In Figure 1, the last outcome in the list was 1, 3, 2, which Allen erased and replaced with 1, 3, 4 after he realized that 1, 2, 3 and 1, 3, 2 represent the same outcome. This demonstrates that Allen's error was not due to misunderstanding the question; he was aware that the problem counted unordered combinations of books, and not arrangements of books. Allen realized that his solution was incorrect, but he was not able to find a numerical expression that accounted for different arrangements of the books being the same outcome. He then decided to implement a listing algorithm that differed from his previous algorithm by requiring that the books be placed in increasing order in any outcome. For example, the outcome 1, 3, 2 would not be counted in this new listing algorithm because the numbers are not in increasing order. He justified that enforcing the increasing order would still produce every outcome, and that every outcome would be produced only once because there is exactly one way to place the numbers in increasing order. His implementation of this listing algorithm is shown in Figure 2. Allen explains the logic of his code as:

Allen: Say I pick book number 5 as my second book. I don't need to pick book 1, 2, 3, 4, or 5 [as the third book] in that case, so I'd only have three books to choose from.

After running his code, Allen realized that the correct solution was exactly one sixth of his original but incorrect solution; that is, that *P(8,3) = 6*C(8,3)*. His additional work sought to justify this ratio.

```
In [7]: count = 0

        for i in range(1,9):
            for j in range(i+1,9):
                for k in range(j+1,9):
                    count = count + 1
                    print(str(i)+" "+str(j)+" "+str(k))
        print count
```

Figure 2: Allen's Listing Algorithm for *C(8,3)*

Listing Algorithm for C(n,3)

After Allen realized the correct solution was one sixth of his original solution, he investigated how the ratio would change as the number of books increased. He said the following:

Allen: That's interesting, 8*7 is 56, I'm fairly certain of that. That is interesting, though. Completely the third value [the value 6 in 8*7*6, his original solution] didn't even really matter it looks like … So this last one was equal to 8*7. I just want to see if bringing the total number of books down by one, does that make it equal 7*6? Is there a relationship there?

To create a conjecture for the value of *C(7,3)*, Allen reasoned about the mathematical expression *8*7*, indicating that he was attempting to find an empirical pattern in the expressions themselves. He seemed to reason that the correct solution would be to take his original solution, and remove the last term in the product. We take this to be an instance of empirical pattern matching, where he was hoping to recognize a pattern in the numerical solutions without reasoning about why that pattern is reflected in the set of outcomes. He was aware that his pattern matching might be incorrect, indicating that dividing by *6* "might just be luck." After changing his computer program to solve the new problem, he observed that the correct answer was *7*5*, which is one sixth of his original answer, Allen decided to investigate the ratio *P(n,3)/C(n,3)* for other values of *n*. This ratio is 6 for every *n*.

To investigate the ratio as *n* increased, Allen wrote a new computer program. Because the number of books in his listing algorithm for *C(8,3)* was only represented by the 9 in each of his for loops (in Python, range(1, n+1) produces the numbers 1 through *n*), he created a variable *book* that could be changed. By replacing the number of books with a variable, he could create a program to calculate *C(n,3)* without writing a new program for every value of *n*. Importantly, this change did not require restructuring the algorithm to accommodate a variable parameter. Allen wrote the function in Figure 3, which inputs the number of books and returns the ratio *P(books,3)/C(books,3*). By iterating through multiple values for *books*, Allen verified that the ratio was 6 for every value of *books*.

```
In [23]: def fun(book):
             count = 0
             for i in range(1,book+1):
                 for j in range(i+1,book+1):
                     for k in range(j+1,book+1):
                         count = count + 1
                         #print(str(i)+" "+str(j)+" "+str(k))
             return (book*(book-1)*(book-2))/count
```

Figure 3: Allen's Listing Algorithm for *C(n, 3)*

Listing Algorithms for *C(n,k)*

After finding that *P(n,3)/C(n,3)=6* for every value of *n*, Allen decided to see how this ratio changed as *k* increased. Here the number of books being selected was represented by the number of nested for loops. This is not easily changed, and creating a function that returns *C(n,k)* for any value of *n* and *k* would require a significant restructuring of the code. Allen's goal was not to create a listing algorithm for *C(n,k)*, but rather to determine a closed-form solution for *C(n,k).* While a listing algorithm for *C(n,k)* may have aided him, he was able to pursue other means of generalizing his algorithms.

Rather than write a single function for *C(n,k)*, Allen wrote two different functions for *k=4* and *k=5*. For each of these, he made conjectures about *P(n,k)/C(n,k)* before he observed the actual ratios. For both values of *k*, Allen's computer programs showed that the ratio was constant. Specifically, his programs returned that *P(n,4)/C(n,4)* = 24, and *P(n,5)/C(n,5)* = 120. Although his conjectures seemed to express numerical pattern recognition based on empirical data rather than conjecture based on mathematical analysis of the counting problem, his persistent comparisons between *P(n,5)/C(n,5), P(n,4)/C(n,4),* and *P(n,3)/C(n,3)* showed that the ratio between the ratios followed a pattern. In describing this pattern, he states:

Allen: What I noticed is each time you go up, you multiply by the next number. So 6 times 4 equals 24, which multiplied by 5 equals 120, which multiplied by 6 equals 720.

After formalizing this pattern, Allen used his knowledge of a closed-form solution for *P(n,k)* to conjecture a closed-form solution for *C(n,k)*, as shown in Figure 4.

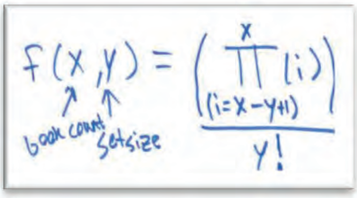

Figure 4: Allen’s Closed-Form Solution for *C(n,k),* or *C(X,Y)*

In this expression, *X* is the number of total books and *Y* is the number of books being selected. Allen asked the interviewers if there was a symbol for repeated multiplication, and we described the notation in the numerator. The numerator of the right side is Allen’s known solution for *P(n,k),* and the denominator is the reciprocal of the conjectured ratio between *P(n,k)* and *C(n,k).* While Allen found this expression through numerical pattern recognition based on empirical data, he was able to justify the closed-form solution by stating that Y! is the number of ways to arrange the selected books, so dividing by Y! essentially removes all repeated occurrences of the outcomes.

Discussion

In these data, Allen appeared to have more difficulty finding an expression for *C(n,k)* than writing a computer program that listed the outcomes to a counting problem. And while Allen used his computer program to find such an expression, there were essentially three big ideas that he reasoned about: (1) generalizing and implementing his computer programs, (2) conjecturing about the values of *C(n,k),* and (3) formalizing and justifying a mathematical expression for *C(n,k).* The first idea was the one that seemed to pose the least challenge to Allen, after he realized that his original solution was incorrect. We differentiate between ideas (2) and (3) because they occurred at different points in the data, and because his ways of reasoning about them were different. As Allen wrote his different computer programs for *C(8,3), C(n,3), C(n,4),* and *C(n,5),* he conjectured about their values based on empirical patterns that mostly concerned how the values were written. For example, when Allen saw that *C(8,3) = 7*8,* and his original solution was *8*7*6,* his conjecture for *C(7,3)* was *7*6* because his original solution would have yielded *7*6*5*. That is to say, his conjecture was that the correct solution would be to remove the smallest term from the incorrect solution, and his reasoning for this was based on the observations from his computer program. In this way, Allen was projecting forward so as to anticipate future values and see if his conjectures were true, but his conjectures were based on the cardinalities of the sets of outcomes rather than the sets of outcomes themselves. It is difficult to say how much of his conjecturing would have remained the same if he had not written the computer programs himself, and instead were given a table of values for *C(n,k),* but we feel that a contribution to his success was repeated conjecturing followed by writing a computer program to verify if the conjecture were true. In contrast, when reasoning about (3) Allen reflected on the data he had already found to formalize a mathematical expression, and then he reasoned about the sets of outcomes as a means to justify that expression.

We do not intend to criticize Allen for his empirical conjectures during stage (2), but as mathematicians it is easy and often justifiable to place more value his reflective behavior during stage (3). However, we are also aware that stage (3) may never have occurred if not for stage (2), and we recommend other researchers to allow times where students can engage in empirical conjecturing or reasoning.

Another difficulty with writing programs to solve combinatorial problems with variable parameter values is that the output of the program is not a symbolic mathematical expression, yet mathematical analysis typically involves symbolic, closed-form expressions. The outcomes of a computer program and mathematical analysis are not the same, so they can be difficult to compare. In our data, Allen was able to create an expression for $C(n,k)$ by comparing the value to a known similar value, $P(n,k)$, as one parameter varied at a time. Future research could examine ways of using and analyzing computer programs with variable parameter values other than as a way to compute fixed instances of parameter values. While Allen used his computer programs to compare the values to other known values, an alternative method would be to examine the behavior of the program as the parameter values changed.

Allen created and generalized a listing algorithm for a problem that he could not solve by hand. The utility of the computer program in Allen's case was not reinforcing known mathematics, but the ability to verify conjectures about unknown mathematics. Because Allen decided on how to proceed during his work, we hypothesize that he was partially motivated because he was given agency over his mathematics. Future research could examine a computational environment as a means of solving unknown mathematics or mathematics that is unfeasible to compute by hand. In combinatorics education, this might mean using the computer to reason about sets of outcomes that students can create listing algorithms to produce, but that are difficult to count with conventional formulas and expressions. In such cases, the end goals might not be to find a closed-form solution that counts the set of outcomes, but to reason about how the size and structure of the set of outcomes changes as parameter values change.

A practical experience in pre-service teacher education focusing on computational thinking

Keywords: Pre-service teacher training, mathematics education, block-based programming.

Introduction

Computational thinking (CT) is a recent topic in most Brazilian schools since it was included in the National Common Core Curriculum – NCCC (*Base Nacional Comum Curricular* – BNCC) in 2018. NCCC aims to guide school curricula and provide for the development of CT through Mathematics teaching (Ministério da Educação, 2018). The purpose of this research is to present how elementary pre-service teachers apply CT skills when they design a lesson to teach elementary mathematics.

Theoretical framework

In this research we consider Selby and Woollard's definition (2013, pp. 5) of CT: it "is a focused approach to problem solving, incorporating thought processes that utilize abstraction, decomposition, algorithmic design, evaluation, and generalizations." This approach combines the four CT pillars showed by BBC Learning (n.d) and the Reference Curriculum in Technology and Computing (Raabe et al., 2020, p. 19): abstraction, algorithms, decomposition, and pattern recognition.

Code programming using block-based programming languages is a popular form to develop CT skills (Hsu et al., 2018). Brennan and Resnick (2012) identified computational concepts by studying activities in the Scratch online community. These concepts are common in many programming languages and include sequences, loops, parallelism, events, conditionals, operators, and data.

Methodology

This research is qualitative in nature and seeks to address the following research question: *how do pre-service teachers include computational thinking concepts when they design elementary mathematics activities from NCCC's perspective?* To discuss this research question, we analyzed an activity developed by three of thirteen participants of a pre-service teacher training process, which took place over four months, with one 3-hour session per week, in a Brazilian private university in 2021. Due to the COVID-19 pandemic, all classes were remote, synchronous, and occurred via a virtual meeting program. The aim of this training process was to discuss CT connection with elementary mathematics teaching. Through a teaching experiment, we proposed tasks to the students in which they had to think how to design mathematics lessons using unplugged and plugged CT for their future primary education classes. Data were collected from pre-service teachers' protocols, training's video recordings, and Scratch's programming code from plugged activities designed. Data were analyzed taking into account CT definition and concepts mentioned before. The analyses of qualitative data sources were divided to identify the frequencies of CT concepts and of aspects of CT definition.

Statement and discussion of results

The proposed lesson had to consider one of the elementary mathematics ability previewed in NCCC, which introduces the concept of geometric orientation to children. Pre-service teachers explored Scratch's programming language and proposed a pre-made scenario presented in Figure 1. They made a small program to provide pupils only with a yellow butterfly flapping the wings.

Figure 1: Plugged activity proposed by students

In the teachers' code programming, we found sequences as expected: 16 loops (repeat and forever), 5 events that occur when the green flag is clicked or a space key is pressed, and 5 parallelism actions, three of which begin simultaneously when the green flag is clicked and two happen when the space key is pressed. Teachers did not consider conditionals, operators, or data in their code.

Pre-service teachers' description about how they constructed this activity reported they did not make the code in one step; they had to split it in small parts (like move to the right, move up, move down…) and synchronize Scratch's actors' movements. Analyzing all data source, we found evidence the participants used all the CT pillars to conclude the task (abstraction, algorithms, decomposition, and pattern recognition).

Synergy of two division algorithms in 4th grade: opportunities and challenges

Silvia Funghi and Alessandro Ramploud

Università di Pisa, Italy; silvia.funghi@dm.unipi.it , alessandro.ramploud@unipi.it

This paper aims at showing the potential of the synergistic use of algorithms as artifacts for the development of mathematical meanings with pupils of primary school. Specifically, we consider two division algorithms introduced in 4th grade and we show how a specific task design, that involves a comparison between the two different algorithms performing the same division, can generate a mathematical discussion. In such a discussion we can identify several situated signs potentially useful for the development of mathematical meanings related to the algorithms' functioning.

Keywords: Sinergy between algorithms; Semiotic Mediation; Artefacts; Canadian division algorithm; TI×- division algorithm.

Introduction

This article presents a study on teaching multiple algorithms for calculating divisions, carried out within a larger project (see www.percontare.it) aimed at providing Italian teachers with a repository of educational activities in Mathematics for primary school that pay particular attention to inclusiveness (Baccaglini-Frank, 2015). A fundamental design feature of the activities is their aim to help students reach a solid construction of mathematical meanings through the use of artefacts, following the Theory of Semiotic Mediation (TSM) (Bartolini Bussi & Mariotti, 2008). This aim is prominent also within the set of activities concerning the introduction of different calculation algorithms for arithmetic operations. In this study we will focus on the teaching and learning of division between natural numbers through two algorithms in fourth grade (age 9-10).

The first algorithm we consider is the "Canadian algorithm" (Lisarelli, Baccaglini-Frank & Di Martino, 2021; Boero & Ferrero, 1988), consisting in a repeated subtraction of the divisor from the dividend. The other one is *"TI×- algorithm"* (Karagiannakis, 2018), that is similar, from a mathematical point of view, to the long division algorithm (see the *Methodology* section). The main difference between these two algorithms can be expressed through the *transparency* construct with respect to the meanings of the division between natural numbers. We want to extend to these algorithms the definition of transparent and opaque representations of numbers introduced by Zazkis & Gadowsky (2001): "A transparent representation has no more and no less meaning than the represented idea(s) or structure(s). An opaque representation emphasizes some aspects of the ideas and structures and de-emphasizes others" (p. 45). We can say that the Canadian algorithm is transparent with respect to the meaning of division, conceived as a progressive distribution, while TI×- algorithm is opaquer with respect to this meaning. Our research hypothesis is that children can make sense of the algorithms, understand *why* they work, and gain deep understanding of division of natural numbers, by becoming fluent with both of them and then comparing them and discovering what is behind the opacity of an algorithm like TI×-. Our main research interest is to test this hypothesis. In the study, we report on our attempt at promoting a mathematical discussion overcoming the opacity of the TI×- algorithm.

Theoretical framework

An *algorithm* can be considered as a cultural product, designed to solve a given class of problems. Schmittau (2003), discussing the role of algorithms within Davidov's curriculum, expressly talks of them as a "symbolic trace of the meaningful mathematical actions required to solve a problem" (p. 240). In this perspective, an algorithm develops historically and is configured as a cultural tool that mediates an individual's knowledge and understanding of Mathematics (Ebby, 2005). The reliability of an algorithm rests on a body of knowledge that is not always visible to those who use it. Traditional algorithms, in fact, are the result of a historical-cultural evolution that has often favored the efficiency of algorithms in a mechanical sense rather than their transparency with respect to mathematical meanings underlying each step (Bass, 2003).

In this perspective, we can interpret didactical activities on algorithms for the arithmetic operations through the lens of a whole tradition of studies which have shown how it is possible for students, through the use of artefacts to accomplish a task, to develop meanings linked to the knowledge incorporated in the artefacts themselves (e.g., Bartolini Bussi & Mariotti, 2008). Starting from a Vygotskian perspective, Bartolini Bussi and Mariotti emphasize the crucial role of social interaction as an engine for student learning, with a focus on the semiotic processes that can occur in the classroom starting with an activity with an artefact, triggered and supported by the teacher. Nevertheless, unlike most of the studies informed by TSM - which concern the use of only one artefact - in this study we chose to use two different algorithms as artefacts. This choice is supported by recent studies that have begun to investigate the possibility of introducing more than one artefact having a common potential with respect to the development of the same mathematical knowledge (e.g., Faggiano et al. 2018; Maffia & Maracci, 2019). These studies confirm that in specifically designed didactical activities, the introduction of more than one artefact can result in a synergy, which can increase the didactic potential of the activity with respect to activities involving a single artefact (Faggiano et al., 2018; Maffia & Maracci, 2019).

Therefore, conceiving algorithms as artefacts can be useful to make visible to the students mathematical meanings related to the body of knowledge that make the algorithms reliable. From the perspective of TSM, starting from the use of algorithms to carry out specific tasks, and participating in an explicit discussion on this use - intentionally orchestrated by the teacher - students can develop knowledge on the nature of the algorithm and the properties of the operations to be performed. More specifically, we present a didactic intervention whose aim was precisely to develop students' knowledge of the mathematical meanings underlying two different division algorithms.

Research questions

1. What signs in the discussion can evolve in the direction of the discovery and understanding of the mathematical meanings underlying the functioning of TI×- algorithm?
2. Can (and if so, how can) the synergy of artefacts foster the emergence of signs related to mathematical meanings in common among the two algorithms involved?

Methodology

According to the TSM framework, the didactic activity was designed to include a part of interaction with artefacts and a subsequent part of mathematical discussion, to be developed in Distance Education (DE) due to the persistence of the SARS-COV-2 pandemic. As showed in other studies (e.g., Ramploud, Funghi & Mellone, 2021), in order to face the constraints of DE, teachers have sometimes chosen to adapt the framework of TSM to their new conditions. In this case, the teacher chose to separate the part of interaction with the artefacts from the discussion: in a first moment students had to calculate the division 874:7 with both algorithms, as homework; then, the class was divided into 4 heterogeneous groups of 7-8 students each, and the next day for each group a lesson in DE of 40 minutes was dedicated to the mathematical discussion starting from the different solutions of the students. The lessons were all video recorded and fully transcribed.

The two algorithms considered were specially chosen in analogy with other studies (e. g., Lisarelli et al., 2021) to allow "to discover various mathematical meanings behind the long division algorithm [in our case, the TI×- algorithm] and their role in unveiling the whys: the role of place value, the hidden powers of ten, [...] the meaning of each digit of the quotient, how each remainder is obtained." (ibidem, p. 3). We describe below the two algorithms for the division presented in the PerContare project.

