $a+b=b+a$, and $c=a+b$. These began with simple diagrams comprising two or three statements of the forms $a+b=c$ and $a+b=b+a$, followed by more complicated diagrams comprising up to nine statements and including $c=a+b$ forms. Pupils were shown how to select statements and click on notation to see if a substitution occurs, and were given a few moments to get to grips with the software's functionality. I then set the task goal of transforming the boxed term into a numeral, and remained present to offer encouragement and ask for verbal elaborations ("what do you think?", "how did you know that would work?", and so on). Each trial lasted around 30 to 40 minutes.

Data were captured as audiovisual movies of the pupils' onscreen interactions and discussion. Data were transcribed and analysed using *Transana* (Woods and Fassnacht 2007). Occurrences of pupils computing results, looking for numeral matches and articulating the distinctive transformational effects of statement forms ("swap", "split" and so on) were coded. A trace of each trial was constructed to examine how such articulations arose, and how they were used by pupils in order to discuss strategies when working through the diagrams.

The six trials reported will be referred to as Trial A through to Trial F. The pupils in trials A to C were deemed mathematically able by their class teachers, and the pupils in trials D to F were deemed average. The trials can usefully be grouped as A, B, C and D, E, F in terms of the extent to which pupils (i) articulated distinct statement forms, and (ii) used these distinctions to work strategically with the diagrams.

FINDINGS

The data are presented here to illustrate the similarities across all trials, and the differences across trials A to C and D to F. I present a visual overview of the six trials, and offer illustrative transcript excerpts.

Visual overview

Figure 2 shows a time-sequenced map of codings across the six trials and was

Figure 2: Time-sequenced coding of the data for computing results, looking for matches of numerals, and articulating commuting and partitioning transformations.

produced using *Transana*. Each block shows an occurrence of pupils computing results, looking for matches of numerals or terms across statements and the boxed term (Figure 1), or articulating the distinctive commuting (“swapping”) or partitioning

(“splitting”) transformational effects of presented statements. The length of each block is somewhat arbitrary. For example, one block of (say) “commute” might reflect pupils working in a trial-and-error manner with one of them suggesting they “swap” numerals, but offering no reason. Another block of similar length might reflect pupils discussing which numerals to commute, and how and why, as part of a shared strategy. As such, Figure 2 provides a useful visual aid for summarising the trials, but does not convey the quality, or the precise quantity, of the pupils’ articulations and strategising. Non-coded segments are those times when either I was speaking, or pupils’ discussion was ambiguous (“Click that one”, “Let’s try this one, no, that one” and so on).

The first thing to note is how little the pupils computed results across the trials (with the exception of Trial C, in which the notably enthusiastic pupils appeared keen to impress me with their computational prowess). Conversely, the pupils did engage in looking for matching numerals, and articulating the commuting properties of $a+b=b+a$ statements. Figure 2 shows that “compute” was prominent in the first ten minutes of each trial (bar Trial A), but was less present than the other codes in the final ten minutes. This reflects how most pupils began by computing results, as would be expected, but changed, sooner or later, to more diagrammatic views.

“Partition” is less prominent across the trials, and does not appear at all in trials E and F. The pupils in trials A to C came, sooner or later, to articulate partitioning transformations as part of their shared strategy for achieving the task goal. After a little practice, they would generally begin a new diagram by identifying partitioning statements, then using commuting statements to shunt the numerals in order to compose them. However, the pupils in Trials D to F rarely articulated partition if at all, and did not use it strategically, instead relying on a less efficient approach characterised by trial-and-error statement selection. It seems, then, that articulating partition is key to strategic discussions when working collaboratively with the diagrams.

Illustrative transcript excerpts

Early on in the trials, after the pupils had been introduced to the software’s functionalities, they articulated computational readings of statements. The following is from Trial E:

- John: 9 add 12 add 1 equals 22.
 Derek: 21.
 John: No it’s 22. 13 add 9.
 Derek: Hm, no 9 add 12. 9, 13 add 12. No, 13 ...
 John: 12 add 1 is ...
 Derek: Yeah 22 because it's 9 add 12 add 1 is 22

Searching for matches of numerals arose across all the trials as the pupils discussed why the software sometimes allowed a selected statement to make a substitution and other times did not. Often they looked for matches of single numerals, rather than terms. The following is from Trial C:

Barbara: 31 plus 19.

Nadine: 19. What's that?

Barbara: 31 ... look for a 31 somewhere.

Nadine: Well I found a 19 and another 19.

Barbara: But we need something that will equal 19. Aha, I found a 31.

At other times pupils attempted near matches, such as trying to use $5+18=23$ to transform $5+8+18$ (Trial C). However, often these near matches were attempted doubtfully when pupils were momentarily stuck, and, overall, they showed greater confidence when attempting exact matches. With prompting, the pupils were often able to explain why a given substitution did not work. From Trial A:

Researcher: Why do you think that wasn't working?

Terry: Maybe because ... 1 and 9 is ...

Arthur: Oh, because it hasn't got that sum in it.

Researcher: What do you mean?

Arthur: Well, because that's got 1 add 9 but then the end of that's got 9 add 1.

Pupils across all the trials readily came to articulate the observed or predicted transformational effects of $a+b=b+a$ statements as "swapping" or "switching" or "changing round". Some pupils did not initially see that this could be helpful for achieving the task goal. For example, when the pupils in Trial F used $31+35=35+31$ to transform $31+35+8 \rightarrow 35+31+8$ they commented:

Colin: That just swapped it.

Imogen: Swapped it around.

However, most pupils came to see a use for commuting numerals sooner or later, as articulated by John (Trial E) when prompted to explain why $16+32=48$ would not transform $13+32+16$:

Researcher: It's not working. Why not?

John: Because we haven't got a 13 yet.

Derek: Yeah we have look.

John: No, in these.

Derek: No.

John: It equals 48. But there is 48 in some things. Yeah, there is in this one.

Researcher: That's not actually the reason. It's not because of that 13.

John: Hm. [Doubtfully] Is it because we went wrong on one of these?

Researcher: No, no.

John: Is it because it's the wrong way round? The 16 and the 32?

Researcher: Is there anything you could do about that?

John: Oh yes, yeah, yeah, yeah, yeah. I thought this was useless but now it's useful. These bits. Okay. Right, now we've just changed it round. Now try. There we go. Now, 13 add 48. Now that one.

All pupils, to a greater or lesser degree, came to articulate potential commutations one or more steps ahead in order to use further statements to make transformations. From trial B:

Yuri: If we can swap them two around.

Linda: Yeah.

Yuri: And swap them with the 33 so we can get the 50 and 11. Go on, that one.

Linda: Huh?

Yuri: That one. Now swap them two around. Now you can get 50 add 11.

At times, some pupils commented on the physical appearance of the boxed term when transformed by $c=a+b$ forms. From Trial C:

Barbara: Now change the 53 into 41 plus 12.

Nadine: Okay now it's a big sum.

However, partition was explicitly articulated only in trials A to D. For example, in Trial A, when the pupils first encountered a diagram containing the form $c=a+b$, Terry inferred its transformational effect, and its use for achieving the task goal:

Terry: Oh! That's the one that you do first! It has to be.

Researcher: Why?

Terry: Because it's splitting up the 40 and the 1.

In trials A to C, the pupils adopted a strategy of starting with $c=a+b$ forms to partition the numerals in the box, then using $a+b=b+a$ and $a+b=c$ forms to commute and compose the term into a single numeral. From trial B:

Yuri: Try splitting the 37 first. Um, you have to click on that. No, hit [i.e. click] all the numbers ...

Linda: 29 add 8.

Yuri: So, 73. 29 add 73 that said so, split, no wait. How do you get that for... Unless you got to switch them two around. So it's...

Linda: Which two around?

Yuri: Them two. Go, go on that. Now switch them two. Now you got that one.

Linda: 29.

However, in trials D to F, this start-with-partitioning strategy was not discovered or adopted by the pupils. They relied on trial-and-error when selecting statements to a greater extent than the pupils in trials A to C. The following example is from Trial D:

Zoë: Try that on the other one.

Kitty: No, it's just swapped them.

Zoë: Shall we try swapping and then we can try ...

Kitty: What shall we try?

Zoë: That one.

Researcher: Why that one Zoë?

Zoë: I don't know.

The contrast across trials was most marked in the later stages when the diagrams are more complicated and so strategic approaches are significantly more efficient.

DISCUSSION AND FURTHER WORK

The data show that the presentation of equality statements as transformational rules enables pupils to explore and talk about arithmetic notation in non-computational ways. Left-to-right readings of individual statements, as widely reported in the literature, are replaced by looking for matches of numerals across statements and terms. The task offered pupils a *utility* (Ainley, Pratt and Hansen 2006) for equality statements, namely making substitutions of notation towards a specified task goal. This utility arose because statements were presented as reusable rules for diagrammatic activity rather than isolated questions of numerical balance.

All the pupils distinguished the commuting transformational effects of $a+b=b+a$ forms, and used this distinction to discuss possible transformations one or two steps ahead. Only half the pupils distinguished the partitioning transformational effects of $c=a+b$ forms, and these pupils were able to use this distinction as part of a strategy that proved advantageous for later, more complicated diagrams.

When the pupils articulated commuting and partitioning effects this does not mean they had a conception of the underlying arithmetic principles. Baroody and Gannon (1984) found that young children can appear to exploit commutation to reduce computational burden, but are often merely indifferent to consistency of outcome. Trial B came from a study in which the last few diagrams contained some false statements, such as $77=11+33$, and the value of the boxed term was not conserved across transformations. Interestingly, the pupils did not comment on this, and when asked afterwards if diagrams had contained false statements were unable to say (Jones, 2008).

This suggests pupils do not coordinate ‘sameness’ and ‘exchanging’ meanings for the equals sign when working with the task.

Current work is exploring how these two meanings for the equals sign might be coordinated using a constructionist approach to task design. Trials C, E and F are from a study in which the pupils subsequently went on to make their own diagrams using provided keypad tools. This requires ensuring numerical balance when inputting statements, and testing that these statements can be used to make substitutions when placing them into a diagram. A second aim of this current work is to find out whether pupils can translate verbalised calculations into notational diagrams. These calculations usually contain implicit partitioning and commuting (as in “ $34+23$. 3 plus 4 is 7, and 30 plus 20 is 50, and 50 add 7 is 57”), which learners must identify and make explicit as statements on the screen in order to achieve the task goals. Early analysis suggests that again articulating partition is key to success.

A future aim, then, is to explore how the selection and sequencing of arithmetic diagrams can help all pupils to notice and articulate partitioning effects.

APPROACHING FUNCTIONS VIA MULTIPLE REPRESENTATIONS: A TEACHING EXPERIMENT WITH CASYOPEE

Jean-Baptiste LAGRANGE, *Laboratoire DIDIREM, Université Paris 7, France*

Tran Kiem MINH, *Laboratoire DIDIREM, Université Paris 7, France*

Abstract: *Casyopée is an evolving project focusing on the development of both software and classroom situations to teach algebra and analysis at upper secondary level. This paper draws on our current research in the ReMath European project focusing on the approach to functions via multiple representations. In this paper, we present the design of an experimental teaching unit for the 11th grade and some preliminary results.*

INTRODUCTION

The notion of function plays a central role in mathematics and for many authors technology can help students to learn about this notion especially because of the representational capabilities of digital environments. Recently, authors extended the range of representations by considering functional dependencies in a non symbolic domain. Falcade and al. (2007) proposed for instance to use Dynamic Geometry as an environment providing a qualitative experience of covariation and of functional dependency in geometry.

An aim of our team in the ReMath project is to develop a teaching unit taking advantage of a wealth of representations of functions offered by technology. In this aim, our software environment - Casyopée - has been extended, adding to the existing symbolic window a geometrical window with strong connections between them. Casyopée's symbolic window is a computer environment for upper secondary students. The fundamental objects in this window are functions, defined by their expressions and domain of definition. Other objects are parameters and values of the variable. Casyopée allows students to work with the usual operations on functions like: algebraic manipulations (factoring and developing expressions, solving equations ...); analytic calculations (differentiating and integrating functions); graphical representations; supports for proof The new window offers the usual dynamic geometry capabilities, like defining fixed and free geometrical objects (points, lines, circles, curves) and constructing others. It also offers distinctive features: geometrical objects can depend on algebraic objects and it is possible to export geometrical dependencies into the symbolic window, in order to build algebraic models of geometrical situations (Lagrange & Chiappini, 2007).

SOLVING A PROBLEM OF FUNCTIONAL DEPENDENCY WITH

CASYOPEE

In order to explain this extension, we expose now the type of problem whose resolution can take advantage of Casyopée, and how. This is an example:

Consider a triangle ABC. Find a rectangle MNPQ with M on [oA], N on [AB], P on [BC], Q on [oC] and with the maximum area

Fig. 1: The geometrical window of Casyopée

Fig. 2: The symbolic window of Casyopée

Constructing a generic triangle ABC in the geometrical window can be done after creating parameters in the symbolic window. For instance, the points can be $A(-a;0)$, $B(0;b)$ and $C(c;0)$, a , b and c being three parameters. Then one can create a free point M on the segment $[oA]$ (o being the origin) and the rectangle can be constructed using dynamic geometry capabilities.

In the Geometric Calculation tab (Fig.1) one can create a calculation for the area of the rectangle MNPQ and then define an independent variable. Numerical values of

calculations and of the variable are displayed dynamically when the user moves free points. The user can then explore the co-dependency between these values. If this co-dependency is functional (i.e., the calculation depends properly on the variable) it can be exported into the symbolic window and Casyopée automatically computes the domain and the algebraic expression of the resulting function. Otherwise, Casyopée gives adequate feedback.

After exporting into the symbolic window, one can work on various algebraic expressions of the function and on graphs. For instance, one can use properties of parabolas, or algebraic transformations or Casyopée's functionality of derivate to find the answer to the question. One can also use the graph of the function to conjecture about the area maximum.

QUESTIONS AND THEORETICAL FRAMEWORKS

As the above example shows, Casyopée offers very varied functionalities and representation of functions:

- means for creating generic dynamic figures,
- geometrical calculations to express a range of quantities that can be considered as dependant variables,
- possibilities of choosing an independent variable like a distance or an abscissa involving free points,... feedbacks about this choice of a variable,
- means to observe numerical covariation between points and calculations, or between an independent variable and a calculation,
- means to export a functional dependency between the chosen variable and a calculation to the symbolic window, resulting in an algebraic form of the function,
- means for treating this algebraic form in various registers.

The overarching question addressed by the Casyopée team is: how to exploit these varied functionalities of representation in order to develop students' understanding of a functional dependency, particularly by articulating a geometrical situation with its algebraic model?

To investigate this question, we built an experimental teaching unit at 11th grade. In this paper, we present first the frameworks that helped us to build this experiment and to interpret our observations. Then we present the experiment and we report on the observation of the last session where students used the wider range of representations.

The first framework is based upon the notion of "setting" introduced by Douady (1986). According to Douady, a *setting* is constituted of objects from a branch of

mathematics, of relationship between these objects, their various expressions and the mental images associated with. When students solve a problem, they can consider this problem in different settings. Switching from a *setting to another* is important in order that students progress and that their conceptions evolve. Students can operate these *changes of setting* spontaneously or they can be helped by the teacher. The setting distinguished here are geometry and algebra,

We also rely upon the notion of *registers of representations* from Duval (1993). Duval stresses that a mathematical object is generally perceived and treated in several registers of representation. He distinguishes two types of transformations of semiotic representations: *treatments* and *conversions*. A treatment is an internal transformation inside a register. A conversion is a transformation of representation that consists of changing of a register of representation, without changing the objects being denoted. It is important that students recognize the same mathematical objects in different registers and they get able to perform both treatments and conversions.

Here we distinguish the geometric and the algebraic settings corresponding to Casyopée's two main windows. In these two settings, the functions modeling a dependency are different objects: a relationship between geometric objects or measures in the geometric setting, and an algebraic form involving a domain and an expression in the algebraic window. In the above problem, students have to switch from the geometric to the algebraic settings and back, to be able to use symbolic means for solving questions that were formulated in the geometric setting. As explained by Lagrange & Chiappini (2007), we expect that, working in the geometric setting, students would understand the problem and the objects involved, and that after switching to algebra, this understanding would help them to make sense of the objects and treatments in the algebraic setting.

Inside each of these two settings the functions can be expressed in several registers. In geometry, especially with dynamic geometry, functions can be represented and explored in different registers: covariations between points and measures, or between measures, or functional dependency between measures. In algebra, functions can be expressed and treated symbolically, by their expressions, by way of graphs and of numerical tables. Mastering these expressions and treatments, and flexibly changing of register are important for students' ability to handle functions and acquire knowledge about this notion.

A third framework is the *instrumental approach*, based on the distinction between artefact and instrument. An artefact is a product of human activity, designed for specific activities. For a given individual, the artefact does not have an instrumental value in itself. It becomes an instrument through a process, called *instrumental genesis*, involving the construction of personal schemes or the appropriation of social pre-existing schemes. Thus, an instrument consists of a part of an artefact and of some

psychological components. The instrumental genesis is a complex process; it requires time and depends on characteristics of artefacts (potentialities and constraints) and on the activities of the subject (Vérillon & Rabardel, 1995).

In the case of an instrument to do or learn mathematics like Casyopée, the instrumental genesis involves interwoven knowledge in mathematics and about the artefact's functionalities. Artigue (2002) showed how this genesis can be complex, even in the case of simple task like framing a function in the graph window. More generally, the many powerful functionalities of CAS tools have a counterpart in the complexity of the associated instrumental genesis (Guin & Trouche, 1999). We are then aware that we must take care of students' genesis when bringing Casyopée into a classroom. Moreover, Casyopée offers a multiplicity of representations in two settings and in several registers. Understanding and handling these representations involves varied mathematical knowledge. Students have then to be progressively introduced to these representations, taking into account the development of their mathematical knowledge.

Constructing the sessions of the experiment, we also used the Theory of Didactical Situations as basis for designing tasks. According to this theory, learning happens by means of a continuous interaction between a subject and a milieu in an *a-didactical situation*. Each action of the subject in milieu is followed by a retro-action (feedback) of the milieu itself, and learning happens through an adaptation of the subject to the milieu. Thus, with regard to Casyopée use, learning does not depend only on the representational capabilities of this software, but also on tasks and on the way they are framed by the teacher. Within this perspective, we looked for situations in which students interact with Casyopée and receive relevant feedbacks. For example, to solve the above problem, students have to choose between different independent variables to explore functional dependencies in the geometrical window and to export a dependency into the algebraic window. In case the variable is inadequate, the feedback they receive is a message from Casyopée. In other cases, the algebraic expression automatically produced by Casyopée can be more or less complex, which is another feedback: too complex expressions have to be avoided in order to ease the subsequent algebraic work.

Concerning the methodology, we use *didactical engineering* (Artigue, 1989), a method in didactic of mathematics, to organize and evaluate the experimental teaching unit, and to answer the research questions. The treatments and interpretations of collected data based on an internal validation which consists in confronting *a priori* analysis of the situation with *a posteriori* analysis. This method produces an ensemble of structured teaching situations in which conditions for provoking students' learning have been planned.

THE EXPERIMENT

Our experimental teaching unit consisted of six sessions. It was experimented in two French 11th grade classes. It was organized in three parts. Consistent with our sensitivity to students' instrumental genesis, each part was designed in order that students learn about mathematical notions while getting acquainted with Casyopée's associated capabilities:

- ❖ The first part (3 sessions) focused on capabilities of Casyopée's symbolic window and on quadratic functions. The aim was that students became familiar with parameter manipulation to investigate algebraic representations of family of functions, while understanding that a quadratic function can have several expressions and the meaning of coefficients in these expressions. The central task was a "target function game": finding the expression of a given form for an unknown function by animating parameters.
- ❖ The second part (two sessions) aimed first to consolidate students' knowledge on geometrical situations and to introduce them to the geometrical window's capabilities. The central task was to build geometric calculations to express areas and to choose relevant independent variables to express dependencies between a free point and the areas. It aimed also to introduce student to coordinating representations in both algebraic and geometrical settings, by way of problems involving areas that could be solved by exporting a function and solving an equation in the symbolic window.
- ❖ Finally, in the third part (one session) of the experimental unit, students had to take advantage of all features of Casyopée and to activate all their algebraic knowledge for solving the optimization problem presented above.

Below, we give some insight on how we are currently exploiting this experiment with regard to our question about Casyopée' potential for multi-representation. We limit ourselves to the final session for which the problem and the students' instrumental genesis should allow to take full advantage of this potential. We draw some elements of a priori analysis of this session and we compare with the a posteriori analysis of the functioning of a two student team.

THE SITUATION IN THE FINAL SESSION: ELEMENTS OF A *PRIORI* ANALYSIS

Tasks

The problem is presented by the teacher by animating a figure in Casyopée's geometrical window:

Let a , b and c be three positive parameters. We consider the points $A(-a;0)$, $B(0;b)$ and $C(c;0)$. We construct the rectangle $MNPQ$ with M on $[oA]$, N on $[AB]$, P on $[BC]$ and Q on $[oC]$. Can we build a rectangle $MNPQ$ with the maximum area?

Fig. 3: The figure built in Casyopée

The tasks proposed to students are then:

- The construction of the rectangle MNPQ: students are required to load a Casyopée file with the parameters' definition and the triangle, then to complete the figure by building the segments $[oA]$, $[AB]$, $[BC]$ and $[oC]$ and to create the free point M and the rectangle's vertexes.
- To create a geometrical calculation for the area of the rectangle MNPQ: this can be obtained by the product of the lengths of two adjacent sides, e.g. $MN \times MQ$
- To explore the situation by moving the point M on the segment $[oA]$.
- To prove the conjecture by algebraic means.

The teacher also asks students to write the proof, indicating their choice of variable and using results displayed by Casyopée. Finally, students are expected to visualize the answer in the geometrical window.

Covariations and representation of functional dependencies

This situation involves two settings and different registers. Students can conjecture the answer to the question by exploring numerical values of the area in the geometrical setting. They can explore the variation of the area in different ways corresponding to different registers of representation. First, they can observe co variation between the point M and the area, looking at the values of the calculation they created for the area of the rectangle, noting that when M moves from A to B the value grows then decreases, with a maximum value when M is the middle of $[oA]$. They can also observe co variation between a measure involving the free point M and the area. For instance, they can observe together the values of the distance oM and of the area. Finally, they can choose an independent variable involving M and observe the functional dependency between this variable and the area.

In the algebraic setting students can apply different algebraic techniques to the algebraic form of the function in order to find a proof. Exporting a function with Casyopée, one obtains a more or less complex algebraic expression reflecting the calcula-

tion's structure. Students then need to expand this expression to recognize a quadratic function. They can then apply their knowledge about these functions to prove the maximum. It is possibly not easy for them, because of the three parameter involved.

They can also use the graphical representation in this algebraic setting to explore the curve, complementing the exploration they did in the geometrical setting: the parabola is familiar to the students and they can easily recognize a maximum.

The situation is partly a-didactical. In each setting, students interact freely with Casyopée and use the feedbacks to understand the situation. Nevertheless, some key points like passing from a co variation to a functional dependency are expected to be difficult for students, although the corresponding action (choosing an independent variable) has been presented in the preceding sessions. Passing from one setting to the other is expected to be far from obvious for students. The corresponding actions in Casyopée (exporting a function in the symbolic window, interpreting a symbolic value in terms of position of a point) have also been presented before, but it is the first time that students have to do it by themselves.

Students can choose their own independent variable between possible choices (oM , x_M , MN , $MQ\dots$) with consequences upon the algebraic expression of function. They can do it alone but it is expected that the teacher mediation will be necessary. It is also possible that they will want to change their choice of a variable in order to obtain a simpler algebraic expression of the function.

We expect a great variety of uses of representations reflecting students' free interactions with the situation. Some students can stay a long time exploring co variations and need teacher mediation to go to functional dependency while others pass more or less quickly to the algebraic setting to consider the function. In this setting, some can prefer to explore graphs, while others prefer working on algebraic expressions. It is possible that some students find too difficult to apply algebraic techniques to the general expression (i.e. with parameters) and prefer to work by replacing these parameters by numbers. In any case, we expect that students will consider several representations, make sense of them and make links between them.

ELEMENTS OF A *POSTERIORI* ANALYSIS: THE CASE OF A TEAM

During the experiment, we observed selected teams of students. In this paper, we focus on a team of two students, which according to the observation in the first five sessions had a favorable instrumental genesis. According to their teacher they were good students.

The explorations in different settings and registers

Creating a geometrical calculation for the area of the rectangle, they typed $MNxMP$ instead of $MNxMQ$ by mistake. They moved M and observed growing numerical

values of this calculation, while, for some positions of M the area was visibly decreasing. This first feedback allowed them to correct the geometrical calculation.

Like most students they had difficulties in choosing an appropriate independent variable, confusing the independent variable and the calculation. They needed help from the teacher to activate the correct button. They chose at first NP . They moved for a long time the point M and observed how numerical values of this variable and of the area $MN \times MQ$ changed. They found an optimal value and interpreted it: "(the optimum) is when N is the midpoint of $[AB]$ I believe, and P is the midpoint of $[BC]$ ". The teacher asked them for a proof. A student suggested an equation in an interrogative tone. Actually, the problems solved in sessions 4 and 5 were about equalities of areas and have been solved by way of an equation.

The teacher guided them to export the function, but they found the resulting expression too complicated. Then they choose another independent variable MQ , and got the same expression after exporting again the function. Finally, they chose x_M as an independent variable, obtained the algebraic expression $b(x-1/ax)(a+c-a(x-1/ax))-c(x-1/ax)$ and expanded it into a quadratic polynomial.

Proving the maximum

The team graphed the function, recognized a parabola, and said that they do not know how to determine the maximum's x -coordinate. Then they wanted to apply an algebraic formula to get this x -coordinate and used Casyopée to expand the expression. For some reason they got a non parametric expanded expression, the parameters being instantiated. Then it was easy for them to obtain by paper/pencil a numerical value of the maximum's x -coordinate. Then they returned to the geometrical window, checked this result and generalized, saying that the maximum is for $x_M=a/2$.

They did not attempt to prove this generalized property by working on the parametric expression and then they only partially solved the problem. Other teams did, but had much difficulty to apply the formula to the parametric quadratic expression.

SYNTHESIS

The observation reported above is globally consistent with the a priori analysis. The students used more or less all registers of representation. The independent variable was recognized as the central feature of the solution, allowing connections between registers. Casyopée offered means for exploration and various feedbacks that helped this recognition. The students' instrumental genesis helped them globally to interact with Casyopée, but important actions like choosing a variable and exporting a function were still unfamiliar. They were influenced by the problems they solved before and it was difficult for them to have a clear approach of an optimization problem. Although they used parameters before and they understood the generalized problem, using parametric expressions was still difficult.

With regard to our question on how to exploit Casyopée's varied functionalities of representation, we can say that, in spite of remaining difficulties, the teaching experiment helped this team to develop an understanding of a functional dependency. We have of course not now a more definite conclusion and we are currently analysing the other teams' observation as well as productions after the experiment. We are especially sensible to the teacher's help to students. In the above observation, we saw this help in crucial episodes, like changing settings and we want to know whether this help was efficient for students' learning, beyond the solution of the problem.