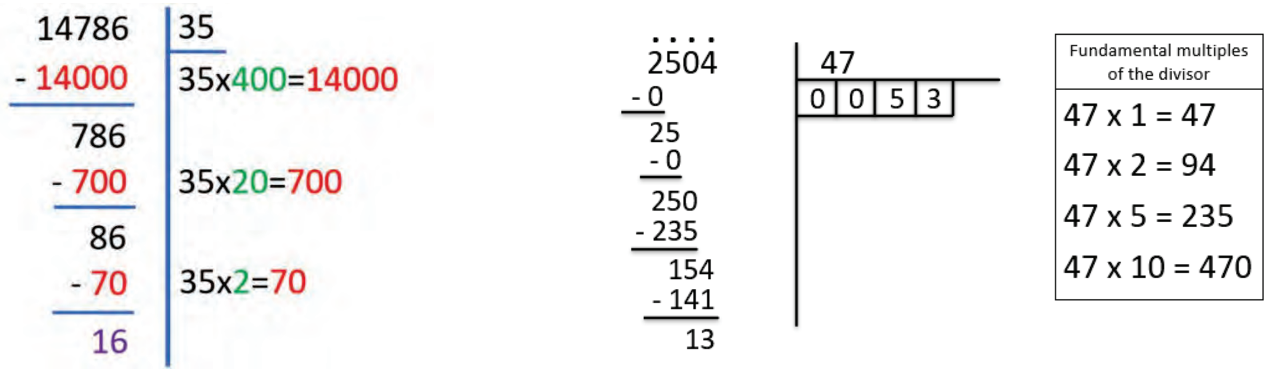

Figure 1: An Optimized Canadian algorithm applied to the division 14786:35 (on the left); TI×- algorithm applied to the division 2504:47 (on the right)

The first is the Canadian Algorithm in its non-optimized version (Boero & Ferrero, 1988). It works like this: the solver identifies a multiple of the divisor that is less than the dividend; then, s/he subtracts this multiple from the dividend. S/he repeats the same reasoning starting from the result of this subtraction (i.e., s/he identifies a multiple of the divisor, which is less than the result of the subtraction, and so on) until s/he obtains a number that is less than the divisor (it could be 0). The left diagram in Figure 1 shows an optimized version of the Canadian algorithm applied to the division 14786:35, where the multiple of the divisor to be subtracted at each step is chosen among those that are also multiples of the highest possible power of 10 (i.e., at the first step 35 ×400 is subtracted, then 3502×, then 352×). The second division algorithm is TI×- algorithm. To illustrate it, we can start from this example: 2504:47 (see Figure 1 on the right). The first step to be carried out consists in writing some useful multiples of the divisor, which we call *fundamental multiples* (on the right in Figure 1). The multiples chosen are ×1, ×2,× 5, ×10, since they are the simplest multiples to calculate (the multiple ×5 can be obtained calculating half of the multiple ×10) and they are sufficient to obtain all the others applying the distributive property (e.g., 47×3=47+94). At this point, we can set up the diagram in Figure 1. We can observe that the number of spaces reserved to the quotient digits corresponds to the number of dividend digits, regardless of the development of the division (in our example, 2504 consists of 4 digits, so the diagram provides 4 spaces for the quotient digits). We therefore carry out the steps according to the acronym «TI×-», thus explicating its meaning:

- **T**ag the first dividend digit from the left, making a dot above it (in our example, the digit 2);
- **I**nsert the number of times the divisor is contained in the tagged digit in the first space dedicated to the quotient digits in the diagram. In our example, 47 is contained in 2 0 times, so we write 0 in the first space reserved for the quotient from the left;
- At this point (we are at the "×" in the acronym) we have to multiply the divisor with the number found, in our example 47×0 = 0;
- Finally, we subtract (we are at the "-" in the acronym) what we obtained from the tagged digit, in our example 2–0 = 2.

We then repeat the same procedure "TI×-". In our example, we now have to tag the digit 5, and transcribe next to the result of the last subtraction carried out, so that we now consider it as the number 25. Now, 47 in 25 is contained 0 times, so we transcribe 0 into the second space dedicated to the quotient, and then we calculate 47×0=0. At this point we subtract 0 from 25, obtaining still 25, and so on. We are therefore able to complete the division when we have tagged all the digits of the dividend, obtaining 53 as quotient, and the remainder 13 as the result of the last subtraction.

At the moment of the discussion we analyze here, participating students had worked since grade 2 on Canadian algorithm, while TI×- algorithm had been introduced for about a month: the students had learned to execute it correctly, but no time of the previous lessons was dedicated to the deepening of the mathematical meanings underlying its functioning.

This work focuses on the analysis of the signs that emerged in the mathematical discussion. We will distinguish between *situated signs, mathematical signs,* and *pivot signs* (Bartolini Bussi & Mariotti, 2008). Situated signs are signs that arise during the activity with the artefact, so they are contextual and understandable only to the participants to the activity at that time; mathematical signs, on the other hand, are the formal signs referring to the mathematical knowledge at the basis of the task designed by the teacher. Finally, pivot signs are particular artefact signs that the teacher can use to support a possible evolution from artefact signs to mathematical signs. We coded the transcripts classifying the signs with the labels “situated signs” (SS), “mathematical signs” (MS), “pivot signs” (PS). We focus especially on signs that could be related to mathematical meanings underlying the two algorithms, in particular those related to positional value of dividend digits and to the meaning of the sign to tag dividend digits in TI×- algorithm.

Data Analysis

To answer to our research questions, we chose to analyze two excerpts of the mathematical discussion of the first lesson, that we believe to be particularly significant to show the potential of synergy for the discovery of relationships between the two algorithms. The mathematical discussion was started by the teacher, who showed on her shared screen the operation 874:7 carried out with the two different algorithms (see Figure 2).

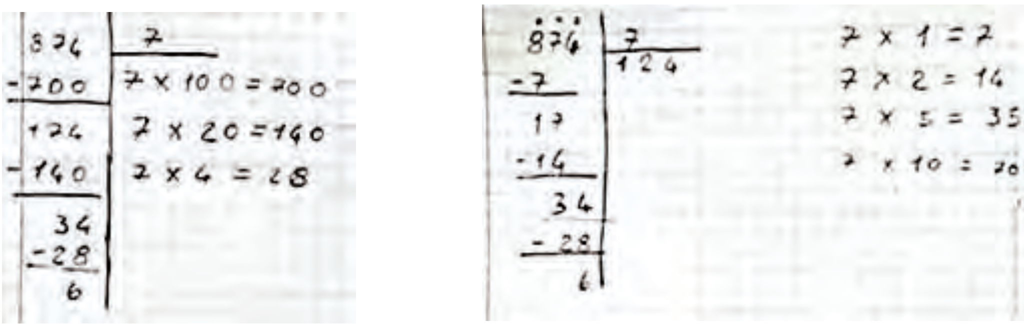

Figure 2: Optimized Canadian algorithm (on the left) and TI×- algorithm (on the right) to calculate the division 874:4

1	P1:	[...] I think that [...] it is not that we do faster in one algorithm, for example in the Canadian algorithm with respect to the TI×- algorithm, because in the Canadian algorithm we subtract bigger numbers, but in the TI×- algorithm we subtract the numbers... [...] 7, 14, 28, though... [the number 7] counts like the hundreds and then it is removed from the hundreds [of the dividend]...
2	Teacher:	Wait, I'll try to repeat what you said [...] in the TI×- algorithm, when I subtract 7, for example… what happens, to this 7 here? What do you mean, P1?
3	P1:	It's like... it's like a hundred [he means 7 hundreds], because ... it's below 8, but not because it is below 8, because it is used as... hundreds.
4	Teacher:	So, you are saying that this 7 is worth 7 hundreds... okay? And in the other algorithm what do we have in the first step, P1? […]
5	P1:	In the first step we have 700 [to subtract].[1]
6	Teacher:	Minus 700, ok.
7	P1:	It is because it involves all the numbers [the Canadian algorithm], but actually I think the TI×- algorithm is faster because you have to write fewer things.

In this first excerpt, the comparison of the two algorithms applied to the same operation allows P1 to make an interesting consideration, linked to positional value of dividend digits in TI×- algorithm (see the reference to MS "hundreds" in lines 1 and 3). In line 3, P1 tries to express something about the dependence of TI×- algorithm from some formal choices, such as tagging and respecting digits' vertical alignment. P1 seems to describe - still at an intuitive level - that the value of 7 subtracted from the dividend digit 8 should not be inferred from its vertical alignment, but from a certain "use" of 7 as hundreds, not better specified. It is only with teacher's intervention (line 4) that the identification of subtracted 7 in TI×- algorithm and subtracted 700 in Canadian algorithm becomes explicit (line 5), so that in line 7 P1 realizes a further step describing a more general difference between the two algorithms – namely, TI×- algorithm's articulation digit-by-digit, absent in Optimized Canadian algorithm.

[1] It is necessary to specify that, unlike in English where 7 hundreds and 700 are both pronounced as "Seven hundreds", in Italian 7 hundreds and 700 are pronounced as two different words, "sette centinaia" and "settecento" respectively. So, we note that in Italian the correspondence between 7 hundreds and 700 is not as transparent also for linguistic reasons.

8	P2:	I think they are both correct and I also noticed another thing: in the Canadian algorithm I see that you will always add a number... if you remove the two zeroes from 700 it becomes 7; if you remove the 4 from 174 it becomes 17. It is as if in Canadian algorithm you add a number [i.e. you write a digit at the end of each subtrahend].
[...]		
9	P2:	I was just thinking of the end [i.e., to the last subtraction 34 – 28 = 6 present as the last step in both algorithms], because when I thought that 700 becomes 7 when one removes the zeroes, it seemed strange to me that the end was identical [in both algorithms] and that you don't remove 4 from 34, so that it doesn't become 3.
10	Teacher:	Then you are saying: the last operation is the same.
11	P2:	Yes, because it is as if the division made different calculations but it has to arrive at the same point, where there is no other way to get to the result, so you have to do that ... that reasoning to get to the result.

In line 8 P2 describes a connection between the two algorithms, but differently from P1 she does not talk in terms of place value. Instead, she uses SSs "remove the zeros" and "add a number [digit]". In the expression "it is as if in Canadian algorithm you add a number", P2 formulates a simile that constitutes evidence of her attempt to describe something she has intuitively grasped but that she is not completely able to express. In this perspective, "add a number" and "remove the zeros" have the value of PS, with the potential to lead P2 to discover mathematical meanings at the basis of TI×- algorithm - in particular, positional reading of dividend digits and of numbers to be subtracted in the various steps. As we see in lines 9 and 11, this observation triggers P2 to deepen the relationships between the two algorithms. Indeed, P2 moves her attention to their last part. In the expression "it seemed strange to me that the end was identical and that you don't remove 4 from 34, so that it doesn't become 3", P2 identifies the last subtraction ("the end") as a common aspect of the two algorithms, but she also observes that this correspondence breaks her previous expectation on how TI×- algorithm works. The expression "you don't remove 4 from 34" is a PS, which recalls the previous sign "remove the zeroes" in line 8. Indeed, also this sign - "you don't remove 4 from 34" - has the potential to lead to the discover of positional reading within TI×- algorithm: the teacher can exploit this sign to support a reflection on the fact that the number 34 does not respect the correspondence identified by P2 because it must be interpreted in term of unities, differently from the other subtracted numbers in the previous steps of TI×- algorithm. SS "the end was identical", moreover, signals a further step towards a recognition of the common process at the basis of both algorithms, with respect to what P2 observed in line 8. In that line, she was still focusing on the perceived distance between the two algorithms; in line 9, instead, the identity of their last subtraction elicits a feeling of "strangeness", pusheing P2 to formulate in line 11 a more general conjecture on the similarities between the two algorithms, moving from a formal description towards meanings. Two significant SSs in this respect are "different calculations" and "same point": these are PSs with the potential to evolve towards a discovery of distributive process common to both algorithms, presented through different formal steps.

Discussion and conclusions

Data analysis shows how the designed task allowed the emergence, in the discussion among the involved children, of situated signs potentially significant for a progressive development of mathematical meanings that are crucial to explain the two algorithms' functioning, especially regarding TI×- algorithm. As we observed, in fact, this second algorithm is opaquer than Canadian one, with respect to the progressive distribution process underlying to both. Regarding the first research question, terms such as "hundreds", "remove the zeros" and "add a number" emerged as potentially crucial signs for this development, since they can lead to a reflection on the dependence of TI×- algorithm on place value of dividend digits. Situated signs as "different calculations" and "same point", instead, are significant because they were used to describe a similarity regarding the general mechanisms at the basis of both algorithms. These signs, in a TSM perspective, could be useful to the teacher to manage the discussion, in order to allow students discover the progressive distribution process underlying both algorithms. Regarding the second research question, the signs "different calculations" and "same point" emerged in relation with the issue of the identity of the last step of both algorithms. As shown by research with a similar approach to the discussion of division algorithms (see Lisarelli et al., 2021), this can be one of the key considerations to develop a "backward" reasoning to build a real argumentation of the two algorithms' functioning, using the more transparent algorithm to shed light on the steps of the opaquer one. This is particularly relevant for the argumentation of the opaquer algorithm's functioning (for Lisarelli et al. it was DMSB algorithm, for us is TI×- algorithm) and the discovery of mathematical meanings at its basis. Therefore, the designed task and the following discussion allowed the emergence of situated signs related to mathematical meanings common to both algorithms involved. It is necessary to underline that, both in our study and in that by Lisarelli et al., the synergy of artefacts could be seen as a substantial identity of distributive process underlying the involved algorithms: the opaquer algorithm can be seen as more refined and efficient on a formal level, through an appropriate recourse to the digits' vertical alignment and their reading according to their place value. Using a metaphor, we can say that this choice of algorithms as artefacts used in synergy transforms one algorithm into a sort of "can opener" of mathematical meanings for the other one. We believe that the analysis presented here contributes both to research concerning the introduction and the use of artefacts in mathematics classroom and to research concerning the teaching of algorithms in primary school. Our study contributes also to discussion about the potential of comparing algorithms and procedures as means of development of students' conceptual and procedural knowledge (e.g., Rittle-Johnson et al., 2017; Weber, 2019), since we highlighted the powerfulness of synergy of algorithms as artefacts, especially when among them intercours a relationship such as the one we described. Further studies are needed to confirm this, and to explore if there are other conditions determining which synergies are useful to develop mathematical meanings.

Acknowledgments

Special thanks: to teacher Roberta for her contribution; to PerContare project (www.percontare.it) supported by Fondazione per la Scuola della Compagnia di San Paolo, Torino, by ASPHI onlus and partially supported by the project "Piano Lauree Scientifiche (PLS)" at the University of Pisa; to all the participating students and teachers, without whom this research would not be possible.

Re-discovering sorting algorithms: the importance of cooperation

Aaron Gaio[1]

[1]University of Trento, Department of Mathematics, Trento, Italy; aaron.gaio@unitn.it

Keywords: Algorithms, Discrete Mathematics, Cooperation.

Introduction and Context

In the growing field of research of elementary discrete mathematics education, the research wants to focus on some aspects of young students, grade 4 to 6, learning about sorting algorithms. Moreover, elementary computer science is gaining attention both from the CS education research community and from the elementary school teachers and heads (Franklin et al, 2015) and new trends in teaching CS in primary education are recently emerging. From a Mathematics Education perspective, we are thinking of our work as able to enhance the study of teaching and learning skills of mathematical practice through discrete mathematics problems, both general skills, such as reasoning, modeling and problem solving skills and others particular to discrete mathematics, such as algorithmic and recursive thinking skills. Here, in particular, we want to underline aspects of cooperative dynamics emerging from some sequence of tasks regarding the above.

The tasks we are going to present are part of a preliminary research that were proposed to various schools and age groups. In a design research paradigm (Plomp and Nieveen, 2007), the activities were tried out many times, always with an a priori analysis together with the teachers and with a retrospective look after each lesson. Students from two different schools were involved: a total of 22 classes in grades ranging from 3rd to 8th. Before this, we did a preliminary survey among teachers (Gaio & Di Paola, 2018). Teachers, especially at lower levels, admit not to have the necessary knowledge to teach discrete mathematics and algorithmic topics in school and are really open to explore new possibilities on the topic.

Background Theory and Methodology

Teaching methods follow the model of Realistic Mathematics Education (Gravemeijer, 1994) and Guided Reinvention of mathematics (Brousseau). Focus is on the activity, on the process of mathematization (Freudenthal, 1973). Realistic Mathematics Education (RME) is an instructional design theory which centers around the view of mathematics as a human activity (Freudenthal); "*The idea is to allow learners to come to regard the knowledge that they acquire as their own private knowledge, knowledge for which they themselves are responsible.*" (Gravemeijer).

The research methodology is that of design research. For the purpose of this thesis, the developmental approach is taken into consideration (Plomp and Nieveen, 2007), the goal being to design and develop a, research based, intervention and constructing design principles in the process of developing it. The goal is to explore new learning and teaching environments, to verify their effectiveness; to develop somehow new methods, instruments, and teaching actions to further improve in the field of problem solving and logical thinking, using somehow unusual topics as algorithms and cryptography are for primary school students. The design experiment is a classroom experiment in which the researcher (or researchers) cooperates with the teachers in assuming teaching responsibilities.

Tasks and data

As stated above, in a longer sequence of tasks, we want to focus on some tasks regarding sorting. The content goal is to teach something about sorting (numbers, quantities, objects), algorithms mode of operation, their speed, and the fact that there might be different algorithms leading to a solution. In some activities basic computational complexity is emerging, even if not formally introduced to children. We want them to re-discover the algorithm (or algorithms) which is good to solve a predetermined problem and get a sense of what it means to order something. Ordering themselves in groups, ordering object using a balance scale. At the end of each task a discussion follows.

Data collected is represented by events selected from the video recordings available. We used an inductive approach in video selecting, beginning with viewing the corpus in its entirety and focus on details later. Some events which were particularly relevant were isolated. We are, with this approach, analyzing selected episodes focusing on the same happening and constantly revising our finding and new hypothesis.

Results and perspectives

As some examples of the results obtained, we have a video-analysis of groups sorting themselves into a given order. Looking at the collaboration between students, one can observe that two different algorithms translate into two totally different group dynamics. There could be one or two students acting as leaders and just giving direction to others in the group, or more cooperative oriented groups, or also when a leader is absent. While using sorting networks, for example, the importance of discussion and the process of dialectic with peers allows students to discover important points in the mathematical situation they are facing, such as a sense of comparison between different numbers, according to Vygotsky's perspective on the zone of proximal development. On a similar example, students find out that if they are greedy - or we might say use a greedy algorithm - then the group might not success in the final goal and the collaboration with the others is important in mathematics, as in many other aspects, to reach (faster and better) results.

Finally, the belief is that this kind of activities can be relevant, beyond a CS perspective, also from a mathematics point of view as described briefly above and deserve a deeper investigation in research.

An exploratory study on mathematics teacher educators' beliefs and understandings about computational thinking

Eirini Geraniou[1] and Jeremy Hodgen[2]

[1]UCL Institute of Education, London, UK; e.geraniou@ucl.ac.uk

[2]UCL Institute of Education, London, UK; jeremy.hodgen@ucl.ac.uk

This paper reports an investigation of mathematics teacher educators' views and perceptions on computational thinking (CT) and its impact on mathematical learning. We conducted semi-structured interviews with experienced mathematics teacher educators, all of whom have extensive experience with the use of digital technologies for mathematical teaching and learning and report on data from two of them. Our aim is to offer insights into how CT is perceived and understood by them, to support them in self-assessing their possession of CT practices, and how to support mathematics teachers and students in gaining CT. We offer ideas regarding the promotion of CT and its integration in mathematics teaching and learning.

Keywords: Computational thinking, mathematics teacher educators, digital technologies.

Introduction

Over the past decade, there has been upsurge of interest in the teaching and learning of computational thinking (CT). The proponents of CT conceive of CT as a critical skill for all that will enable humankind to harness the power of computers for the common good (e.g., Wing, 2006). As a result, many countries are in the process of introducing CT into their school curricula, either as a new dedicated subject, a cross-curricular theme, or integrated within an existing subject, such as mathematics (see, e.g., Bocconi et al., 2018; see also, Royal Society, 2018). The relationship between CT and mathematics has been of particular interest. Indeed, some see CT as offering the potential to transform school mathematics (eg, Perez, 2018), but realising this potential will be a challenge, for students, mathematics teachers and mathematics teacher educators (MTEs).

Teacher education will be critical in enabling mathematics teachers to realise the potential of CT to transform mathematics. Yet, to date, educational literature on CT, or computational competency or the "new digital age competency" as sometimes is referred to, (e.g., Grover & Pea, 2013, Li et al., 2020) has mainly focused on students' CT. In this paper, we address this gap by investigating MTEs' CT and their computational practices. We present initial findings from an exploratory study, investigating the views of two experienced MTEs, who both have extensive experience with the use of digital technologies for mathematical teaching and learning, including specifically with teachers. We discuss their views on CT from a practitioner and a research perspective, debating about assessing the possession of CT and how to support mathematics teachers and students in gaining CT. We conclude by offering ideas about the promotion of CT and its integration in mathematics teaching and learning.

Computational Thinking and Mathematics Education

CT was first mentioned by Papert (1980) in his seminal *Mindstorms* book, it gained more momentum when Wing re-introduced it in her 2006 pivotal paper making the case for CT as a critical skill for all. Wing (2010) defined CT as "*the thought processes involved in formulating problems and their solutions so that the solutions are represented in a form that can be effectively carried out by an information-processing agent*". (Cuny, Snyder & Wing, 2010). Many researchers (e.g., Brennan & Resnick, 2012; Grover & Pea, 2013) have attempted to clarify this definition. This work emphasises that CT is less about the use of technology and computers and more about the concepts, practices and processes involved (e.g., Lodi, 2020). In Shute et al.'s (2017) terms, CT is "a way of thinking and acting, with or without the assistance of computers" (p.143).

The consensus of research (e.g., Shute et al., 2017) is that, whilst there are practices in common, CT is a distinct and separate discipline to mathematics. However, CT involves practices that are also required in mathematics, such as "decomposition, abstraction, algorithm design, debugging, iteration, and generalization" (Li et al., 2020, p.156). For the purposes of this paper, we will draw on Perez's (2018) summary of the literature on CT practices and dispositions as outlined in Table 1.

Table 1: Perez's (2018) categorization of CT practices and dispositions adapted (see Figure 2, p.428)

Computational Thinking Practices	
Problem Solving	*Abstraction & Generalisation*
Assessing and pursuing different approaches and solutions to a problem	Collecting, organizing, manipulating, and representing data
Generalizing and transferring problem-solving processes to other situations	Abstracting the essential elements of a situation or task
Using incremental and iterative approached, decomposing tasks into smaller pieces	Thinking in levels andunderstanding relationships within a system
Reusing, remixing, and innovating	Choosing effective tools and models for working with data
Efficient and effective combinations of resources, testing and debugging	Developing algorithms and automations
Formulating problems so that they can be analyzed using programs and other tools	Designing and using computational models and simulations
Computational Thinking Dispositions	
• Confidence in dealing with complexity • Persistence in working with difficult problems • Tolerance for ambiguity • The ability to deal with open-ended problems • The ability to communicate and work with others to achieve a common goal or solution	

Teachers' Computational Thinking

Some research has examined the teaching of CT both in general (see Grover & Pea's, 2013, review) and specifically in mathematics and other STEM subjects (see, e.g., Lee et al., 2020). A particularly fruitful avenue of research has investigated the use of Scratch programming in mathematics (e.g., Sung et al., 2018) with some potentially promising results (e.g., Boylan et al., 2018). However, the efficacy of such pedagogic initiatives is dependent on mathematics teachers' knowledge, beliefs and attitudes about CT. Some small-scale research has begun to examine the issues and challenges in this area. Sands et al.'s (2018) survey of 74 US teachers' views of CT suggests that one challenge may be teachers' limited understanding of CT. For example, they found that most respondents viewed CT as synonymous with doing mathematics and using computer or technology. Angeli and

Jaipal-Jamani (2018) examined the effects of an intervention on 21 preservice science teachers' CT in a small-scale study. They found that the use of scaffolded programmed scripts resulted in increased CT skills amongst the preservice teachers. However, they found that these increased skills were limited to lower levels of CT and, hence, their study highlights the difficulty of developing higher order CT skills such as generalisation and abstraction. Israel and Lash (2020) carried out a study in one US elementary school examining the integration of CT into mathematics teaching, mostly using the Scratch environment with some lessons using Code.org materials. They found that, despite a very strong commitment from the school and its teachers to CT and integrating CT and mathematics, relatively few of the lessons showed evidence of an integrated approach to teaching CT and mathematics. Chevalier et al.'s (2020) study suggests ways in which these challenges can be addressed. They found out that it is important "not only having a good understanding of CT (e.g., not focusing exclusively on acquiring programming skills), but also thinking and planning carefully in developing and implementing educational activities to develop students' CT" (as cited in Li et al., 2020, p.154).

Teacher Education and MTEs' Computational Thinking

As Lee et al. (2020) observe, teacher education and professional development are critical to the development of effective CT teaching (Weintrop et al., 2016). Yet, we are unaware of any research examining MTEs' knowledge, beliefs and attitudes about CT. To help us reflect on MTEs' CT practices, we decided to have initial discussions with MTE, who have extensive expertise in teacher education and research in the use of digital technologies for mathematical teaching and learning. Such MTEs' beliefs can support our investigation on what CT is, what CT practices are, what the relationship between CT and mathematical thinking is, how CT practices can be promoted among mathematics teachers, why CT practices are useful (or not) and what they offer to mathematics education.

The Exploratory Study

Our aim was to answer the following Research Questions: What are MTEs' CT practices? What are their views on mathematics teachers' CT processes and the link between mathematical thinking and CT? In order to gain insights to these questions, we carried out an exploratory study and interviewed three MTEs with expertise in digital technologies and mathematics. In this paper, due to constraints of space, we present vignettes of only 2 of those MTEs, whom we will refer to as Carole and Naomi. Both Carole and Naomi have school teaching experience, but also lengthy experience as MTEs (Carole over 10 years and Naomi over 7 years). They both have a doctorate in mathematics education and their research interests lie in the use of digital technologies for mathematics teaching and learning, but also in mathematics teacher knowledge.

The interviews consisted of 2 parts. In the 1st part, the interviewees had to solve a task, using the Think-Aloud protocol (Güss, 2018). We asked interviewees to reflect on (a) the programming aspects, (b) mathematical definitions, (c) the structure of the mathematical and the tool's language, and (d) the algorithms. Given that CT is a relatively new area of interest, we wanted a task that would enable the interviewees to articulate various aspects of CT practices. Hence, we chose a task that they were familiar with and involved a digital tool of their choice. This has an advantage of generating a range of ideas in a relatively short space of time, but has some limitations in terms of comparing the MTEs' beliefs. In the 2nd part, we asked them for their own definition of CT and how this relates to the definition by Cuny, Snyder & Wing (2010), which was mentioned earlier and states that CT is "*the thought processes involved in formulating problems and their solutions so that the solutions are represented in a form that can be effectively carried out by an information-processing agent*". Then, we asked them to reflect upon their own approach to solving their task in relation to the CT practices as presented by Perez (2018) in Table 1, identifying which CT practices they used. We asked them to (a) Reflect on mathematics teachers' CT: You have used this task with teachers, what aspects would you highlight to teachers in terms of what is different to pen-and-paper mathematics? How would you design a task to make teachers aware of key elements and features relevant to CT?; (b) Reflect on CT and mathematical thinking, knowledge, teaching, learning, pedagogy. How is CT linked to mathematics? What pedagogical strategies regarding CT would you use with teachers?

Carole's Vignette

A mathematical task

We asked Carole to tackle the 'Rich Aunt' task, a problem that she has used frequently in teacher education at M-level. In this problem, students are asked to decide between one of three gift schemes:

a) £100 now, £90 next year, £80 the year after, and so on;
b) £10 now, £20 next year, £30 the year after, and so on;
c) £1 now, £2 next year, £4 the year after that, and so on.

To solve the task, Carole used Excel to create a table using a formula and dragging across cells to create a table and a graph comparing the annual value of each scheme. Carole uses this task to enable teachers to "experience the power of Excel", because, without Excel, it would be more "time-consuming". However, one doesn't always need to think mathematically: "That's the problem with excel you are not even aware that you actually typed in a formula. … Which is slightly different to having an awareness of a formula behind it, the mathematical formula behind that."

Carole's definition of Computational Thinking

Initially, Carole conceived of CT as synonymous with computer programming such as Scratch and Logo and didn't consider the Rich Aunt task involved CT, saying that she had engaged Excel as a tool using "a simple formula to generate numbers by copying and dragging cells" rather than "thinking the problem through" as would be required for programming. When presented with the list of CT Practices [Table 1], she identified several practices that she had used in the task: pursuing different approaches, using incremental and iterative approaches, innovating, debugging, formulating problems for analysis using tools, organising and representing data and using computational models. She did not consider that she had used algorithms or automation, despite her use of formulae in Excel. She defined CT as "adapting your mathematical thinking to the tool at hand which has got computational power … you think of the mathematics first and then how do I go about using this tool …. You almost have a plan of how you're going to investigate the maths problem and really the tool is just a tool that helps you execute that plan."

Carole said that largely CT is part of mathematics, although she felt that algorithms and automation are "*not necessarily*" to be part of mathematics. She considered CT to be more about working with what is already known in contrast to mathematics which enables one to work with the "*unknown*".

Naomi's Vignette

A mathematical task

We asked Naomi to tackle the task presented in Figure 1 further below, which she has given to mathematics teachers for research purposes. In this task, teachers were asked to explore the 3 diagrams presented in GeoGebra and discuss how to use them when teaching one of the Circle Theorems ("the angle at the centre of the circle is twice the angle at the circumference") to a mathematics class. When discussing this task, Naomi commented on the teachers' keenness to avoid exploring complex diagrams, demonstrating lack of confidence in dealing with complexity. Naomi reflected upon the value of looking at a simpler case to support mathematical thinking and work towards proving a conjecture. Choosing such a special case to make a conjecture simpler to think about, could be considered as decomposing the given task into smaller pieces, which is a CT practice as presented in Table 1. Naomi also reflected upon the importance of task design considering the constraints of the tool in use. GeoGebra may have been chosen due to its dynamicity and the benefit of exploring many different cases, but Naomi argued that you may find some level of dynamicity when using pen and paper. In fact there is some rigidity and inflexibility in GeoGebra as it follows certain mathematical rules, referring to rounding errors as well as the fact that the theorem 'broke' for certain extreme cases. She referred to a tension between Geogebra as a mathematical tool and a tool for mathematics pedagogy and suggested that this tension may prompt productive mathematical thinking.

Naomi's definition of Computational Thinking

Naomi defined CT as "not just about programming, it is about a wider understanding of using computers, but even more broader than that digital technology to solve problems […] kind of using the software tools for an investigative process" to solve a mathematical problem in our case. She later on added that CT is "part of problem-solving or in other words, it's about incorporating another tool into your problem-solving kit". After being presented with the definition as shared in the literature, Naomi reflected: "You need to appreciate that you put things in order… so that could be perhaps tending to be an algorithmic process (putting things in order) so that GeoGebra then becomes a useful tool, as you construct things". It is also worth mentioning Naomi's view on what the "information processing agent" is and that it might be restrictive. This phrase may seem to imply the use of a digital tool, but Naomi offered her own personal definition mentioning any tool that can support the problem-solving processes. "That decision making about what's the right tool to use […] is that fuzzy boundary of computational thinking [and] other kind[s] of tool-based thinking".

When presented with the list of CT Practices [Table 1], Naomi identified several practices that she had used in the task: efficient and effective combinations of resources, testing and debugging, formulating problems so that they can be analyzed using programs and other tools, abstracting the essential elements of a situation of task, thinking in levels and understanding relationships within a system, choosing effective tools and models for working with data. Naomi considered some of the practices to be poorly defined. For example, she argued that "thinking in levels and understanding relationships within a system" is difficult to interpret as she is not sure what is meant by "levels", although she speculated that it might be related to "different levels of abstraction". She commented that "Reusing, remixing and innovating" didn't make sense to her. She argued that "testing and debugging" should have a more prominent role in CT. To justify this, she gave as an example the GeoGebra diagram and when teachers dragged the points to explore the diagram, 'testing' special cases, such as 360 degrees or 0 degrees, and addressing the pedagogical challenges created by rounding errors in GeoGebra.

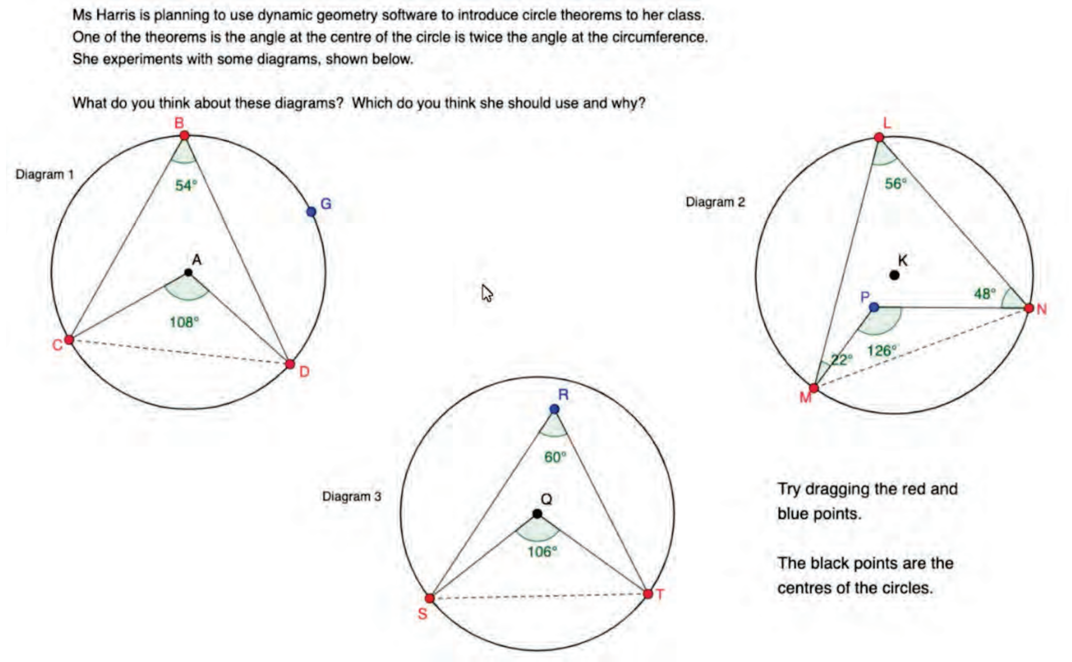

Figure 1: The GeoGebra task Naomi used for research purposes and discussed during her interview

Conclusion

Our study indicated that both Carole and Naomi were skilled in CT and mathematics to solve and discuss a familiar task. Unlike the teachers in Sands et al.'s (2018) neither viewed CT as synonymous with doing mathematics nor simply using digital tools to do mathematics, although both appeared to view CT as closely tied to computers and other digital tools. Nevertheless, their understandings and beliefs about CT were somewhat different. Naomi considered CT to be distinct from mathematics and involving an understanding of how to use digital tools to investigate problems in mathematics and beyond. As such her beliefs were broadly in accordance with the consensus of the academic literature, albeit she appeared to believe CT to be closely related to digital tools. In contrast, Carol appeared to view CT largely as part of mathematics and synonymous with programming. Indeed, she did not consider that using a spreadsheet such as Excel involved any CT. We note here that Carol's views may have been influenced by the particular task she discussed in that the automation and iteration involved very well-understood mathematics: addition, subtraction and multiplication. Despite Perez's (2018) claim that the practices identified in his review represent a concensus in mathematics education, the two MTEs found some of the practices identified to be unclear and poorly defined. This is despite both MTEs being highly skilled in the use of digital technologies in mathematics. Whilst Naomi appeared to believe that constructing algorithms provided a focus for thinking mathematically, Carole appeared to believe that using algorithms meant that mathematical thinking was no longer necessary. This highlights a tension between a common purpose in mathematics education of using digital tools to outsource some of the mundane and well-understood mathematical work, whereas in CT, it is crucial to consider, construct and adapt some of the less mundane mathematical processes such as analysing, generalising and abstracting (Pérez, 2018). Crucially, in CT, such processes are designed to be carried out by the information processing agent, which may be, but is not necessarily, a digital tool.

Our study suggests that MTEs would benefit from opportunities to explicitly engage with the nature of CT and its relationship to mathematics and to the application (and non-application) of technology. In doing so, a critical research task is to articulate the nature of Computational Thinking Pedagogical Content Knowledge (CTPCK) as a new term and its relationship to existing work, such as PCK in mathematics and the TPACK (Technological Pedagogical Content Knowledge, Koehler et al., 2013), which we hope to discuss in our future papers. Our future work entails the investigation of mathematics teacher educators' perspectives on what CT is and assess their CT skills, which elements in particular mathematics teachers possess and which ones they should acquire to enrich their mathematics teaching practice.