EQUALITY RELATION AND STRUCTURAL PROPERTIES [1]

Marchini Carlo^a, Cockburn Anne^b, Parslow-Williams Paul^b, Vighi Paola^a

^a Mathematics Department University of Parma - ITALY ; ^b School of Education and Lifelong Learning University of East Anglia, Norwich -U.K.

We present the results of a questionnaire on equality we administrated to a large and vertical sample of Italian students. Some of the questions were devised to investigate the presence of relational thinking.

INTRODUCTION – THE SCENARIO OF THE RESEARCH

This paper emanated from an international study of arithmetical misconceptions in primary schools (Cockburn & Littler, 2008) part of which considered equality (Parslow-Williams & Cockburn, 2008). One way to detect whether a wrong answer can be attributed to a misconception or a slip (Schlöglmann, 2007), is to analyse the persistence of the same wrong answer through a range of school grades. Here we focus on a questionnaire on equality administered to 1,147 Italian seven to sixteen and a group of university students in their first year. (cf. table 1 below).

THEORETICAL FRAMEWORK AND THE AIM OF RESEARCH

It has been well documented that an understanding of equality is crucial to the development of algebraic thinking (Alexandrou-Leonidou & Philippou, 2007; Attorps & Tossavainen, 2007; Puig, Ainley, Arcavi & Bagni, 2007).). Here we focus on formal number sentences, building on the work of Molina, Castro & Mason (2007) and, in particular, *relational thinking* – a term that Molina *et al.* (2007) borrow from Carpenter, Franke & Levi (2003). The student employs *relational thinking* if s/he

“makes use of relations between the elements in the sentence and relations which constitute the structure of arithmetic. Students who solved number sentences by using relational thinking (RT) employ their number sense and what Slavit (1999) called “operation sense” to consider arithmetic expressions from a structural perspective rather than simply a procedural one. When using relational thinking, sentences are considered as wholes instead of as processes to carry out step by step.” (Molina *et al.*, 2007, p. 925)

The term *relational thinking* here is the opposite of procedural thinking. Although it sounds similar to Skemp’s (1976) *relational understanding*, i.e. “knowing what to do and why” (Skemp, 1976, p. 21), in this context it focuses on different aspects of learning. In our opinion *relational thinking* is very similar to *relational interpretation* of equality detected by Alexandrou-Leonidou & Philippou (2007) and very closely related to *conceptual knowledge*, as proposed by Attorps & Tossavainen (2007) as opposed to *procedural knowledge*. The latter adopted the framework of Sfard (1991) and focused on the mathematical properties of the equality relation, i.e. reflexivity, symmetry and transitivity and, using a sample of 10 qualified and 75 pre-service secondary mathematics teachers, concluded that a lack of understanding of these proper-

ties impairs the development of the concept of equation. In Italy the structural approaches to arithmetic and algebra, together with equations, are usually introduced in grade 9. Early structural approaches and equations are, however, in the curricula for grades 6, 7 and 8. In the light of the above, this study investigated

- whether there was evidence of relational thinking in grades 2 - 5;
- how the structural notions taught of pupils in grades 6 - 11 influenced the responses;
- misconceptions about aspects surrounding equality amongst the students.

METHODOLOGY

The questionnaire

All pupils were given a written questionnaire containing a series of equality problems. Our questionnaire comprised simple number sentences using similar questions and symbols to those found in the literature (cf. Radford (2000), Hejný & Slezáková (2007), and Behr, Erlwanger & Nichols (1980)).

Zan (2000) suggested that misconceptions may exist in a sort of ‘grey’ zone beneath the complete consciousness of the person. Our questions were intended therefore to be sensitive enough to reveal misconceptions and relational thinking without being too direct, since this can make the subjects aware of their errors, resulting in an immediate correction before they commit themselves to writing an answer.

We decided to avoid the issue of having both signs ‘+’ and ‘-’, in the same calculation, as an awareness of both algorithms was required to find the solution. The questionnaire was four pages in length [2]: 2a and 2s presented addition and subtraction problems respectively, using mainly single digit numbers; in 3a and 3s numbers were between 20 and 100. The first six questions on each page were designed to build confidence and involve two given numbers, one operational sign, ‘+’ or ‘-’. On all pages a firm knowledge of symmetry of equal relation can help solve the first six questions; in 2a form, two of them focus explicitly on the symmetry of the equality relation. The next four questions have three given numbers, two operational signs (cf. Behr *et al.* (1980), Sáenz-Ludlow & Walgamuth (1998) and Alexandrou-Leonidou & Philippou (2007)). These were followed by ‘open’ questions [3] with two operational sign, two boxes and two given numbers, as $a+\square = \square+b$; $\square+a = \square+b$; $a-\square = b-\square$ (we have yet to come across such examples in the literature). These were intended to reveal the possible use of reflexivity of equality, the commutative property of addition and awareness of 0 and its formal properties. We also tested the presence of the ‘commutative property’ of subtraction. Other less common open and closed questions were devised to detect the possible awareness of the transitive property of equality, with two-equality schema such as $a\pm b = c\pm\square = \square$ or with three-equality schemas such as $a\pm b = c\pm\square = d\pm\square = \square$ and $a\pm\square = b\pm\square = c\pm\square = \square$. These can be solved correctly by direct calculation showing the *non-RT behaviour* or by the use of structural properties, ap-

plying the different *RT behaviours* of Molina *et al.* (2007). For the reflexivity of equality in forms 2a and 3a we included a question of the schema $a = \square$.

The questionnaire instructions were intentionally open-ended: we asked “Can you complete these number sentences?”, without specifying which type of number could be used (naturals, relative integers, rationals or reals), thus leaving the possibility that older students could apply their knowledge about the various numbers systems.

The sample

As we had to rely on volunteers teachers, our sample was determined by their response. The number of returned questionnaires was as shown in Table 1.

Grade	2	3	4	5	6	7	8	9	10	11	Univ
No.	76	131	58	228	282	172	161	62	22	47	112

Table 1: The sample structure

The size of the sample (1,147 respondents giving 62,898 answers) and its breadth (11 different grades) allowed us to compare our data with the research literature; observe whether such findings might be extended to older students and detect any new phenomena. Due to the scope of the study, the conditions of the test administration were largely un-specified (time, day, duration of the test, surveillance during the proof, and so on) except in case of university students who were given 15 minutes to complete the questionnaire.

THE RESULTS

Interestingly, regardless of age, the majority of solvers only used natural numbers. Due to the lack of space we focus on sample questions (while retaining the original questionnaire ‘numbering’).

1. The first six questions on each page and symmetry of equal relation.

A-priori analysis. In the questions 2a. (b) $5+\square=8$ and 2a. (f) $8=5+\square$ the role of symmetry is evident, since the numbers involved are the same (‘strict’). In other examples we can speak of a symmetry ‘at large’ for the structure of the number statements, but not for the numbers involved. This gave us the opportunity to examine whether some pupils were ‘blind to the symmetric property of the equality’ (Attorps & Tossavainen, 2007), in the ‘strict’ sense and/or the ‘at large’ meaning. For each pair the correct answers to both questions can be obtained by computation; in case of 2a. (b) and 2a. (f), the result is 3, for both. For this pair, a difference in the result or the lack of one answer can be attributed to an incomplete mastery of the formal property of equality. For the remaining pairs we presume that a right answer to one question of the pair and the firm awareness of equality relation symmetry may suggest a good strategy for solving the other question of the couple, even if the numbers are different: a solver of $79-\square=25$ who has trouble with $53=78-\square$, can think of this second task in the form

78-□=53 to find the right answer. A right answer of only one question of these couples can suggest an ‘at large’ non-application of the symmetry in the pair.

A-posteriori analysis. The case simplicity of 2a. (b) and 2a.(f) resulted in high success rates: 98,14% and 95,40% respectively. People responding differently to the two tasks, certainly gave an incorrect answer. Individuals who responded incorrectly, are highly likely to a lack of their understanding of symmetry. However, in the case of the other pairs, the situation is more complex since we cannot exclude wrong computations even if symmetry was being used. In table 2 we distinguish between the ‘strict’ symmetry non-application and the ‘at large’ non-application. Data in the latter case are obtained cumulatively for the other eleven pairs (sample no. 12,993).

	number of at least one wrong or missing answer		rate of symmetry non-application		rate of contemporary success	
	<i>strict</i>	large	<i>strict</i>	large	<i>strict</i>	large
Grades 2-5 [4]	46	891	93.48%	79,91%	90.67%	78.33%
Grades 6-8	18	1090	83.33%	74,86%	97.07%	83.90%
Grades 9-11	4	231	75.00%	62,77%	96.95%	83.94%
University		47		89,36%		93.01%
χ -test	8.68E-6	3.38E-94	0.29	1.27E-7	3.29E-6	3.04E-24
Global sample	68	2259	89.71%	75,92%	94.51%	82.61%

Table 2: The non-application of symmetry of equality.

Values of the χ -test less than 0.05 (0.01) show that difference among grade classes are statistically significant; the result 0.29 is consequence of small numbers.

Reference the sum of the numbers of all the wrong and missing answers to at least one of two tasks suggests that a lack of awareness of the formal property is the greater source of error.

2. The task 2a. (k) $5 + \square = \square + 7$

A-priori analysis. The task is open with the choice of one of two missing numbers determining the other. The location of the boxes invites, possibly, the reflexive property of equality without the need for any sort of calculation e.g. $5 + \boxed{7} = \boxed{5} + 7$. The neutral role of 0 with addition could inspire the answer $5 + \boxed{2} = \boxed{0} + 7$. Other structural answers using the formal property of negative numbers (and 0) are $5 + \boxed{0} = \boxed{-2} + 7$ and $5 + \boxed{-5} = \boxed{-7} + 7$. Relational thinking offers a criterion for revealing a wrong answer: the given numbers are odd, therefore the two inserted numbers must have the same *even parity*. The repetition of a box could prompt (wrongly) younger pupils, in particular, into thinking that the numbers they are required to insert must be the same.

A-posteriori analysis. Of 1,143 students that were given this question, 1,057 responded, of which 842 gave the right answer (73.76%) suggesting that the task was relatively easy. Each answer given (right or wrong) used natural numbers. It is interesting to note the distribution of the structural answers by age of pupils. We suspect

that the infrequent use of zero to solve the problems e.g. $5 + \boxed{2} = \boxed{0} + 7$ could be due to a ‘fear’ of 0 - i.e. the complex acknowledgment of 0 as a number - or, simply reflect that individuals were unacquainted with this mathematical character.

2a. (k) $5 + \square = \square + 7$	correct response	presence of the answer $5 + \boxed{7} = \boxed{5} + 7$	presence of the answer $5 + \boxed{2} = \boxed{0} + 7$	commonest correct response (with frequency)
Grades 2-5	62.47%	7.26%	7.66%	$5 + \boxed{4} = \boxed{2} + 7$ (26.21%)
Grades 6-8	78.21%	6.86%	6.24%	$5 + \boxed{3} = \boxed{1} + 7$ (34.93%)
Grades 9-11	86.26%	2.65%	0.88%	$5 + \boxed{3} = \boxed{1} + 7$ (46.02%)
χ -test	4.79E-10	0.21	0.04	
Global sample	73.67%	6.41%	5.94%	$5 + \boxed{3} = \boxed{1} + 7$ (32.30%)

Table 3: The relational thinking presence and the commonest right answers to 2a.(k).

The commonest incorrect response was $5 + \boxed{2} = \boxed{7} + 7$ (with 18.14% of the 215 wrong answers). To interpret this we can consider the application of “Three First Numbers – TFN” and then “Answer After Equal Sign–AAES” modalities of Alexandrou-Leonidou & Philippou, (2007). The presence of two equal boxes, did not appear to be highly relevant as only the 8.37% of incorrect responses used the same number twice: $5 + \boxed{a} = \boxed{a} + 7$ ($a=1$ or $a=2$ having the greatest frequency). The *even parity* criterion was found in all of the 842 exact answerers and in 26.98% of the wrong answers, giving a total rate of 85.15% of the answers. We have also an *echo effect*: when the given numbers are odd, the percentage of correct answers using a pair of odd numbers is 62.59%.

3. The task 2s. (k) $6 - \square = 8 - \square$

A-priori analysis. This task is also open with the first number determining the second. Moreover, if restricted to natural numbers, the subtrahend must be less than minuend. The location of boxes may invite the following answer $6 - \boxed{6} = 8 - \boxed{8}$, a solution using 0 as result of both members of equality. Alternatively the neutral role of 0 when subtracting could be employed e.g. $6 - \boxed{0} = 8 - \boxed{2}$. For other aspects the a-priori analysis of this task is similar to the previous one. We expected a wrong relational thinking answer in the ‘commutativity’ of subtraction, i.e. the answer $6 - \boxed{8} = 8 - \boxed{6}$.

A-posteriori analysis. 1,056 students were given the question; 953 responded, 762

2s.k) $6 - \square = 8 - \square$	rate of success	rate of re- sponse $6 - \boxed{6} = 8 - \boxed{8}$	rate of re- sponse $6 - \boxed{0} = 8 - \boxed{2}$	rates of commonest right answer $6 - \boxed{2} = 8 - \boxed{4}$
Grades 2-5	61.09%	3.16%	2.76%	31.58%
Grades 6-8	76.06%	2.78%	1.05%	38.12%
Grades 9-11	80.15%	1.90%	3.43%	28.57%
χ -test	9.33E-7	0.24	0.24	0.09
Global sample	72.16%	2.76%	2.86%	35.17%

Table 4: The relational thinking presence and the commonest right answers to 2s. (k).

did so correctly (success rate 72.16%), suggesting that this task was relatively easy even if slightly harder than 2a. (k). Table 4 summarises the use of relational thinking. The *echo effect* appeared to be present as 56.17% of the right answers used pairs of even numbers. The *even parity* criterion is present in 87.20% cases. In this case the commonest correct answer is similar for all grades. Again we could argue that the commonest right answers were influenced by the fear of using 0 combined with the *echo effect*. The commonest wrong answer was $6-\boxed{2}=8-\boxed{2}$ (12.04% of the 191 wrong answers) and we could consider this kind of response motivated by application of TFN twice assuming that the second box is filled in first. Of the wrong answers, the structural, but incorrect, response $6-\boxed{8}=8-\boxed{6}$ was given in 4.19% cases. The value 0.09 of the χ -test show that the differences among grades classes are not statistically significant.

4. The task 3a. (k) $\square + 21 = \square + 11$

A-priori analysis. As above the task is open and has ‘freedom grade one’. The location of boxes may invite the use of commutative property of addition, i.e. $\boxed{11}+21 = \boxed{21}+11$. Moreover the neutral element of addition could reduce computation e.g. $\boxed{0}+21 = \boxed{10}+11$. Questions 2a.(k) and 3a.(k) have the same quantity of given numbers and addition symbols, but the boxes are differently placed: in 2a.(k) reflexivity of equality is at stake while in 3a.(k) the commutativity of addition is involved.

3a.k) $\square + 21 = \square + 11$	rate of success	rate of response $\boxed{11}+21 = \boxed{21}+11$	rate of response $\boxed{0}+21 = \boxed{10}+11$	rate of commonest right answer $\boxed{10}+21 = \boxed{20}+11$
Grades 3-5	60.52%	9.22%	2.84%	26.24%
Grades 6-8	72.17%	10.76%	4.48%	28.92%
Grades 9-11	80.92%	11.32%	4.72%	31.13%
University	94.64%	11.32%	6.60%	42.45%
χ -test	1.04E-10	0.94	0.57	0.03
Global sample	73.03%	9.14%	4.51%	30.54%

Table 5: The relational thinking presence and the commonest right answers to 3a. (k).

A-posteriori analysis. This task was administered to 1,094 students from grade 3 to first year of University: 979 responded with 799 of them giving the right answer (success rate 73.03%), comparable with the success rate for 2a. (k). Here *RT* appears to become more evident with increasing age. The use of 0 as the neutral element in addition is similar to that in task 2a. (k) but the commutativity of addition is more prevalent. Multiples of ten - excluding 0 - were found in 53.82% of the correct answers. The *even parity* criterion occurred in 83.86% responses. In 3a. (k) question the *echo effect* was not evident as 60.33% of the right answers had a pair of even numbers. The commonest wrong answer is $\boxed{32}+21 = \boxed{53}+11$ (6.11%). We hypothesize that the first box is filled in when the task is interpreted as $\square = 21+11$, in a sort of “Left Side Sum-LSS” modality. The completion of the second box is suggested by AAES modality (Alexandrou-Leonidou & Philippou, 2007).

In our opinion, the presence of two digit numbers had a double effect: the attempts decrease from 92.48% of 2a. (k) to 89.49% of 3a. (k) and this may be significant as the latter sample excluded 2nd graders but included first year university students. Secondly it may be that the presence of two digit number in this task activates a more attentive approach to the computation (the answers to other questions support this) and we could attribute to this attitude the greater presence of *RT*.

5. The tasks of type $a = \square$.

A-priori analysis. Behr *et al.* (1980) include examples of the type $a = a$, with given numbers and so we incorporated 2a. (l), $9 = \square$, and 3a. (n), $42 = \square$. To solve them one needs only apply the reflexive property of equality. These are closed tasks and do not require computation.

We anticipated that the absence of operational symbols would be destabilizing and

	9= \square success rate	9= \square with operational signs	42= \square success rate	42= \square with operational signs
Grades 3-5	76.67%	35.00%	70.82%	43.48%
Grades 6-8	73.17%	59.68%	72.98%	39.60%
Grades 9-11	67.94%	86.67%	67.94%	57.89%
University			92.86%	100%
χ -test	0.10	2.11E-6	1.53E-5	0.02
Global sample	74.01%	54.70%	73.70%	44.77%

Table 6: Comparison of results of the tasks 2a. (l) and 3a. (n).

The result in no answer or the use of operational symbols (cf. Behr *et al.*, 1980). location of the two tasks in their form allowed us to explore if there was a *tiredness effect*, influencing the rates of answer and success.

A-posteriori analysis. Task 2a. (l) was given to grades 2 - 11 (1,239) with 1,151 responding with 917 of correct (74.01%). The majority of incorrect answers (54.70%) express the result with operational symbols and the computation on the proposed numbers gives 9, showing a procedural interpretation of the sign =. The commonest answer of this kind is $9 = \boxed{3^2}$, in 44.53% of all ‘operational’ answers and was given by the majority of 6th graders and above.

Task 3a. (n), $42 = \square$, was given 1,190 grade 3-11 and 1st year university students, 1,049 responded with 877 of them giving the right answer (73.70%). The ‘operational’ answer rate is 44.77% and the commonest ‘operational’ responses were, globally, $40+2$ (19.48%) and $21+21$ (18.18%).

6. The task 2a. (m) $5 + 4 = \square + 6 = \square$

A-priori analysis. This task is the first which presents more than one equality sign. It is a closed task. The ‘chain’ of equality asks for the transitive property of equality.

Wrong answers suggest a lack of awareness of it. The most probable incorrect response is $5+4 = \boxed{9}+6 = \boxed{15}$ (cf. Alexandrou-Leonidou & Philippou, 2007).

A-posteriori analysis. 1,104 students responded with 718 giving the right answer (62.82%). As was expected the commonest wrong answer (70,47%) was $5+4 = \boxed{9}+6 = \boxed{15}$. This suggests either the pupils filled in the second box before completing the first or that they worked step by step from left to right. In either cases such results bring into question their intuition as Semadeni (2008) states:

“The transitivity of equality: “if $A = B$ and $B = C$ then $A = C$ ” was regarded by Fischbein (1987, pp. 24, 44, 59) as intuitively true. Piaget et al. (1987b, p.4) regards transitivity as an example of a systematic type of necessity...Transitivity is part of the deep intuition of equality (for numbers, for geometric points, for sets), involved in a multitude of deductive inferences.” (p.10)

7. The task 3s. (m) $48 - \square = 47 - \square = 46 - \square = \square$

A-priori analysis. This task is complex: it is open-ended, involves two-digit numbers, three subtraction signs and three equalities. Despite having four boxes to fill, it has ‘freedom grade one’.

3s.m) $48-\square=47-\square=46-\square=\square$	rate of success	$48-\boxed{48}=47-\boxed{47}=46-\boxed{46}=\boxed{0}$	$48-\boxed{2}=47-\boxed{1}=46-\boxed{0}=\boxed{46}$	commonest right answer rate $48-\boxed{3}=47-\boxed{2}=46-\boxed{1}=\boxed{45}$
Grades 3-5	56.99%	2.73%	9.09%	20.00%
Grades 6-8	56.91%	4.29%	12.29%	27.14%
Grades 9-11	60.77%	0%	7.59%	48.10%
University	83.04%	2.15%	6.45%	61.29%
χ -test	3.64E-6	0.22	0.29	6.5E-12
Global sample	60.19%	3.16%	10.28%	33.54%

Table 7: The presence of relational thinking regarding 0 and the commonest right answers to 3s.m).

To solve these questions correctly an explicit awareness of transitive property seems to be required. The task allows simple solutions involving *RT* and formal properties of 0 in many ways: $48-\boxed{48}=47-\boxed{47}=46-\boxed{46}=\boxed{0}$, or $48-\boxed{2}=47-\boxed{1}=46-\boxed{0}=46$. It is also possible to apply negative numbers, or fraction and so on, but no one did.

A-posteriori analysis. 896 – out of a possible 1,050 - responded with 632 giving the right answer (60.19%). The commonest correct answer reveals that the learners are at different levels of understanding, growing with age, taking care of the additive decomposition of numbers by fives: $48 = 45+3$, $47 = 45+2$ and so on. The structural properties of zero were most common in first eight grades of schooling. 41 pupils gave incorrect answers (22.65%) applying the transitive property of equality only once. 47.51% of those who were incorrect responded $48-\boxed{1}=47-\boxed{1}=46-\boxed{1}=\boxed{45}$.

CONCLUSIONS

The questionnaire enabled us to explore a phenomenology linked to relational thinking expressed by the reflexive, symmetric and transitive property of equality, the roles of zero respect to addition and subtraction and the commutativity of addition.

Our study is peculiar in the variety of schools and age range sampled. In this sense other similar experience known in literature took place in smaller school, segments. Another feature of our paper is that we are interested here in the right answers, even if sometimes we quote, also, wrong answers. Our research would have been more rigorous had we selected the sample statistically. Therefore our paper cannot be used for drawing general conclusions, statistically sound, about relational thinking, nevertheless in our feeling it might open a new trend of study about the equality, pointing out that this subject needs an attentive reflection regarding the way and the time in which the concept of equality is presented (in itself), let it grant that is introduced somewhere and somehow.

Overall primary school pupils were slightly better (even if in many cases differences are not statistically significant) than the older respondents in their application of relational thinking in specific tasks, but the presence of two-digit numbers appeared to hindered them. Nevertheless, a small but significant group demonstrated structural thinking provoking the question of how to extend such thinking to others. The transmissive teaching methods in Italy may explain why relational thinking does not appear to improve between grades 6 and 11 even if the structural properties of operations are taught explicitly, suggesting a parallel presence of relational and procedural thinking, independent from teaching. For symmetry our pupils confirmed the Attorps & Tossavainen (2007) results with prospective teachers.

There was a global score progression with increasing age. Addition questions were easier than subtraction; generally, pupils responded more appropriately to one digit answers than to two digit problems. Answering more complex questions under conditions of stress (e.g. tiredness) suggests that the students possessing a 'reified understanding' (described by Sfard (1991) as 'being able to see something familiar in a different light') of formal properties have an important tool which saves time and mental energies. Students who were aware of formal properties tended to cope better than others under conditions of complexity and stress. The prevalence of such knowledge was low however and in some cases appeared to decrease with age despite such topics being introduced in Italian Secondary School. Few participants (even from University) reificated the reflexive property of equality, and the function of zero in addition and subtraction. The commutative property of addition was more apparent. The more complex nature of the statements of symmetry and transitivity of equality do not necessarily indicate their presence, but only their absence. The sub-sample of university students appeared to have the awareness of these arithmetic tasks, but, surprisingly, more than 1/5 of the sub-sample responded to 3s. (m) incorrectly with

more than $\frac{1}{3}$ of them revealing a lack of a global view, answering $48 - \boxed{1} = 47 - \boxed{1} = 46 - \boxed{1} = \boxed{45}$, and of the transitive property of equality!

NOTES

[1] The authors gratefully acknowledge the support of the British Academy (Grant no. LRG-42447) which provided a platform for this study.

[2] The questionnaire presents 54 questions divided in four forms: 2a, 2s, 3a, 3s (the digit refers the grade of primary school and the letter 'a' is for addition and 's' is for subtraction). The integral version of questionnaire and the report of results are available at the web-site <http://www.unipr.it/arpa/urdidmat/M2ip>.

[3] When a solution is uniquely determined, e.g. $32 + 25 = \square + 16 = \square$ we use the adjective 'close'; whenever the solver is free to choose the suitable numbers, e.g. $48 - \square = 47 - \square = 46 - \square = \square$ we use 'open'.

[4] Italian children start school 6-years-old. Primary school comprises five grades; stage one of secondary school, grade 6, 7 and 8, and the final stage of secondary school 9 to 13.

STRUCTURE OF ALGEBRAIC COMPETENCIES

Reinhard Oldenburg

Institut für Didaktik der Mathematik und Informatik

Universität Frankfurt/M., Germany

This paper reports a research study that aims at understanding interrelationships between algebraic abilities. Theoretical considerations drawn from the literature suggest various interconnections. To gain empirical evidence a test was developed and the findings analyzed by fitting different statistical models.

INTRODUCTION

Ideally, algebra lessons lead students to develop a profound understanding of algebraic concepts and the ability to see algebra as a central and connected branch of mathematics and the ability to apply algebra to a wide range of topics. If this happens, then students can be said to have a high algebraic competency. Even with this aim in mind, it is not clear how to design algebra courses. There are many approaches to the teaching of algebra (see e.g. Bednarz et al. 1996) and they obviously differ in the algebraic concepts that are given priority. The field of algebraic concepts is very broad, e.g. mastering the concept of an equation is a long process in which various aspects of the equation concepts are learned and they all interact with other algebraic concepts. To help in planning the algebraic learning process, it would thus be useful to gain more insight into the inner structure and dependencies of these algebraic concepts.

Such insight can be expected from empirical studies of various designs. Interpretative studies are valuable and some have been performed, especially as they allow to link theory and observations. However, they usually focus on a small number of students and it often remains unclear, how representative they are. Quantitative studies, on the other hand, often lack a deeper connection to theories.

The quantitative study reported here tries to apply advanced statistical models on a test that was developed to reflect certain theoretical assertions about the learning of algebra. In this paper, only results from a single use of the test are reported but this study is part of a larger research project that will collect longitudinal data as well.

THEORETICAL FRAMEWORK AND RESEARCH QUESTIONS

Algebra deals with a lot of objects, including numbers, variables, expressions, functions and relations, and each of these can play many different roles. School algebra thus is composed of many ingredients. Several theories have been developed that give some structure to this large field and we will mention some of them that were used implicitly in our study.