Algorithmics in Arithmetic: Revealing algorithmic activities in a first-year arithmetic course for preservice teachers

Ulrich Kortenkamp

University of Potsdam, Germany; ulrich.kortenkamp@uni-potsdam.de

The science of algorithms, that is, the design of algorithms and the analysis of their correctness, complexity or efficiency, is at the intersection of mathematics and computer science, as outlined in the scope and focus of the new thematic working group 11 of CERME12. However, one might question whether algorithmics is indeed a relevant topic for mathematics education. This paper investigates whether algorithmic activities are included in a first-year mathematics course for preservice elementary school teachers. Indeed, for 25 of 26 lectures in the course algorithmic activities could be identified.

Keywords: Arithmetic, preservice teacher education, elementary school mathematics, mathematics education.

Introduction

The new founded TWG11 that meets for the first time at CERME12 is focused on *algorithmics*, which is, according to the description of the TWG, the science of the design and analysis of algorithms. In this article, I try to give reasons for including such a group for a conference on mathematics education, by identifying algorithmic activities (to be defined later) in a lecture that is clearly addressing the needs of prospective elementary school mathematics teachers.

Before we can describe *algorithmic activities*, we have to explain what we mean by *algorithm*. In mathematics education, some prominent algorithms usually serve as defining examples, like the long division. More generally, according to Cormen (2009)[1], "an ***algorithm*** is any well-defined computational procedure that takes some value, or set of values, as ***input*** and produces some value, or set of values, as ***output***. An algorithm is thus a sequence of computational steps that transform the input into the output" (emphasis as in the original text). Of course, the output is not just any output, but should be the answer to the problem that is encoded by the input. Thus, the long division algorithm is an algorithm that receives a dividend and a divisor as input, and gives the quotient and remainder as output. An algorithm that produces the correct answer to any feasible input is called *correct* and is said to solve the corresponding computational problem (Cormen, 2009).

An algorithm needs to be created or *designed* by someone in order to be used. It has to be formulated or *specified precisely* in some language, for example in a natural language like English, in (pseudo code) as a description in or almost in a programming language, or in hardware that represents the algorithm (Cormen, 2009). If there is such a specification, it can be used to *carry out* the algorithm either manually or by a machine (usually a computer).

[1] While there is a vast amount of literature on algorithms in theoretical computer science, I refrain from citing all possible sources. For further sources that support the general statements on algorithms, please use the overview in the notes for Chapter 1 of Cormen (2009).

There might be several algorithms that solve the same computational problem. This calls for *comparing algorithms* for the same problem with respect to their efficiency in terms of *time* (number of computational steps needed to solve a problem) or *space* (usually the amount of memory needed to store intermediate results), or both. Here, it is important that these measures are dependent on the input, and some algorithms might be better in certain instances than others, even if they solve the same problem.

Other measures that might be surprising at first are *elegance* or *simplicity*. The latter can be defined by the number of different computational steps (or *elementary operations*) used by an algorithm, for example. *Elegance* is not as easy to define in general, as it is often the case for solutions to problems in mathematics that are called "elegant". In Aigner & Ziegler (2010) this is discussed briefly for proofs of theorems that are worthy to be included in "The Book, in which God maintains the perfect proofs for mathematical theorems," – and they just refuse to define or characterize what constitutes such a proof. At the same time, they claim for many of the proofs given, that they are "elegant", again without a proper definition of elegant. For this paper, we can follow their lead and just conclude that it is possible to compare algorithms with respect to various measures.

In theoretical computer science there is much more work about algorithms that we cannot cover in this paper, but still we were able to identify several *algorithmic activities* in the last paragraphs:

- Design of algorithms: Creating an algorithm applicable to a class of problems
- Specification of algorithms: Describing the algorithm in a (formal) language
- Carrying out algorithms: Following the specification of an algorithm step by step
- Proving the correctness of algorithms: Finding arguments why the algorithm indeed solves the class of problems, either formally or pre-formal
- Comparing algorithms with respect to time (number of steps while carrying out), space (memory needed for bookkeeping during execution), elegance, or simplicity

In mathematics education, algorithms are often associated with mindlessly carrying out algorithms. Not only it is possible to *carry out algorithms* consciously, but this constitutes only a fraction of the possible algorithmic activities. For example, Krauthausen (1993) claims that it is a worthwhile activity to compare different approaches to written algorithms for multiplication, and Lisarelli et al. (2021) describe how 6^{th} graders compare division algorithms.

There definitely is a common ground for algorithmics both in mathematics and computer science. In Knuth (1985) it is discussed to what extend mathematical thinking and algorithmic thinking coincide, without a final conclusion, but highlighting several occurrences of algorithmic thinking in a sample of mathematics books. Knuth chose nine math books and analyzed the content on page 100 of each book, which is a very intriguing methodological approach.

In our research we want to find out, which algorithmic activities are relevant to mathematics education. As a first approach to this question, we analyze a lecture that is part of the study program for prospective elementary school teachers. So, to refine the research question, we ask: *Which algorithmic activities can be identified in a first-year arithmetic course for prospective primary school teachers at a German university?*

Context

The lecture that will be analyzed is part of the B.Ed. study program “Grundschulpädagogik” (elementary school pedagogy) at the University of Potsdam, Germany and has been created by the author and a colleague in 2010 at the University of Education Karlsruhe, Germany. It was held every year by author since then, and has been adapted to various settings in elementary teacher study programs at Karlsruhe (2010-2011), Potsdam (2014-2021) and the University of Halle-Wittenberg (2012-2013). The number of students in the course varied between 100 and more than 200, and it was always compulsory for the students. In Halle-Wittenberg, also prospective secondary school teachers were attending the lecture, and in Potsdam students of inclusive education both for elementary and secondary school have to attend the lecture. Starting 2021, the lecture has been made available as an Open Educational Resource (OER)[2].

The universities in Halle-Wittenberg and Potsdam are the only universities involved in elementary teacher education in their respective states, so all elementary school teachers in the states Sachsen-Anhalt (Halle-Wittenberg) and later Brandenburg (Potsdam) who studied mathematics during these years should have been affected by the algorithmic activities contained in the course.

The course curriculum matches the regulations of the module in the accredited study programs. For accreditation of the programs it is necessary that they cover the topics and competences as given by the Standing Conference of the Ministers of Education and Cultural Affairs (Kultusministerkonferenz, 2019), which are based on the more detailed information of the German mathematical societies (DMV et al., 2008). While we only consider a single course as opposed to surveying all arithmetic courses in Germany, we still have reason to believe that the results are in line with other courses at other German universities, as the course adheres to the national standards, has been created by two lecturers with different biographies, was used in at least three universities and has been based on existing literature.

The course itself has been designed without an explicit focus on algorithmics. As such, it stands for a generic first-year mathematics course in teacher education, or any other elementary mathematics course in mathematics teacher education. Our goal is to identify algorithmic activities in existing courses, and not to design a course that includes algorithmic activities, thus proving the fact that algorithmic activities are relevant in mathematics teacher education.

Data and Methodology

The data used for the study are the lecture slides that are provided as PDF files as accompanying material (1156 pages). For further details, also the original Keynote presentation (1446 slides) in the version of the academic year 2020/21 was available. Due to the Corona pandemic, the complete course has been recorded in short video clips of about 5-15 minutes that could be used asynchronously by the students. The complete video material (13+13 lectures for winter and summer semester, altogether 213 video clips with a total playing time of 28 hours, 19 minutes and 10 seconds,

[2] Currently available at https://openup.uni-potsdam.de/course/view.php?id=65 through a guest login. A full version of the course in German will be published later.

was available for in-depth analysis in cases where the presentation slides did not show the activities in detail.

As a second data source, the accompanying exercises and the interactive materials used in demonstrations and for self-explorations by the students is available. However, this study focuses on the content that was presented through the video lectures.

The material was reviewed by the author and each part of the lecture was classified depending on whether any algorithmic activity as described above could be identified. As our research question is not of quantitative nature, we refrained from asking a second person to code the data. Also, we are aware of the limitation that the author of the course and this paper is the same person.

The data was coded on a per-slide basis, using the slides and videos for clarification in some cases. For each video it was noted whether algorithmic activities could be identified on the slides. If so, they were categorized in the categories *Design (D), Formulation (F), Carrying out (CAR), Correctness proof (COR)*, and *Comparison or Analysis (COM).* Both the activity and the page number in the PDF slides were noted. The involved algorithms were recorded as well, and in some cases additional remarks. After coding, the data was aggregated for each episode in both series.

Results

The number of clips that contained algorithmic activities is shown in the table below, together with a short description of the algorithm involved in these activities.

Table 1. Algorithmic Activities identified in the lecture on arithmetic (S=Series, E=Episode)

S	E	German title of episode	Algorithms used	D	F	CAR	COR	COM
1	1	Mengen	Set Product		2		1	
1	2	Aussagen	Boolean operations / variables / loops	3	3	3	2	2
1	3	Beweisbedürfnisse und Beweistechniken	Find number not divisible	2	1	1	1	
1	4	Was machen wir gleich?	Change of representation / Completing a relation to an equivalence relation			2		
1	5	Everybody needs somebody to love - Abbildungen und Zahlen	Functions in General	1				
1	6	Zählen von Kardinalzahlen mit Ordinalzahlen	Counting and Peano	2	2	3	2	2
1	7	Vollständige Induktion	Induction / Zone theorem	1		1	2	1
1	8	Rechnen - Addition und Subtraktion	Addition by counting	2	3	1	2	1
1	9	Rechnen - Multiplikation und Division	Multiplication as repeated addition / division in various ways	4	4	2	4	2
1	10	GZSZ: Große Zahlen, Schöne Zahlen	Repeated bundling, base change	2	4	3	2	1
1	11	Rechnen in Stellenwertsystemen I: Addition und Subtraktion	Base change	1	4	4	2	2

S	E	German title of episode	Algorithms used	D	F	CAR	COR	COM
1	12	Mach mal Schräggitter & Wir bauen uns einen Computer	Written multiplication / hardware addition	4	4	3	2	3
1	13	Division in Stellenwertsystemen	Long division	3	3	5	2	3
2	1	Die ganzen Zahlen $\mathbb{Z}$	Multiplication of whole numbers (sign rules)				1	
2	2	Teilbarkeit, Teilen und Reste	Divisibility rules	3	6	2	4	4
2	3	Der Hauptsatz der Arithmetik	Euclidean algorithm etc.	4	3	3	4	2
2	4	Der Chinesische Restsatz	Chinese remainder theorem	3	2	1	4	1
2	5	Von $\mathbb{Z}$ nach $\mathbb{Q}$	Solving linear equations	1	1		1	1
2	6	Wie viele Rationale Zahlen gibt es?	Counting fractions	1	1	1		
2	7	Bruchrechnung in der Schule – Bruchzahlen	–					
2	8	Bruchrechnung in der Schule – Addition und Subtraktion	Addition	1	1	1		1
2	9	Bruchrechnung in der Schule – Multiplikation und Division & Dezimalzahlen	Division of fractions	1	1		1	
2	10	小数と分数 – Eine Reise durch die Klasse 3-6 in Japan	Multiplication algorithm	1	1		1	
2	11	Alles wird eins – Arithmetische und Geometrische Folgen	Representation of fractions	1	2	3	3	1
2	12	Reelle Zahlen	Approximation using Heron and nested intervals	2	4	2	3	2
2	13	$\mathbb{R}$ gebe mir ein $\mathbb{C}$	Algorithmic view on coordinates		1			1
		TOTAL		**43**	**53**	**41**	**44**	**30**

The data shows, that indeed all but one lecture feature algorithmic activities. In S2E7 fractions and their representation in school are introduced and discussed. In that lecture, no operations with fractions are used, so it is difficult to describe an algorithm that is based on several steps using operations.

Most algorithms are designed prior to their formulation. Instead of coming out of the blue (or the textbook), algorithms are depicted as something that is created by someone. We see that it is hardly the case that algorithms are just used without a proper introduction, that is, a focus on their design. Also, most algorithms are discussed for their correctness, at least in part.

The comparison and analysis of algorithms is the activity that happens the least. This can be related to the fact that in many situations standard algorithms exists.

In S2E7–S2E10 less algorithmic activities can be seen. These three lectures focus on teaching fractions in school, both in Germany and Japan. They rely on typical content found in textbooks, and do not introduce new mathematical content, but mostly subject-specific pedagogical content. Still, algorithmic activities are highlighted whenever possible.

An activity that was found in the additional material is a homework project called "Maths around the world". It takes place between the first and second semester of the lecture, and students are asked to find as many as possible interesting ways to do written calculation. Usually, they ask people from other generations (their grandparents) or friends from all over the world, or they have a migration background themselves and can report about their own experience in school. This activity is focused on analyzing and comparing algorithms, and shall compensate for the fact that most of the content in the lecture is being presented instead of experiencing it in a constructivist manner.

Discussion

As can be seen from the results, algorithmic activities are indeed integrated into all lectures but one. This gives rise to the question whether S2E7, the lecture on fractions and their models, could be enhanced with algorithmic activities, too. One possible activity could be an algorithm that creates models from fractions (or vice versa). Further inspection shows that this would be in line with a digital activity that is available in the moodle course and has been used to create the lecture slides as well. Figure 1 shows a Cinderella (Richter-Gebert & Kortenkamp, 2012) based interactive construction that students can use to explore fractions. The construction of such a representation can be described through an algorithm, which can be discussed in the lecture.

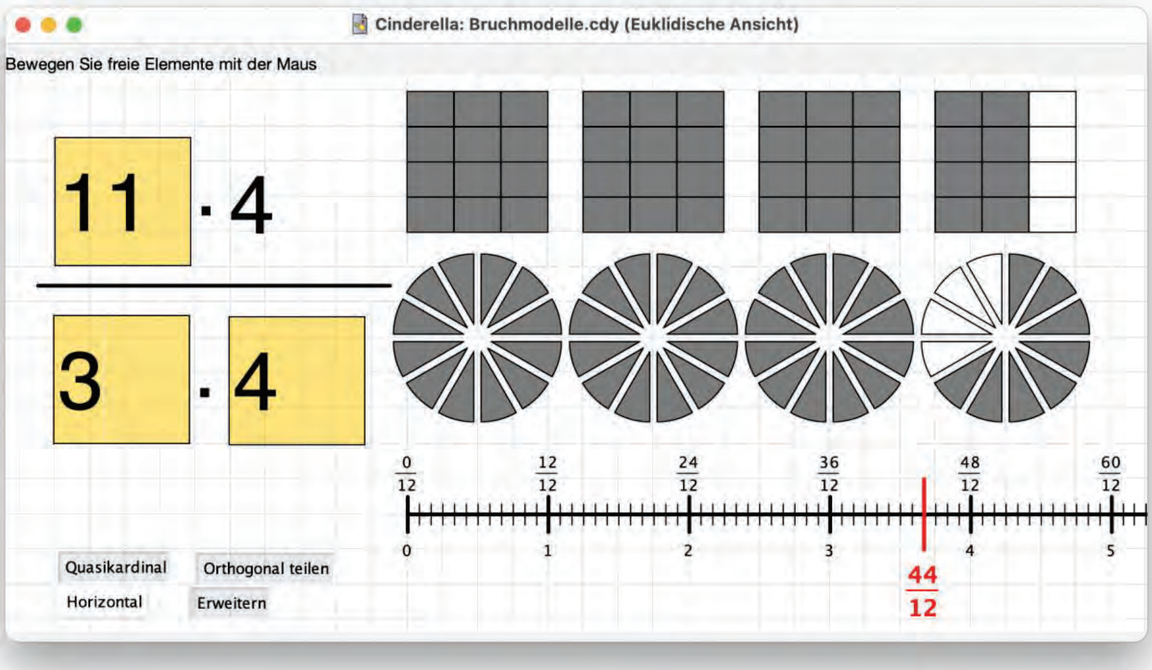

Figure 1. A dynamic representation of various fraction representations used in S2E7. The yellow fields can be changed using the mouse or keyboard and the representations change accordingly.

Although there are lots of algorithmic activities that are already incorporated in the lecture, we ask whether it is possible do more comparison and analysis. The comparison of algorithms is a very important element of the "Maths around the world" activity, where a lot of different algorithms for the same tasks are collected by the students. The question whether all algorithms lead to the same result concerns the correctness, but students identify differences like a faster execution, a better understandability, or a more general or more specialized approach. This also leads to the important insight that they should appreciate and embrace approaches that their future students in the classroom already know from their parents or by their own invention. Another very prominent algorithm comparison takes place in S2E12, where square roots of numbers are approximated through Heron's algorithm and a traditional nested intervals approach. Students experience again that both algorithms lead to the same result (and thus are equivalent), but Heron's method finds an approximation with a given accuracy much faster. This introduces students to questions about the efficiency of algorithms that constitute an important part of computer science and shows that not only the problem itself can have a certain complexity, but it also depends on the algorithm that is used to solve it. So, it would be great to find more opportunities for comparison. Unfortunately, this introduces another problem, as the teacher students would have to learn more algorithms and might complain about additional content for their examination.

Conclusion and Future Work

All in all, we can state that algorithmic activities are indeed an integral part of the arithmetic course we analyzed. While this could have been caused by background of the author of this paper, who also created the course, it still shows that algorithmic activities can be included in arithmetic organically.

The results from this study will be used to redesign the course, again. In particular, the homework assignments will be redesigned to include more algorithmic activities that are carried out by the students themselves, complementing the algorithmic activities that they experience during the lecture or in the video clips.

As a further step, we will apply the same methodology to other lectures in the B.Ed./M.Ed. program in mathematics education, to find out whether the results are specific to arithmetic – due to its computational roots – or can be generalized to other parts of mathematics as well. It is worthwhile to analyze other courses, in other subject areas like geometry, stochastics or algebra, from other authors and to see whether they already contain algorithmic activities, and to see how the inclusion could be achieved or strengthened based on the examples found in this course.

Acknowledgment

The "Arithmetic and its didactics" course would not have been possible without the discussions with and contributions of the teaching and student assistants who accompanied me over several years of refinement of the original course created by Mutfried Hartmann, University of Education Karlsruhe and myself. In particular, I want to mention Johanna Goral and Karen Reitz-Koncebovski, who analyzed the content of the course and forced me to disclose the implicit design principles of the course, and Felix Grohmann, who helped to create the OER version of course.

From written addition to written subtraction: A proposal to develop and understand algorithms through algorithmic thinking

Markus Leifeld[1] and Sebastian Rezat[2]

[1]Paderborn University, Institute of Mathematics, Paderborn, Germany; leifeldm@math.upb.de

[2]Paderborn University, Institute of Mathematics, Paderborn, Germany; srezat@math.upb.de

Keywords: Written algorithms, elementary school mathematics, algorithmic thinking, subtraction.

Children have to be prepared to participate in an increasingly digitalized society and education is regarded to be the elementary key for children to participate in digital change. In Germany, the Standing Conference of the Ministers of Education and Cultural Affairs (KMK) has launched a strategy for education in the digital world. This strategy comprises a framework of competencies to be acquired by students during primary and secondary education. One of these competencies relates particularly to problem solving by using and/or developing algorithms.

Due to the traditional role of algorithms in mathematics, mathematics education is one area, besides informatics education, where thinking about and the development of algorithms may be promoted. Mathematics education research on written algorithms has shown that the written algorithms are on the one hand preferred by learners, but on the other hand are mostly carried out without understanding (Fischer et al., 2019; Jensen & Gasteiger, 2019). This has generally led to a critical consideration of the role of algorithms in primary education (Selter, 2000; Hurst & Huntley, 2018).

The notion of algorithmic thinking is associated with the two previous mentioned problem contexts: It is regarded as “a key element of the new digital literacy”, and “it can contribute to a deeper mathematical understanding” (Stephens & Kadjevich, 2019, p. 117). Algorithmic thinking comprises cognitive abilities such as decomposition and abstraction and is required whenever an algorithm is to be understood, tested, improved or designed (Stephens & Kadjevich, 2019).

In summary, in the context of algorithms in primary mathematics education three main strands can be identified and need to be followed:

1. Political demands starting from the role of algorithms in society (Use/development of new algorithms).
2. Teaching and learning algorithms with understanding in mathematics education
3. Algorithmic thinking as a possible link between problem context 1 and 2.

Research Question

The question is how these strands can be connected in mathematics education. There is a need for learning environments related to the learning of algorithms that contribute to a deeper understanding of algorithms and also foster algorithmic thinking. Therefore, our research question is, how to design a learning environment for the learning of written algorithms in primary school that fosters algorithmic thinking and contributes to students understanding of the algorithms.

Theoretical framework

We present a proposal of a learning environment, as part of a design-research project that connects the three strands related to algorithms in elementary school. The main idea of the learning environment is that algorithmic thinking is fostered by deriving written subtraction from the algorithm of written addition.

Students learn the difference between “putting together” (addition) and “taking away” (subtraction) as inverse operations in first and second grade. While written arithmetic is widely taught through demonstration (Jensen & Gasteiger, 2019), our instructional approach is to use the commonalities of the written addition and subtraction algorithms. Both algorithms are similar in the way that they calculate each place value separately and proceed from the smallest place value to the biggest, i.e. from right to left. However, the operation (add/subtract) to be carried out with each place value and the carry-over are inverse in addition and subtraction algorithms. Addition carries ten units of a place value to the next larger one, while subtraction works the other way around and borrows one unit of juxtaposed larger place value and regroups it into ten smaller ones.

The idea is that students decompose the iterative steps of written addition and invert them separately, and thus derive the written subtraction algorithm from written addition. This way, they carry out the two main aspects of algorithmic thinking. The students should discover that the steps of both algorithms are almost identical and only have to be inverted with regard to the operators "add/subtract" and "carry/borrow" (abstraction).

Consequently, the students use the discovered structure of the algorithm of written addition and refine it to written subtraction as step-by-step instructions to solve a subtraction problem with the derivative of an already known and formulated algorithm (developing new algorithms).

In a next step the learning environment will be tested with students who have just learned written addition in order to improve it with the goal to foster students’ understanding of written subtraction through algorithmic thinking.

[2]RWTH Aachen University, Germany; stefan.pohlkamp@matha.rwth-aachen.de

Mathematics is used to address civic problems, and mathematical skills also are also a basis for a critical attitude of responsible citizens. As algorithms are more and more presented as solutions to social problems, it is necessary to highlight how mathematics education can contribute to a reflected handling as well as an evaluation of the topic. For this purpose, exemplary algorithms from civic applications such as proportional representation, fair distribution, and algorithmic decision-making systems are the starting point for an analysis. The question is how discussing relevant algorithms promotes a deeper mathematical and contextual understanding. Linking both enfolds a mathematics-specific empowerment in an issue of general interest. As a conclusion, this results in a sketch of what algorithmic literacy could look like as an educational ideal of teaching algorithm in mathematics.

Keywords: Algorithmics, citizenship education, critical literacy, mathematical applications.

Motivation from the perspective of education theory

In a digital world where a lot of data emerges algorithms are presented as solutions to social problems, e.g. sentences based on algorithms as *fair* decisions. So, algorithms are too important to leave the concept obscure to most citizens who have a right to transparency and a say in the basic structures of society. According to Fischer (2012), citizen participation in a dialogue with experts requires basic knowledge and reflection skills on the part of lay citizen. How can mathematics education contribute to such basic knowledge and reflection skills regarding algorithms in civic contexts?

Considering the mathematical-contextual dichotomy of civic issues, a promotion of mathematical enlightenment must analyse both mathematical and contextual characteristics as well as their social relevance (Winter 1990). This paper will therefore explore how addressing civic extra-mathematical applications can foster a deeper understanding of algorithms and stimulate reflection on their use. Mathematics cannot only be used for a description of reality, but also for defining public quantifications, e.g. poverty line or tax rate. Since a major aspect of citizen empowerment through mathematics involves addressing the "formatting power of mathematics" (Skovsmose 1998, p. 197), the examples in this paper will focus on a prescriptive, hence non-descriptive, use of mathematics and algorithms. In a first step, classical algorithms are examined in their mathematical-contextual dichotomy regarding algorithmic literacy and citizen empowerment. An outlook will suggest why algorithmic decision-making systems pose an even greater societal challenge and raise new questions for this perspective. Beyond the reflection on algorithms currently envisaged in the context of algorithmics (Lagrange 2019, p. 33), there is a need for a fundamental awareness for the relevance of algorithms in everyday life, that is so necessary that "algorithmic literacy" (Oldridge 2017) refers terminologically to this ideal.

Comparing algorithms within mathematics and in applications

A very accessible definition for an algorithm would be that of a problem-solving tool that given a certain input, produces an output using a finite set of successive instructions, but it lacks the complex and constructive traits of algorithms (Modeste et al. 2010, pp. 53–54). From an educational perspective the broader definition provides important insights, but the specifications have enlightening potential, too. The constructedness of algorithms directly leads to the responsibilities of their application as part of a socially constructed reality. While intra-mathematical algorithms, e.g. the Euclidean algorithm as a paradigm, provide purely mathematical results (ibid., p. 58), extra-mathematical algorithms are based on a real issue that has been mathematised, and their output has a meaning outside of mathematics. An example of experiencing, learning, and testing such extra-mathematical algorithms is the fair distribution of an amount less than the sum of two individual claims. The Talmud suggests the following algorithm (Young 1994, p. 67): Distribute the resource equally until one receives half of one's claim. Distribute the resource to the other one until the missing amount to the full claim equals the correspondent opponent's missing amount. Now continue to distribute the resource equally. The algorithm terminates as soon as the resource is spent. If e.g. a resource is worth 300 and Mara is entitled to 300 and Nele to 200, we obtain the distribution (200, 100). For comparison, the proportional approach would deliver (180, 120).

Comparing the Euclidean algorithm with the Talmud algorithm reveals an important difference for the reflection of algorithms: In the first case, the algorithm is there to extract a well-defined result and to do so as elegantly as possible. In the second case, the result is not so clearly defined: What does *fair* mean? In addition, the calculation of the proportionality shows that the extra-mathematical meaning of an algorithm's output cannot only be vague in advance, but also ambiguous as different mathematical approaches (the alternative here is just a calculation) produce divergent solutions.

Proportional representation as a starting point for mathematical investigations

The importance of a mathematical investigation of different algorithms for a social problem can be illustrated by the example of proportional representation. If one allows only integer allocations, proportionality is not a solution. Under this constraint, there are several methods to get the output of a parliament composition, considering the share of votes as the input (e.g. Balinski & Young 2001). Three of them (Hamilton, Jefferson and Webster) are currently used in different German parliaments: Why is there no unitary solution and where are mathematical differences?

In order to distribute M seats, the Hamilton method starts with the rule of three and gives each party i the rounded down quota $q_i = M \cdot \frac{v_i}{V}$ (v_i: votes for party i, V: total votes); if there are still n seats that haven't been distributed yet, each of the n parties with the largest remainder gets one more seat. The divisor methods, on the other hand, are based on the following algorithm: Each v_i is divided by the same random starting divisor and the quotient is rounded with a certain rule (the Jefferson method rounds down, while the Webster method rounds to the nearest). If the sum of all these results is greater/less than M, the past step is repeated with a greater/smaller divisor. If the sum equals M, each party gets the rounded quotient as the number of seats (if M is missed due to the same rounding limit for several parties, the decision between these parties is made, for example, by drawing lots).

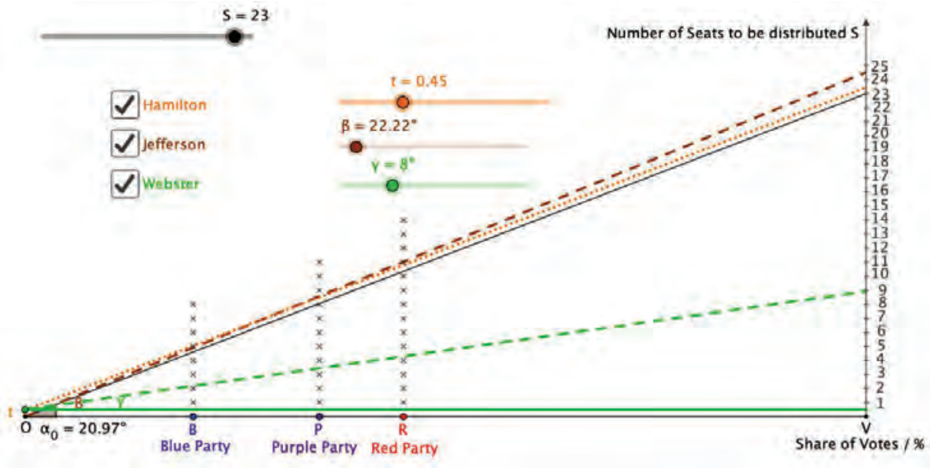

Figure 1: Visualisation of the algorithms of proportional apportionment

The obviously significant contextual consequence of a different parliament motivates the mathematical comparison of the algorithms. While their outputs can be easily contrasted, it is more difficult to compare the procedures of the algorithms. The intercept theorem offers a geometrical, dynamical visualisation (Figure 1). The length from O to the point of a party in relation to the horizontal leg corresponds to the party's vote share. Therefore, the length of the vertical leg through the point of a party indicates proportional seat share of this party. As there are normally less crosses for integer seats under the hypotenuse than seats to be distributed, the algorithm of the Hamilton method is consistent with the *translation* of the hypotenuse. The *rotation* of the hypothenuse can easily be derived from the visualisation as the common principle of the methods of Jefferson and Webster. This initiates a discussion on mathematical characteristics of the algorithms as well as contextual effects: The divisor methods preserve the original proportions, while in Hamilton method the triangle resolves in O. What does that mean mathematically? When does a method (not) favor larger parties? In which way can such a bias be desirable?

Since all algorithms try to approximate the mathematical concept of proportionality with integers, a comparison with mathematical means like the intercept theorem is possible and accessible. Nevertheless, this doesn't lead to an obvious best solution. It is a human decision which method should be prescribed in the electoral law. The importance lies in the fact that the methods can lead to slightly different results, which can even be decisive for the government in the case of narrow majorities. The existent pluralism in Germany document that the political choice between the methods is not so unequivocal as well. The fact that there are also other possible calculations of the divisor methods, each of which leads in each case to the same result, is not to be deepened here, even if it does enable a discussion on the result equivalence of algorithms.

Difficulty of the distinction and transparency: algorithms for fair distribution

With recourse to the distribution of a scarce resource, there is another algorithm with a variant of the „first come, first serve"-principle: Firstly one calculates all permutations of the different claims. For every permutation the resource is allocated along the order, until it is spent. The actual allocation is the arithmetic mean of all these allocations: If a resource is worth 300 and Mara is entitled to 300 and Nele to 200, we obtain the distribution (300, 0) if Mara is first; otherwise, it is (100, 200). The solution

Table 1: Talmud (Shapley) solution to the claims of three wives (Young 1994, pp. 71–72)

	$c_1 = 100$	$c_2 = 200$	$c_3 = 300$
$R = 100$	$33\frac{1}{3}$	$33\frac{1}{3}$	$33\frac{1}{3}$
$R = 200$	50 $(33\frac{1}{3})$	75 $(83\frac{1}{3})$	75 $(83\frac{1}{3})$
$R = 300$	50	100	150

of this so-called Shapley value would be equivalent to the Talmud algorithm. Applying both algorithms to other examples with two claims leads to the correct hypothesis that this algorithm coincides with the Shapley solution for two claimants (Young 1994, pp. 67–70). However, the Talmud presents a second example of a fair distribution, but this time with three claims and varying resource values (Tab. 1). Obviously, this distribution doesn’t follow the proportional logic ($R \neq 300$), nor is the Shapley algorithm behind it ($R = 200$). The algorithm behind this centuries old Talmudic allocation rule has only been discovered in 1985 (Young 1994, p. 72). Its implementation for two claims has been described above, although there is a simpler and older solution in this special case, that doesn’t work for more than two claims. The long time of not knowing the algorithm exemplifies how difficult and lengthy it can be to reconstruct an unknown algorithm, even if the known input and output are rather accessible. At the same time, it becomes obvious how dissatisfying it is to obtain only the result without insight into the process or even an explanation.

Further conclusions can be drawn: Firstly, for certain inputs it is not possible to differentiate between some algorithms (Shapley vs. Talmud algorithm for two claims), so the constraints for this limited result equivalence should not be neglected. Secondly, even for a supposedly simple distribution there is no single solution, and one must choose between the alternatives. As there is no algorithm for objective fairness, the extra- and intra-mathematical reasons for a particular algorithm and against the other are significant. All ends up to the idea that both the mathematical and contextual aspects of socially relevant algorithms should be potentially transparent for interested citizens. But we have seen a degradation of transparency so far. In the case of proportional representation, the idea of propor-tionality determines the various algorithms and can easily be communicated. However, fairness has not such a clear mathematical landmark. Thus, the results appear even more subjective and debatable. Algorithms are used to create a fair process, in the sense that there are no arbitrary changing rules. The results are legitimated only by the *incorruptible* algorithm. But the choice of an algorithm itself is subjective and ambiguous. This contradicts the view that algorithms are neutral, which is ultimately a deduction from the myths about mathematics (Hersh 1991). For the aim of a critical citizenship, the daily experience of being confronted with established algorithms and its results can be facilitating by exemplarily implementing algorithms in a concrete context. An online game about fake news has shown that simulating the producer’s perspective promotes awareness for a further reflected consum-mation of fake news (Roozenbeek & van der Linden 2019). In analogy, students should formulate and compare different algorithms to solve social issues. In this way, they become sensitised for the important mathematical and contextual aspects in the face of existing or newly deployed algorithms. Until now, algorithms have been a tool that helped humans respond to civic problems. As seen above, the use of algorithms does not automatically lead to one suitable solution though. To find appropriate solutions to a problem, one must consider the mathematical properties and contextual consequences of the algorithm. Therefore, this aspect of algorithmic literacy refers to 'literacy through mathematics' since mathematics helps to understand the algorithm. Moreover, citizens should critically reflect the use of algorithms in the world and their stance on the issue. This requires 'literacy towards mathematics'. A simple example would be that if two friends must share a scarce resource, they can dismiss all algorithmic approaches and decide to not use algorithms or even mathematics to solve their problem. A more elaborate position would comprise the awareness, that the use of an algorithm doesn't form itself an indisputable legitimacy and that certainty in computation is not equivalent with unambiguity in an extra-mathematical context.

Automated decisions through algorithms: playful insights

It is precisely because of their constructive character and the clear step-by-step instructions that algorithms are potentially transparent and assessable. The use of artificial intelligence and algorithmic decision-making systems (ADMS) changes this. Nowadays, ADMS take over the decision and share only the final results without disclosing the finding process. Examples are decisions from banks, insurances, employers as well as from the justice system; common hope is to improve the fairness of the respective processes (MacCarthy 2019). These non-transparent techniques can no longer be completely retraced, but in a democracy a majority should be able to control and accept at least their fundamental principles. It includes the critical evaluation of cultural practices involving algorithms in ADMS. The didactic problem is that there can be no enlightenment if nothing can be made transparent. One approach is to analyze the functionality in easy, transparent examples and then to reflect further on the consequences if not all processes were longer traceable. One good teaching unit to do so is the Good-Monkey-Bad-Monkey-Game under creative common license (Lindner & Seegerer n.d., pp. 4–7). The basis is a data set of images of monkeys with different characteristics (smiling, eye shape etc.) and the information whether this monkey bites or not (for examples of such images see Figure 2).

By means of a training set, students must construct a decision tree as an algorithm to determine whether a monkey bites. The algorithmic decision trees are then checked on a test set. Even for the simplest version of the game, more than one decision tree is a fitting solution. Therefore, students are confronted with the ambiguity of a possible algorithm. In the extended version of the game, it is more difficult, first, to find a splitting for the training set, that, second, fits in the test set. In addition, there is one monkey in the test set that doesn't fit because of different, so far unknown properties. This undecidable case shows the limitations of this method, especially concerning the quality of the training and test set, from which reality may still differ. Instead of deterministic predictions as "every non-smiling monkey with x-shaped eyes always bites", such decision trees rather result in good probabilities. Figure 2 shows a constructed variation where x-shaped eyes still implicate biting, but there is only a stochastic correlation between smiling and biting (original data in the last column of Figure 2). A non-smiling monkey without x-shaped eyes bites with a probability of $\frac{2}{3}$: should it be

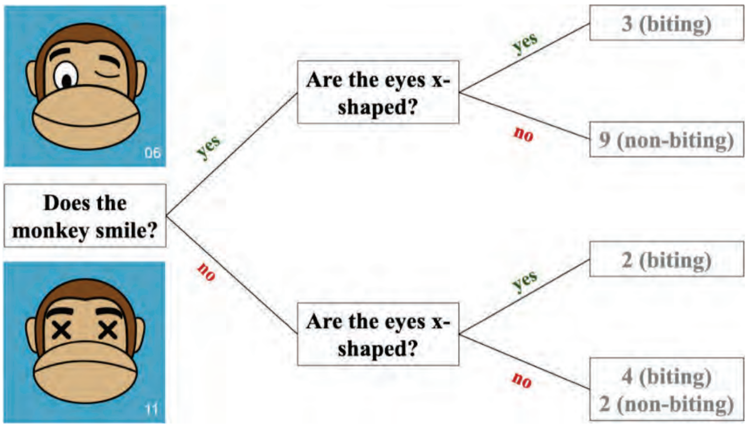

Figure 2: Decision tree for a non-deterministic variant of the monkey-game

isolated or incarcerated? Mathematically, the mistake is smaller, if such an animal is treated as a biting one. Socially, one can argue that punishing an innocent monkey is faultier than sparing the troubled one. If one omits the distinction of the eyes in this decision, a non-smiling monkey bites with a probability of $\frac{3}{4}$. The probability of punishing an innocent has decreased, although we have less information and fewer steps in the algorithms to the detriment of more biting monkeys that could be spared. Generally, less information or fewer steps go hand in hand with a greater uncertainty, but less work could justify a greater deviation regarding the cost-benefit calculation. E.g., not distinguishing the eyes of smiling monkeys leads to a $\frac{3}{4}$ chance of non-biting instead of a deterministic statement: Is this good enough in the related context? However, the characteristic of the x-shaped eyes is more compelling than smiling. If a monkey has x-shaped eyes, it is without any further distinction and without doubt clear that it bites. Hence, a decision tree starting with the x-shaped eyes would need less steps than Figure 2. The efficacy of an algorithm could be theoretically verified – in practice, the permutation possibilities grow fast with additional information –, but how can an algorithm take the other arguments into account?