Variables play the central role in our investigation because they are a link between most of the other objects mentioned. Variables are used in many different ways in algebra. Küchemann (1979) gave six ways of using variables. From the perspective of

integrating these modes of variable usage into a scheme we found that these modes, although useful in explaining students results, are bit unhandy. When looking at algebra problems from textbooks we found that his “Letter ignored” is not of great importance and test items regarding it seem always a bit artificial. Moreover, it may be subsumed to the aspect of a variable as generalized number. The use of a variable as a reference to a non-arithmetical object “Letter as object” is (which restricts itself to standard school algebra) an important misconception that is viable only in a very limited subset of algebra. As a misconception it should not be included into the structure of abilities that are to be mastered by the students. Malle (1993) gave a short list of three aspects which proved a bit coarse when classifying textbook problems and test items. A synthesis of these approaches that works well for the classification of the role of variables in different problems turned out to be very similar to the one found by Drijvers (2003) in his empirical study, see below. It is worth to make explicit the operations that are linked with the different roles of variables. This shall emphasize the fact that the role of a variable is not only determined by the algebraic context but also by the subject working with it, e.g. the x in $2x+1=4$ may be viewed as an unknown which is to be determined or as a placeholder where one can insert numbers or expressions.

- Placeholder P (operation: substitute (not only numbers but general expressions))
- Unknown U (operation: determine)
- General number G (undetermined; operation: expressing relations)
 - Ga: General number used in analyzing expressions
 - Gm: General number used for modeling (describing)
- Variable as changing quantity V (operation: change the value)
 - Vi: independent variable (operation: change at will)
 - Vd: dependent variable (operation: observe change)
 - Vr: variable in a relation without predetermination what variables is changed independently as in Ohm’s law $U=RI$.
- Variable as a symbolic element of the symbolic algebraic calculus: C (i.e. operation: use as structure-less object in symbolic manipulations)

Different researchers have advocated the point of view that mathematical objects are constructed from operations (Sfard 1991, Dubinsky 1991, Gray & Tall 1994). While the theories of these authors differ in detail, the broad picture seems similar and naturally explains e.g. the creation of symbolic expressions as encapsulated calculation sequences. It is not as clear to which processes the concept of a variable is linked. Therefore, we associated the above mentioned processes to each aspect of variables. Obviously, different operations lead to different objects, but nevertheless, mathematicians look at variable as a single concept which can be used under different aspects. It is therefore interesting to note that the operation of substitution has tight relations to all the other operations except those operations associated with the last aspect of the above list. We therefore formulate the following hypothesis:

Substitution is a central operation in algebra and the competence to use it properly is at the heart of algebra in the sense that it makes other operations easy as well, with the exception of the symbolic calculus aspect. Put in more technical language, this states that the ability to use substitutions should be a good indicator variable for performance in other algebraic tasks.

Checking the validity of this hypothesis is one of our research questions. The next question is much more open: To what extent do these aspects of 'variable' depend on each other?

METHODOLOGY

There exist many tests for algebraic achievement but most items test syntactic term rewriting or formal equation solving capabilities. Far fewer test items exist that assess algebraic understanding and algebraic concepts developed by the students. A notable exception is Küchemann's work in the late 70s and early 80s. For this study we developed a new test that is somewhat in the spirit of Küchemann and uses many of his items, but most items were developed to reflect the various aspects of variables described above. In addition, there were test items on the relation between equations and functions.

The study was conducted at the beginning of grade 11 (age approximately 16 years) of a German high school (Gymnasium). There were 141 students from six classrooms in the study. Unlike most other German schools this particular high school starts at grade 11 and thus collects students who were recently at a large number of different schools. Although this sample is not representative of German students, it can be expected to span the breadth of the population better than samples from classes that had the homogenizing effect of a common school culture. However, the mean achievement level is supposed to be below that of an average grade 11 high school.

The test was compiled for this study but most of the items had been used in our research group before. The test consists of 43 items, two of which are multiple choice items, while the others ask for a free form response. The answers were rated on a point scale as the following example of a rating rule indicated:

- Item 2a (from Küchemann 1979): Give a short answer and explanation: What is greater? $n+2$ or $2n$?
- 0 Points= no response; false response without argumentation
 - 1 Points= example; some explanation; wrong answer with detailed explanation
 - 2 Points= example with explanation; detailed explanation without case distinction
 - 3 Points= almost correct with case distinction
 - 4 Points= completely correct

Some examples of the test items are shown below; their association to aspects of 'variable' are shown in square brackets:

Item 4: (based on Küchemann 1979) Let r be the number of rolls and c the number of croissants bought at a bakery. A roll costs 30ct, a croissant is 70ct.

- a) What is the meaning of $30r+70c$? [G]
- b) How many parts have been bought all together? [G]

Item 6a,b,c (from Küchemann 1979): Work out the circumference of the following figures:

[G]

Item 9: a) Assume that the equation $a=b+3$ always holds. What happens to a if b is increased by 2? [V] (from Küchemann 1979)

c) Assume that the equation $a=2b+3$ always holds. What happens to b if a is increased by 2? [V]

Item 13: It is known that $x=6$ is a solution of $(x+1)^3 + x = 349$. How then can one get a solution of $(5x+1)^3 + 5x = 349$? [G] (from Küchemann 1979)

Item 14: Simplify the following expressions a) $(a-3)^2 - a^2$ b) $(x-x^3) \cdot (x+x^3)$ c) $\sqrt{36+4a^2}$ d) $\frac{1}{n} - \frac{1}{n+1}$ [C]

Item 16: Given the examples $7 \cdot 9 = 8^2 - 1$ and $11 \cdot 13 = 12^2 - 1$, formulate a general rule and justify it. [G]

Item 17: A function is defined by: $f(x) = x^3 - 2$. Determine

a) $f(2) =$ b) $f(y) =$ c) $f(x+1) =$ d) $x \cdot f(x) =$
[P]

Item 19: What must be substitute for x in the expression $2(x^2-1)$ to obtain the desired result? [P]

Desired Result	Substitute $x = \dots$
6	
-2	
$2((a+1)^2-1)$	
$2(b^2+2b)$	

The test items were classified by the aspects of variables they involve and by the relevance of the abilities to handle functions (Fun), relations (Rel), syntactical expression manipulation (Syn), working with unknowns (Unk), handling substitutions (Sub) and translating between algebra and geometry (Geo). Of course, this classification is build upon assumptions about typical solution strategies.

Besides more traditional statistical methods, this study uses structural equational modeling as a tool to model dependencies. While this technique is frequently used in many empirical sciences, it seems that its use in the mathematics education community not as widespread and I know of no application of this technique to gain insight

into concepts of algebra. However, I believe that this statistical tool is appropriate here, because it allows us to work with hidden variables that cannot be observed directly (e.g. the person's understanding of a variable as a general number) and to model relations among latent and observed variables.

RESULTS AND INTERPRETATION

The test contained several items developed and used by Küchemann 30 years ago. Despite the passage of time, our results were very similar, thereby underpinning the validity of his study. The order of empirical difficulty of the items turned out to be precisely the same as that found by Küchemann. Also the percentage of students that solved the items were remarkable close (despite the fact that we tested 16 year old students while Küchemann tested 14 year olds), with one interesting difference regarding the 'letter as object' aspect. We found Item 6a was solved by 74% while Küchemann found 94% (for 6b and 6c we found 74%, 58%, Küchemann found 68%, 64%). These numbers become interesting when combining with the result that item 4a was solved only by 14% and 4b only by 7%. Most students that failed on 4a showed a clear object interpretation reading $30r+70c$ to mean 30 rolls and 70 croissants. However, many more students were able to solve 6a and 6b, which are described by Küchemann as items that can be solved successfully using 'letter as object'. Using a variable as reference to an object should be differentiated into two aspects: The misconception that a variable can stand as shorthand for any object, and the conception that a variable stands for some measureable quantity, such as the length of a segment. This latter interpretation is at the heart of an approach to algebra by Davydov, Dougherty and others (see Gerhard 2008) that is suitable also for younger children. Interestingly, the sum of points of 6a and 6b show a correlation with the total test score of $r=0.62$ indicating that the ability to solve these items show much more than a misconception.

Next we gather some results from analyzing cumulative variables as described above. Together, these variables accounted for approximately 70% of all test items. According to the Kolmogorov-Smirnov-Test they can be considered to be normally distributed. Then a multivariate regression of the total score to these Variables was performed. The standardized beta-weights (with standard errors) were:

Variable	Standard. Beta(SE)
Syn (syntactic manipulation)	0.15(0.03)
Geo (geometry)	0.28(0.03)
Sub (substitution)	0.26(0.04)
Gen (working with general numbers)	0.22(0.04)
Fun (functions)	0.07(0.04)
Rel (relations)	0.38 (0.04)

The interpretation of these numbers must of course take into account that they reflect to some extent the composition of the test. There were eight items that were taken together to form the Rel variable, but only four that formed the Fun variable. Yet this can't explain the dramatic difference in beta weights. We conclude that understanding of algebraic relations is an important component of algebraic competency. It is also interesting that the Geo variable that consists of only five items is that important. One may draw the conclusion that expressing relations among quantities is at the heart of algebra. It is therefore justified to exercise this extensively in introductory algebra lessons.

Then an analysis of covariance gave first insight into interdependences. The interesting findings were: There is almost no correlation between the syntactic manipulation (Syn) and Geo ($r=0.09$), Sub ($r=0.09$), Gen ($r=0.10$), Fun ($r=0.13$), Rel ($r=0.02$). The scale Syn consists of item 14 (which has two more sub-items than shown) on the simplification of expressions and of two items on solving linear equations. The result means that syntactic manipulation and conceptual understanding are two different dimensions. The assumption implicit in some teachers position on teaching algebra that learning the symbolic algorithms will lead to insight seems thus to be false. To further support this point we give the following two-way table:

Number of students		Score on syntactical items	
		Above average	Below average
Score on other items	Above average	37	27
	Below average	36	41

The χ^2 -test gives $p=0.19$ on that, compatible with the assumption of independence (which is certainly not correct, but there is only a very weak relationship.)

This almost-independence result was stronger than expected and future studies should investigate this again. An interesting observation is that the connection is somewhat stronger for higher achieving students.

On the other hand the highest correlation ($r=0.63$) is between Rel and Subs. Subs also correlates with Geo ($r=0.44$), Gen ($r=0.54$) and Fun ($r=0.54$). All of these correlations are highly significant ($p<0.01$). This supports the hypothesis about the fundamental role of substitution given above.

Next, we report some results from the path model study. Although this interpretation was not intended by Drijvers (2003) we made up a structural equation model (more specific, a path diagram) from his diagram given below (Fig. 1). The model fit was acceptable according to Hair's (Hair et al. 1998) recommendations with $CMIN/df=1.96<2.0$ and Parsimony-Adjusted Measure PCFI=0.56. We found that the concept of placeholder loads most on the changing quantity (our role V of a variable; path weight and standard error: 1.14(0.48)), then on Unkown (U, weight 0.37(0.12)) and negligible on the generalizing aspect (G, weight 0.08(0.04)). The other arrows

carry small weights as well. While the first two results are plausible, the question arises what influences the important aspect of a variable as a generalized number if not the placeholder aspect.

Fig. 1

The following model (Fig. 2) includes all of our five variable aspects. The latent variables are named by the short cuts of the variable aspects defined in the theory section. This model provides almost good model fit $CMIN/df=1.53$, $PCFI=0.67$. Nevertheless many of the estimates for regression weights are rather small and we will refine and modify the model shortly to get better results. Nevertheless this model shows some interesting results. First the arrows that relate the calculus aspect C with other aspects carry small weights. This feature is common to all models we tried and reflects the fact mentioned above, that syntactic manipulation is almost independent from the rest of the test. Another interesting fact is that there is a substantial (and significant) weight for the arrow from G to V. This is naturally interpreted as the implication that a general number can be viewed as standing for changing numbers. On the other hand, students learning algebra may first master the aspect of changing quantities and only later develop the general concept of a variable that stands for a general number without reference to a particular number. Therefore we omit this arrow in later models.

Fig. 2

The above path-model can be refined by splitting the aspect of general number as indicated in the theory section into the aspect of using the general number for analyzing

or for modeling. Furthermore, we will omit the syntactic aspect of a variable as an element of algebraic calculus, because it is essentially independent from the rest. With these decisions made we tried out many linear structural equational models but concluded that the following one is the best choice. Some other models provide a slightly better model fit, but this model (Fig. 3) has two important properties: It is plausible from the theoretical point of view and can therefore be easily interpreted. Its advantage from the statistical point of view is that most of its path coefficients are either significant or close to significant. The model fit is adequate with $CMIN/df=1.92$ and $PCFI=0.55$. The estimates for regression weights (with standard errors in parentheses) are:

Place holder P	→	Unknown UK	0.15 (0.07)	
Place holder P	→	General Number Ga	0.031 (0.024)	
Place holder P	→	General Number Gm	-0.003 (0.341)	
≈0				
Place holder P	→	Variable V	-0.76(0.42)	
Unknown UK	→	General Number Ga	0.30 (0.16)	
Unknown UK	→	General Number Gm	-0.64(2.8)	
≈0				
Unknown UK	→	Variable V	6.6 (2.0)	
General Number Ga	→	General Number Gm	2.5 (1.9)	
Variable V	→	General Number Gm	0.077 (0.44)	
≈0				

Fig. 3

Compared to the above model based on Drijvers diagram it may seem strange that the arrow $P \rightarrow V$ has a negative weight. This result does not claim that there is a negative correlation between these abilities but only that the direct influence is negative taking into account the large influence from the arrows $P \rightarrow UK$ and $UK \rightarrow V$ which both have positive weights. In fact, when omitting the $UK \rightarrow V$ arrow from the model, the arrow $P \rightarrow V$ gets massively positive (1.6). The negative weight in our model is therefore plausible: Learning to handle variables as placeholders may pave the way to seeing

variable as unknowns and this in turn helps develop the full concept; however students who can only deal with placeholders are unlikely to see variables as quantities that can change because a placeholder once filled with a number is constant.

The path weight for $G_a \rightarrow G_m$ was 2.5(1.9). When reversing the arrow it became negligible. This can be interpreted to mean that learning to analyze situations with variables is a prerequisite to modeling situations that are initially free of algebraic symbolization. On the other hand the aspect V is not helpful for algebraic modeling. This may give a hint that at the level of modeling situations by algebraic equations one is working at a rather high level where individual values of variables and their change is not considered. We hypothesize that the aspect of change is not important in forming the model but in its validation. But this conclusion can't be drawn from the data of this study.

Is it possible to assign students a single latent variable “algebraic competence”? To test this we fitted two simple models to the data. One model with only one latent variable “algebraic competence” and one model with latent variables “Univariate” and “Multivariate”. The model with two latent variables has a model fit of $CMIN/df=1.78$, while the model with a single latent variable has a model fit of $CMIN/df=2.99$. This substantial difference may be seen as support for the hypothesis that algebraic competency is a higher dimensional construct, because here we have a higher dimensional modeling that fits the data better. Nevertheless, the test as a whole fits the assumptions of the one-dimensional Rasch model. Hence we conclude, that structural equational models can reveal detailed results.

CONCLUSION AND OUTLOOK

The findings of this study lead to two different kinds of conclusions. The first kind concerns the results from analysis of covariance and fitting the structural models. They indicate that the activities of describing general geometric situations algebraically are good indicators for overall performance. Similarly, substitution is a fundamental operation in algebra that shapes the meaning of algebraic constructs.

The second kind of conclusion concerns the level of algebraic competency reached in grade 11 and this is more specific to the situation in Germany (although the study does not claim to be representative for all German schools). While some areas (in particular, solving linear equations and using binomial formulas) show acceptable results, other parts of algebraic thinking, especially those that serve as a backbone in introductory calculus courses, reveal a serious lack of competence. Either a solution has to be found to cure the algebra decrease or one should consider curricular changes in grades 11 and later that eliminate the need for those kinds of algebraic thinking; however, this would mean dropping calculus from the curriculum.

The future work of this research project is aimed at improving the situation. In collaboration with schools we aim to use this test as diagnostic instrument to help us assign tasks that will improve the construction of algebraic meaning. This includes the

use of new algebraic technology (Oldenburg 2007) and the use of experiments (Ludwig & Oldenburg 2006).

GENERALIZATION AND CONTROL IN ALGEBRA

Mabel Panizza²⁶

Universidad de Buenos Aires (CBC), Argentina

This study addresses the importance of a pedagogical approach that contemplates generalizations students make spontaneously, due to the high value generalizations have in the learning of algebra and the construction of mathematical rationality. I consider the problem of the control of spontaneous generalizations, from the perspective of both didactic interventions and student's learning. I analyze the problem of the internal validation in the case of algebraic writings. I show various examples of pre-university students' (17-18 years) spontaneous generalizations and handling of control. The study suggests the necessity to face this problem from the beginning of the secondary school.

INTRODUCTION

Algebra constitutes a domain which favours the progress of mathematical rationality from the beginning of secondary school, through reasoning involving generalization. Moreover, generalization processes are of a great value in the production of knowledge (personal and scientific) (Garnham & Oakhill, 1993).

The ability to generalize is a common faculty of human reasoning, not specific of any content, which raises (not content-specific) learning questions. However, the ability to generalize in a particular domain involves specific learning problems within this domain. Various authors have considered the question of generalization in algebra, and favouring generalization activities is now seen as being an approach to algebra (see Bednarz, Kieran, Lee, 1996). Specially, justification related to generalization processes has been considered by Radford (1996) and, from a different perspective, by Balacheff (1987, 1991), amongst others.

However, students do not generalize only when faced to **generalization activities** (so as to find numerical or geometrical patterns, laws governing numbers, or the construction of formulas, etc). They also make generalizations in the context of tasks which do not require finding any regularity. This is what we call **spontaneous generalizations** (Panizza 2005a, 2005b).

From the point of view of the teacher's interventions, this sets the problem of anticipation. How can the teacher be attentive to the emergence of such spontaneous processes? Moreover, the student perceives differently the necessity to justify generalization, according to the more or less spontaneous character of the generalization, inasmuch as mathematical rationality is under construction.

26 mpanizza@mail.retina.ar

On the other hand, algebraic environment differs clearly from numerical and geometrical environments from the point of view of the *feedback* given to the student's activities.

It is important to consider this question in a systematic way through the various approaches to algebra (described in Bernardz, Kieran, Lee, 1996), which provide very different contexts for the emergence of such processes; in particular, from the point of view of the possibilities of control within algebraic environment or by means of conversion to other semiotic 'registers' (Duval, 1995, 2006).

I claim that such a pedagogical approach in the domain of algebra may favour the construction of mathematical rationality in secondary school.

RESEARCH METHODS

The data presented in this paper were obtained through qualitative methods: observation of regular classrooms and case studies, focusing on student's reasoning when analysing statements written in symbolic language. The research was conducted within four different pre-university (17-18 years) algebra courses.

The observations were conducted in a systematic way. A set of tasks was selected to be administered in class by the teacher, in order to observe the procedures of students when analysing statements written in symbolic language, especially when trying to determine conditions under which algebraic statements are true. Special attention was directed to: the verbal and symbolic descriptions students produced, based on their observations and descriptions of objects of reference of statements (instantiations); its influence on the processes of statements (re)formulation; the *treatments* (in the sense of Duval) they do within the algebraic writings register and the capacity for going over from the formulation of statements in symbolic language to a representation of the statement in other register (*conversions*, in the sense of Duval), very especially the use of this capacity for control. The data consisted of notes from classroom observations and the student's written works.

The study allowed identifying some phenomena among which the different kinds (according to its origin) of *spontaneous generalizations* presented in this paper.

For the case studies, four students that were considered representatives of the studied phenomenon were chosen from the algebra courses (their real names have been changed in this paper). The intention was to find specific features related to spontaneous generalizations, through mini-clinical interviews, all of them audio recorded. The reactions of students facing counterexamples provided by the interviewer in the context of their spontaneous generalizations, together with their perception (or lack of it) of the necessity of control and their processes of control inside or outside the register of algebraic writings, were observed.

The study showed that students often do (new) spontaneous generalizations based on the counterexamples provided by the interviewer and that their spontaneous generali-

zations are based on *local associations* of few examples which are not representatives of the objects of reference of the statements.

SPONTANEOUS GENERALIZATIONS: WHICH? WHY? WHAT? WHERE? HOW?

What are the spontaneous generalizations? Why it is important to take them into account in the class of mathematics? In what contexts do they emerge? How?

Spontaneous generalizations: which?

Let us see some examples, taken from the observations in the algebra courses:

Faced to the problem “Find the real values of x such that $x^2 \geq x$ ”, Belén and María answered that “ $x^2 \geq x$ is true for every real number” without solving the equation, but they arrived there by different ways. Inquired by the teacher, Belén argued “*it is evident, the square of any number is always greater than the number itself!*”. María, instead, argued “*I have tried with several examples, 1, 2, 3, -1, -2, -3, and so...*”

Belén seems to have generalized to real numbers the property valid for natural and integer numbers (*extension of schemes of knowledge*, see Vergnaud, 1996). María seems to have done an *induction process*.

I wish to point out that both have done a generalization **even if the activity was not a generalization one**. It is also important to notice that both arrived to the **same conclusion** by **different ways** of reasoning. I will come back to this point. Nevertheless, both examples are very familiar. But let us turn to another one.

The problem:

“Decide if the following implication is true or false:

$$\forall x \in \mathbf{R}: (2x^2 > x(x+1) \Rightarrow x > 1)”$$

was given in class in order to analyze the algebraic competence of students to decide the relation between the solution sets of two inequalities - in an implication context -. Brenda’s production is especially illustrative of the “problem” of **spontaneous generalizations** arising within the frame of a task.

When solving it, Brenda considers diverse examples, $x = 0$, $x = 1$, $x = 2$, $x = 3$, $x = -1$, $x = -2$, $x = -3$, $x = -4$ analyzing the value of truth of the antecedent and the consequent in each case. She concludes, correctly, that the statement is false, because “*it is possible to find values of x smaller than 1 that fulfil $2x^2 > x(x+1)$* ”

The professor asks her to explain how she arrived at the answer.

Brenda says that “*-2, -3, -4 are counterexamples, because for them the antecedent is true and the consequent is false*”.

According to the task, Brenda could have finished there, but she adds, immediately:

“*Ah, it was $|x|$ what we should have put!, what is true is:*

$\forall x \in \mathbb{R}: (2x^2 > x(x+1) \Rightarrow |x| > 1)$ ".

According to my interpretation, Brenda makes a spontaneous generalization of the set of counterexamples used by her to argue ($x = -4$, $x = -3$, $x = -2$), and proposes a statement that she considers true. It is to note that the task did not require to find any regularity. Brenda does it spontaneously, perhaps with the intention of finding a true statement (Balacheff, 1987).

I want to draw attention to the fact that from the point of view of the logical complexity, Brenda could have analyzed the value of truth of her statement, since the original task was correctly solved and both statements required the same logical competences. Even though we can think about a greater difficulty to find the counterexamples - in as much these are in the interval $[-1,0)$ -, I want to point out that Brenda does not consider it **necessary** to analyze her statement, she does not even consider it at all. She displays her affirmation beyond. So?

So, spontaneous generalizations: why?

Because a large part of the learning achievements resides in the capacity to generalize. By generalizing students construct knowledge. The emergence of these processes in the class is most important, as much for the learning of algebra as for the development of the mathematical rationality.

But conclusions require validation. This necessity –as it is well known -, is acquired, if it ever is, in the very long term.

On the other hand, when the generalization is a spontaneous one and therefore it is not directly related to the task to be solved- as in the cases of Brenda, María and Belén- it is difficult for the professor to anticipate it. In addition, a same result can come from different processes of generalization, as in the case of María and Belén. This is about something that usually occurs in the class of mathematics, and it is difficult for the teachers to have appropriate resources of intervention. So?

So, spontaneous generalizations: what?

This problem has led me to consider the generalization trying to deal with this phenomenon in its diverse manifestations. To do so, I tried to find the student's processes of generalization in their amplest sense, such as those of transference of a domain to another one (see Sierpiska, 1995). I also consider extension of knowledge schemes as generalization, as it has been studied by Vergnaud (1996) in the domain of mathematics, by Leonard and Sackur (1990) through the notion of local bits of knowledge; and by Harel and Tall, -quoted by Mason (1996)- through expansive, reconstructive, and disjunctive generalization. So?

So, spontaneous generalizations: where?

I consider that the different contexts of use, the nature of the task, the forms that are used for representation, the meaning granted to the letters, can originate different types of spontaneous generalizations.

The contexts provided by different approaches to algebra must be studied from this point of view: these contexts, give rise to specific spontaneous generalizations? Are there particularities of these contexts in relation to the control possibilities? (Balacheff, 2001). So?

So, spontaneous generalizations: how?

Up to now, I have found a lot of spontaneous generalizations, and I find it fruitful to consider them as of different kinds. According to its origin (for a particular student in a particular moment), a spontaneous generalization may be of nature:

2. conceptual (based on the content to which the statement refers to), as Belén did in extending the range of an existing scheme (“*it is evident, the square of any number is always greater than such a number!*”);
3. logic (based on an inadequate understanding of logical connectors or rules of reasoning), as María did when considering that with several examples she had arrived at a true conjecture (“*I have proved it with several examples, 1, 2, 3, -1, -2, -3, and so...*”)
4. semiotic (based on an analysis of the content of the semiotic representation (Duval, 1995, 2006).

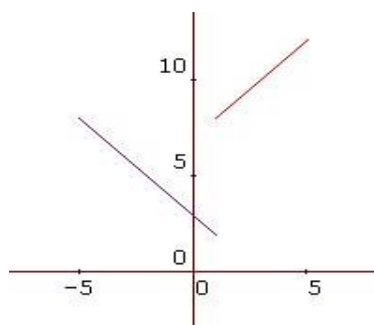

I think that this typology is interesting because it helps the teacher in the identification of leading elements of spontaneous generalizations on the part of the students, in the possibility of interpreting them and making them evolve.

Let us see an example of the later (semiotic) kind

Problem: Study the properties of the function

$$f(x) = \begin{cases} -x+3 & \text{if } x < 1 \\ x+7 & \text{if } x \geq 1 \end{cases}$$

Taking into account the habitual scales that students use to plot functions I posed the hypothesis that -looking at those graphs- :

students would decide the *injective character* of the function. And it is what 40% of the group of students actually did. They generalized the *content* of the graphic semi-

otic representation and decided that it was representative of the function in its complete domain.

As in the case of Brenda, the students who responded to the problem in agreement with our anticipation did not consider it even necessary to make a control.

In order to advance in this point, clinical interviews were made. Let us see the processing of control that Ana Paula makes, faced to a counterexample provided by the interviewer. Ana Paula had stated that the function is injective, having done an incomplete analytical study (she analyzed each branch ($x < 1$ and $x \geq 1$) of the function in isolation) and looking at the plot.

Let us see (minor episodes have been skipped):

The researcher suggests her to analyze the pair of values $x_1 = -6$, $x_2 = 2$

Ana Paula does some calculations

Ana Paula: Oh, yes, it's true...it is not injective... (*she thinks*)...What should I have put to see it was not injective? A negative number and a positive one?