Via such decision trees students deal with the construction and validation aspect of algorithms. By thinking in terms of case distinctions and conditional probabilities, they experience how a computer generates decisions themselves. While the algorithms so far have been independent from the context (e.g. the parliament size doesn't change the principle of the algorithms), the decision tree relies on the data of the context. In a second zoo with other monkeys the decision tree could be totally different. This raises the question of how objective and unambiguous such algorithms are for automated decision-making. With reference to statistical literacy, the critical evaluation can be extended to the origin of data (Gal 2002, p. 11): Were the monkeys with the x-shaped eyes hungry or have they been mistreated because of existing prejudices? The algorithm can't be neutral if the reference data is biased. This may not seem so central to the example of the biting monkeys, but what if job applications are pre-sorted using ADMS or recidivism is predicted for criminals?

Algorithmic literacy: towards a reflection of algorithms and ADMS

Algorithms and ADMS are used to solve real civic problems. This can be a starting point for a detailed mathematical analysis. It becomes clear that algorithms are neither unambiguous nor objective, e.g., a proportional representation by different algorithms can lead to different compositions of the parlia-

Table 2: Categorisation for a critical evaluation of socially relevant algorithms

fair distributions</td></tr>
</table>

ment. Mathematical explorations (such as geometric representations) can help to answer the question of whether two algorithms produce the same output and how they differ. The extra-mathematical interpretation draws students' attention to the existence of such a pluralism.

Following Jablonka’s (2017, p. 44) categories of explicitness for the relation between mathematics and the context as well as for the intra-mathematical model, we would like to classify the discussed examples in terms to the explicitness of selected aspects of algorithms. The vertical axis is used to categorise the relationship between mathematics and context: while the greatest common divisor is explicitly defined as a mathematical output, ‘fairness’ of a distribution is a fuzzy concept. This category is a continuum rather than a dichotomy, since proportionality is well-defined within mathematics, but its application to seat distributions with integer seats is ambiguous. For the monkey game, ‘well-defined’ means whether the monkey bites (or with what probability), the consequences of how to deal with the monkey are yet not so clear. The second axis makes a difference whether an instruction is independent of the context: the Euclidean algorithm works the same for every two natural numbers. Decision trees, as in the monkey game, are based on data; with new information about other monkeys, the rule for decision making will change. The societal challenge is the fourth category of the “unknown-unknown” (ibid.). Indeed, there are more dimensions to what is unknown. Furthermore, one can differentiate whether humans don’t see the algorithm behind a decision or are not able to understand it. Maybe an understanding of some ADMS and its application is even not possible in a semantic way. To raise awareness for the inaccessible unknown-unknown, the only possibility is to discuss the other categories and to imagine losing their defining feature.

Teaching algorithms must thematize the consequences of implementations in social contexts. Zweig et al. (2018) propose general competencies for such a necessary algorithmic literacy. Respective mathematic-specific competencies with a citizen empowering potential are concretised, analogously to statistical literacy, in “worry questions” (Gal 2002, p. 17), e.g.: (1) What is the specific output and purpose of the algorithm and who has developed it? (2) Where did the data come from and what happens if the input changes? (3) How is the result derived? What is the underlying mathematical model of the algorithm? Are there alternative or equivalent models? (4) What is known and what is *not*? Is this adequate? In the sense of the mathematical-contextual dichotomy, mathematics education can contribute to an algorithmic literacy by focusing on the intra- and extra-mathematical characteristics of algorithms in civic contexts and on the interdependence between mathematics and the context.

Exemplifying algorithmic thinking in mathematics education

In this paper, we consider the construct of algorithmic thinking in mathematics education. We are convinced that algorithmic thinking is an invaluable way of thinking for students to develop, and so we are motivated to promote theoretical discussions in the field about the nature and utility of algorithmic thinking. We present three examples of algorithmic thinking – a mathematical example, an example from a mathematician interview, and an example from an undergraduate student interview. We then briefly review some relevant literature related to algorithmic thinking, and we conclude with some avenues for future research. Our goal is to further conversations about and refinements of characterizations of this important topic.

Keywords: Algorithmic thinking, Computing, Mathematicians, Undergraduate students.

Introduction and Motivation.

The phrase "algorithmic thinking" (AT) has appeared intermittently in mathematics education literature for the past several decades (e.g., Abramovich, 2015; Knuth, 1985; Schwank, 1993; Stephens, 2018), and it seems to be gaining a resurgence of interest with corresponding attention in computation and computational thinking in mathematics settings. In this article, we explore the construct of algorithmic thinking in mathematics education research. We are motivated by observations from our research with students and mathematicians, as well as in our own mathematical experiences. We have noticed a certain kind of algorithmic approach to problems, particularly within computational, machine-based settings, which reflect the presence of algorithmic thinking. These approaches, and the reasoning that underlies them, seem to be useful and valuable, and thus they represent a phenomenon that we want to better understand. In addition, we are motivated by the increasing presence of the term AT in mathematics and CS education literature, and we want to facilitate consistency and coherence for how it might be used in mathematics education.

We have two goals in this paper. First, we aim to exemplify AT within computational settings. We provide examples of such approaches in three ways: in mathematical examples, in interview data with mathematicians, and in data with undergraduate students. These examples allow us to illustrate what we mean by algorithmic approaches, hopefully facilitating better communication and discussion about the construct of AT. Second, given the existence of such algorithmic approaches and their reflection of AT, we briefly situate these ideas within math education literature and suggest ways to explore AT in future work. Ultimately, we aim to establish a shared understanding of algorithmic thinking, which could contribute to broader interests within the mathematics education community about the nature of thinking and problem solving in an increasingly computational world.

Broadly, an algorithm can be characterized as a set of steps to accomplish a given task. This broad definition allows for the term algorithm to include non-mathematical tasks like making a cup of coffee, as well as encompassing processes like the bisection method presented below. Rasmussen, Zandieh, King, and Teppo (2005) offered a definition of "algorithm" that serves as a useful starting point and highlights one way to characterize a distinction between an algorithm and a procedure in mathematics. Rasmussen et al. noted, "we use the term 'procedure' to indicate steps used to solve a particular task, and the term 'algorithm' as a reference for a generalized procedure that is effective across a wide range of tasks" (2005, p. 63). Implicit in this characterization is that there is often an underlying, generalizable approach of way of thinking on which an algorithm is based. Gravemeijer and van Galen (2003) made an analogy between mathematical algorithms and facts, using the example of the formula for area of a triangle (p. 115). To *know* a formula such as $A = ½\, b\, h$ implies that one can apply that formula to calculate area across a range of examples. This is consistent with the notion of a generalized procedure, and this is the general perspective of algorithms that we take in our work. Further, we acknowledge that any process could technically be considered algorithmic if it involves steps of any kind, but we are interested in approaches that foreground the *development* of an algorithm as opposed to only the performance or implementation of algorithms.

The phenomenon that we discuss in this paper is the ability to develop, explain, and iterate the steps of an algorithm in a mathematical context. Our examples highlight algorithmic approaches within a computational setting because such a setting tends to foreground the value of such approaches.

Examples of Algorithmic Approaches.

We offer examples of algebraic approaches in three contexts: a mathematical example, an example from an interview with a mathematician, and an example from an interview with an undergraduate student. In each of these cases we explain what makes the approach algorithmic, and we also discuss potential affordances of such an approach. Our aim is to demonstrate what we mean by algorithmic approaches, and also to make the case that such approaches arise in a variety of settings and situations.

An algorithmic approach in a mathematical example – the bisection method.

We begin with a mathematical example. We focus on an example of solving equations, which is a classical and central topic in mathematics. The standard approach to solving $f(x) = 0$ is to apply a sequence of algebraic operations to both sides of the equation, with the ultimate goal of isolating $\boldsymbol{x}$ on one side. This works well for certain classes of equations like polynomials of degree at most four and some equations involving trigonometric, exponential, and logarithmic functions. In more general situations it is usually not possible to find an explicit formula for the solution. However, the Intermediate Value Theorem tells us that a solution does exist even in very general situations: "Let f be a continuous function defined on the real interval $[a,b]$. If $f(a)$ and $f(b)$ have opposite signs, then f must have a zero at some real number c in (a,b)."

The Intermediate Value Theorem says nothing about where in $[a, b]$ the zero is, but it can help us to develop a strategy for computing approximations to the zero. Perhaps the most obvious approach is systematic guessing, and the simplest guess is the midpoint $m = (a + b)/2$. If we compute $f(m)$ and determine its sign, we see that we can limit our attention to a smaller interval $[a_1, b_1]$:

1. If $f(m) = 0$, we have stumbled upon the zero c and there is nothing more to do so we set $[a_1, b_1] = [m, m]$.
2. If $f(m) \neq 0$, then f has opposite signs at the two ends of either the subinterval $[a, m]$ or the other subinterval $[m, b]$. In the former case we set $[a_1, b_1] = [a, m]$, in the latter case we set $[a_1, b_1] = [m, b]$.

This process can be repeated with the new interval $[a_1, b_1]$, and we then obtain a new interval $[a_2, b_2]$. If we repeat again and again we obtain a sequence of ever smaller intervals $[a_3, b_3]$, … , $[a_n, b_n]$, … . We note that c is located inside each of the subintervals, but the length of the intervals is halved each time. We can then conclude that if we stop this process after n steps, we know that the current midpoint satisfies $|c - m_n| \leq (b - a)/2^n$. This is a very different approach toward solving an equation than balancing the two sides of the equals sign. Rather, this approach, which is known as the bisection method, is inherently algorithmic, and the big idea is that by iterating steps in this process, we can ensure that we can find as close an approximation to the actual zero as we would like. In fact, this idea can be adapted into a proof of the Intermediate Value Theorem. In addition, this idea can be made more specific in the form of pseudocode that describes the steps more precisely, as in Figure 1.

$a_0 = a; b_0 = b;$
for $i = 1, 2, \ldots, N$
    $m_{i-1} = (a_{i-1} + b_{i-1})/2;$
    if $f(m_{i-1}) == 0$
        $a_i = b_i = m_{i-1};$
    if $f(a_{i-1})f(m_{i-1}) < 0$
        $a_i = a_{i-1};$
        $b_i = m_{i-1};$
    else
        $a_i = m_{i-1};$
        $b_i = b_{i-1};$

$m_N = (a_N + b_N)/2;$

Figure 1: Pseudocode for an algorithm that represents the bisection method

This algorithm may be converted into code in a suitable language, and we then have our own substitute for the "solve-button" on advanced calculators. This algorithmic approach to solving equations naturally raises some questions, such as *Is this a valid way to solve an equation? What is gained by converting the algorithm into code and running the resulting program on examples?*
What do students gain from understanding such an approach to solving equations? We would consider the approach of iteratively finding the zeros of the function via the bisection method as we described it as inherently algorithmic because it involves first designing and then implementing an

iterative series of steps, which could generalize regardless of the function. The iterative, algorithmic process is foregrounded in this approach.

An algorithmic approach from a mathematician interview – summing primes.

As another example of an algorithmic approach, and the importance and potential usefulness of such an approach, we draw on an excerpt from a conversation with a mathematician, pseudonym Michael, about the role of algorithms in teaching mathematics at the post-secondary level. The excerpt comes from one of a set of interviews we conducted with research mathematicians about how they use computation in their work. In the first of these interviews, the interviewer (the first author of this paper) noticed the mathematician returning to the importance of algorithms and what he called "algorithmic approaches," so the interviewer asked him to expound on these ideas. Michael, a mathematical biologist, began with an example from a mathematics course that he regularly taught:

Michael: It's been interesting to observe that there are some people who just don't get how to do algorithms…So for instance, a really simple example that I always have at least one student ask me in the computational course—I ask them to sum the first hundred prime numbers using MatLab, and MatLab has this function called Primes. And the way that function works is you put in a number, and it returns all the primes less than that number. And I always have students ask me, 'but I only want the first hundred. I don't know which prime is the hundredth one.' So, and it's funny because other people just go, obviously, 'Oh pick a big number and just take the first hundred…And so that second one was a series of steps: pick a large number, plug it in the function, take the first hundred, and you're done. The other ones are like, I don't know if they don't, can't translate the question into a series of steps like that.

To us, Michael articulated an algorithmic approach that some students were able to leverage. Notably, he seemed to be describing a difference between students who do or do not have such an approach at hand (or, we would interpret, do or do not think in such a way on such a problem), and he was also implying some practical ramifications for not being able to think in such a way. That is, without the algorithmic approach he described students get stuck on the problem and do not know how to proceed. We consider this a description of an algorithm and not a procedure because it suggests an underlying approach that could be generalizable regardless of which prime is being considered. Thus, it is important to help students gain access to these approaches and to try to make some progress on these ideas. This example sets up a distinction in this professor's mind that there is something akin to thinking algorithmically (or to think in such a way as to leverage that approach), there are affordances to such an approach, and not everyone automatically uses that approach.

An algorithmic approach in a student interview – articulating "the way a computer thinks."

As a final example, we offer an example from an interview with a pair of undergraduate engineering majors who were enrolled in a vector calculus class, Corey and CJ (pseudonyms). These data came from a paired teaching experiment that occurred for a total of 12 hours over nine 60-90-minute sessions, during which the students wrote Python programs to list outcomes and solve combinatorial problems. We present an episode from the fifth session, in which the students were solving the Marbles problem: *Suppose you have six different marbles in a bag. Write out all of the* *possible ways you could pick two marbles out of the bag, without replacement.* They were asked to write code that would solve the problem. CJ listed the outcomes by hand as seen in Figure 2.

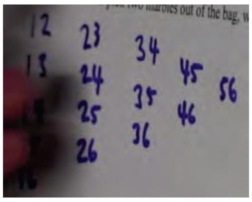

Figure 2: CJ's list of outcomes for the Marbles problem

Confident of their list, the students began to think about how to code the problem. CJ had an insight based on the list he had written by hand: "If we're just trying to list – the second one it looks at has to be bigger than that one." The interviewer asked him to follow up on this. CJ wrote the code in Figure 3, which lists pairs from the set of marbles via nested looping, where the conditional statement only prints outcomes in which the second term in the pair is bigger than the previous term. The *total* here acts as a counter, which is incremented each time and is printed at the end (yielding 15).

```
marbles = [1, 2, 3, 4, 5, 6]
total = 0

for i in marbles:
    for j in marbles:
        if i != j and j > i:
            print(i, j)
            total = total + 1
print(total)
```

```
1 2
1 3
1 4
1 5
1 6
2 3
2 4
2 5
2 6
3 4
3 5
3 6
4 5
4 6
5 6
15
```

Figure 3: CJ and Corey's code and output for the Marbles problem

Int. 1: CJ, you observed something in there about the second column.

CJ: If it just goes through **systematically the way a computer thinks**, looking at the next one and then using it; then our second column always has to be bigger than our first column. If *j* is bigger than *i*, then it won't ever print 2 and then 1. […] The *i* not equal to j that just makes it so it can't be 1, 1; or 2, 2. If *j* was bigger than *i*, then print it. These are all the orders, it won't ever do the same combination twice because it won't choose 1 and 2; then 2 and 1.

Corey: [Corey adds to the code in Figure 3] And *j* is greater than *i*.

Int. 1: Cool. If you do it, can you describe how many you think you'll get and what you think the outcomes will look like? Do you think – ?

CJ: I think it'll go through how I did it.

Corey: I think it'll go exactly the way he did it.

Int. 1: Great. What about your program makes you think it'll run through in that way?

CJ: Looking at *i* first, it's gonna go through everything that could have 1, and everything that's bigger than 1. Then it's gonna go to the next part; then it's gonna go to 2; then it's gonna look at everything that's bigger than two and print everything with that.

CJ reasoned about an algorithmic approach in this problem. This is seen when he discussed going systematically "the way a computer thinks," which suggests and underlying, generalizable approach rather than just one procedure. He was thinking about what algorithmic process the computer might adopt to list the outcomes. He connected his listing process to what the computer might do and correctly asserted that their code would list the outcomes as he had. We argue that the students adopted an algorithmic approach in writing their code, and they thought about what process the computer might complete to accomplish a task. In this sense, kind of algorithmic thinking we are describing is important students' engagement with computational practices like programming. In addition to helping students think about computational practices like programming, such an approach can also useful in highlighting combinatorial ideas. Lockwood & De Chenne (2020) explored how students' reasoning about conditional statements like "if j != i" and "if j > i" supported students' reasoning about permutations and combinations, respectively. Thus, the algorithmic thinking used to reason about programming can then also help to enrich students' mathematical understanding as well.

To summarize this section, we highlighted three instances of algorithmic approaches that emerged in our data and our mathematical experiences. These examples are meant to illustrate what we mean by algorithmic approaches and also to motivate our focus on better understanding such approaches. Each example shares common features – the construction of a systematic, step-by-step process which could (though does not have to) be programmed into a machine. We suggest that there is some way of thinking that underlies these algorithmic approaches, and this is what we want to try to characterize and understand. AT could be the construct that underlies algorithmic approaches, and, ultimately, these examples compel us to explore what AT might entail and why it might be important. Having exemplified what we mean by an algorithmic approach, we now briefly review mathematics education literature for existing characterizations of AT.

Algorithmic Thinking in Mathematics Education.

There are some perspectives in math education literature that frame AT as characterizing *a way of thinking* rather than thinking about algorithms themselves. This is in line with the approaches we exemplified in this paper. The phrase "algorithmic thinking" appears occasionally in mathematics education literature, and the construct is used in a variety of ways. Knuth (1985) proposed a distinction between "algorithmic thinking" and "mathematical thinking" as an effort to distinguish the thought processes of computer scientists from those of mathematicians. Ultimately, Knuth concluded that there is no such singular concept as mathematical thinking, nor is there for algorithmic thinking, but rather each is comprised of a set of modes of thought. Many of these modes overlap (e.g., formula manipulation, abstract reasoning, information structures) with a few exceptions. Notably, "mathematical thinking" includes the infinite while algorithmic thinking does not; and algorithmic thinking accounts for problem complexity (i.e., the "cost" of running an algorithm), which does not typically surface in mathematics. Knuth's characterization of algorithmic thinking seemed to contribute primarily to highlighting some of the overlap—and some of the distinctions—of the disciplines of mathematics and computer science.