Researcher: I don't know, you find out.

Ana Paula: I am searching so that they are the same... (*she thinks*)

Ana Paula: Of course, as $-x$ changes the sign it is as if I had two positives, one adds up 3 and the other 7, I must get the same result... (*she equals to 10, she thinks and finds -7 and 3*)

Ana Paula: -7 and 3... $(-7) + 3 = 3 + 7$, and thus I prove it is not injective

Researcher: Wasn't it proved with -6 and 2 ?...

Ana Paula: Yes, of course I had already verified it (*she still searches for counterexamples*)

Researcher: Why are you searching other counterexamples?

Ana Paula: Because if I had to do it again I would do it wrongly once again, because before I did it analytically, I verified it in the plot and I got the same result in both of them. Even more, I did a value table and I didn't put -6 and 2 . I don't understand where was my mistake (reviewing her previous works).

Researcher: aha...

Ana Paula: Has the difference between x_1 and x_2 to be constant?

Let's see, $x_1 - x_2$ equals to image

Researcher: Which image?

Ana Paula: Of both!... (*she gets at a loss in the calculations*).

Ana Paula: Oh no! There are going to be infinite providing the image is greater or equal to 8. What can I do to find them?

Researcher: The image of x_1 has to be the same as that of x_2 .

Ana Paula: I've already said it, it is the definition.

Researcher: You've said it but you didn't use it...

Ana Paula: Aha! (*she finally does some calculations and arrives to the equation*).

$$-x_1 + 3 = x_2 + 7$$

$$x_2 + x_1 = -4, x_1 < 1, x_2 \geq 1$$

To make control, Ana Paula analyzes the problem in various representations (graphical, algebraic, by tables) without integrating them. This example is representative of what happens with many students. Next I set out to analyze this problem, specially the problem of control related to the **algebraic writings**.

PROBLEMS OF CONTROL

Two aspects seem essential; on the one hand, the problem of the recognition of the **necessity** of control of the conclusions; on the other hand, supposing that the student has this ability, the problem of the **possibility** of making this control is posed (Panizza 2005b).

The problem of the necessity of control

In relation to the first point, perceiving the **necessity** of control is different according to whether generalization is a spontaneous one or it is obtained as asked for by the task. In the latter case, necessity of control is intrinsic to the task. Indeed, when someone **must** make a generalization, a suitable representation of the task should include the control necessity, that is to say the need to adjust the conjecture to the data. In addition, as Radford (1996) indicates "representations (in generalization) as mathematical symbols are not independent of the goal. They require a certain anticipation of the goal". That means, according to my interpretation, that in the **generalization activities** the control occurs like a process, during the resolution itself, through the re-representations that are made on the data, based on the analysis of the goal. On the contrary, for **spontaneous generalizations** the necessity of control is not intrinsic to the task, since generalization is not directly related to the goal. The examples of María, Belén, Brenda and Ana Paula are representative of this claim. However, many students may perceive this necessity. Ana Paula, faced to a counterexample provided by the interviewer, tries to control by shifting to other representations (graphical, algebraic, by tables). Anyway she does not succeed. This leads us to the problem of the **possibility** of control.

The possibility of control within the algebraic writings register

I claim that the **possibility** of control within the algebraic writings register is difficult as the retroaction does not work in the same way that in the arithmetical writings register or the material geometrical figures domain (Panizza & Drouhard, 2002).

In fact, in the arithmetical writings register, when students arrive by reasoning at an equality of the type $2 = 3$, this writing in itself gives them information that plays the role of an element of control.

In the same way, in the material geometrical figures domain, when, faced to the famous problem of extension of a puzzle of Nadine and Guy Brousseau (1987), the pupils make inadequate extensions, the fact that the resulting pieces do not fit, constitutes an element of control.

Algebra is quite different. As Drouhard (1995) shows, when students arrive at $(a + b)^2 = a^2 + b^2$ they believe that the teacher just “prefers another rule”, for instance $(a + b)^2 = a^2 + 2ab + b^2$ (“*You made a transformation and I made another one...*”).

This example illustrates a general problem: that the register of the algebraic writings does not offer the students good elements of feedback and control.

Rojano (1994) establishes a similar conclusion (quoting Freudenthal), when analyzing the differences of feedback of the errors in arithmetic and natural language - provided by numerical contexts and daily communication -, unlike the feedback in the register of algebra. However, these characteristics of algebra are not sufficient to determine the conduct of control of a particular student in a particular context. The possibility that certain information can act as a feedback also depends on:

3. the student’s abilities to “see” such information;
4. his possibilities to enter in contradiction (see Balacheff, 1987);
5. his capacity to deal with different types of statements (of existence, individuals, generals);
6. his linguistic skills on letters (syntax and semantics) (see Kirshner, 1989, Duval, 1995, Durand Guerrier, 1996, Panizza, Sadovsky & Sessa, 1998, Drouhard, Panizza, Puig & Radford, 2006);
7. his conceptual and operating skills on numbers, variables, unknowns and parameters (see Janvier, 1996).

I consider that an education that contemplates the fact that these skills are developed in parallel and in an interrelated way, must find didactic strategies for helping students to develop control means *inside* and *outside* the register of the algebraic writings. I adhere to the didactic frame of reference provided by Duval (ibidem) with the notion of *conversion* between different semiotic representation registers, especially for what control possibilities concerns.

CONCLUSIONS AND PERSPECTIVES

This study shows that pre-university students make different types of *spontaneous generalizations* in contexts of explanation, proof or discovery, without neither having acquired conscience of the necessity of justification of the conclusions, nor abilities for making control. From my point of view, this suggests the need of a pedagogical

approach at secondary school that considers educational interventions in front of the students' spontaneous generalizations, in order to help them to improve mathematical reasoning.

I think that much more research is still needed for that. Specially, concerning the spontaneous transferences -such as analogies and metaphors- of algebra domain to another one, and the different approaches to algebra as contexts of emergence of spontaneous generalizations, their particularities and problems of control.

FROM AREA TO NUMBER THEORY: A CASE STUDY

Maria Iatridou* Ioannis Papadopoulos**

*Hellenic Secondary Education **University of Patras

In this paper we examine the way two 10th graders cope with a tiling problem that involves elementary concepts of number theory (more specifically linear Diophantine equations) in the geometrical context of a rectangle's area. The students' problem solving process is considered from two perspectives: the interplay between different approaches relevant to the conceptual backdrop of the task and the range of executive control skills showed by the students. Finally the issue of the setting of modeling problem solving situations into number theory tasks is also commented.

INTRODUCTION

Modeling problem solving situations into generalization tasks related to number theory is useful for learning mathematics and includes two stages: modeling and solving the number theory tasks that emerge. On the one hand, solving generalization tasks dealing with number theory serves as a tool for developing patterns, as a vehicle towards appreciation of structure, as a gateway to algebra, as a rich domain for investigating and conjecturing at any level of experience (Zazkis, 2007). However despite of their significance number theory related concepts are not sufficiently featured in mathematics education. Consequently many issues related to the structure of natural numbers and the relationships among numbers are not well grasped by learners (Sinclair, Zazkis & Liljedahl, 2004). On the other hand according to Mamona-Downs and Papadopoulos (2006) when students have an accumulated experience on problem solving they can affect changes in approach and are able to take advantage of overt structural features appearing within the task environment. Moreover they can show a deeper understanding of the nature of mathematical generalizations. In their work which lasted 3 years they followed some students from the 5th grade up to their 7th with emphasis on problem solving techniques relevant to area. Three years later we follow two of these students who currently attend the 10th grade (15 years old) during their effort to cope with a non-standard task concerning problem solving activity relevant to elementary number theory concepts. The case is interesting since it displays executive control skills related to the way the students proceed when they have to work on a new domain and to the handling and establishment of a 'model' that could lead to the generalization. This is why we try to explore in this paper the interplay of the students among different approaches during their problem solving path towards generalization and at the same time to refer to the actions of the students concerning decision making and executive control. In the next section we present the task and describe the students' background. After that in the next two sections we present the problem solving approaches followed by our students (Katerina for the first, Nikos for the second). These are followed by a discussion section trying to shed

light on these two axes (i.e., the interplay and the control issues) and finally the conclusions.

DESCRIPTION OF THE STUDY AND STUDENTS' BACKGROUND

Katerina and Nikos were 10th graders and they had participated in an earlier study conducted by Mamona-Downs and Papadopoulos (2006) aiming to explore and enhance the students' comprehension of the concept of area with an emphasis on problem solving techniques for the estimation of the area of irregular shapes. Their participation in this resulted in the creation of a "tool-bag" of available techniques as well as in an accumulated experience on the usage of these techniques. The conceptual framework now mainly lies in number theory. However in the official curricula (for 10th graders in Greece) the only reference to number theory concepts is a tiny one commenting the divisibility rules for the numbers 2, 3, 5, 9, 10.

This is the problem we posed to the students:

Which of the rectangles below could be covered completely using an integral number of tiles each of dimensions 5cm by 7cm but without breaking any tile?

Rectangle A: dimensions 30cm by 42cm

Rectangle B: dimensions 30cm by 40cm

Rectangle C: dimensions 23cm by 35cm

Rectangle D: dimensions 26cm by 35cm.

For each rectangle that could be covered according to the above condition show how the tiles would be placed inside the rectangle.

Now, we want to cover a rectangle with an integer number of (rectangular) tiles. Each tile is of dimensions 5cm by 7cm. What could be the possible dimensions of the rectangle?

The mathematical problem is: define a set of necessary and sufficient conditions on a , b so that there exists a rectangle of dimensions a by b , that can be covered completely with tiles of dimensions 5 by 7. Look at the side of length a : if there are s tiles that touch it with the side of length 5 and k tiles that touch it with the side of length 7, then $a = 5s + 7k$. The same reasoning applied to b gives $b = 5s' + 7k'$, where s , k , s' , k' , are non negative integers. Now if c denotes the total number of tiles used then the area ab of the rectangle should be $35c$. Therefore 35 divides ab . Thus, there are three cases: i) 35 divides a , ii) 35 divides b , or iii) non of the previous, but since 35 divides ab , 7 must divides a and 5 divides b (or vice versa). Consequently, a and b should satisfy one of the following necessary conditions: i) $a = 35m$, $b = 5s' + 7k'$, ii) $b = 35n$, $a = 5s + 7k$ iii) $a = 7q$, $b = 5t$ (or vice versa). It is easy then to be shown, that these conditions are also sufficient. Thus, even though the context of the task seems to be geometrical with its relevance to area, however a crucial aspect in solving the task is the usage of a Diophantine linear equation $ax + by = c$ where the unknowns x and y are allowed to take only natural numbers as solutions. The task consists of two parts. In the first part

four rectangles have been carefully selected to help the solver when finishing the first part to be able to reach the generalization asked in the second part.

The problem solving session lasted one hour, without any intervention from the researchers, and the students were asked to vocalize their thoughts while performing the task (for thinking aloud protocol and protocol analysis, see Schoenfeld, 1985). Protocol analysis gathered in non-intervention problem-solving session is considered especially appropriate for documenting the presence or absence of executive control decisions in problem solving and demonstrating the consequences of those executive decisions (Schoenfeld, 1985). The students' effort was tape-recorded, transcribed, and translated from Greek into English for the purpose of the paper.

THE FIRST PROBLEM SOLVING APPROACH - KATERINA

Katerina's first criterion for deciding whether the four rectangles can be covered completely by the tile was based on whether the dimensions of the four rectangles were multiples of the dimensions of the tile. This is why her answer was positive only for the rectangle A (since $30=5*6$ and $42=7*6$) and negative for the remaining three ones. She used the quotient of their areas ($E1/E2$, $E1$ the area of rectangle A and $E2$ the area of the tile) as a way to determine the number of the tiles required for the covering and not as a criterion to decide whether the tiling is possible). She tried then (according to the task) to show how the tiles will be placed inside the rectangle. The visual aspect of this action made the student to realize her mistake and to re-examine the four rectangles:

K.1.23. The tiles could be placed in any orientation in the interior of the big rectangle.

K.1.24. It is not necessary to be placed all of them in a similar orientation.

After that she verified that the rectangle A could be covered according to the task's statement. For the rectangle B she worked with an interplay between an arithmetical and geometrical-visual approach and she realized that the case of tiles with different orientation could mean that she could work with an 'equation' since she was not able to proceed geometrically. Now, it is the first time a linear combination is involved:

K.1.37. It could be $5x+7y=30$

K.1.38. It must be a rectangle with length of 30cm and this has to be expressed with tiles of length 5cm and 7cm.

She was not able to express her thought using proper mathematical terms. Her intention was to say that this equation did not have integer solutions (the case for an unknown to be equal with zero is excluded). So she decided to use terms such as 'round numbers' to show that it is needed for x and y to be integer numbers:

K.1.42. However this case is not possible... (*the above mentioned equation*)

K.1.43. We could not expect to have 'round' numbers for x and y .

For the rectangle C she decided to rely on the question whether the length of the side of the rectangle could be written as a linear combination of the dimensions of the tile. The lack of relevant knowledge on this domain provoked a certain technique for

overcoming this difficulty. She worked with successive multiples of 7 plus the remainder (expressed in multiples of 5). She followed the same line of thought for the rectangle D. The criterion of the linear combination was already established and by the technique of the successive multiples she founded that:

K.1.67. For the side of 26cm it is necessary to have 3 tiles of length 7cm and 1 tile of 5cm.

Immediately she turned to the visualization in order to verify that indeed this can be done, working independently on each dimension of the rectangle D (Fig. 1, left).

For the second part of the task she started with two steps that according to her opinion could help her:

K.1.74. I will use drawings because it seems to me easier in that way

K.1.76. How could I use the findings of the first part of the task?

She rejects the condition of E1 being an integer multiple of E2 as the unique criterion since:

K.1.87. ...it might be necessary for a tile (or some tiles) to be split.

Her model for finding the possible dimensions of any rectangle that could be covered by tiling using an area unit (tile) with dimensions 5 by 7 includes two cases exploiting her previous findings of the first part of the task.

Fig.1 Katerina's (left) and Nikos's (right) visual approach on rectangle D

So, in the first case:

K.1.92. If all the tiles are oriented uniformly then the asked dimensions of the rectangle could be multiples of 5 or 7.

K.1.93. I will make a draw

K.1.94. It is a shape whose length is multiple of 7 and its width multiple of 5.

The second case resulted mainly as a consequence of the rectangle D and two conditions must be satisfied: one side must be multiple of the Least Common Multiple of the dimensions of the tile and the second dimension linear combination of them.

K.1.101. Length must be common multiple of 7 and 5 whereas width must be sum of tiles that are oriented some of them horizontally and some vertically.

She tried then to refine her model asking for a rule that governs the common multiples of 5 and 7 (i.e., of 35). For the number 5 she knew the divisibility rule (the last

digit must be 0 or 5). However she could not give any rule for the 7 or the 35. Finally she concluded with a recapitulation of her model trying to describe in a more formal way the second case of the model:

K.1.110. The rectangle in the second case should have one of its dimensions common multiple of both 5 and 7 and the other one sum of multiples of 5 and 7 at the same time.

THE SECOND PROBLEM SOLVING APPROACH - NIKOS

Nikos's first step was to interpret the statement of the problem in terms of conditions for the correct tiling: a) there is a rectangular region that has to be covered and b) the tile is a structural element of the task:

N.1.5. It means that each rectangle must be covered and for the measurement I must use an integer number of tiles

N.1.6. So we could consider this rectangle of 5 by 7 as a measurement unit

In his work and for each one of the four rectangles we can distinguish a concrete line of thought. For the rectangle A, his criterion was (as in Katerina's case) the proportionality of the sides, i.e. whether the dimensions of the rectangle were multiples of the dimensions of the tile. We have to mention here that his way of reading the task was non-linear in the sense that he did not follow the instructions of the task in the given order. Thus, he did not initially give answers for all the rectangles but after deciding for each rectangle, he proceeded to the specification of the way the tiles could be placed in the rectangle. In case there was not proportionality among the lengths of the sides of the rectangle and the tile -as it happened in the rectangle B- he used the criterion of $E1/E2$ as a way to ensure a negative answer. This quotient was not an integer number and this meant that there could not be coverage according to the task's statement. As he explained:

N.1.20. Because the ratio of their areas is not an integer

Now, in the rectangle C, the $E1/E2$ was an integer but the dimensions were not proportional. It is interesting the fact that his decision about $E1/E2$ is justified by the fact that $E2(=35\text{cm}^2)$ is a factor of $E1(=23*35)$, a relationship often overlooked even by pre-service elementary school teachers (Zazkis & Campbell, 1996). In their study and in an analogous quotient, teachers first calculated the product and then divided. At that point, Nikos asked for the linear combination that satisfies one of the dimensions since the second is multiple of 5:

N.1.24. When the area is 23 by 35, then obviously this product is divided by 35 which is the area of the unit (*tile*)

N.1.27. The point is **the way** the tiles must be placed

N.1.29. We could have $3*7+2$, $2*7+9$

N.1.34. $5+5+5+8$, $4*5+3$,....

N.1.35. For the 23 cm I can't make any **combination** of 5s and 7s.

In the rectangle D, he applied directly the rule of the linear combination that could satisfy the side of 26cm since the other one (35cm) was multiple of 5 (Fig.1, right). Trying to describe how the tiling will take place he worked initially independently on each side. However the way the tiles will be placed in one dimension affects the way the tiles will be placed in the second. This made him to turn towards a consideration of both dimensions at the same time. Despite this method could be considered adequate for him to give an answer for each rectangle, he preferred to re-check all the given rectangles, to verify his answers before making his final decision.

For the second part of the task he started with an impressive conjecture:

N.1.83. Obviously, if we want to cover a rectangle with this specific unit of dimensions 5 by 7, then the rectangle's sides must be the sum of multiples of 5 and 7 at the same time.

N.1.84. The case of $0 \cdot 5$ and $0 \cdot 7$ must be included in this.

However he still considers the two dimensions separately. Trying to figure out what would be the general case for the asked dimensions of the rectangle he created some arithmetical examples, fulfilling the need for linear combination for each dimension, without considering the fact that there is an interrelationship among the two dimensions since the area of the rectangle must be a multiple of 35:

N.1.102. We could say that $a=5x+7y$ (where 'a' is one of the rectangle's dimensions)

N.1.103. and similarly $b=5z+7w$

N.1.104. The product of these dimensions a and b will be the area

N.1.105. I can choose for a and b any sum of multiples. For example, $a=5+14=19$, $b=15+28=43$. So, the area is $19 \cdot 43$

N.1.106. However in that case I have for the area a number that is not divided by 35.

N.1.107. So, 35 must divide the product $a \cdot b$ which is the area of the rectangle.

N.1.112. Thus, $a=5x+7y$, $b=5z+7w$ and the quotient $ab/35$ must be an integer.

Trying to establish a model that would describe all the possible cases he was also influenced by the four rectangles of the first part of the task. He decided that his model would include two types of rectangles:

N.1.141. The first type concerns rectangles with one side multiple of 5 and the other multiple of 7. So, $a=5x$ and $b=7y$, which is $a=5x+0 \cdot 7$ and similarly $b=0 \cdot 5+7y$.

N.1.142. Consequently the area of such a rectangle divided by 35 gives an integer number as quotient.

N.1.154. And it is in accordance with the general form I conjectured earlier

For the second type he decided that:

N.1.159. One of the rectangle's side will be a sum of multiples of 5 and 7 at the same time

N.1.160. whereas the second side will be a multiple of 35

N.1.171. that is $a=5x+7y$ and $b=35z$

N.1.172. I think that these latter conditions form the most general form for the dimensions of any rectangle able to be covered with rectangular tiles 5 by 7.

After that, Nikos applied this most general form for each of the four rectangles examined in the first part to check the validity of this form. Furthermore he made clear that the first type of rectangles could be incorporated in the second:

N.1.188. ...to incorporate the first type which essentially is a special case in the second type which is more general..

Finally Nikos proceeded to a refinement of his model determining the circumstances that do not allow a rectangle to be covered according to the task giving a certain counterexample:

N.1.213. The second side must be always multiple of 35 and it can be constructed using either 5s or 7s.

N.1.218. This is the only solution because 35 is the Least Common Multiple of 5 and 7

N.1.219. This means that it is not possible to have a rectangle for which both its dimensions are linear combinations of 5s and 7s.

N.1.220. When I say that a is a linear combination of 5s and 7s, I mean that $a=5x+7y$ but not a multiple of 5 or 7.

DISCUSSION

In relevance to our research questions we could make some comments on our field-work.

1. Interplay among differing modes of thinking

During their attempts to solve the problem the students worked in tandem with two pairs of modes. The first pair included the arithmetical mode and visualization. Both students started arithmetically even though the context of the task was relevant to area that is geometrical. Katerina from the very beginning used the visual aspect as a tool. She started arithmetically but when she was unable to proceed with numbers she preferred to make drawings that would help her (K.1.74). In the same spirit some times she moved from the visual context to algebra. At some point she clarified that the tiles could be posed not necessarily with the same orientation. However she was not able to proceed geometrically and she preferred to turn to algebra asking for an equation (K.1.37). Nikos did not choose to work with this pair of modes. He mainly worked arithmetically and he turned to the visual aspect only to show the way the tiles could be placed in the interior of the four rectangles in the first part of the task. The second pair of modes has to do with the way students dealt with the dimensions of each rectangle. Working with the first mode dimensions were considered by the students separately as two unconnected objects (arithmetical mode). Thus, they made calculations (they summed, multiplied, divided) to determine the way the tiles should be placed in one dimension. In the second mode the dimensions were interrelated (geometrical mode, relevant to area). The fact is that the way the tiles will be placed in the first dimension influences the way the tiles will be placed in the second dimension. Working independently in two dimensions does not guarantee that the total area of the rectangle will be integer multiple of 35 which is the tile's area. Both students made successive movements between these two modes. Their initial approach was to

work separately for each dimension and only then they made the connection about the interrelation of the two dimensions. For example in Nikos's work (N.1.102-N.1.112) it is clear that his working on the two dimensions separately resulted in a rectangle that could not be covered with integer number of tiles since its area was not multiple of 35.

As a result of this interplay emerges -for Nikos in particular- the issue of putting forward a set of conditions (N.1.112) that are evidently realized as being *necessary* and later an equivalent set of conditions (N.1.172) that are seen as *sufficient* (because the covering of the relevant rectangles can be explicitly constructed).

2. Executive control and decision making issues

The students realized many actions that indicate interesting executive control and decision making skills. Katerina rejected her initial approach which was based only on the criterion of proportionality among the rectangle's and the tile's dimensions. This was because her turn to visualization made her to realize that it was not necessary for the tiles to be placed in a uniform orientation. This turn seemed to be in practice an important act of control. The task's statement did not give any direction concerning the way the tiles could be placed inside the rectangle. It was up to her to interpret correctly the statement. Later when she tried to solve the Diophantine equation she applied the technique of the successive multiples. According to this technique if one has to solve the equation $ax+by=c$ starts with positive multiples of a and then examines whether c minus ax is multiple of b or vice versa (i.e., one starts with multiples of b). This is an act of control since the solving of the equation was dealing with the task's limitation to use an integer number of tiles without breaking any of them. When she decided to deal with the second part of the task her first thought was to use her previous results (K.1.76). Moreover, an important act of control was the 'model' she proposed for estimating the possible dimensions of any rectangle that could be covered with an integer number of tiles according to the statement of the task (K.1.92, K.1.110). She exploited her previous findings (the four rectangles of the first part), and progressively she established this 'model' checking step by step its accordance with these rectangles as also with examples generated by herself. The choice of examples is especially important since not every example facilitates a successful generalization. Nikos also made an analogous proposition of a 'model'. He was also based on the four rectangles of the first part of the task. The steps followed by his line of thought reveal presence of control: First look if there is proportionality among the dimensions. See also whether $E1/E2$ is not an integer. This means that your answer has to be negative. It is not necessary always to make the long division $E1/E2$. Instead, see whether $E2$ is factor of the $E1$ (N.1.24). Now if sides are not proportional and $E1/E2$ is an integer, then construct the Diophantine equation and apply a strategy to find integer solutions. He also used to check always the consistency of his generalization model against particular examples and this is important. The continuous checking of their steps that both students showed is especially significant as an act of

control since students checking is not usually part of the algebraic thinking of the students when they make generalizations (Lee and Wheeler, 1987). A capable problem solver recognizes a correct approach and insists on it. This evaluation of a specific approach could also be considered as an act of control. Nikos recognized the applicability of the linear combination and he used it to check the plausibility of his answers always according to task conditions (N.1.154). This often turn to the tasks' statement was a common pattern for both students. However, perhaps the most important act of control of both students was their effort to refine their model regardless of whether they succeeded. Katerina tried without success to achieve a condition for the second side to be common multiple of 5 and 7. Nikos however did manage to refine his 'model' determining whether it is impossible for a rectangle to be covered according to the task's requirements (N.1. 219). Such an asking for a counterexample actually is an important act of control.

CONCLUSIONS

According to Douady and Parzysz (1998) when a problem allows the solver to move between different modes during the problem solving process then an interplay between these different modes is caused. They claim that the effort of the solver to reach the solution results to the relations of these modes as well as to the usage of some tools that belong to each of them. Additionally "...this interaction provides new questions, conjectures, solving strategies, by appealing to tools or techniques whose relevance was not predictable under the initial formulation..." (p. 176). Both of our students were able to apply this interplay among two pairs of modes. In the first pair (arithmetical-visual) this interplay was used as a way that allowed overcoming difficulties about how to proceed or for verifying or checking the validity of an argument. In the second pair of modes the one mode (arithmetical, working on one dimension) was indicative of a surface understanding of the structural elements of the task. However it seemed that finally the students did show a deeper understanding of these elements through the other mode considering both dimensions at the same time (geometric, interrelated dimensions).

'Executive control' and 'decision making' constitute in general the issue of control in problem solving. Executive control is concerned with the solver's evaluation of the status of his/her current working vis-à-vis the solver's aims (Schoenfeld, 1985). In general, this requires mature deliberation in projecting the potential of the present line of thought, married with an anticipation how this might fit in with the system suggested from the task. In our study and despite their age, these 15-years old students showed considerable control skills in relation to the task's requirements on the one hand and the specification of the 'model' they proposed for solving the task on the other. The existed experience enabled students becoming capable to make generalizations.

Concluding we could refer to some final remarks that emphasize the significance of our results. It is common thesis that the task design is a crucial parameter for teaching

and learning algebra at every level. So, in reference to our work, we could claim that the setting of modelling problem solving situations into number theory tasks allows students to:

5. transfer knowledge from one domain to another during their successful interplay among different modes of thinking (algebraic thinking and geometrical one).
6. construct and propose a ‘model’ that possibly describes the situation and facilitates the generalization
7. generate examples that check the consistency of their model, and
8. generate counterexamples that result to the refinement of the proposed ‘model’.

Obviously it would be an exaggeration for these conclusions to be generalized since we dealt with two students and this study could be better considered as a case study. However these findings were encouraging enough to call for a design of a future research on these aspects of problem solving.

ALLEGORIES IN THE TEACHING AND LEARNING OF MATHEMATICS

Reinert A. Rinvold

Hedmark University College, Norway

Andreas Lorange

NLA College of Teacher Education, Norway

This paper explores how the concept allegory from literature theory can be used in the teaching and learning of mathematics. A cognitive allegory theory is developed in analogy with the metaphor theory of Lakoff and Johnson (1980). The theory differs from the traditional view. For instance an allegory is also a cognitive mapping and not only a narrative. The paper draws upon data from a study of how teacher training students learn the concept of linear congruence equations. The students are given word problems which were translated to congruence equations and later used to solve other word problems.

INTRODUCTION

Researchers like Lakoff, Núñez, Sfard and Presmeg have elaborated the role of metaphors in mathematics and mathematics education, see for instance Lakoff and Núñez (2000), Sfard (1994) and Presmeg (1997). Allegory is another concept from literature theory which so far has been sparsely used in mathematics education. In this paper we suggest that the concept of allegory can be applied to this field. Our contribution is to develop allegory as a part of mathematics education theory, in a way similar to how metaphors have been used in the tradition initiated by Lakoff and Johnson (1980).

METAPHORS AND ALLEGORIES

Traditionally a metaphor is a figure of speech in which a phrase denoting one kind of object or idea is used in place of another. An example is “You are straight on target with your reply.” In this view of metaphors “straight on target” is a figure which means something else. The phrase can be translated to literal speech, for instance “precise and relevant”. In cognitive metaphor theory metaphors are not as in the old traditional view, seen as isolated phrases, but as systems structuring concepts and thought. Such systems map one domain into another such that the target domain inherits structure from the source domain. An example is “argument is war”, Lakoff and Johnson (1980, p. 4).

Target is a concept from warfare. If an argument is compared to an arrow or a bullet, we can characterize the argument by describing how the arrow aims at the target. But,

the metaphorical mapping can also express lots of other things. An example is “The teacher went into a defensive position when faced with critique”. ‘Defensive’ is also part of military jargon, just like ‘targets’ is. In the tradition initiated by Lakoff and Johnson it is stressed that metaphors create or modify abstract concepts. The metaphor “argument is war”, is modifying or giving a special interpretation of what argument is. In other cases metaphors create a complete new concept.

Allegories are similar to metaphors, but have the structure of narratives and are usually more extensive. The New Encyclopædia Britannica has this definition:

...allegories are forms of imaginative literature or spoken utterance constructed in such a way that their readers or listeners are encouraged to look for meanings hidden beneath the literal surface of the fiction. A story is told or perhaps enacted whose details when interpreted – are found to correspond to the details of some other system of relation (its hidden, allegorical sense) (Fadiman, 1986, p.110)

Like metaphors, an allegory maps one domain onto another one, but the source domain is a narrative. Different parts of the source narrative are mapped into different parts of the target domain. An example from the Bible is Galatians 4:24, in which the word ‘allegory’ appears in the King James Version of the Bible. Two covenants are compared to the first two sons of Abraham by a freewoman and a bondwoman. An allegory maps objects and persons of a narrative to a more abstract domain. Each woman is mapped to a covenant, and the story told by the Apostle Paul gives flesh and meaning to the rather abstract concepts of a new and an old covenant. Both this allegory of Paul and the parables of Jesus have clear didactical purposes. They are designed by a teacher. These kinds of allegories are the focus of this paper, but of course mathematical ideas and conceptions are the goal, not spiritual ones. The word ‘conception’ is used to avoid non-cognitive interpretations of the alternative word ‘concept’, see Sfard (1991, p. 3) and Rinvold (2007, p. 4). A conception is a cognitive network in which several allegories and metaphors can be nodes. It isn’t uncommon to think that concepts are primarily given by formal definitions. Such definitions are just an aspect of conceptions and not at all a complete description.

We restrict our attention to allegories which include a timeline. This means that the narratives move in time. All the parables of Jesus are like that and so are most narratives. In mathematics education many text problems have the form of narratives. Such problems will be called narrative text problems. In this paper ‘text problem’ will always mean ‘narrative text problem’. On the other hand, narrative is a wider concept than text problem. A narrative is neither necessarily a problem nor given by a text.

Not all narrative text problems are allegories. This is only the case if a narrative text problem is going to represent or create something else, which usually is more abstract. Consider the following text problem: “John was hiking in the mountains. The first day he walked 20 km and the next day 25 km. What is the total distance he walked these two days?” This problem isn’t likely to represent something outside it-

self. Most students will solve the problem, forget it, and go on to the next one. The following narrative is different:

Peter has an urn containing balls. On each ball it's written a prime number. The urn may contain more than one ball with the same number. Peter asks Andrew to draw as many balls as he wants. Then Andrew is asked to find the product of the numbers on the drawn balls. When Andrew has told what the product is, Peter starts calculating. After a while he says: "I know which balls you have drawn". How is this possible? What would happen if composite numbers had been written on the balls?

With possible guidance from a teacher, this story can help the students to understand unique factorization in prime numbers and the role of such numbers. Drawing of a ball represents a factor. The information that Peter is able to tell which balls Andrew has drawn, corresponds to uniqueness of prime factorization. The fact that he isn't able to tell the order the balls were drawn, represents the commutative law. The narrative is used to create understanding of an abstract property of numbers. The problem isn't just a problem among many, but may have a lasting effect.

Even if the teacher tells a story intended to be an allegory, the learners don't always understand it in this way. Relating to a constructivist epistemology, it is the learners themselves who develop allegories. An allegory may be idiosyncratic and has elements of individual variation.

METHOD

This paper uses data from a study of how teacher training students learn the mathematical concept of linear congruence equations. The study was conducted in March 2008 by the authors on our own students. The data consist of participant observation of a teaching and learning session and three videotaped and partially transcribed interviews. One of the researchers interviews the teacher of the lesson, who at the same time is the other researcher. Both researchers together interview groups of either two or three students. As part of the sessions, students work together with a text problem. The researchers then ask questions helping the students to describe their reasoning process. The student interviews were conducted two days after the lesson, and the teacher interview the day after that. The transcriptions, descriptions and interpretations of the teacher interview were read by the interviewee, discussed with the researcher and then adjusted. Later, in the process of writing the paper, the teacher sometimes remembered thoughts and events from the lesson which can't directly be read from the data. Such thoughts aren't presented as data, but have without doubt influenced interpretations and directions of the paper.

CONGRUENCE CALCULUS

The lesson is based on several text problems given to the students. The first problems concern week days. Exercise 1 asked them to calculate the weekday of 31st March,

given that 1st January was a Tuesday. The teacher gave comments and discussed solutions in between. The students themselves made tables resembling calendars.

0	1	2	3	4	5	6
7	8	9	10	11	12	13
14	15	16	17	18	19	20
21	22	23	24	25	26	27
28	29	30				

After their work the teacher showed them the table above on a blackboard. Then he introduced the signs ‘ \equiv ’ and ‘mod’ for congruent numbers. From 1st January to 31st January is 30 days. He pointed to the numerals 2 and 30 in the table and connected them with a red line. Then the teacher said that 2 and 30 are in the same column and wrote $30 \equiv 2 \pmod{7}$. Mathematically this means that 30 and 2 have the same remainder upon division by seven. In other words, the difference between 30 and 2 is an integer multiple of 7. Practically, the meaning is that 30 days from now and 2 days from now differs with a number of integer weeks. The identity was followed by $29 \equiv 1 \pmod{7}$ and $31 \equiv 3 \pmod{7}$ since 2008 is a leap year and March has 31 days. Finally the teacher wrote

$$30 + 29 + 31 \equiv 2 + 1 + 3 \equiv 6 \pmod{7}.$$

The move of six days forwards from a Tuesday gives a Monday, so that is the weekday of 31st March.

NARRATIVE TEXT PROBLEMS

After three other text problems having to do with calculation of week days, the students were given what we call the Duckburg problem:

A ship arrives at the harbour of Duckburg today, which is a Monday. Then the ship arrives at the harbour every third day. Some days later the ship arrives at Duckburg harbour on a Wednesday (two weekdays later). How many arrivals later can this be?

According to our observations, all students made a table with the weekdays from Monday to Sunday in the first row. There was some variation in the content of the tables, but in some way all students marked the days when the ship arrived. They all discovered the first solution of the problem, and some even found a formula for the number of arrivals when the ship arrives on a Wednesday. The student work was followed up by the teacher in a plenary session. As support for the introduction of congruence equations, he made a protocol for the arrivals of the ship by writing the identities

$$3 \cdot 1 \equiv 3 \pmod{7}, 3 \cdot 2 \equiv 6 \pmod{7}, 3 \cdot 3 \equiv 2 \pmod{7}, 3 \cdot 4 \equiv 5 \pmod{7}, \dots$$

He simultaneously said things like “three times four is in the same column as five”, referring to the table. Then the teacher related the text problem to the mathematical

formulation “which multiplies of three are in the same column as two when divided by seven”. Finally the congruence equation $3x \equiv 2 \pmod{7}$ was presented as a translation of the Duckburg text problem. The lesson continued with the demonstration of algebraic techniques for solving the equation. These techniques are part of the motivation for the translation, but we don’t discuss the solving process in the paper.

The Duckburg narrative is built upon the culturally shared concepts of days, weeks and calendars and the well-known phenomenon of ships regularly arriving at harbour cities. The name Duckburg, which is the domicile of the Disney figure Donald Duck, is used to make it clear that we are talking about a fantasy world in which details can be changed. Duckburg is a name which is easy to remember and with positive associations for most students. Also, this cartoon city is placed close to the sea, Grøsfjeld (2007), so arrivals of ships are relevant.

Later in the lesson the students were given the running track problem:

An athlete runs intervals of 300 m on a 400 meters running track. She starts at the starting line, runs 300 meters and stops. She continues this way. After a while she stops 100 meters after the starting line. How many 300 meter intervals has she run?

The students at first worked with the task themselves using a table. A drawing of the track was introduced afterwards by the teacher in the plenary. He used the drawing to simulate the intervals of the runner. This problem also corresponds to a linear congruence equation, but the situation is sufficiently different from the Duckburg problem to supplement it.

FROM NARRATIVE TO PROTOTYPE

Lakoff and Johnson (1980) claim that usually we place things and phenomena in categories by comparing with a typical or prototypical member. A prototypical bird has wings, is able to fly, lay eggs and has a beak. A picture of a blue jay is used by some dictionaries when defining birds. The blue jay is a candidate for a prototypical bird in countries where this bird is well known. We will use interview data to argue that the Duckburg problem has the potential to be a prototypical text problem for linear congruence equations. The argument is based on the way the Duckburg problem is used by the group of three students to solve the following text problem which also corresponds to a linear congruence equation:

Oda is sick and has to take a tablet every fifth hour, both day and night, in order to get well. She takes the first tablet at five in the morning. A friend calls her when her watch has just passed one o’clock. Her watch is analogue, that is, has rotating hands. How many tablets has Oda taken? There are several correct answers.

The students work for about twenty minutes with the problem and are then interviewed. In the interview one of the students was passive and seemed to participate only to a restricted degree. The active ones were Kari and Lise. A reason why they used so much time is that the problem is structurally more different from the Duck-

burg problem than we intended. In particular, Lise mentioned several times in the interview that she was confused because the problem was unclear. In fact, one of the researchers had forgotten to specify that Oda had just taken a tablet when the friend called. However, the students demonstrated understanding of the problem and were able to solve it with the extra constraint when asked to. Some statements by Kari support the claim that the Duckburg problem and some of its structure were used in the solution process. One example appears when Kari and Lise had written the congruence equation $5x \equiv 8 \pmod{12}$ on their sheets. When asked why the right hand side is 8, Kari said:

Kari: I remember when we worked on the problem with the ships which arrived at the harbour, we started with a Monday. Then we were going to find Wednesday, which was two days later, so we would have two there.

The student refers to the Duckburg problem which corresponds to the equation $3x \equiv 2 \pmod{7}$. The numeral 2 on the right hand side corresponds to 2 days later. In analogy, one o'clock is 8 hours later than five. We think this is the reason why the students wrote 8 on the right hand side of the equation $5x \equiv 8 \pmod{12}$. This is supported by another statement from the interview:

Kari: Then we draw a table with 12 columns. We started with the hour she took the first tablet, which was at five o'clock. (...) Then we counted every fifth hour...

The students made the same type of table as in the Duckburg problem. Five was the first column in the tablet case, as Monday was the first in the Duckburg problem. They counted how many hours after the first tablet she takes the next and would have got the same result if the first one was taken at for instance two o'clock. Another argument is this mentioning of the running track case:

Kari: Recognizing the running track task. Then 0 and 12 were the same. It was the starting line. Do we have to start with 0 then? But, now 0 is at 5 o'clock. If she starts at 5 there, then...

Without doubt, Kari now uses five o'clock as the zero point. The students however, didn't notice a minor difference between the questions in the problems. In the Duckburg problem the question is how many days *after the first* arrival the ship arrives at Wednesday. In the tablet case we asked how many tablets she has taken, *including the first* one. If Oda had taken the first tablet at hospital, and we had asked how many tablets Oda has taken at home, their equation had been correct. Then $5 \cdot 1 \equiv 5$ would have meant that she took the first tablet at home 5 hours after the one at hospital. The identity $5 \cdot 4 \equiv 20 \equiv 8$ would have meant that she took the fourth tablet at home 20 hours after the one at hospital. In some sense the wrong equation is more convincing than $5x \equiv 1 \pmod{12}$, which has $x \equiv 5$ as solution. In the latter case the students could just have put in the numbers 5, 1 and 12 given in the problem, without any understanding.

The students' use of the Duckburg problem and its structure is an argument that the Duckburg problem is on its way to becoming a prototype for a category of narratives. A more thorough study would have been necessary in order to claim with strength that some text problem has been established as a prototype. A possible weakness in our study is that only one student orally indicates this kind of reasoning. However, the students wrote the equation $5x \equiv 8 \pmod{12}$ collaboratively and Kari said that "we worked with the problem". This may indicate that at least Lise also shared her ideas.

ALLEGORIES AND GENERALIZATION

The transformation of a narrative text problem to a prototype for a class of such problems is an important step in giving a problem lasting value in mathematical thinking. This is one aspect of making the special case represent something general. In the Duckburg problem we can change the involved numbers without changing the structure of the narrative. Clearly, there is nothing special in "every third day" or "two weekdays later". The general is represented by the special case. The related "principle of generalization" is investigated in Rinvold (2007). To change the numbers of weekdays from seven to something else is also possible, but needs more imagination because weeks with seven days are so deeply established in our culture.

We think that the narrative of Duckburg has the potential of becoming an allegory for linear congruence equations with one unknown. When the narrative is turned into a prototype, each part of the narrative represents a part of a generalized narrative. For instance "arrives every third day" represents "a tablet every fifth hour" and "runs an interval of 300 meter" in the two other example problems. But, the parts of the Duckburg narrative also represent parts of a formal linear congruence equation. These representations can be made clearer with the help of mappings. In the latter case the source domain is the Duckburg problem and the target domain is the class of congruence equations.

"Every third day" is mapped onto $3x$, "two days later" onto 2 and the number of weekdays is mapped onto 7 in the equation $3x \equiv 2 \pmod{7}$.

In the lesson the students were given some context free congruence equations and told how to translate these into Duckburg problems. When given the equation $2x \equiv 3 \pmod{8}$, one of the groups introduced a new weekday and drew a table. They quickly realized that the problem had no solution. With eight columns, steps of two weekdays can't lead to the same place as a change of three weekdays. The students said that it was a cheating exercise since there was no solution. In the beginning of the interview the students were asked about their experience of the lesson.

Kari: When we used the practical situations as starting points, we could in the end see a congruence equation, and then the numbers gave meaning. We could know what $4x$ really represents. When I recalled the ships, it gave meaning.

This could refer to the equation $4x \equiv 1 \pmod{7}$ which was one of the translation problems from the lesson. The formal congruence equation in the beginning seems to give little meaning to the students. The ships were part of the Duckburg problem and are used by the student to refer to that problem. We infer that translation of context free congruence equations into variants of the Duckburg problem was a main source of the meaning which emerged.

ALLEGORIES AND THE SOLVING OF TEXT PROBLEMS

When solving text problems allegories can be intermediate stages between the given narrative and a mathematical model.

The idea of prototypes means that new text problems given to the students won't be directly mapped to a mathematical model, but first to a prototype like the Duckburg problem.

A prototypical narrative in the learning of mathematics is a mathematized narrative. The given text problem or narrative also has to be mathematized to some degree in order to be mapped onto the prototype.

A crucial question is which qualities these mappings have for the students. Certainly, their versions of the mappings can differ from the intentions of the teacher. At best, the mappings reflect the mathematical structures effectively, but the mappings may also be based on superficial aspects of the text problems. Clement (1982) identified a syntactic and a semantic way of thinking when students tried to solve word problems for equations. The syntactic variant consists of a word by word translation of the text problem to algebraic language. Another kind of syntactic translation is based on possibly superficial similarities between the text problem and other text problems known to give a specific mathematical model. When working with the tablet problem, the student Kari made the following utterance:

Kari: We thought that it was $5x$ because it was every fifth hour she had to take the tablet and that was because the ship arrived every fifth day.

We see that the phrase "every fifth" appears in both problems. This may be interpreted as a sign that the student compared the appearance of words in the two problems. However, the ship in the Duckburg problem arrives every third day, not every fifth. In fact, some of the students, certainly including Kari, during the lesson also

solved a variation of the Duckburg problem corresponding to the congruence equation $5x \equiv 3 \pmod{7}$. This at least indicates that she compared with the appropriate version. Another argument that the translation has a semantic flavour is that in the lesson Kari, together with a group of students, generalized the Duckburg problem. They investigated what happens when the interval between arrivals or the number of weekdays ahead were changed.

Part of our theoretical thinking is that allegories are one of the sources for semantic meaning. When one text problem has been transformed to an allegory, the comparison with other text problems will no longer be just syntactical. Clement's semantic way of thinking means a mapping from a narrative or text problem to a mathematized version of the problem, and then a mapping to the congruence equation.

This is similar to the mappings of Parzysz (1999):

In the case of the Duckburg problem, the emphasis on the table, the columns and the introduction of mathematical signs means that the teacher intended to support the development of a mathematical structuring of the narrative. In the lesson the teacher explicitly sets up a mapping from the pseudo-concrete model to the congruence equation. For instance “the numbers which are multiples of three” was translated to ‘ $3x$ ’. The text problem is still a real situation for the student, but mathematical language has been introduced in order to change the students’ interpretation of the situation, making the translation to formal mathematics precise and smooth.

The term “real situation” is not as clear as commonsense language may suggest. We interpret ‘real’ as “real for the student”, as in RME, the Dutch approach to mathematics education (see van den Heuvel-Panhuizen, 2003). One point is that ‘real’ doesn’t have to mean practical or related to everyday life. The student Kari used the phrase ‘practical situation’ referring to the Duckburg problem, but imagined situations such as weeks with eight days can also be ‘real’. A situation isn’t something objective, but an experienced or imagined phenomenon. A narrative may create a situation in the mind of the student, but the process of mathematization also has a role in shaping the situation for the student. The degree of mathematization and semantic interpretation decides the quality of the mappings.

QUESTIONS FOR RESEARCH

This paper introduces the idea of cognitive allegories in mathematics education and supports this by discussions based on one limited empirical study. Obviously there is a need for more studies to establish that the concept of allegories is a fruitful one for

the use of narratives and text problems for conceptual learning in mathematics. It is necessary to have more thorough studies to establish that students transform introduced narratives into prototypes and allegories and how they do this. Other mathematical concepts and other potential allegories have to be studied. We also need to develop criteria for the design of such narratives. Another interesting task is to study how several allegories can be used for the same concept. We think that a single allegory usually isn't enough to develop a rich intuition. In our study the running track problem is a candidate for a complementing allegory, but only very limited evidence for this can be inferred from the data.

ROLE OF AN ARTEFACT OF DYNAMIC ALGEBRA IN THE CONCEPTUALISATION OF THE ALGEBRAIC EQUALITY

G. Chiappini*, E. Robotti*, J. Trgalova**

*Consiglio Nazionale delle Ricerche, Istituto Tecnologie Didattiche, Genova (Italy)

**National Institute for Pedagogical Research, Lyon and LIG, Grenoble (France)

In this contribution, we explore the impact of Alnuset, an artefact of dynamic algebra, on the conceptualisation of algebraic equality. Many research works report about obstacles to conceptualise this notion due to interference of the previous arithmetic knowledge. New meanings need to be assigned to the equal sign and to letters used in algebraic expressions. Based on the hypothesis that Alnuset can be effectively used to mediate the conceptual development necessary to master the algebraic equality notion, two experiments have been designed and implemented in Italy and in France. They are reported in the second part of this paper.

Keywords: *Alnuset, semiotic mediation, conceptualisation of algebraic equality*

INTRODUCTION

The research reported in this paper is carried out in the framework of the ReMath project (<http://remath.cti.gr>) addressing the issue of using technologies in mathematics classes “*taking a ‘learning through representing’ approach and focusing on the didactical functionality of digital media*”. The work is “*based on evidence from experience involving a cyclical process of a) developing six state-of-the-art dynamic digital artefacts [DDA] for representing mathematics [...], b) developing scenarios for the use of these artefacts for educational added value, and c) carrying out empirical research involving cross-experimentation in realistic educational contexts*”. This paper presents the research concerning Alnuset, one of the 6 DDA developed within the project. First, some theoretical considerations related to the notion of algebraic equality, at stake in this paper, are presented. Next, our research hypotheses are discussed and Alnuset is briefly presented. Finally, two experiments involving this artefact are described and the main results are discussed.

THE NOTION OF ALGEBRAIC EQUALITY

Important conceptual developments are needed to pass from numerical expressions and arithmetic propositions to literal expressions and elementary algebra propositions. As a matter of fact, in arithmetic only numbers and symbols of operations are used and the control of what expressions and propositions denote can be realized through some simple computations. In elementary algebra, instead, letters are used to denote numbers in indeterminate way and new conceptualisations are necessary to maintain an operative, semantic and structural control on what expressions and

propositions denote (Drouhard 1995; Arzarello et al. 2002). The necessity of this conceptual development emerges clearly with the construction of the notion of algebraic equality. On the morphological plan, equality is a writing composed by two expressions or by an expression and a number connected by the “=” sign. On the semantic plan, equality denotes a truth value (true/false) related to the statement of a comparison. When the expression(s) composing the equality is (are) strictly numerical, it is easy verifying its truth value through some simple calculations (e.g., $2*3+2=8$ is true while $2*3+2=9$ is false). Experiences with numerical equality contribute to structure a sense of computational result for the “=” sign. This sense can be an obstacle in the conceptualisation of algebraic equality as relation between two terms, as highlighted by several researches (Kieran 1989, Filloy et al. 2000). When the expression(s) composing the equality is (are) literal the equality can present different senses because the value assumed by the letter can condition differently its truth value. In these cases the “=” sign should suggest to verify numerical conditions of the variable for which its two terms are equal. There are cases where the two terms could never be equal whatever the value of the letter is, as in $2(x+3)=4x-2(x-1)$. In other cases to interpret equality on the semantic plane, it is necessary to distinguish if it has to be considered as equation or as identity. The “=” sign assigns to the equality the sense of equation when its two members are equal only for specific values of the letter. For example, the equality $2x-5=x-1$ is true only for $x=4$ and it is false for all other values. Instead, the “=” sign gives to the equality the sense of identity when its two members are equal whatever the numerical value of the letter is, as in $2x+1=x+(x+1)$. In order to master algebraic equality, a conceptual development of notions of equation, identity, truth value, truth set and equivalent equation is necessary. Moreover, to express the way in which a letter can condition the truth value of an equality, it is necessary to develop a capability to use universal and existential quantifiers, even though in implicit way.

RESEARCH HYPOTHESIS

Traditionally, conceptual construction of algebraic equality is pursued through solving equations using techniques of symbolic manipulation. Empirical evidence and results of research have highlighted that in many cases this approach does not favour a construction of an appropriate sense either for the notion of algebraic equality or for that of solution of equation. In more recent years, a functional approach to algebra has been introduced within the didactical practice allowing to articulate algebraic and graphical registers of representations (Duval 1993). Even in this approach difficulties emerge. These regard the interpretation of a graph. For example, for the solution of equations of the type $ax+b=cx+d$, the intersection of the two lines in the graph has to be interpreted as indicator of the fact that the equation has a solution. Moreover this solution has to be read on the x-axis in correspondence of the intersection point of the lines. As Yerushalmy and Chazan (2002) observed, this approach is not devoid of obstacles: students can interpret the graph as comparing two functions ($y=ax+b$ and

$y=cx+d$) or as a solution set of a system of two equations in two unknowns, instead of an equation in a single variable. Our research hypothesis is that Alnuset, an artefact of dynamic algebra recently developed, can be effectively used to mediate conceptual development necessary to master the notion of algebraic equality. Further in the paper we discuss this hypothesis referring to some results of two experimentations.

SHORT DESCRIPTION OF ALNUSET

Alnuset is constituted of three components, Algebraic Line, Symbolic Manipulator and Functions, strictly integrated with each other. They enable quantitative, symbolic and functional techniques to operate with algebraic expressions and propositions.

The main characteristic of Algebraic Line component is the representation of an algebraic variable as a mobile point on the numerical line, which can be dragged with the mouse along the line. This feature has transformed the number line into an algebraic line where it is possible to operate with algebraic expressions and propositions through techniques of quantitative and dynamic nature. These techniques focus on numerical quantities indicated by an expression when its variable is dragged along the line or on numerical quantities that make true a proposition. These techniques make a dynamic algebra possible. The main characteristic of Symbolic Manipulator component is the possibility to transform algebraic expressions and propositions through a set of particular commands. These commands correspond to basic properties of operations, properties of equality and inequality, logic operations among propositions, operations among sets. Another characteristic is the possibility to create a new transformation rule once it has been proved. These characteristics support the development of skills regarding the algebraic transformation and they contribute to assign a meaning of proof to it. The main characteristic of Functions component is the possibility to operatively integrate Algebraic Line with Cartesian Plane, where graphs of expressions can be represented automatically. Moreover, dragging the point corresponding to the variable on the algebraic line makes the expression containing the variable move accordingly on the line. On Cartesian Plane, the point defined by the couple of values of the variable and of the expression moves on the graph. These characteristics support two integrated conceptions about the notion of function: a dynamic conception developed on Algebraic Line and a static one associated to the graph on Cartesian Plane. For a more detailed description of Alnuset, we refer to the work of Chiappini and Pedemonte presented in this edition of CERME within the working group 7.

EXPERIMENTATIONS

As we mentioned above, the development of DDAs was followed by a design of learning scenarios involving these tools and the implementation of these scenarios “*in realistic contexts*”. ReMath partners decided that each DDA would be experimented not only by the designer team, but also by an other team that did not participate to the DDA development. Such “cross-experimentation” of the DDA was intended to highlight the impact of theoretical frameworks and of contextual issues on the design of

both DDA and learning scenarios. Indeed, each team was free to set up educational goals taking account of institutional constraints and to choose theoretical approaches to frame the scenario design process. Thus, the experiments involving a given DDA were not meant to be compared, but rather to validate design choices related both to the DDA and the learning scenarios.