The NCTM handbook reported on differences between algorithmic thinking and recursive thinking. Although this is an interesting characterization, we note that their definition is quite broad and could apply to almost any process or mathematical situation. They define algorithmic thinking as follows:

> *Algorithmic thinking* is a method of thinking and guiding thought processes that uses step-by-step procedures, requires inputs and produces outputs, requires decisions about the quality and appropriateness of information coming in and information going out, and monitors the thought processes as a means of controlling and directing the thinking process. In essence, algorithmic thinking is simultaneously a method of thinking and a means for thinking about one’s thinking.

Schwank (1993) investigated what she referred to as different mental models that students might apply to algorithmic thinking, although she does not define algorithmic thinking in this paper. The types of tasks that she used to characterize algorithmic thinking were more aligned with typical computer science or computer programming tasks. In this work, the term “algorithmic thinking” implicitly referred to the types of thinking necessary to construct algorithms, although Schwank’s primary argument was that there are multiple ways of doing so. More recently, Abramovich (2015) used the phrase “algorithmic thinking” somewhat analogously to how other researchers have used “procedural knowledge” in conversations about the relationship between procedural knowledge and conceptual understanding for learning mathematics. Abramovich described how problem posing—the cyclical act of extending a concrete (often procedural) problem to a more generalized case—could promote a link between procedural skills and conceptual understanding. There continue to be new contributions to the discussion of algorithmic thinking and how it can be integrated meaningfully in to the mathematics curriculum (e.g., Stephens, 2018; Stephens & Kadijevich (2020)). Stephens (2018) argues for AT as one type of reasoning and suggests that we consider ways to leverage powerful developments in programming to improve mathematics education.

Another line of research emphasizes activities and practices related to the creation of algorithms, such as *algorithmatizing,* which is an approach through which students develop algorithms through carefully chosen contextual problems that require students to model a particular situation, reflect on their solution procedures, and develop increasingly sophisticated models and procedures that can translate to other situations (Gavemeijer & van Galen, 2003, p. 114). The process of learning to use and understand algorithms implies their construction—or reinvention—on the part of students, rather than the acquisition of algorithms as existing objects. At the post-secondary level, students in a differential equations class reinvented Euler’s method for approximating solutions to differential equations, following the careful selection of tasks that facilitated the generalization of procedures (Rasmussen & King, 2000; Rasmussen et al., 2005). By engaging in algorithmitizing, which involves reasoning about and developing algorithms, students must necessarily think critically about what is entailed in that algorithm. Thus, algorithmitizing can be thought of as an external activity that reflects thinking about an algorithm.

To summarize, in the mathematics education research literature, the term AT has been used and construed in a variety of ways. There are similarities in terms of presenting a general approach toward solving problems, but we think there is room to specify a more consistent and coherent characterization of AT in math education. (Regrettably, due to space, we do not elaborate AT in the computer science education literature, although that is another rich resource and set of perspectives).

Future Work Toward Characterizing Algorithmic Thinking

Having exemplified algorithmic approaches that we feel represent AT, and having briefly reviewed some relevant literature, we conclude with some ideas for more work that needs to be done to explore and elaborate the construct of AT. There is not clear consensus among research communities about what AT is or how it should be characterized or defined, and more work should be done to study explore what is entailed in AT. Once characterizations of AT are established, empirical studies can be designed to explore how students, instructors, and mathematicians engage with and employ AT. One potential future area of research is to explore how students interpret, evaluate, and/or debug existing algorithms. In addition, we acknowledge that AT should be framed within other kinds of thinking – such as computational thinking (Wing, 2006, 2008), mathematical thinking, or recursive thinking – and we believe that more work is needed to relate such constructs and terms. In this brief paper we do not have space to explore AT's relationship to those other kinds of thinking, but there is potential for rich theoretical investigations. It would also be worthwhile to explore the computer science education literature as it relates to AT and to compare and contrast the development and use of algorithms in computer science versus mathematics and other fields.

Graph problems as a means for accessing the abstraction skills

Janka Medová[1], Gregor Milicic[2] and Matthias Ludwig[2]

[1]Constantine the Philosopher University in Nitra, Faculty of Natural Sciences and Informatics, Tr. A. Hlinku 1, 949 74 Nitra, Slovakia; jmedova@ukf.sk

Computational thinking is an important 21st century skill. The ability to design own algorithm, i.e. algorithmic thinking is its integral part. Graph algorithms seem to be a promising mathematical content contributing to development of algorithmic thinking. However, in order to apply the corresponding skills to the problem at hand, first a corresponding representations has to be found. This step of abstraction is crucial for the application of skills to unknown situations and can be seen as a prerequisite for the algorithmic thinking. Solutions of the representation problem of 58 undergraduate students were analysed. Most students chose the diagram as a representation of the situation, only three students used the adjacency matrix and no students chose the incidence matrix or adjacency list, the other known representations. This may indicate that more activities are needed for enhancing students' ability to represent the graph, either by matrices or by a diagram.

Keywords: Algorithmic thinking, computational thinking, abstraction, graphs, graph theory.

Introduction

With the continuous digitalization of our daily life the development of corresponding digital competencies is crucial for future generations. The importance of "[...] thought processes involved in formulating a problem and expressing its solution(s) in such a way that a computer - human or machine - can effectively carry out" (Wing, 2017, pp. 8) is more and more recognized. Thus the corresponding competencies are increasingly integrated into the current curricula referred under the term of Computational Thinking (CT) (Bocconi et al., 2016) including concepts such as logical reasoning, abstraction, decomposition, generalisation or algorithmic thinking, understood as "[…] the ability to think in terms of sequences and rules as a way of solving problems or understanding situations." (Csizmadia et al., 2015, p. 7).

The abstraction is the one crucial aspects of the CT describing the process of "… reducing the unnecessary detail" of a situation, problem, or artefact (Bocconi et al., 2016, pp. 18). Certain proficiency in abstraction is a crucial aspect during the process of problem solving, for mathematics as well as for computer science (Ferrari, 2003). Without the ability to simplify a given problem or situation in the process of abstraction resulting to a corresponding mathematical or computational representation, the remaining problem-solving process is bound to fail, nor can other maybe suitable solving strategies or algorithms be applied, as the corresponding requirements cannot be checked. This may lead to an unfeasible choice of problem-solving process for the given problem, resulting inevitably in an incorrect solution.

Graph problems offer a good starting point to address and foster abstraction (Milicic et al. 2021) as some applications of graph algorithms are easy to be explained and offer the suitable environment for mathematical investigations with low demands on previous knowledge, e.g. constructing Eulerian trail (Geschke et al., 2005), minimum spanning tree (Vidermanová & Melušová, 2011) or estimating chromatic number of graph (Prayitno et al., 2022). In order to obtain a graph from the application or a problem from the real world, firstly the redundant and unnecessary information have to be identified and removed. Redundant information are details of the given problem not contributing in any way to the problem-solving process and can therefore be omitted. Unnecessary information are details not related to the problem which should be solved. Graph problems offer therefore many possibilities to address and foster abstraction as the first step and following, algorithmic thinking subsequently. Despite existing algorithmic thinking skills, the process of abstraction can still be challenging for students (Wetzel et al., 2020), emphasizing the importance of addressing especially this aspect of CT in the school environment.

Like in other fields of mathematics, e.g., arithmetic or algebra, using multiple different representations and linking between them can enhance conceptual understanding of given topic (Hodnik Čadež, 2018; Griffin, 2004). Moreover, the graph representations have to be handled differently while implementing graph algorithms in programming languages and also lead to different space complexity of the produced instantiations.

The earlier findings (e.g. Hazzan & Hadar, 2005) shown that students often overestimate the value of diagrammatic representation of graph. This results to decrease of the level of abstraction while dealing with graph theory concepts and may cause the difficulties related to the recognition of the details of graph algorithms (Dagdilelis & Satratzemi, 1998). However, the recent study of Prayitno et al. (2022) reveals that students are able to come up with both, diagrammatic and matrix representation of the graph while solving novel problems stemming from graph theory and both types of representation can lead to correct solutions of the problem in algorithmic graph theory.

In this paper we present the initial results of an exploratory study with university students. It was conducted in order to identify any possible challenges students face when they are asked to abstract a given graph problem and condense the corresponding information in the suitable representation. As graphs have different representations, it is not clear which of them is preferred by students. We formulated the following three research questions:

1. To what extent are the undergraduate students able to use abstraction in order to represent the relation given by the computer model by the means of graph theory?
2. What representations do they prefer?
3. What kinds of mistake can occur there?

Methodology

To conduct this research, we analysed the submitted solutions of the 58 undergraduate students. All of them were in year 1 of the bachelor study programme Applied informatics and took the paper and pencil test focused on algorithmic graph theory as a part of assessment of the course Discrete mathematics 2 focused on combinatorics and graph theory. The test itself consisted of 6 problems. One of them is analysed in further details in this paper. The written informed consent was requested and collected after the students got their whole evaluation and passed/failed the course. The all of these 58 students attempted to solve the problem and provided their consent.

We expected that the participants are equipped with a decent knowledge of programming and therefore possess adequate algorithmic thinking skills, as they have passed the introductory course in programming in the previous semester, covering work with variables including arrays, sequences, conditionals, loops with numbered (for loops) and conditional repetition (while loops) of instructions. The test was administered at the end of the second semester of their study before the exam in regular programming course comprising the use of procedures, recursion, dynamic variables (FIFO/LIFO structures) and object-oriented programming. The different representations of graph, diagrams, incidence matrix, adjacency matrix and adjacency list were integral part of the discrete mathematics course.

The task of finding a graph that represents which area shares an edge with each other in the two dimensions is a frequently occurring problem when teaching and learning graph problems. Using the means of augmented reality (Buchner, 2018), we extended this problem by another dimension by not using planar areas, but some three-dimensional objects, see Figure 1a and 1b as one of the three different situations used in the exam.

We derived this task using the elements from the SOMA cube puzzle (Peter-Orth, 1985). The task was formulated as follows: “Represent the adjacency of the all parts of the kit (consisting of the 3 or 4 cubes) from which the ‘sofa’ is assembled. The tiny gap between the parts is only for better clarity.” The students were asked to scan a respective QR code and open a webpage inside a browser on their mobile device or with their web camera. No additional hard- or software aids were thus necessary in order to solve the task. By pointing the camera at the marker, the object as seen in Figure 1a and 1b was visible using Augmented Reality (AR). The students could turn the object around on their screen and shrink or enlarge it using common gestures with their fingers on the screen[1]. A solution using a diagram as representation is given in Figure 1c.

(a) (b) (c)

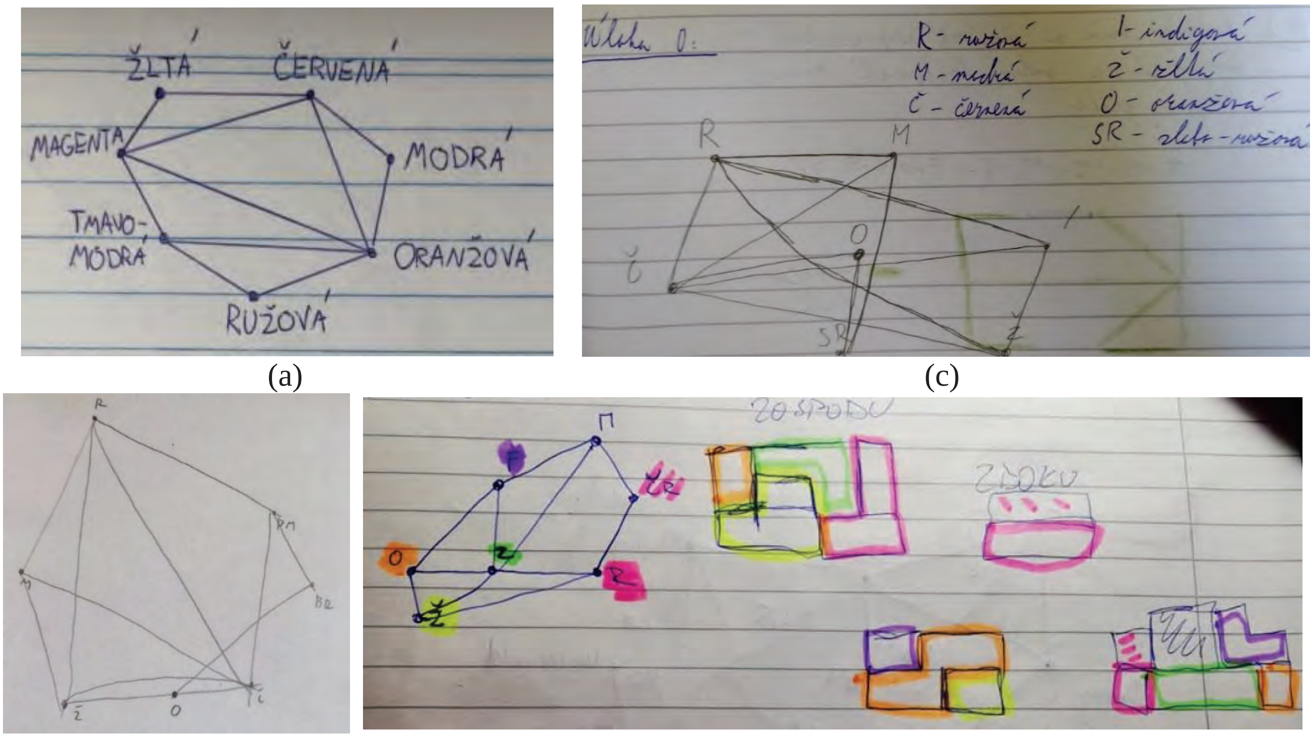
Figure 1: Two views of the sofa consisting of SOMA cube elements (a and b) and diagram of its graph representation (c)

[1] See https://colette-project.eu/AR/somas.html for the used AR-marker as well as the presented setting (Soma Sofa 1).

Findings

Out of the 58 solutions submitted by the students, 45, i.e., 77.6 % were correct. Although the students were not instructed which representation they should use, only the 3 students used the form of adjacency matrix, one of them used the adjacency matrix and the diagram, while other used the representation of the graph by a diagram. No students used incidence matrix or adjacency list. This may result from the dominant use of the diagram representation of graph during the lectures and problem-solving sessions throughout the whole semester.

Different names of vertices were used among the correct solutions. Only one student labelled the vertices as v_1, v_2, etc. and on top he provided a table which label means the solid of what colour. Some students used the full colour names (Figure 2a), some just the abbreviations (Figure 2b) and some also included a list of abbreviations (Figures 2c and 2d). Most solutions have the vertices placed in shape of regular heptagon (Figures 2a and 2b), only occasionally the vertices were placed in different configurations (Figure 2c). One student also used the colours and drew the bottom and side view (Figure 2d) on top of the graph representation.



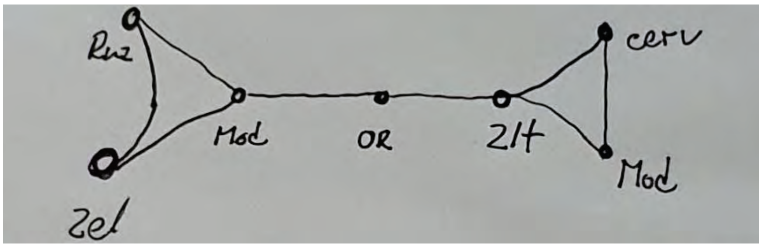
(a) (c)

(b) (d)

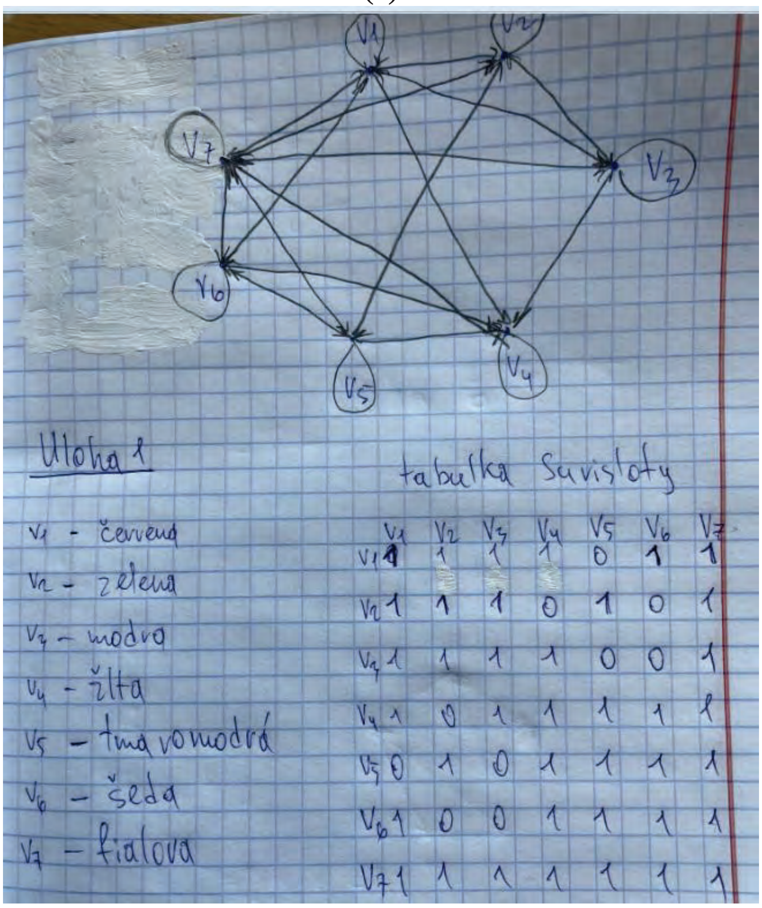
Figure 2: Students' solutions with different labelling of vertices

Ružová = pink; modrá = blue; červená = red; indigová = indigo; žltá = yellow; oranžová = orange; slabo-ružová = light pink; tmavo-modrá = dark blue. BR probably states for bledoružová = light pink and BM for bledomodrá = ligh blue. Zospodu = bottom view; zboku = side view.

The majority of incorrect solutions can be considered as flips when one or more edges were missing. The solution in Figure 3a is an example of solution where quite a lot of edges were missing. Furthermore, the student did not distinguish between the two shades of blue. On the other hand, the solution in Figure 3b represents a solution with excess edges. In addition, the student considered the relation of being adjacent as reflexive.