Italian experimentation

The experimentation activity reported below, lasting 1h40, has involved a class of 15-16 year-old students (Grade 10) attending a Classic Lyceum. The students worked in pairs using Alnuset. Previously, they had carried out 6 activities with Alnuset centred on notions concerning algebraic expressions. The whole teaching experiment lasted about 20 hours. The activity considered in this paper is centred on solving a 2nd degree equation. In the previous school year, students had learnt to solve 1st degree equations through symbolic manipulation. In this activity notions of conditioned equality, solution of an equation, equivalent equations, truth value of an equality and truth set of an equation are addressed. The didactical goal is the conceptual development of these notions while the research goal is the study of Alnuset mediation in this conceptual development. The activity comprises several tasks. The first task aims at allowing students to explicit their own conception of the algebraic equality notion.

Task: Consider the following two polynomials: x^2+2 ; $2x+3$. Explain what it means putting the equal sign between them, or, in other words, how you interpret the following writing $x^2+2=2x+3$.

Many students attribute to the “=” sign the meaning of computation result. Nevertheless they were already faced with 1st degree equations. A typical students’ answer is: *“To put the equal sign between two polynomial expressions means that these expressions have the same result”*. For many students inserting the equal sign between two expressions suggests the idea that the computation result of the two terms has to be equal when a value is assigned to the letter.

In the following task students were asked to represent the two expressions on the algebraic line of Alnuset to verify their answers. Dragging the mobile point x along the line (and observing that the points corresponding to the two expressions move accordingly), all students noted that there are only two values of x for which the points of the two expressions are close to each other, almost coincident. Through this exploration students experienced that equality of two expressions is conditioned by numerical values of the variable, which is crucial to develop the conditioned equality notion. In previous activities with Alnuset, students experienced that every point of the algebraic line is associated to a post-it that contains all expressions constructed by the user denoting that point. In order to verify equality of two expressions, the students tried to find values of x for which the two expressions belong to the same post-it. Since these irrational values had to be constructed on the line, the students could not verify this directly: *“we don’t*

understand what is the number...it will be 2 point something...even if we use zoom in we don't understand ...". The technique mediated by Alnuset to find these irrational numbers requires transforming the equation into its canonical form ($x^2-2x-1=0$), representing its associated polynomial on the line and using a specific command to find roots of this polynomial. Our hypothesis was that this technique could favour a conceptual development of notions of equivalent equations and of truth value of an equation. The transformation was realized in the Symbolic Manipulator and was guided by the following task:

Task: Select the equation and use the rule $A=B \Leftrightarrow A-B=0$ to transform it. Translate the result produced by this rule into natural language.

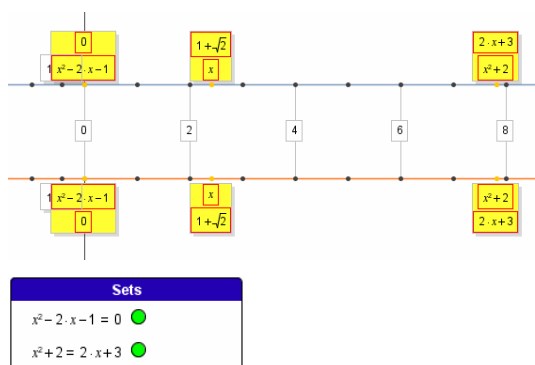

This task focuses on the rule $A=B \Leftrightarrow A-B=0$ of the manipulator through which it is possible to transform the equality preserving the equivalence. We report two students' answers: *"If two terms are equal, then their difference is zero"*; *"it means that if two expressions are equal, subtracting them the result will be zero"*. The conditional form of these sentences reflects a construction of an idea for the notion of conditioned equality used to justify the result produced by the rule. This does not mean that the students have understood the equivalence between the two equations in terms of preservation of the same truth set. Such understanding is the aim of the whole activity and its achievement requires several conceptual developments. First of all, students have to understand that the values of x for which x^2+2 is equal to $2x+3$ are the same for which x^2-2x-1 is equal to 0.

The following task was assigned to favour exploring such quantitative relations:

Task: Make a hypothesis about the relationship among the three polynomials x^2+2 ; $2x+3$; x^2-2x-1 imagining what you could observe if you represented them on the algebraic line and if you dragged x . Use algebraic line to verify your hypothesis.

A posteriori, we realized that the formulation of this task was misleading since it oriented the students to search for a relation among the three polynomials rather than between couples of terms of the two equations. Some students dragged the variable to explore if there were values of x for which the three polynomials could denote the same value on the line. They verified that such a value does not exist. Even if this exploration was not expected, it proved an important reference to overcome the following misconception, quite common in the students, concerning the equivalence of equations: two equations are equivalent if all their terms are equal for some values of the variable. A new formulation of the task by the experimenters allowed students to focus on couples of terms of the two equations. Exploiting the drag of the variable x they understood that, in order to find values of x for which x^2+2 is equal to $2x+3$, it is sufficient to find values of x for which x^2-2x-1 is equal to 0. Subsequently they used the command $E=0$ to find the irrational roots of the polynomial x^2-2x-1 and to automatically represent them on the line (the student drags x to approximate the polynomial to 0 and the system automatically produces the exact value of the root). Through

this experience an idea of equivalent equation begin to emerge. This idea will be consolidated through the exploitation of a new dynamic feedback offered by the system. We note that in the algebraic line environment expressions are represented on the line while equalities are represented in a specific window named “sets” and they are associated to a marker (a little dot) whose colour is managed automatically by the system. The marker is green if, for the current value of the variable on the line, the equality is true and, conversely, it is red if the equality is false. Dragging the variable allowed students to explore the truth of equalities and to construct a meaning for this notion, as shown in the following dialogue.

Student: If I drag x on $1 + \sqrt{2}$ and on $1 - \sqrt{2}$, the expressions of the first equation belong to the same post-it, namely $x^2 - 2x - 1$ and 0 are coincident for these values of x .

For the same values of x even $x^2 + 2$ and $2x + 3$ belong to a same post-it.

Student 1: When x is $1 - \sqrt{2}$ the two expressions are equal and these [dots] are green. So, since the solution of this equation is $1 - \sqrt{2}$ then also for the other equation is the same.

Student 2: and for the other value [$1 + \sqrt{2}$] it is true the same

Student 1: yes, for these values the two equations are true

To support the conceptual development necessary to master the notion of truth set of an equation, two other operative and representative possibilities of the algebraic line were exploited: a graphic editor to construct the truth set of an equality and a new feedback of the system to validate it. The graphic editor allows to operate on the line to define a numerical set that the system automatically translates into the formal set language associating it to a coloured marker. We note that the green/red colour of the marker means that the current variable value on the line is/is not an element of the set. As expected, students used this feedback to validate the defined numerical set as truth set of the equation, verifying the green colour accordance between equation marker and set marker during the drag of the variable on the line: “for the values $1 + \sqrt{2}$ and $1 - \sqrt{2}$ the two equations $x^2 + 2 = 2x + 3$ and $x^2 - 2x - 1 = 0$ have the same truth set. In our opinion, the two expressions from one side and the other side of the $=$ sign belong to the same post-it when x assumes the values of their solutions”.

French experimentation

Let us remind that the French team that experimented activities described in this section was not involved in the development of Alnuset. Therefore, a preliminary step before designing a learning scenario with Alnuset consisted in an analysis of the tool

from the usability and acceptability point of view (Tricot et al. 2003). This analysis brought to light main functionalities supposed to enhance learning of functions and equations, notions at the core of the Grade 10 math curriculum: dynamic representation of the relationship between a variable and an expression involving this variable and possibility to articulate different registers of representation of algebraic expressions (Krotoff 2008). In addition, praxeological analysis (Chevallard 1992) of the above mentioned mathematical objects allowed identifying types of tasks and comparing techniques available in Alnuset with institutional techniques identified in the Grade 10 textbook. This analysis shows that while institutional techniques are based on algebraic transformations on algebraic expressions, Alnuset techniques rely on visual observations of expressions (their position on the algebraic line, colour feedback...), and (almost) no algebraic treatment is needed when applying these techniques (Krotoff 2008). Thus, Alnuset seemed to be an appropriate tool to help students develop conceptual understanding of notions of function and equation, without adding difficulties linked to algebraic treatment that many students do not master well enough.

Although the French experiment was designed independently from the Italian one presented above, both experiments shared some didactic goals, in particular conceptual understanding of notions related to the notion of equation: meaning of a letter as variable or as unknown and of the “=” sign, understanding of what a solution of an equation means. Therefore, below we present only activities and results related to these common concerns. Our research goal was both to investigate to what extent the new representation of algebraic expressions provided by Alnuset contributes to the conceptual understanding of the notions at stake, and to study instrumental geneses (Rabardel, 1995) in students when interacting with Alnuset.

The experiment took place in a Grade 10 class with 34 students (15-16 years old), during two sessions lasting 3 hours altogether, held in a computer lab where students worked in pairs on a computer. Their work was framed by worksheets describing tasks and asking questions the students had to answer. Written productions are one kind of gathered data. Moreover, a few student pairs’ verbal exchanges were audio recorded and this data provided us with the possibility to carry out case studies, namely as regards studying instrumental genesis in students. Results reported below draw mostly on these case studies.

The first task involving equations was finding solutions of $f(x)=4$, with $f(x)=x^2$, after having studied the function f with Alnuset. The task was intentionally quite simple: the students could either solve the equation algebraically and verify the result with Alnuset, or solve the equation with the tool by dragging x along the algebraic line and looking for values for which x^2 coincides with 4. Both strategies appeared to almost the same extent. However, students who used the exploration strategy to find solutions with Alnuset succeeded better than those who used the tool just to verify the results found by solving the equation algebraically, since these often provided only one,

positive, solution. Alnuset turned out to be an efficient tool helping students to overcome their conception $x^2=k^2 \Leftrightarrow x=k$.

The next task, solving the equation $x^2=3x+4$, was proposed to prompt students to use Alnuset technique of dragging x on the line and searching for values for which the equality is true. Indeed, the students did not know yet algebraic techniques for solving such 2nd degree equation. Using the Alnuset technique requires to make sense of the “=” sign as meaning that the two expressions have the same value for some value of x , and thus also to distinguish between a letter standing for a variable and for an unknown. The students were first asked to determine whether 1, -1 and 2 are solutions of the equation. This question was intended to reveal students’ conceptions of the notion of solution of an equation. Almost all students succeeded the activity. However, the following dialogue between two students reveals the student’s S1 conception of a solution linked to the arithmetic sense of the “=” sign:

S1: You have to find 1. No, $3x+4$ must be equal to 1, the solution.

S2: No, you have to put x on 1 and the... what do you call it [*pointing at $3x+4$*]... Because x^2 should be equal to... the thing, equation and this isn’t the case (Fig. 2a).

S1: But it’s the result this [*pointing at 1*].

Indeed, it seems that S1 considers a solution of an equation to be the “result” or the value of the expressions: if 1 is a solution of $x^2=3x+4$, then $(x^2=) 3x+4=1$. This conception emerged also when the students checked for -1 . The student S2 grasped the targeted technique: “*On the other hand, -1 is the solution since $f(-1)$ equals this equals this equals this*” (Fig. 2b), and explains it to S1: “*To find the solutions, you drag x until x^2 and $3x+4$ overlap*”.

Figure 2. (a) 1 is not a solution since x^2 and $3x+4$ do not overlap when x is on 1; (b) -1 is the solution.

The students were then asked to find other solutions of the equation if there are any. This task was much more difficult for the students. Only half of the pairs succeeded it. The main obstacle was the fact that when $x=4$ (the other solution), the expressions x^2 and $3x+4$ went out of the screen. The students did not spontaneously resort to using “tracking” functionality allowing to keep visualising the expressions taking bigger values, which the students had used previously. Teacher’s intervention was necessary to remind the availability of this functionality, which helped the students to successfully finish the task. Such observations point to the issue of instrumental genesis in students, which can be a rather long-term process, especially in the case of

innovative functionalities such as “tracking” or “E=0” command as we will see in the following example.

Next, the students were asked to find solutions of the equation $x^2=x+3$. This equation has irrational roots, therefore the technique based on dragging x and making the expressions overlap is not efficient anymore. The aim was to introduce the E=0 command allowing to find irrational roots of the expression x^2-x-3 and thus bring the idea of equivalent equations $A=B$ and $A-B=0$. Most students used first the strategy relying on dragging x on the line and either provided approximate values of solutions (e.g., 2,3 and $-1,3$) or framed the solutions by integers (e.g., $-2 < x < 0$ and $2 < x < 4$). Teacher intervention was necessary to clarify that exact solutions were to be found and suggest using the E=0 command. Students encountered two main difficulties with using this command. The first difficulty was making a link between the expression $E(x)$ they needed to find to be able to solve the given equation of the type $A=B$ (the question intended to guide them was “What equation of the type $E(x)=0$ allows solving the given equation? Explain.”). The teacher had to state more precisely that Alnuset only provides a tool for solving equations with the right side equal to 0, and that it is then necessary to transform the given equation in a way to have 0 on the right side. Such intervention helped most students to find an adequate expression and use the E=0 command. The other difficulty was linked to the use of the E=0 command. In fact, to solve an equation with Alnuset, one has to use this command as many times as the equation has solutions. Although the students were aware that the equation has two solutions (most of them provided two approximate values at the beginning of the task), they did not think of using the command twice in order to find both solutions, and thus provided only a single solution. This difficulty is linked to the development of a scheme of using the E=0 command, which supposes to anticipate the number of solutions of a given equation and to be aware of the fact that applying the command gives a single solution at a time. This is quite unusual comparing to traditional algebraic techniques.

CONCLUSION

These two experimentations enable a first evaluation of the mediation offered by Alnuset. In both experiments Alnuset was exploited both as a tool to verify already developed conjectures and as a tool to explore algebraic phenomena in order to arise and validate new conjectures. It allows designing learning scenarios with characteristics that are deeply different, according to given contexts (institutional, cultural, social...) and educational goals to be pursued. The two experimentations lasted differently and this allowed to evidence that: (i) the instrumental genesis of the Alnuset instrumental techniques may be quite short for some of them (e.g., using drag mode for determining equivalence of two expressions) and longer for others (e.g., using E=0 command to solve polynomial equations and interpreting associated feedback); (ii) the instrumented techniques can be controlled by mathematical justifications and previous knowledge, correct or not. On the other hand, the French experiment showed that when the previous mathematical knowledge is rather fragile and the students are not very confident with it, resorting to the tool can help them carry out successfully the tasks they would not succeed without using the tool; (iii) the instrumented techniques produce representative dynamic events that can be easily related to algebraic notions and meaning involved in the activity.

Both experiments evidenced the importance of teacher’s role in supporting the development of students’ instrumental genesis at the beginning of the activity with Al-

nuset. Moreover, the role of the teacher remains very important during the whole activity to orient discussions and considerations about instrumental issues that have to be intertwined with algebraic knowledge involved in the activity.

COMMUNICATING A SENSE OF ELEMENTARY ALGEBRA TO PRESERVICE PRIMARY TEACHERS

Franziska Siebel and Astrid Fischer

Goethe Universität Frankfurt

This article reports on a university course for preservice primary teachers on ‘patterns and structures in primary school to prepare algebraic thinking’. We believe, if arithmetic is taught with an algebraic awareness, e.g. looking for patterns within arithmetic problems, algebraic thinking could be enhanced in primary school and the ‘cognitive gap’ between arithmetic and algebra would be reduced. In order to teach with an algebraic awareness the teachers must have developed such awareness themselves. We present the design of a course with which we contributed to this. The course serves us as a pilot experience for gaining hypotheses on the needs of teacher students and on good teaching interventions. We conclude the article with research questions in this field of teacher education.

THEORETICAL FRAMEWORK AND FOCUS OF THE PAPER

It is well known that there are many-faceted difficulties in learning algebra (see for example the contributions in Bednarz et al., 1996). Also the working group on algebraic thinking of CERME 5 has considered many features constituting elementary algebra and problems of learners. Some of the contributions are concerned with problems of constructing new mathematical objects (as formal or as abstract, cognitive objects) when dealing with algebraic expressions (e.g. Dörfler, 2007; Fischer, 2007a; Lagrange, 2007). Others point to students’ often limited or inappropriate ways of interpreting symbolic arithmetic or algebraic expressions (e.g. Alexandrou-Leonidou and Philippou, 2007; Molina et al., 2007; Papaieronymou, 2007). What do these many-faced difficulties have in common with the learning of algebra? The working group agreed on one central theme of algebra underlying all other aspects discussed: ‘expressing generality’ (Puig et al., 2007). However, students often do not experience this feature in their algebra classes.

One reason for these difficulties is the so-called ‘cognitive gap’ between arithmetic and algebra. Herscovics and Linchevski (1994) highlight some aspects of it. Features like the manipulation of variables occurring twice or more in a formal expression demand truly new cognitive abilities or constructions as compared to an arithmetic viewpoint. Similarly, they suggest a new viewpoint is required to comprehend formal arithmetic expressions as entities in their own right, or to look for patterns and structures in arithmetic problems. As a consequence of the observed gap, students have to cope with several changes to their habit of solving problems, their ways of interpreting signs, their ideas on what mathematics is about.

In this article we propose that some of the features of this gap between arithmetic and algebra are not so much due to the given characteristics of the two areas of mathemat-

ics, but to a tradition of teaching arithmetic common to many countries. This tradition focuses on ways of interpreting arithmetic expressions and treating them, which cannot be extended to the algebraic sign system. What is more, the tradition of teaching arithmetic narrows the focus of mathematics to calculations and results, giving little scope for the search for general patterns and the discussion of structures. Things can be done differently. The way formal expressions are interpreted in algebra can also be used for interpreting arithmetic expressions. For example the expression $3+4$ need not only be understood as a description of an activity but also as a sign for a number. Many other characteristics of algebra could effectively first be established within arithmetic contexts. A lot of research exists on including algebraic activities in mathematical learning environments for primary school children. For example several studies (e.g. Carraher et al., 2008; Fischer, 2007b; Söbbeke, 2005) report on the understanding of arithmetic or geometric patterns by young children who are not yet familiar with the conventions of the formal algebraic sign system. When they become familiar with activities of this kind in primary school children might be better prepared for the step to algebra.

But how can primary school teachers be persuaded to teach these issues? For a pilot experience we designed a university course aimed at preparing (future) primary teachers for integrating algebraic aspects in the math classes. In this article we will explain our grounds for the design of the course and report on our experiences. At the end we suggest ideas for further research to help evaluate the course and develop it further.

A central issue for our course was how to persuade primary school teachers to engage in algebraic ideas. Understandably, primary school teachers tend to focus on the goals set by curricula for the first school years. Often they are not aware of the consequences of their attitudes for the children's learning of further mathematical concepts. Moreover, many of them do not see a connection between learning mathematics in primary school and algebra in secondary schools. And those who do are not aware of different ways of dealing with arithmetic. Therefore, we consider it a necessary prerequisite to help (future) primary teachers look at the mathematics in primary school from an algebraic perspective and to show them how they can integrate pre-algebraic thinking without losing track of their primary goals.

Mason (2007) gives some ideas on how teachers can learn to deal with the subject of expressing generality. One central point is the highlighting of typical mathematical processes involved in the search for general patterns and in their representation and use. This is one important connection between the general goals of mathematics and our specific interest in advancing algebraic thinking in primary school. We recognised different though interwoven aspects of 'algebraic awareness':

- *Experience with problem solving activities*, e.g. analysing and describing patterns and structures, continuing patterns, using structures for calculations and problem solving,

- *Knowledge of different mode of representations and structures* of problems, solution methods and solutions,
- The *disposition* to look for patterns and structures in arithmetic problems and to argue with them and to perceive arithmetic expressions as processes and as objects.

All of these aspects can be provoked within arithmetic and geometric contexts in primary school (grade 1 to 4).

CONCEPTUAL DESIGN OF THE COURSE

In the course we had four main goals:

- The students experience algebraic thinking within arithmetic and geometric contexts. They are encouraged by personal success and gain a broadened view on mathematical tasks.
- The students understand challenges of (pre)algebraic thinking as part of mathematics fitting in the goals of primary school.
- The students design and analyse mathematical problems concerning arithmetic or geometric patterns in a context of primary school either within a case study or while analysing schoolbooks.
- The students reflect upon learning mathematics themselves and by children.

Organisational frame

The class met three hours each week for one semester (14 weeks) and was open for advanced students who had already taken some mathematics and mathematics education for primary school. Twenty three students attended the course. To obtain credits each student had either to undertake and write a report of a short empirical study with one or more children, or write a theoretical theses comparing two series of schoolbooks.

Progression

1. Introducing the course subject

During the first weeks of the course the students were presented with mathematical problems, which comprised different aspects of algebra and algebraic thinking. With this activate approach the students experienced algebraic thinking instead of dealing with a theoretical definition. We chose problems which highlighted characteristic aspects of algebraic thinking. Quite a number of these problems dealt with the discovery and expression of patterns. The students had to solve them with their preferred problem solving strategy and with at least one strategy that children in primary school might use. The class reflected upon the solutions, the solution methods and different ways of presenting both. Furthermore, problem solving strategies were elaborated and

differences were highlighted between problems which appeared to be very similar at first sight but turned out to have very different algebraic potentials.

figure 2

Figure 1 shows problems from a worksheet on “number walls”. Three-layer number walls involving additive structures within integers are an often used format in German school books. They are constructed as indicated in figure 2 (where a , b , and c are integers).

The first task on the worksheet presents a typical arithmetic task: the sum of integers has to be calculated. Note, however, that if used to *introduce* number walls, this already demands some degree of structural analysis. The second task also starts with the calculation of sums. But the request to write down observations leads to a closer examination; the different walls have to be compared. Describing differences and commonalities of the six walls with the same integers in the bottom bricks demands a careful study of the walls. Verbalising the observation and explaining the findings helps the discovery of a mathematical pattern. Finally, the number walls of the third task cannot be worked out in the same straightforward way. They present disconnected problems (one of them is not solvable within integers) which can be tackled in different ways. Asking for the approach implies an explicit reflection on it; asking for other solutions and for the number of other solutions guides students towards a structural approach to the task.

Other problems given to the students offer different views of symbolical terms like the equal sign and expressions like the sums of two numbers. Given “ $3+4=$ ”, say, whereas one view sees the equal sign as an instruction to calculate ($3+4$ adds up to 7), another promotes the view of the equal sign as a balance and of the sum as being a number ($3+4$ is the same number as $2+5$). Cognitively the latter demands a view of an arithmetical expression as a number as well as a process (cf. Gray and Tall, 1994). Furthermore, the students were given problems on number sequences, geometric visualisations of such, arithmetic laws and (dis)connected arithmetic word problems.

Although the problems were basically taken from German schoolbooks for classes 1 to 4, the students had numerous difficulties solving them. Many of them made very formal use of variables, often with little or no understanding of the meaning. This caused mistakes on the one hand and impeded discussion of mathematical relations on the other hand. Moreover, the students frequently had difficulties to think of strategies without using variables. Often they thought of only one alternative strategy: systematic trial and improvement. Yet, they did not always acknowledge this as a valuable mathematical strategy.

Working on the given problems, the students were surprised by their experiences:

- 8.** There are mathematical tasks with different ways of solving them, some problems can even have different solutions.
- 9.** Strategies can be found which do not involve the formal algebraic sign system are possible. But to find such strategies requires insight into the structure.
- 10.** The inherent structure of similar looking problems can be very different.
- 11.** These problems offer challenges on different levels. Some of these challenges are revealed to the students only when working on them.

These experiences were facilitated by questions attached to the mathematical problems, which emphasised mathematical activities like visualising, comparing and arguing.

Besides solving the problems the students reflected upon the mathematical activities required by the children. Through this, we raised ideas of what algebraic thinking is about.

We concluded the introductory unit by taking a more theoretical standpoint. In class we discussed the paper of Lorenz (2006) on possibilities and challenges in using geometric representations of arithmetic patterns for illuminating the structure and solving problems about them. The claims of the text could well be investigated through some of the examples the class had worked on in the previous weeks.

The class then developed a notion of ‘good’ mathematical problems in general and in respect to algebraic thinking. The class agreed on the following features to constitute ‘good’ problems:

A ‘good’ mathematical problem must be

- 9.** open to different approaches or different solutions,
- 10.** given with a mathematical goal,
- 11.** easy enough for every child in class to start solving the problem and to obtain a (partial) result, but also
- 12.** challenging even for high achieving children.

The feature specifically relevant for the course is the encouragement of algebraic thinking. We listed the following characteristics of algebraic thought which can be found within arithmetic or geometric contexts:

- unknowns not only at the end of an expression,
- equal sign as balance sign,
- arithmetic expressions as representations of numbers,
- describing patterns,
- calculating big numbers effectively using structures instead of extensive calculations.

These criteria are neither original or exhaustive. But they reflect the views the students had developed at this point on the course and used as basis for their own work. Throughout the rest of the course these criteria served as an orientation for the students when developing and evaluating mathematical problems for primary school.

2. Preparing and realizing the individual projects

The students then started with their own projects. Seven carried out a case study with a child in primary school. Each of them prepared a short sequence of problems he or she was going to use in the interview. This sequence had to be analysed with respect to its algebraic potential. There was opportunity in class to have these sequences discussed in small groups and to work them through before they were used in the interviews.

After the interviews were accomplished the students had to transcribe interesting parts and analyse the children's performance. The students in Frankfurt have plenty of experience with carrying out interviews and analysing them with respect to interaction. Therefore we decided not to elaborate on these issues. Nevertheless we devoted one lesson to tools for analysing transcripts. We focused on gaining mathematical knowledge through working on representations. For this we read a paper on the epistemological triangle of Steinbring (2000). In this text two analyses are presented in which students explain and develop ideas on a mathematical problem. However this text turned out to be very difficult. It is too theory laden for our students to enable them to extract general principles and apply them for their own analyses.

Students who aimed for a theoretical thesis each had to analyse two series of schoolbooks for classes 1 to 4. Each student had to select two formats of problems like a sequence of problems with a common pattern or number walls recurring in his or her schoolbooks in different classes. He or she had to give an analysis of these formats pointing to their algebraic potential. On the ground of this analysis he or she had to evaluate the way the schoolbook makes use of these formats and compare the two series of schoolbooks. The students of this group, too, were given the opportunity to

have some examples from their schoolbooks discussed in class. In addition, throughout the whole course such formats served as examples for different aspects.

The individual projects were mainly worked on at home. Meanwhile, we were able to introduce several theoretical articles on mathematics education which discuss issues related to our subject. Our main focus was to interrelate educational theories with the students' own mathematical activities as well as with their design and analysis of problems. Through this, we also deepened the students' algebraic understanding.

We covered topics like learning, practising and problem categories. In particular, we compared learning mathematics via instruction to learning via discovery (cp. Wittmann, 1994) and related the findings to previous class sessions. Practising – not only algorithms of calculation but also mathematical processes like problem solving, representing mathematical ideas, argumentation – was connected to the different learning theories (cp. Winter, 1984) and discussed for one specific problem. The task of determining whether problems are open (for different solutions and solution methods) informative (regarding the learner's thinking) and process-oriented (which means, if they support mathematical activities like discovering, arguing and further elaborations; Sundermann and Selter, 2006), leads to reflecting on problems, varying and exploring them.

These articles addressed general principles of teaching mathematics in primary school. We found plenty of opportunities to interpret and understand them in respect to our subject of inducing algebraic thinking. Thus this subject appeared in the general context of teaching mathematics in primary school not as an exotic theme but as one way of complying with these general goals that are commonly shared.

3. Presenting the students' projects

In the last unit of the course the students presented some of their results. Those writing a theoretical thesis chose examples of their analytical work and some theoretical aspects related to it. Those doing an empirical analyses presented crucial aspects of their interview analyses. All of them were asked to look for ways of presentation that would actively involve the class.

The students who analysed schoolbooks had to think of criteria for their analysis first. It turned out that they used the criteria listed in the introduction only as a starting point. In order to build their criteria most of them chose one or more topics on learning mathematics we discussed during the second part of the course. It is pleasant to see that they altogether made careful analyses covering important aspects of algebraic thinking which proved a good insight into the formats.

For example one student gave an overview on which pages the formats occur in the schoolbooks before she went into quantitative and qualitative analyses. She did not only list the pages but stated the type of task linked to it, like discussing calculation rules, completing the format and comparing numbers of neighboured formats. This

affected her quantitative analysis: She put the frequency of a format into perspective with the aligned task. While she noted that in one book the format was used more often she also claimed that a lot of the tasks merely practise calculating.

At the beginning of the term another student commented on a schoolbook she had seen in use in primary school. She reported that the school children would love to work on the book and do their work autonomously. Her submitted analysis of this schoolbook shows that she gained a broadened view on mathematics teaching. She stated that this particular schoolbook is based on a theory of mathematics education of tiny steps but little structural understanding of mathematics problems.

CONCLUSION AND FUTURE PROSPECTIVES

Overall we are satisfied with this course since we met our goals for most part. The students gained (more) competencies solving mathematical problems with an algebraic notion. They intend to integrate (pre-)algebraic thinking in their mathematics classes through designing adequate mathematical tasks and an appropriate attitude. They gained competencies in judging maths problems in school books and their own, as well as reflecting on their interventions. Our evaluation corresponds well with the students' feedback.

It turned out that the aspects of algebraic thinking were best understood when they were directly linked to their own experiences – and more than once – and reflected upon afterwards. For example the students had to solve a variety of problems with patterns during the first sessions which were originally designed for primary school. We reflected upon them: The students had to present their results, find different solution methods, vary the tasks, compare it with other tasks, etc. The attitude to look for patterns became an important issue for the group and the focus on patterns can be traced to the students' projects. In contrast some algebraic characteristics were not understood quite as well, like the notion of the equal sign as a balance sign. This is perhaps because we did not mention those characteristics quite as often, or because we looked at them from a more theoretical perspective.

We believe that it was not only the students who learnt a lot about (pre-)algebraic thinking: we also benefited from this course. We learnt something about the thinking of university students, gained perspectives on teaching them and at the same time got deeper insight of the potential of mathematical tasks for teaching algebraic thinking.

This teaching experience serves as a pilot study for us. On the basis of this experience we see several research questions that would be worth following up.

- The course seems to indicate that student teachers do need help to get an algebraic awareness, even though they have used much algebra in their own time at school. A quantitative empirical study of teachers' performances in observing patterns and structures in geometric or arithmetic contexts should

give hard evidence on this issue. One could also investigate how, during a course like ours, students' ideas about arithmetic lessons change.

- We do not know very much about the inner representations student teachers have of principles of algebraic notation and algebraic argumentation. A qualitative empirical investigation on this issue might help us to better understand some of the underlying difficulties. In connection with this, the effects of some of the principles we applied during the course should be evaluated by empirical studies. The results of these studies might inform the development of curricula for teacher education.
- An underlying assumption of our course is that children who work on describing and using patterns in the context of arithmetic problems will be better prepared for algebra than students who only do calculations in their arithmetic classes in primary school. This conforms with theoretical positions on the nature of algebraic thinking in scientific literature. However, more empirical evidence is needed to investigate this claim.

CONCEPTION OF VARIANCE AND INVARIANCE AS A POSSIBLE PASSAGE FROM EARLY SCHOOL MATHEMATICS TO ALGEBRA

Ilya Sinitsky*, Bat-Sheva Ilany**

*Gordon Academic College of Education, Haifa, Israel; **Beit-Berl College, Israel

Change and invariance appear at the very early stages of learning mathematics. In this theoretical paper, examples of topics and tasks from primary school mathematics with various kinds of interplay between variation and invariants are presented. Application of this approach might be a tool that helps to improve non-formal algebraic thinking of students. We present some examples of pre-service teachers' reasoning in terms of variances and invariance.

INTRODUCTION

For over fifty years, mathematics educators have studied ways of teaching algebra. Beyond viewing algebra as generalized arithmetic, various classifications for meaning of algebra, algebraic symbolism, procedures and skills have been proposed (Usiskin, 1988). In algebra, students have to manipulate letters of different natures such as unknown numbers (Tahta, 1972), parameters, and variables. Required skills include specific rules for manipulating expressions and an ability to construct and analyze patterns. These components form the basis for the structure of school algebra, which appears to students to be abstract and rather artificial. Through dealing with transformation of algebraic expressions, students can hardly recognize the core ideas of algebra, such as application of standard arithmetic procedures to unknown or unspecified numbers.

From the point of view of primary school teachers, algebra is comprised of letters, rules of operations with expressions, and formulas to solve equations. Moreover, the term *pre-algebra* in the school math curricula stands for some “advanced arithmetic” topics that are linked with future algebra, mostly chronologically but not conceptually.

Since 2005, the awareness of pre- and in-service teachers about algebra has been one of the “hot” issues of annual conferences on training primary school math teachers in Israel. In order to match the course *Algebraic Thinking* to the needs of pre-service primary school mathematics teachers, a systematic study on their vision of algebra has been initiated. Preliminary results of this research show that only a few of these students are aware of non-formal components of algebra (Sinitsky, Ilany, & Guberman, 2009).

What mathematical concept could help pre- and in-service teachers to construct relevant algebraic comprehension? School algebra is a combination of generalized arithmetic, calculations with letters, and properties of operations (Merzlyakov &

Shirshov, 1977). In general, it requires reasoning on connections and relations between objects, for example, finding similarities and dissimilarities between objects. The question “what changes and what does not change?” seems to be fruitful in a meta-cognitive discourse that concerns problem-solving activity (Mason, 2007; Mevarech & Kramarski, 2003). We propose to apply this question at the very early stages of mathematical learning as a possible tool to connect primary school mathematics with algebra.

WHY VARIANCE AND INVARIANCE?

The two notions of *variance* and *invariance* are strongly linked, since “invariance only makes sense and is only detectable when there is variation” (Mason, 2007). Mason claims that “invariance in the midst of change” is one of three pervasive mathematical themes. Watson and Mason (2005) have elaborated the theory of possible variation and permissible change for the needs of mathematical pedagogy. The use of the concept of variance and invariance with pre-service teachers can develop their algebraic thinking and provide them with tools to construct examples.

The issue of learning processes is related to the human ability to associate and to distinguish between different characteristics of the same object. Research (Stavy & Tirosh, 2000; Stavy, Tsamir, & Tirosh, 2002) shows that reasoning patterns “same A then same B” and “more A then more B” are prevalent among students, and direct analogy causes deep misconceptions in the learning of mathematics. Refining comprehension of various types of interconnections between change and invariance may be fruitful for improving cognitive schemes of students.

Starting from secondary school, students systematically face algebraic notation and formalism. The most significant feature of algebra for students is manipulating with letters. It seems to them (and to their teachers) as a switch from four arithmetic operations with numeric operands into *terra incognita* of some quantities that are both unknown and tend to change.

Although the abilities to deal with varying objects, to explain, and to formulate are the very essence of secondary school algebra, students are expected to grapple with these based on their experience in primary school. In the framework of systematic construction of formal algebraic concepts, pre-algebra is responsible for the development of pre-abstract apprehensions of algebra (Linchevski, 1995).

In this paper, we bring up some issues from primary school mathematics and observe these problems in terms of change and invariance. We refer, at a non-formal level, to the main components of school algebra mentioned by Linchevski, i.e. using variables and algebraic transformations, generalization, structuring, and equations.

We proposed related mathematical activities for pre-service primary school mathematics teachers, and discuss some relevant classroom findings in the last paragraph and in the appendix.

VARIANCE AND INVARIANCE INTERPLAY IN PRIMARY SCHOOL

Word problems and algorithms of school algebra often have an origin, or an analogy, in primary school mathematics. Despite the concrete numerical form of arithmetic problems, they usually enable some algebraic generalizations into patterns for several number sets with suitable restrictions. For example, the property of being divisible by 9 is invariant in relation to any change in order of digits. Analysis of mathematical problems of primary school from the point of view of algebraic concepts may be fruitful for students as a step to constructing their algebraic thinking.

A consideration of variation, change, and invariance may help to provide a non-formal algebraic vision of arithmetic issues. Every mathematical situation provides a variety of variance–invariance links. Moreover, a suitable set of variations and related invariants that describe a task may provide a way to solve it. We illustrate the appearance and application of the “change and invariance” concept in a number of topics from primary school mathematics.

Quantities and numbers

The most fundamental example of invariant is human ability to count (Invariant, n. d.). It starts with the transition from objects to quantities and develops through numerous activities of counting objects of different nature. At this stage, quantity is invariant of physical properties of specific objects. Children also learn to count a given set of objects in different ways, and discover that the result is invariant of various (correct) counting procedures.

Thus, a basic conception of equality of quantities arises: the equality represents the fact that the same quantity is obtained or described in two different ways. There is also the possibility of inverting the problem: which changes are allowed within a given quantity? This question seems concerns a misconception of equality. Linchevski and Herscovics (1996) have connected cognitive difficulties in the transition from arithmetic to algebra to dual procedural-structural algebraic thinking. A well-known example of such difficulties is the comprehension of the expression $34+7=$ as a command to carry out an action (Gray & Tall, 1991). Accordingly, in the equation $8+4=\Delta+5$ the unknown is interpreted by students as the result of adding $8+4$. In contrast, the idea of equality as an idiom of invariance invites possible changes.

An appropriate didactical scheme for primary school students is to focus on problems of decomposition of given number into a sum of two addends. Typical questions require producing additional presentations based on a given one as demonstrated in this activity:

- $8=3+5$ How can you split the same number 8 into another sum of two addends?
- How does a change in the first addend influence the second one?

- How does the change of addends of two “adjacent” decompositions vary? (At a higher level this leads to a conclusion on invariance of parity for differences of addends for several decompositions of the same number)
- For a given odd (or even) number, what can you say about the parity of addends in each decomposition?

This activity invites students to discover the role of invariant quantities in a game of changing in.

In discussions with pre-service teachers, the same questions were followed by further generalizations. For instance, the last question on parity leads to a conclusion on the invariance of parity of algebraic sums of numbers, with arbitrary distribution of +/- signs, through an analogy to the arithmetic expression. A choice of signs +/- does not influence the parity of the expression $a_1 \pm a_2 \pm \dots \pm a_k$ (for integers a_1, a_2, \dots, a_k). At an advanced level, the same mathematical situation leads to combinatorial tasks, such as:

- In how many ways can we split a given natural number into the sum of equal addends?
- Can you arrange any presentation of an arbitrary multiple of three as a sum of consecutive addends by first splitting it into a sum of equal addends?
- In how many ways can we split a given natural number into sum of consecutive addends?

In the appendix, we present examples of pre-service primary school math teachers' response to some of these questions.

With this cluster of problems, we explored the concept of permissible changes within a given invariant in a variety of mathematical questions and levels.

Comparison of quantities in terms of change and invariance

In addition to invariance, the very basic process of counting deals with *variation* of quantity. Adding each new object to a given set of objects generates a new quantity that is greater than the given one. These examples are taken from the Curricula for Primary School in Israel (Curriculum, 2006): the sum $5+1$ is greater than 5, and the sum $67+2$ is less by 1 than the sum $67+3$.

From the point of view of invariance and change, students try “to find the same” in a pair of arithmetic expressions. The same operand plays a role of a parameter, i.e. arbitrary but the same number. The only cause for different values of given expressions is the difference in second operands. Therefore, to compare two quantities one looks at them in a structural manner: namely, noting the similarity and the difference between them. For example, comparing the results of other arithmetic operations when one of the operands is the same for both expressions:

- Which one of the differences is greater: $856 - 47$ or $856 - 44$?
- What is the difference between the two products: 84×123 and 83×123 ?

- Shirli arranged dolls in nine rows with the same number in every row. She added two dolls to each row. By how many dolls did the total number of dolls increase?

In school algebra, the presence of an unknown quantity typically turns the simple problem of comparing two similar expressions into a difficult one for students. For example, the comparing the pair $a-7$ and $a+7$ as opposed to the pair $7-a$ and $7+a$.

Further, in order to compare more “remote” arithmetic expressions, one can try to interpret them as a different change of the same connecting expression. When pre-service teachers discussed how to compare two differences, i.e. $1234-528$ and $1243-516$, they constructed intermediate expressions, $1234-516$ or $1243-528$. In a similar way, they proposed using the product 83×123 for comparison of products 84×123 and 83×124 . This method of comparison is also an algebraic one: two expressions $a*b$ and $c*d$ are interpreted as changes of the same basic structure $a*d$ or $c*b$.

Computational algorithms and techniques

In school algebra, most procedures cause changes in algebraic expressions yet preserve equality or inequality. This issue is not new for students. Almost every process of computation includes some transformation of a given arithmetic expression to another one. The transformation is valid provided it keeps invariant the value of the expression. In fact, both the rules of arithmetic operations and standard computational algorithms preserve the invariants:

- To calculate the sum $123+456$, one groups similar units of addends, $123+456=(100+400)+(20+50)+(3+6)$ – this is a direct analogy of gathering similar terms in algebraic expressions.
- The difference $123-49$ can be replaced by a new expression that retains the value of the given one: $123-49=124-50$.

Fraction reduction and expansion are additional examples in elementary school of variation that preserves value.

The ability to find a suitable variation of a given expression that preserves its value is a useful starting point for oral calculations. A necessary condition to apply is the invariance of the value under the change of form of the calculated expression.

We have studied the strategies pre-service primary school math teachers apply to calculate sums of arithmetic progressions (Sinitsky & Ilany, 2008). Only 5% of the students succeeded in recalling a suitable formula and applying it correctly. After taking part in series of assignments concerning interplay of change and invariance, the students were given similar tasks. They tried to calculate sums by reducing them to

known series in various ways

$(2+3+\dots+26 \rightarrow 1+2+\dots+25; 3+6+9+\dots+60=[2+4+\dots+40]+[1+2+\dots+20])$.

Number properties and range of generalization

When students manipulate algebraic expressions, the application of natural intuitive reasoning schemes “same A then same B” or “more A then more B” leads them to false reasoning: “ $x^2 = y^2$ implies $x = y$ ”, “ $-x > 2$, therefore $x > -2$ ”. In terms of change and invariance, this is a problem of connection between different invariants.

There are numerous examples of correct ways of reasoning when letters A and B stand for the property of numbers. Examples of correct propositions concerning squares of natural numbers: “If the unit digits of two numbers are the same their squares have the same unit digit”; “The squares of numbers with the same parity are also of the same parity”; “As natural numbers increase so do their squares”.

Such a convenient tie between invariants and changes invites a wide generalizing. Accordingly, questions that lead to counter examples and determination of range of possible changes or invariants are crucial: “Does changing the order of a sum change the result?”; “Does equal square/rectangle/parallelogram area imply the same perimeter?”; “Does multiplying a number by 2 increase the number of its divisors?”

Generalizing regularities and solving problems without algebraic formalism

An equation composed to solve a word problem algebraically expresses an invariance of some (typically unknown) value. For example, in problems that concerns motion, the same distance that two vehicles cover in different manners is the invariant of the two processes involved. Hence, the ability to identify invariance through some changes is useful for solving mathematical problems.

At primary school level, the search for invariance is an effective tool to discover regularities in numerical tables and in tables of arithmetic operations. For example, in the hundred table (see appendix, example 2) numbers increase constantly, but the change between adjacent cells in any row or column is invariant of the cell position. Similarly, the difference of products of diagonals of any 2×2 square is an invariant of the choice of square.

The next stage of proving those propositions typically involves some algebraic manipulation. Detecting a proper invariant for the problem can help avoiding formal algebra and provide a transparent proof with a generic example (Mason & Pimm, 1984). This type of reasoning is presented in the appendix.

Coming back to word problems and relevant equations, we illustrate another aspect of interaction between variation and invariance in pre-algebra mathematics. This interplay may provide non-algebraic solutions for some word problems. For example:

John bought two kinds of items: pencils that cost 30 cents each and pens that cost 50 cents each. He paid 6.20 euro for 16 items. How many pencils and how many pens did John buy?

We restate here a well-known arithmetic solution of the problem with an emphasis on variation and invariance. We start with the possibility that John bought 16 pencils at a cost of 4.80 euro. Now we need *to vary* the cost, keeping *invariant* the number of items. The answer to the question “How many pencils do we need to exchange for pens to increase the total price by 1.40?” provides the solution of the problem. In this approach, the total number of items is an invariant of the process. An alternative method of solution starts from any combination of items that provides the desirable cost (for example, 10 pens and 4 pencils). The next step is to vary the number of items keeping the total cost invariant.

A taxonomy of change and invariants

Due to many characteristics of each object or process, every variance results in several changes and introduces invariants as well. Alternatively, preserving some invariant permits variances of other properties. Thus, there are many possibilities of interrelation between change and invariance. The same sort of connection can occur in various mathematical problems and topics.

From the above and other examples, we have derived a suggested taxonomy for change, variance, and invariance:

- An invariant is given *a priori*, and the focus is on possible changes and related invariants.
- To understand the action of *prescribed change*, we look for imposed variations and for given invariants.
- To solve a problem, it is necessary to *find some key invariant* of all the procedures involved.
- To treat a mathematical situation, we *introduce a suitable variation* or a sequence of variations.

Within this classification, the two latter cases seem to be more complicated since they involve *construction* of relevant objects or procedures. On the other hand, a specific kind of relation between variation and invariance is connected more with the method of solving the problem than with the problem itself. Thus, various solutions of the same problem may bring into play different kinds of interaction of change and invariance or even a combination of those interactions.

PEDAGOGICAL ASPECTS OF THE APPROACH

We require that primary school mathematics teachers be competent to recognize relevant kinds of variations and invariants in various issues and problems of elementary mathematics. We need to start introducing this concept in teachers' education to en-

sure that they can construct an additional didactical tool for mathematical discourse in a classroom.

To test the influence of discourse in terms of interplay between variance and invariance on algebraic thinking of students, we designed an experimental study. The research involved future and current teachers of mathematics at elementary school. We tried to learn if, and to what extent, discourse on variance and invariance influenced beliefs and knowledge on the ability of further application of non-formal algebraic reasoning. In addition to checking the validity of our conjectures, we would like to improve the awareness of school educators about the use of variation and invariance at primary school level.

So far, pre-service teachers have participated in the study through problem solving activities in the framework of their courses in pedagogical colleges. Throughout these activities, they have discussed the ideas of variance and invariance with specific mathematical issues. We have found that future teachers have begun to construct examples for teaching in elementary school that invite algebraic thinking and argumentation in terms of change, comparison and invariants (Sinitsky & Ilany, 2008).

To promote this concept, we designed additional mathematical assignments. Each task includes a cluster of math problems on different issues at various levels of difficulty *united by the same relation of variance and invariance*. The starting point is part of the school curriculum, should be familiar to every pre-service teacher, and is a basis for further generalizations and analogies. The style of all the assignments is that of open problems in order to stimulate various approaches and strategies.

CONCLUSION

In this paper, we discussed applications of conception of changes and invariants in primary school mathematics. We looked at numerical problems from a point of view that is general and in many cases algebraic. The same types of connection can be detected in different mathematical issues. The ability to recognize variation and invariants may be an effective tool in constructing non-formal algebraic thinking of students. However, as a necessary stage, it requires the awareness of teachers on the subject. Some preliminary evidence on pre-service teachers' activities seems encouraging and invites further wide-scale research.

Acknowledgments

We wish to express our appreciation to the participants of the Working Group on Algebraic Thinking at CERME 6. Their questions and comments during fruitful discussions undoubtedly influenced the final version of this paper.

APPENDIX: IT LOOKS LIKE ALGEBRA

Two samples of reasoning involving variance and invariance interplay are presented.

1. Representations of natural number as a sum of consequent addends – fragment of transcript of discussion with pre-service primary school mathematics teachers

Students wrote down all the pairs with the given product, 30, and constructed sample sums of equal addends.

Student A: *“I start with equal addends. Now, for $30=10+10+10$, I keep the total sum but vary the addends: (she moves a finger from the first term to the third one and has marked it with an arrow) $30=10+10+10$. We get $30=9+10+11$, and it is possible to do this for each of these sums of equal addends! For example, I can derive from this sum (she points $30=6+6+6+6+6$) another sum of consequent addends: $30=4+5+6+7+8$ and... No, it does not work with $30=15+15$: we need the sum to be invariant but also keep a middle term, and there is no middle addend here. Ah, I can try to split each one of 15s, but it changes the number of addends...”*

Students also obtained representation of 30 as a sum of four consequent addends: $30=6+7+8+9$, and tried to derive sum of consequent addends from the sum of fifteen equal ones.

Student B: *“But we need negative numbers. Aha, after the cancellation we get exactly the same sum! It means that for every presentation of natural number as a sum of consequent natural numbers we can make more sums if we use integer numbers that will be cancelled after that, for example, $12=3+4+5$ and also $12=(-2)+(-1)+0+1+2+3+4+5$, because $(-2)+(-1)+0+1+2=0$ ”*

2. Divisibility of differences of two-digit numbers with “inverted” digits – sample proof

Conjecture: The difference of two two-digit numbers, where the second number has the same digits as the first one but in inverted order, is a multiple of 9.

How can we introduce the justification of this proposition without algebraic formalism in the framework of discussion with the students?

Let us check, what is the same in each pair of these numbers? They have the same digits, therefore also the same sum of digits. Now, let us mark an arbitrary pair of these numbers in a hundred table, for instance, 62 and 26. Their difference is just a distance between cells. Can we construct the route from 26 to 62 that keeps **invariant** the sum of digits? The route passes through 35, 44 and 53 before reaching 62. Each step increases the number by 9 (see “decomposition” of one of the steps in the table), therefore the total difference is a multiple of 9. Moreover, the difference between inverted two-digit numbers equals the number of such steps multiplied by 9.

GROWING PATTERNS AS EXAMPLES FOR DEVELOPING A NEW VIEW ONTO ALGEBRA AND ARITHMETIC

Claudia Böttinger & Elke Söbbeke

University of Duisburg-Essen, Germany

Sequences of growing patterns play an increasing role in the context of introducing terms. In this paper we reflect a new view onto the role of those particular visualisations for arithmetic and as well for algebra. By using a pupil's document we illustrate in this paper the theoretical framework of our concept.

Keywords: *representation/growing pattern, pre-algebra, children's interpretation, building structures and relations into diagrams*

1 Perspectives on the Mathematical Knowledge on the Way to Algebra

On their way from arithmetic to algebra, students have to develop a new awareness for the general, for the variation and the variable. At this period a new way of thinking, a new understanding of the previously acquired mathematical concepts, symbols and operations and thus a new interpretation of old knowledge becomes necessary. Students of elementary school become acquainted with equations in arithmetic lessons primarily in the context of calculating. In a special kind of lesson culture they learn more or less subconsciously that by dealing with equations they have to calculate the part on the left of the equal sign and after that to note the result on the right ("Task-Result-Interpretation"; Winter 1982). In many cases the equal sign is interpreted as a sign demanding to calculate. In many cases its function as a symbol of equality is not spoken about or used in every day arithmetic lessons. Such restriction in the interpretation, understanding and use of arithmetic terms and symbols is an obstacle not only for the later algebraic comprehension, but also for developing successful calculation strategies for the elementary arithmetical operations in the following school years.

Today algebra is seen as the lingua franca of higher mathematics (Hefendehl-Hebeker & Oldenburg 2008). However, algebra does not obtain the meaning and power of such a superior language if its status is restricted to the transformation and calculation of terms. Algebra has to be a "system characterised by indeterminacy of objects, an analytic nature of thinking and symbolic ways of designating objects" (Cooper & Warren 2008, 24). Therefore it is indispensable for the construction of algebraic comprehension not merely to calculate terms, but increasingly to see them in their structures, in order to understand formulae and principles. "The equation (or formula) must not be perceived as a sort of calculation shorthand note but rather as a type of scheme, which can in different ways be rearranged and be filled with concrete content" (Winter 1982, 210).

Various studies are concerned with the transition from arithmetic to algebra, which is accompanied by ruptures and discontinuities from the arithmetical to the algebraical

view (cf. Bednarz & Janvier 1996). In our paper we focus not only on ruptures in the transition from one view (e. g. arithmetic, geometric) to another but also on reinterpretations and developments within one view in the context of growing patterns.

2 Growing Patterns and Mathematical Visualizations as Mediators between old and new Mathematical Knowledge

If the substance of algebra is seen in the way it represents the principles and structures of mathematics and not in terms of the “behaviours“ of algebra (such as simplification and factorisation) (...) (cf. Cooper & Warren 2008, 24), then it is important for the introduction to algebra to make meaningful learning possible for the students, which at the same time constructs basic ideas that are sustainable in the long term. That means that such learning and exploring of algebraic ideas is always situated in the difficult balance between a rather empirical view on concrete objects and actions on the one hand and a certainly more challenging but in the long run necessary and profitable view on relations and structures on the other hand.

On their way to algebra it is necessary especially for young students to open a learning arrangement and an exploring field in which they can move between these poles of an empirical view on concrete objects and actions and a more abstract view on relations and structures. Structured mathematical visualization and growing patterns constitute such a learning environment, which merges those poles in a natural way.

Mathematical visualization and growing patterns - as a special type of mathematical visualization (for example to represent mathematical principles) - can mediate between the mathematical structure and the student’s thinking because of their special “double nature” (they are on the one hand concrete objects, which can be dealt with, which can be pointed at and counted, which can be manipulatively changed, and at the same time they are symbolic representatives of abstract mathematical ideas).

Mathematical visualizations and growing patterns are well-known to elementary and secondary school children from their daily mathematics classes. Geometrical patterns, which must be interpreted arithmetically, are used in class for various purposes. Steinweg (2002) notes that in text books dot patterns appear to practice calculating skills and thus function as visualizations, while sequences of dot patterns are to be explored as a separate and independent subject (cf. Steinweg 2002, 129-151). It is obvious that in everyday mathematics lessons dot patterns have predominantly the function of a methodological-didactical aid. Here is a parallel to the restricted view on equations and the equal sign mentioned above. Only in rare and isolated instances the structures incorporated in mathematical visualizations and growing patterns as well as equations are being purposefully explored and mentioned by the children. Against this backdrop Schwank and Novinska (2008) complain that didactic materials must be rescued from their shadow existence as mere aids and acquire a role as playing fields, in which genuine thinking processes can develop. Central questions such as “How many” and “if ... then” in dealing with this type of materials open a smooth transition to algebraic thinking - at first based on representations which become ac-

cessible through interaction, speech and graphics (cf. Schwank und Novinska 2007, 121).

3 Features in the exploration of growing patterns on the way to Algebra

If sequences of patterns support this new view – not only to figure out arithmetic terms, but to notice the underlying structure, transpose, re-organize and reinterpret them in a positive manner, then the following five aspects seem to be of particular importance. These categories were developed by connecting first results of a case study in progress (cf. Böttinger 2007) and the results of a completed case study (cf. Söbbeke 2005). In order to interpret representations more and more in the function as a representative of relations and structures and thus to focus on the abstract and generalizable “pre-algebraic aspects” it was necessary to connect in this paper two analysis instruments and to use them both to analyse the interpretations of student Ron. In order to describe the interplay between the geometrical, the arithmetical and the algebraic view it was necessary to develop an analysis instrument (cf. Böttinger 2007) by analysing the transcriptions of the interviews. While the analysis instrument “*Four levels of VISA*” (cf. 3.5) combines various aspects of structuring and interpreting a visual representation, in the analysis instrument “*Model of categories*” (cf. 3.1-3.4) these particular features were separated, adapted to sequences of growing patterns and the gradation was worked out by analysing the interviews.

The aim of the first case study (cf. Böttinger 2007) is to describe more precise on the basis of 20 interviews with 4th-grade children, in which way children translate geometrical relations in a sequence of growing patterns into arithmetic terms and in which way generalisations are carried out. The hypothesis is that there is no direct way from the geometrical representation to an arithmetical one and finally to an algebraic view. Instead there will be an interplay between these different views. In order to describe this interplay an analysis instrument (cf. Model of categories, Fig. 1; cf. Böttinger 2007) had been developed on the basis of the interview data.

3.1 Features concerning the structuring of single patterns

Fig. 1

In order to continue and examine the sequence a single pattern has to be structured. A subdivision can correspond to the *intended* structure of that person who composed the assignment on the one hand. On the other hand it can be an *individual* one, which does not correspond to a priori intended ideas.

3.2 *Features concerning the flexible re-organisation of single patterns*

In order to generate the idea of an equation one must be aware of different perceptions of a single pattern in the sequence. The aim is to identify the equality of arithmetic or algebraic expressions on the basis of the corresponding underlying geometric structure. Closely connected to this view is that transformations of equations correspond to changing the view on geometric structures. In analysing the children's interpretation one has to consider the flexibility during the process of work. It is essential to draw a comparison to the preceding interpretations of the child and to verify, to what extent a change of view occurs. This can be without new arrangement within the single pattern, e. g. when the number of dots is solely calculated in different ways. On the other hand a proper structural reinterpretation and re-organization exists, when the child builds fundamentally different structures into the diagram as in the step before.

3.3 *Features concerning the relation between geometric and arithmetic structures.*

Within her study Steinweg (2002) has worked out by what criteria children continue sequences of growing patterns. She distinguishes between a continuation by a figural aspect or by an arithmetical aspect. The figural aspect is concerned with the location of the dots and the external form built by the dots and the arithmetical aspect with the total number of dots in a single pattern. Steinweg accents that only the combination of figural and cardinal aspects lead to the intended continuation. Besides the distinction between a pure geometric view and a pure arithmetic view one has to regard the possible connections between both parameters. This can happen by a number of points, but also additive or more complex relations (e. g. multiplicative ones) can be identified.

3.4 *Features concerning relations within the patterns*

If sequences of patterns are used for algebraic investigation, one has to distinguish two totally different views. While the explicit formula uses the inner structure of a single figure, which must be suitable for all following figures, a recursive formula uses relations between consecutive patterns (cf. Carraher & Schliemann 2006). With the help of recursive formulas it is described, how the number of points changes from one pattern to the next. This view can be a great obstruction if the number of points in the 10th pattern is to be figured out. The student has to calculate step by step each particular pattern and simultaneously he has to control the number of steps. In addition, the indication of the recursion alone is incomplete to describe the building principle, because an initial condition is needed (Carraher, Schliemann, 2007, 697). From the

union of both perspectives interesting formulas can arise. Furthermore a dependence e. g. between the width and the height of a figure leads to dependent variables that describe exactly these features of the pattern.

3.5 Features concerning the interpretation visualizations (VISA)

In the second study (cf. Söbbeke) on the basis of detailed case studies with children of elementary school four levels of children's ability to build structures into mathematical representation (ViSA) had been distinguished. The underlying assumption of the study was that learning of mathematics has to be understood as a process of the children's more and more differentiated way of understanding and interpreting abstract patterns and structures (cf. Steinbring 2005). Visual representations are a tool to represent abstract mathematical concepts as well as to think about them or to talk about these with children. Growing patterns, as a special type of visualization, are often used to represent structures and relations in order to understand elementary mathematical principles (for example triangle numbers as an example to explore sums of odd numbers, etc.). The important information is not based in the concrete features of the material, but on the abstract, the relations and the structures within the material. Thus, what is decisive for a mathematical cognition in the figures is not the colours or the number of points; it is rather the function, which the concrete feature of the material takes for something. This means, the structure of the representation makes the understanding of a mathematical legality possible, but it cannot be read directly or immediately perceived with one's senses; it must be actively *interpreted* into the representation. In the empirical study (cf. Söbbeke 2005) it had been analyzed in how far the learning child succeeded in building such abstract structures and relations into the diagram. On this basis *Four Levels of Visual Structuring Ability* had been distinguished. These four levels characterize the children's interpretations in a spread of concrete and empirical interpretations on the one hand (cf. level one, left pole of the spread) and relational und structural interpretations on the other hand (cf. level IV, right pole of the spread) (cf. Söbbeke 2005).

Fig. 2: Four Levels of Visual Structuring Ability (ViSA).

4 Using Growing patterns to Support Students' Way to Algebra

- Ron on his Way to an Abstract and Multi-relational View of the Pattern -

The following examples are to show how the student Ron (4th grade) deals with the challenge to use growing patterns and to interpret them more and more in the function as a representative of relations and structures and thus to focus on the abstract and generalizable “pre-algebraic aspects” in the representation. For this we connect in this paper for the first time two different analysis instruments and use them both to analyse the interpretations of student Ron. The scenes presented are not to deliver a thorough methodical analysis. Instead the analyse in this paper can be seen as a first approximation to grasp and to describe the fundamental elements of the children’s way to algebra by using growing patterns, which had been pointed out in 3.1 to 3.5. The analysis is not extracted from a finalized study, but it is an example of a new approach to the theme, to the underling structure and to a more detailed view onto sequences of growing patterns. In the *first* part of the different interview phases (*beginning, in course, end*) the elements of the aspects 3.1 to 3.4 had been described with the instrument “*Model of Categories of Changing Modes of Representation*“ (see fig. 1). In the second part of the interview phases Ron’s interpretations had been assigned to the “*Four Levels of Visual Structurizing Ability (ViSA)*” (cf. 3.5, fig. 2).

Fig.

At the *beginning of this interview* scene, Ron is presented the first three figures of the growing pattern and he is asked to describe what he can see (Fig. 3)

Ron	(16 seconds break) Mhm. (5 seconds break) Mhm (laughing). (10 seconds break) There at the bottom there is always one more (he points to lowest the row of dots in the first, the second, the third pattern). Five, six, seven (he touches the lower part of the first, the second, the third pattern) This next row. There are always some more.
Ron	Here there are, there are three more (he touches with his pencil the upper part of the second pattern). Here there are five more (he touches the third pattern with his pencil). (..) Since those I can remove (he puts his forefinger onto the third pattern), I can take away, because these are still there (he touches with the pencil the second pattern, afterwards he points to the not covered points of the third pattern). (...) Three, five. (6 sec. break, he moves the left forefinger to both left points of the bottom row in the third pattern, stops for a moment and takes the finger away from the paper) Mhm.

After 30 seconds reflecting about this task Ron starts to compare the three patterns. He structures the three figures into two parts: the horizontal row of dots at the bottom of the pattern and the field of dots placed at the top. In his first approach Ron does not pay attention to the part at the top of the pattern, but describes that the row of dots increases from one figure to the next and names the numbers “five”, “six”, “seven”. In the analysis, considering the aspects 3.1 - 3.4, Ron shows that at the beginning of the interview he had developed an idea of the structure of the lower part of the pattern. Ron determines the number of dots in this part of the pattern and finds a recursive relation between the figures: “five, six, seven. ... There are always some more”. He builds a relation between the geometrical figure and the arithmetic in finding out the number of dots in the lower part of the pattern. Ron does not make it explicit, but

his repetition of the number series can be seen as an indication that the number series and in association the structure of the lower part could always go on in this way. Against the background of his first interpretations, the number series can be understood as a preliminary stage of a recursive building principle: from one figure to the next you always have to add one point. Already at this early stage of the examination of the pattern you can see a first level of generalization.

After reflecting about 30 seconds about the upper part of the figures, Ron starts to describe the increasing of dots from the second to the third pattern. Ron structures the upper part into two groups: on

Fig.

the one hand, he sees the group of dots that had been seen in the previous figure, and on the other hand those, that had been added in the new following one: “Since those I can remove (he puts his forefinger onto the third pattern), I can take away, because these are still there”. In his approaches to understand the structure of the upper part, Ron shows a first re-organization of the pattern. He does not analyse the two parts of the figures separate, but tries to understand in what way the first pattern could be identified in the second one and the second one in the third one. In the meantime he points with his finger on special areas of the lower part of the pattern, which he had described before in his first analysis of the pattern (the vertical row of dots). The numbers “three” and “five”, he denominates, correspond presumably to the numbers of dots in the upper part of the pattern, marked for a better understanding here in white colour (see Fig. 4). Ron uses the numbers of dots and structures and builds first elemental relations between the different patterns into the diagram (he covers with his hands parts of the previous patterns etc.). As a kind of arithmetical information, Ron determines the number of dots in the particular figures. At the beginning of this interview the analyse shows a first recursive view on the pattern; however, Ron does not generalize this recursive view further, but applies it solely to the partly figures.

Altogether Ron’s interpretation of the pattern could be attributed to the 2nd level of *ViSA* (cf. 3.5). The child moves away from the concrete aspects of the representation (numbers of dots) and focuses increasingly on abstract relations and structures (two parts of the pattern; angle-structure of the added dots in the new figure). But the elements of interpretation often stand isolated as concrete objects, without building *rich* relations between them (for example relations between the structure of the part at the bottom and at the top of the pattern; relations between the different figures). Sometimes only sections of the diagram are taken into consideration. In interpretations on this level there is a typical mediation between partial empirical interpretations and first structural interpretations. But often the children’s interpretations are still inflexible and they do not look at the representation as a multi-faceted structural diagram.

In the *course of the interview*, Ron notices that he had always forgotten to pay attention to one point in the lower part of the pattern, while analysing the increasing of the patterns:

Ron	O no, I didn't count those (he taps the bottom row of points in the second pattern). That means, there would be four new ones (he touches the second pattern) and here there would be six new ones (he touches the third pattern).
-----	--

After that Ron constructs a recursive geometrical building principle into the growing pattern and tries to translate it into an arithmetical building principle. In the course of the interview Ron has been asked to find an arithmetical task, which corresponds to the given pattern. For this he finds calculation tasks, which correspond with the result ("16") to the number of given dots in the third pattern. Ron interpretes and explains the proposal of the potential task "3·3+7", given by the interviewer, solely against the background of the calculating result und does not indicate a relation between the structure of the arithmetic task and the structur of the pattern. For Ron it is crucial that the number of the dots corresponds with the result of the calucating task.

He finds the calculating task "10·3+4" in the 5th pattern, that can be seen als an analogon to the proposal of the interviewer in the 3th pattern ("3·3+7"). Presumably Ron takes the aspect "number of dots" on and tries to build an analog construction (second factor of multiplication is "3" or a task with a multiplative term) like in the task of the interviewer. Finally, at the end of the interview Ron is asked to determine the number of dots in the sixth pattern. He starts to draw the sixth pattern onto the interview sheet.

Ron	Five, six, seven, eight, nine, ten (in the meantime he draws 10 points in a row beside the 5 th pattern). The first new points, this would be here, one, two, three, four, five, six (while speaking he draws a row of 6 points directly over the row of 10 points; cf. Fig 5). One, two, three, four five, six, (he draws - always counting until six - four further rows consisting of 6 points). One, two, three, four, five (with his pencil he touches the dots of the first column, but omits the corresponding dot at the bottom). Now another one (he draws a further row consisting of 6 points over the 5 th 6-row). Six. Ready. One, two, three, four, five, six, seven (he touches the dots of the first column including the corresponding dot at the bottom), seven. Six times seven is 42 plus four, 44.
-----	---

At first Ron divides the 6th pattern into two parts: At the bottom he builds a long horizontal row consisting of 10 dots, in the upper part a rectangular field consisting of six rows of six dots. Subsequently he carries out an interesting new interpretation of the pattern. He structures it into a rectangle of seven rows of six dots, which reaches into the horizontal line at the bottom. Beside this 6x7-field of dots he regards two points at the left and two at the right-hand side – at whole 4

Fig. 5

points. To figure out the total amount of numbers in the 6th pattern Ron uses for the first time the inner structure of a single pattern. In comparison to his proceeding before this represents a change of view in connection with a new structuring. The relation between the geometric arrangement of the dots is no longer determined by the cardinality of a set of points but by a complex structural relation – namely a multiplicative one. By that Ron changes from his formerly recursive view onto the sequence and considers a single pattern in an explicit manner. The structure he uses is an intended one and in principle it is applicable to all patterns. But at this stage of the interview Ron does not express or indicate this generalisation.

Ron's interpretation of the pattern could be attributed to the *third level of ViSA*. In interpretations on this level *intended structures* and *relations* can be identified (for example relation between the part of the bottom and at the top of the figure; field of 6x7 dots; constancy of 4 dots in the part at the bottom). On this occasion different and multi-faceted aspects of the representation are recognised. In comparison to level II, the structures are *manifoldly coordinated* and more *flexibly re-organised*. The structures are no longer isolated, but seen as part of the whole and separated and put together in a structural way. You always find the use of *structural relations*, *coordination* and *re-organisation* of elements. In all, this level III of ViSA can be characterized by the combination of building structures with the increasing use of relations and re-organisations.

5 Conclusion

For a fundamental pre-algebraic comprehension it is indispensable to focus on structures, on the abstract and the general, right from the start of children's mathematics education. In this paper, growing patterns have been discussed and analysed as exploring fields on the way to focus on structures and relations. Structure sense seems to be a fundamental requirement to interpret sequences of growing patterns in an algebraical manner. Both analysing instruments examine in different ways how young children deal with the challenge to interpret this special visualization in a more structured, generalized and elementary "algebraic" way.

The examples of Ron indicate that this kind of structuring, translation and generalization does not take place in a direct and straight way. The child can partly understand the geometrical structures, translate them into arithmetic ones. It can change the view back to the geometric pattern and re-organise and re-structure the diagram. It seems that generalization is not always the "end" of this process; in fact ideas of generalization can be developed before comprehending the whole structure of the patterns.

An analysis of selected parts of the interview shows that in the *process of the examination* and the *interaction* between the student and the interviewer the child gradually develops a more differentiated, relational and generalized view onto the used diagrams, which can be described in detail by the system of categories and in a more summarising manner by means of ViSA (see e.g. the development of Ron's interpre-

tation from level II to level III). Altogether the excerpts of the interview with Ron serve to demonstrate the change in children's interpretations in a exemplary way and to accompany and better understand their way – to an increasingly open, general and flexible view onto relations and structures within diagrams.

STEPS TOWARDS A STRUCTURAL CONCEPTION OF THE NOTION OF VARIABLE

Annika M. Wille

University of Bremen

If students acquire a new mathematical notion, according to Sfard (1991), they pass through different phases: an operational and a structural phase. At a grammar school in Bremen, Germany, students of age 12 to 14 first came into contact with the notion of variable using a simple programming language without a computer. As a part of the learning environment the students wrote imaginary dialogues in which they let two protagonists talk about different tasks. The imaginary dialogues of the students are analysed against the background of Sfard's theory of the dual nature of mathematical conception. In particular, the different steps towards a structural conception of the notion of variable in the context of the programming learning environment are elaborated.

INTRODUCTION

If we look at a mathematical notion, we can think about what it is in the mathematical world, how it is defined, which properties it has, and how it relates to other parts of mathematics or we can consider how a human being thinks about it and what kind of inner picture has been built. Anna Sfard (1991) distinguishes here between the word *notion* or *concept* on the one hand and *conception* on the other hand.

The whole cluster of internal representations and associations evoked by the concept - the concept's counterpart in the internal, subjective "universe of human knowing" - will be referred to as a "conception". (Sfard, 1991, p. 3)

According to Sfard, a conception of a mathematical notion has two complementary sides, an operational and a structural one, in which a learner first passes through operational phases until a structural conception can be developed. She also points out that

without the abstract objects all our mental activity would be more difficult. (Sfard, 1991, p. 28)

In this article the development of the conception of variable is considered. The underlying question of the presented analysis is: what are steps towards a structural conception of the notion of variable? To approach an answer the findings of a qualitative analysis of imaginary dialogues written by students of age 12 to 14 from one class will be presented.

THEORETICAL FRAMEWORK

The theory of reification

Sfard (1991) presents a theoretical framework for the acquisition of a mathematical notion. She distinguishes between an *operational* and a *structural conception* of the same mathematical notion. If a learner has acquired an operational conception, she or he will know how to operate with the notion, i.e. with algorithms, processes and actions. For a structural conception it is necessary to recognise the notion as a mathematical object. Sfard expects that the operational conception precedes the structural. In this process from operational to structural three steps occur: *interiorization*, a process with familiar objects, *condensation*, where the former processes become separate entities and *reification*:

to see this new entity as an integrated, object-like whole. (Sfard, 1991, p. 18)

While a learner can come gradually from interiorization to condensation, Sfard speaks of a *leap* when it comes to reification:

“Reification (...) is defined as an ontological shift – a sudden ability to see something familiar in a totally new light. Thus, whereas interiorization and condensation are gradual, quantitative rather than qualitative changes, reification is an instantaneous quantum leap: a process solidifies into object, into a static structure.” (Sfard, 1991, p. 19-20)

Sfard & Linchevski (1994) used the framework of the theory of reification to study the case of algebra. In particular, they focused on the transition from operational to structural regarding a variable as a fixed unknown on the one hand and in a functional context on the other hand. Sfard (1991) asks the question how to diagnose the stages towards a conceptual development and proposes:

"It seems that we have no choice but to describe each phase in the formation of abstract objects in terms of such external characteristics as student's behaviour, attitudes and skills." (Sfard, 1991, p. 18)

Mathematical writing

Mathematical writing by students has been the issue of several studies, compare Borasi & Rose (1989), Clarke, Waywood & Stephens (1993), Gallin & Ruf (1998), and Shield & Galbraith (1998). Gallin & Ruf investigated the use of *journals* (in German: Reisetagebücher) in order to establish a written dialogue between the students and the teacher. While writing their journals the students can approach the regular mathematics in their singular way.

Imaginary dialogues are a different type of mathematical writing (Wille, 2008). In an imaginary dialogue the student lets two protagonists solve a mathematical task or talk about a mathematical question. Usually one protagonist understands the task better than the other. In this way the student can decide what particular themes she or he addresses. Unlike in journal writing, in an imaginary dialogue, one finds a lot of exploratory writing. On the other hand, in contrast to pure exploratory writing, like

writing a letter to someone and explaining something, in imaginary dialogues the protagonists can develop a solution of a task and the protagonists can point at possible learning difficulties.

LEARNING ENVIRONMENT

The learning environment is designed for first experiences with the notion of variable. The students do not start with a single variable as a fixed unknown. Instead, they get to know a simple programming language which is executed by the students without a computer but with a little wooden robot on a sheet of paper with a coordinate grid. The programming language has similarities to LOGO (Papert, 1980). Here, as a “memory” each robot needs matchboxes on which letters for the names of variables like “a” and “b” are written. These matchboxes serve as *preset reifications* of the notion of variable, which the students fill by hand instead of assigning a number to a symbolic variable. For example to move three steps forward, the program will look like this

a ← 3

forward(a)

While executing the first line it must be assured that exactly three matches are in the matchbox named “a”. In the second line, the robot will be moved into the direction it faces. The matchboxes must be used in order to move a robot, since the direct command “forward(3)” is not part of the programming language. Next to these commands there is also the command “turnaround()”, which lets the robot turn by 180°. Furthermore there are a right and a left turn, commands to place the robot on a certain intersection point on the coordinate grid and different command loops. That way students can write and execute programs in order to move their robot on the grid while assigning variable by filling matchboxes with matches.

In the learning environment the programming of the robot can be combined with writing imaginary dialogues. One of the first tasks can be the following: The students get a sheet of paper with “a ← “ and “b ← “ on top and “turnaround()” in the middle. On another sheet of paper eight paper commands “forward(a)” and eight paper commands “forward(b)” can be cut out. The students get the following exercise with the name “cut out and explore”:

On the next sheet of paper you see a program that is not finished yet. You can use commands out of a construction kit and put them above and below the command “turnaround()”. 1. Cut out as many commands as you need and write a program with them. 2. Execute your program with the matchboxes and the robot. 3. Try to write such a program that the robot comes back to his starting point. 4. For which values a and b does your program function? Are there different possible values? 5. Write your favourite program and name many values with which it works.

Right after this lesson the students get the following homework (*dialogue A*):

Two students talk about the last task “cut out and explore”. One of the students can do it easily, the other has more difficulties. Write a dialogue in which the two students talk about the task. Write at least one page.

In the next task a simple program is presented, where over the turnaround command there are two commands “forward(a)” and under it one command “forward(b)”. There is also a table given for a and b with values (1,2), (2,4), (3,6) and (4,7). A beginning of a dialogue is also part of the task where two students talk about whether the numbers in the table should be switched. One protagonist draws also the following picture:

Figure 1

The students are asked to work with the program first, decide, if the table is correct and finish the dialogue (*dialogue B*). After further tasks with the robot a third imaginary dialogue task (*dialogue C*) is given. The students get the following picture:

Fig

ure 2

Now the students are asked to think of an interesting program of a similar form, find the proper presentations like in Figure 2 and write an imaginary dialogue about it.

METHOD

The study was carried out in a class of a grammar school (Gymnasium) in Bremen, Germany, in 2008 with the above mentioned learning environment. The students wrote three different dialogues A, B and C. Dialogue A was written after the second lesson, dialogue B after three more days and dialogue C after about three weeks. The imaginary dialogues A and B were given as homework, dialogue C was written in the classroom. Since not all students did their homework or some let the protagonists talk about only non-mathematical tasks, for the analysis 16 A-dialogues, 15 B-dialogues and 22 C-dialogues could be used. For the qualitative analysis of the imaginary dialogues the framework of Sfard's theory of reification was used. The analysis was carried out in three steps:

13.examination by *four criteria*: recognised structures, occurring aspects of the notion of variable, phase in which the student is (i.e. interiorization, condensation, mixed form/indistinct, or reification), mentioned preset reification

14.creation of a *mind map* of the seen structures for each dialogue A, B, and C

15.creation of *tables* that includes the information of the mind maps and the phases

In order to examine by the four criteria, most dialogues were first transcribed and then interpreted in detail. The students' development was classified according to the phases according to these criteria:

- *interiorization*: the student can handle the program: processing the program, filling matchboxes with matches, etc.
- *condensation*: the student deals with variables as with objects but does not see them as objects, the input and output is more important than the process itself
- *mixed form/indistinct*: it cannot be decided if the student already reificated the notion of variable, variables are used in a tight relation to preset reifications
- *reification*: variables are seen as independent objects

FINDINGS

All imaginary dialogues mentioned here were written in German and translated by the author.

Mini-statistics

We can observe a shift of the students of this class from interiorization to reification as Sfard predicted. It must be mentioned that the tasks for the dialogues A, B and C were similar, but different. Thus, there is the possibility that the observed shift also depends on the different tasks. In the following table, the number of students in a certain phase of a certain dialogue is denoted:

	i	c	m	r	Total
A	11	2	2	1	16
B	5	5	3	2	15
C	4	5	6	7	22

Table 1: number of students in a certain phase

Structures recognised by the students

The structures that were recognised by the students are shown in the tables of the Figures 3 and 4. The tables should be read like a tree from left to right where each

row is a branch. It is also listed which phase is assigned to the specific imaginary dialogue, in which the student recognised the structure. The letters i, c, m and r stand for the phases interiorization, condensation, mixed form/indistinct and reification. There are several crosses, if several students see the same structure. Some of the structures that can be seen as examples of *preliminary steps of reification* are discussed below. In the following, for example “Figure 3, structures in A, 7” refers to the seen structure in A written in row 7 which is here “segmentation of the distance – in segments a and b”.

structures in A

		i	c	m	r
comparison of the number of steps		x			
independence of the notation	name of variable is free to choose	x			
segmentation of the commands	search for a segmentation	x			
	same amount of commands with a and b with an example			x	x
segmentation of the distance	in steps without a and b	x			
	in segments a and b		x		
preform of abstraction	forward(a) and box content synonymical			x	
preform of substitution	preform of “a is 1”			x	
preform of reification	abstraction of matchboxes		x		
	paper commands “a’s” and “b’s”			x	
	relationship between the number of “a’s” and “b’s”			x	
	a and b as steps			x	
abstraction	a as a value in different contexts				x

structures in B

		i	c	m	r
correlation of the values in the table		x			
pre-understanding of equations	preform of symmetry in equations	x			
	correlation between program and substitution in equation	x			
	preform of the understanding of equations		x		
structure of explanation	abstract, concrete, example				x
correlation between term and distance			x		x
correlation between a and b	comparison of undefined step sizes with the notion “a” and “b”		x		x
	b is the double of a				xx
abstraction	variables as independent objects				x

Figure 3: structures in A and B

structures in C

		i	c	m	r
1	commutativity of the commands			x	
2	different substitutions possible				x
3	structure in table	multiple addition	x		
4		as the times table		x	
5		proportion between a- and b-values		x	
6		correlation between values in the table		x	
7	variable as common name for something	">a<" as name for a mathbox, column and field		x	
8		generic term for values, commands and distances		x	
9	correlation between a and b	as values			x
10		b is the double of a		x	xxx
11		it is "the same" with other values			x
12		how many of "a" yield "b"			x
13		concrete assignment unimportant		x	x
14	letters a and b	instead of a number of intersection points		x	
15		as a fixed unknown		x	
16		stand for a number of steps			x
17		stand for numbers in the language use	x		
18		stand for numbers	xx		x
19	step size as a scale				xx
20	preform of reification	"a)" and "b)" instead of concrete numbers in the language use	x		
21		notation "a=7" for values of the table		x	
22		a and b as generic term for values in the table		x	
23	understanding of equations	symmetry		x	
24		cancellation			x
25		equation as a summary of examples			x
26	expansion of the number of variables				x
27	abstraction	variables as independent objects			xxxx
28		terms as independent objects			x