(a)

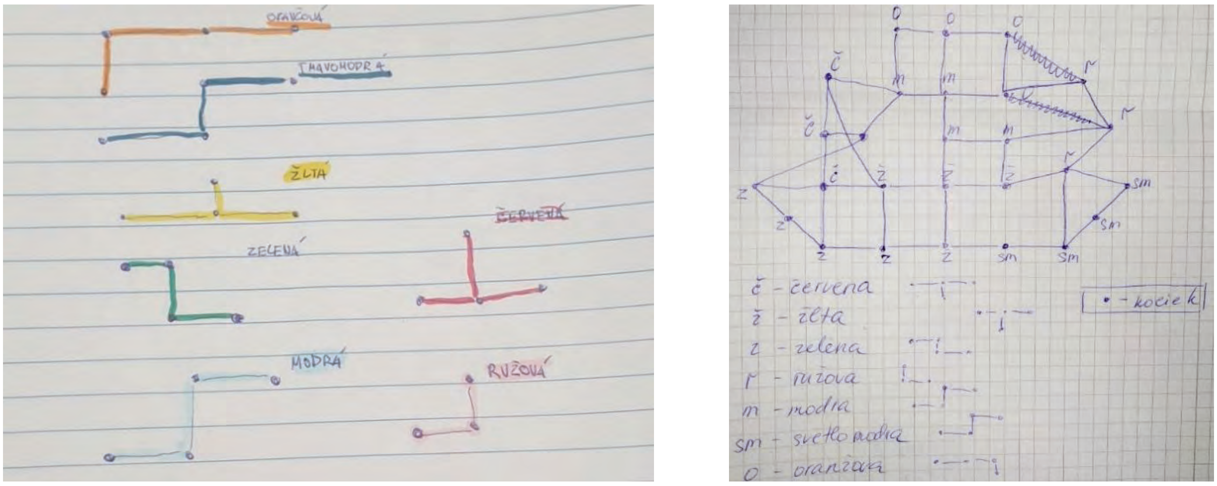


(b)

Figure 3: Examples of incorrect students' solutions

On top on typical solutions in Figure 2, there were several solutions demonstrating unique approach to the representation. For instance, two students considered the small unit cubes instead of the tricubes and tetracubes as vertices (Figure 4). One of them (solution in Figure 4a) further concluded that the graph is not connected as he considered the tiny gaps between the parts of the given problem as separating. The second unique student's solution (Figure 4b) is a correct one for this choice of representation. The corrections made by student demonstrate that it was quite challenging to keep tracking of so many (27) vertices.

The matrix representation of graph was preferred by only three of 58 participating students, two of them were correct. The incorrect representation by adjacency matrix (Figure 3b) was the only case when student used two different representations. Even though the diagram fits the matrix, the represented graph does not fit the adjacency of part of the SOMA 'sofa'.



(a) (b)

Figure 4: Solution of students' representing the cubes as the vertices

Discussion

The rate of correct solutions was much lower than expected in case of the students who passed the introductory course of programming and the course focused on the graph theory specifically. The observed success-rate was even lower than the success-rate of a similar group of students solving modelling problems in algorithmic graph theory (Medová et al., 2019). One of the possible explanations vests in that during the course and in ample cases of textbooks the problem situation is already given by diagram representation of graph and the abstraction job as such is already done by the author of the task (Fojtík, 2021). Also, pre-prepared 'suitable illustrative graphs … using colours' are often considered an effective mean 'to emphasize the characteristics of the concepts' (Milková, 2009). However, the informed choice of suitable representation is one of the crucial aspects when tackling unstructured open problems (Swan & Burkhardt, 2014) particularly in algorithmics, and influenced by the level of abstraction of the solver. Therefore, the process of abstraction itself, regardless the type of representation, is essential and crucial for solving problems in the situations requiring to omit the unnecessary and redundant information (Wetzel et al., 2020), most frequently in cases of real-life applications. The students should estimate the necessity of the information based on the definition of the particular problem.

Our findings suggest that the students used mostly the diagrammatic representation of graphs. It complies with the observation by Hazzan and Hadar (2005) than students tend to over emphasize the visual aspect of graph theory. The students may use the diagrammatic representation because the problem was not set to any complex problem situation, because, as stated by González et al. (2021) even the students with low level of reasoning in graph theory should be aware of limitations of the different known representations for different purposes. On the other hand, as we stated in our previous work (Milicic et al., 2021) any different representations of graphs can lead to different variables for representing the graph in the computer and it may be easier to analyse or use for subsequent tasks and solving processes. Adjacency and incidence matrices can directly lead to use of arrays and adjacency list is just a small step to the FIFO list. In contrast to diagram, the representations of graph by matrix and list permit to get the information about the adjacency of two vertices in constant time but the instantiations vary in space complexity. Even though the diagrammatic representation cannot be used for computer processing, it seems to be suitable for students while learning the principles of algorithms (Melušová & Vidermanová, 2011).

Conclusions

The tasks to represent the relations between the parts of geometric shapes are often used in graph theory education. The technology of augmented reality enables us to use some three-dimensional geometric shapes instead of usual planar problems without any additional hard- or software aids. The task to omit the redundant information and come up with an abstract representation caused some difficulties even in case of students equipped with their decent programming capability and experience. It seems that more attention should be paid to different representations of graph during the course, particularly to creating the representation by students instead of pre-prepared graphs.

However, the extent to which is the level of abstraction connected to the ability to solve (modelling) problems in algorithmic graph theory is still to be investigated and estimated.

Acknowledgment

The project is (partially) funded by the ERASMUS+ grant program of the European Union under grant no. 2020-1-DE03-KA201-077363 and by Slovak Research and Development Agency, grant no. APVV-20-0599. An app-based learning environment for building algebraic competencies through algorithmic thinking

Joscha Müller-Späth[1]
[1]TU Dortmund University, Faculty of Mathematics, Germany;
joscha.mueller-spaeth@tu-dortmund.de

Keywords: Algebraic thinking, algorithmic thinking, programming app, primary school education.

Introduction

In recent years, the demand for the implementation of computer science (CS) content in German primary schools has strongly increased, so that there are several projects investigating its implementation. However, since a stand-alone subject CS in German primary schools is not a realistic scenario, relevant topics and competences should be integrated into existing school subjects (Schmid et al., 2018), e.g. mathematics.

Algorithms, Arithmetic, and Algebra

The connection of algorithmic, arithmetic and algebraic thinking can be realised by primary school children through the use of algorithms during programming activities (Agatolio et al., 2018). Kilhamn and Bråting (2019) also see an intersection between algebraic and computational thinking. However, this should be investigated especially with regard to whether programming activities support or limit the development of students' algebraic thinking. In their paper, they conclude that there are programming activities that have an impact on students' algebraic thinking (especially with regard to symbolisation). As an interesting open research area they define the question of whether structures embedded in algorithms can lead to "the development of algebraic thinking in terms of an increased focus on structure and generalization" (Kilhamn & Bråting, 2019, pp. 571–572).

In my PhD project I will examine intersections between primary CS and mathematics education with the focus on how the structures of an algorithm can influence generalisation in understanding an arithmetic topic. Therefore, a learning environment including an app (see Figure 1) with additional supportive tasks is developed. With this, primary school students can use and study the similarities of arithmetic and algorithmic structures with the goal to come to algebraic generalisations.

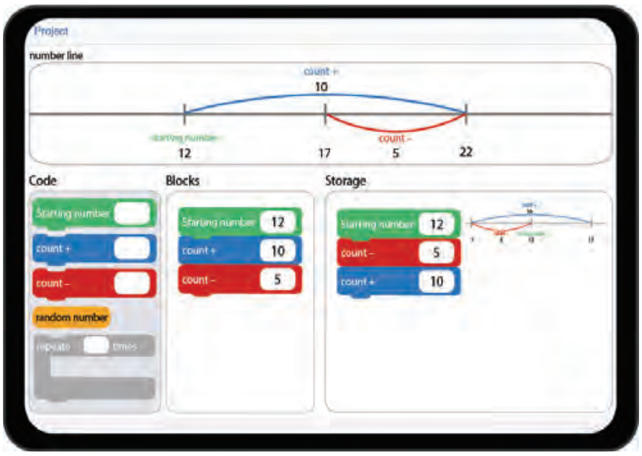

Figure 1: App 'Rechenketten'

Research Question

The learning environment and the research study are structured by the following research question: *To what extent can (1) understanding and analysing, (2) modifying, and (3) developing an algorithm help to obtain algebraic discoveries in terms of generalised arithmetic structures?*

Design of the Learning Environment

To explore and generalise arithmetic structures as a transition to algebraic thinking (e.g. Kaput, 2008), students use the arithmetic task format "Rechenketten" (arithmetic Chain, see Figure 1) to explore several arithmetic structures such as the property of commutativity, the distributivity or multiplication as repeated addition. The app is developed with the intention that these structures can be seen simultaneously in the arithmetic and algorithmic representation[1] so that a linking of representations is possible.

Therefore, three corresponding tasks are structured along the three aspects (1)–(3) of the research question: Task series 1 aims at understanding and analysing similarities and differences between the representations (1). Task series 2 aims at modifying e.g. inappropriate representations (2). Task series 3 encourages the development of algorithms as solutions to problem-containing arithmetic tasks (3).

Design of the Research study

In the sense of developmental research (Prediger & Link, 2012), a learning environment for the use of the app is to be (further) developed. In order to investigate learners' cognitive processes in terms of our research question, fourth graders will be interviewed after having used the app. The interviews will be videographed, transcribed and analysed using qualitative methods such as Grounded Theory.

For this purpose, a piloting of the app and the tasks was carried out in the autumn 2021. The insights gained from this will flow into further development so that the first design experiments can be carried out in spring 2022. These will then be evaluated to provide new insights for theory and practice.

Task design for promoting pupils' algorithmic thinking in problem-solving context without using computers

Rafalska Maryna

LINE, Université Côte d'Azur, France; maryna.rafalska@univ-cotedazur.fr

The paper presents the task design aimed at the emergence of the algorithmic thinking of pupils in the problem-solving context without using computers. Discussing the results of the experimentations carried out at the grade 5th, it aims to offer an account of the conditions and constraints for effective algorithmic problem-solving as well as to identify mechanisms that emerge.

Keywords: Algorithm, algorithmic thinking, problem-solving, task design.

Introduction

(Re)appearance of algorithmics and programming in school curricula of many countries has impulsed research addressing the development of pupils algorithmic thinking. In existing literature, including the one that relates to mathematical education, this concept is usually studied through the lens of programming (Hickmott et al., 2018; Bråting, & Kilhamn, 2020). To date, there has been limited empirical research about the conditions and constraints for the emergence of algorithmic thinking in a non-programming context. In this paper, we take a step toward addressing this need for research by studying algorithmic thinking via analysis of pupils' algorithmic activity in problem-solving context without use of computers. More precisely, we are interested in the pupils' activity related to the conception and implementation of an algorithm in order to solve a problem as well as reflecting on solutions through the analysis and proof of the algorithm. As a definition of an algorithm, we use the following one:

> Algorithm – a problem-solving procedure that in a finite number of constructive, non-ambiguous, effective and organized steps produces the answer to the given problem for all instances of this problem. (Modeste, 2012, p. 25).

This paper reports on research work in progress that has several goals. The first one is to design a set of tasks and the associated sequence of lessons aimed at the emergence of pupils' algorithmic activity. The second one is to examine whether the design is effective. In particular, to check whether and to what extent it favorize the construction, analysis and proof of the algorithms by pupils. The third one is to contribute to the development of a theory that would help to explain the mechanisms that emerged during the scenario implementation.

Theoretical framework

This study is a design-based research (Barab, & Squire, 2004) based on the hypothesis that unplugged problem-solving (i.e., problem-solving without using a computer (Bell et al., 2009)) constitutes a favorable context for the emergence of pupils' algorithmic thinking.

The task design draws upon principles from the Theory of Didactical Situations (TDS) (Brousseau, 1997). More specifically, the tasks were designed as *a-didactical* situations, where the pupils' interactions with the organized *milieu* are supposed to lead to the construction of the algorithms that are the optimal solution of the given problem. This implies that pupils' "basic knowledge" should be sufficient to start the work. The *milieu* must provide pupils with feedbacks to their trials in such a way that they can tell without teacher interferences whether they succeeded or failed. Pupils in a situation should be able to experience the limitations of their strategies developed at the earlier stages of problem-solving and make them evolve towards the algorithms that constitute a solution for the given problem.

In our choice of mathematical problem for task design, we based ourselves on the notion of fundamental problem for algorithm (FPA) proposed in (Modeste, 2012) with reference to the concept of fundamental situation from TDS (Brousseau, 1997). FPA could be seen as a problem that evokes the concept of algorithm and is adapted for the tasks design aimed at engaging the pupils in algorithmic activity. As the criteria of FPA, Modeste (ibid.) proposes the following: it should be algorithmically solvable; the notion of algorithm is indispensable for its solving; it evokes the problems that handle the algorithm as a tool (aspects of effectiveness and problem) as well as an object (aspects of complexity, proof, theoretical models). The key value of FPA is that it could be used for design of tasks/didactical situations for a class. These situations should be aligned with the criteria of FPA mentioned above. In particular, they should evoke an algorithm not only as a step-by-step procedure but also as a general problem-solving method that can be applied to all instances of the problem as well as to provide a favorable *milieu* for provoking questions about proof and complexity of the algorithm at stake.

Methodology

The research we report in this paper concerns the first cycle of the design that included the phases of development, *a priori* analysis, implementation, *a posteriori* analysis and refinement. The phase of development was carried out in parallel with the analysis of the strategies susceptible to appear during problem-solving. The experimentation phase used to collect data was followed by the analysis of pupils' strategies that appeared in the class. On the basis of the comparison between anticipated strategies with actual ones, we concluded about the potentialities of designed situations in promoting algorithmic activity of pupils and whether the task design should be improved.

In order to identify the mechanisms that emerge during the implementation of the developed sequence of lessons, we analyzed pupils' decisions and actions with material *milieu* as well as their discourses produced at the private and social levels. In particular, we paid special attention to explanations and arguments expressed inside a group and during the collective discussion regarding the question about the reasons why the strategies work.

In what follows, we first describe the problem of list sorting that, as we claim, is a fundamental problem for algorithm. Then, we present the set of designed situations, explain their link to the problem of list sorting as well as the analysis of anticipated solving strategies. We conclude the methodology section with a description of the designed sequence of lessons, experimental conditions and data collection. In the subsequent section, we present and discuss the results of the implementation of the developed lessons sequence in a class. The last section is devoted to conclusions and perspectives of the research.

The problem of list sorting

Formulation of the problem. In a model of computation with the only allowed operations of comparison and exchange, sort a non-empty list $L = (e_k), k = 1 \dots n$ (of objects comparable two by two) according to an order relation $\preccurlyeq$.

We use the term "model of computation" as a set of allowed operations in reference to the computation and complexity theory (Bilardi, & Pietracaprina, 2011). The relation of order $\preccurlyeq$ in a list is a binary relation that permits to compare the lists' elements between them in a coherent way. To sort a non-empty list $L = (e_k), k = 1 \dots n$ according to the relation of order $\preccurlyeq$ means to find a list $L' = (e'_k), k = 1 \dots n$ with the elements that are a permutation of the elements of L such as $\forall\, i,\, j = 1 \dots n,\; i \leq j \Rightarrow e'_i \preccurlyeq e'_j$. The "*operation of comparison*" is an operation that permits to receive the answer "yes" or "no" to the question "Is $e_i \preccurlyeq e_j$, i,j=1…n ?". The "*operation of exchange*" could be defined by the transposition of the elements e_i and e_j, $e_i \neq e_j$, $i = 1 \dots n, j = 1 \dots n$ in the list L that allows to obtain a list $L'' = (e''_k),\; k = 1 \dots n$ where $e''_k = e_k \;\; \forall k \neq i, j,\;\; e''_i = e_j$, $e''_j = e_i$.

The formulated problem responds to all criteria described above. Indeed, it is algorithmically solvable and many sort algorithms exist. Problem-solving includes the phases of elaboration and validation of an algorithm. The existence of many sort algorithms raises the questions of their comparison from the point of view of their complexity and finding the optimal one. This provides a possibility to study an algorithm not only as a tool but also as an object. On the basis of the problem of list sorting, we designed a set of problem-solving situations that we describe in the following section.

Set of problem-solving situations

The designed sequence of problem situations includes three games using the playing cards as manipulatives. In each game, a pupil has thirteen playing cards of the same suit and a cardboard grid with predefined ten places situated in one line. At the beginning of every game a pupil shuffles the cards, chooses randomly ten cards (without looking at their values) and puts them up-side down on the grid (one card per place). The rules of the games vary from one game to another, but the goal is the same, i.e., to sort the cards in ascending order, using only the three allowed operations: "take two cards", "put the two cards in ascending order", "put the cards on the places".

Game 0 (individual). A pupil should sort the cards individually, turning no more than two cards at a time and using the three allowed operations. There is no restriction for the number of comparisons to make (a pupil can turn the cards two by two as many times as he wants). Once the pupil thinks that all cards have been sorted, he can turn them to check this.

Game 1 (in pairs). For this game, the pupils play in pairs. Only one grid and thirteen cards of the same suit are needed. The first pupil (which we call in the following "operator") shuffles the cards, chooses randomly ten cards from thirteen and puts them on the grid without showing their values to another pupil. The second pupil ("player") must sort the cards which values he doesn't see, giving the instructions to the operator that correspond to the three allowed operations. The operator should execute the commands precisely and formally (without giving any information to the player). When the player thinks that the cards are sorted, he says "stop" and the operator turns the cards. The player wins if all cards are in the right order. The pupils exchange their roles once the player's attempt to sort the cards is finished.

Game 2 (in small groups). The pupils play in small groups of four persons. At every time there are one player and three operators that manipulate the cards on their grids. The rules of the game are the same as in the previous game, but, this time, the goal of the player is to sort the cards of all operators at the same time giving the instructions composed by the three allowed operations. The pupils exchange their roles once the player's attempt to sort the cards is finished.

Game 3 (in the whole class). This game follows the same rules as the previous one but this time, the goal is to sort the cards of all pupils of the class at the same time using the minimum possible comparisons. Each group send a delegate who has only one attempt.

Being a didactical variable, the number of cards to sort in the games could vary. But it should not be too small in order to provide a *milieu* sufficient to foster the development of sorting algorithms by pupils and not equal to the total number of cards (in order to avoid the "trivial" algorithm where one can deduce the final position of a card from its value).

As a possible prolongation of the proposed games, we may consider the problem-solving situations where the pupils investigate the possibility to sort more than 10 cards (11, 12, 20, 100 cards) and eventually any number of cards. The last refers to the proof of an algorithm (by recurrence, by invariant) and offers the possibility to study the complexity of an algorithm as a function of *n*. The notions of complexity in time and space could be also introduced considering the programming context.

Link to the problem of list sorting

The games 0 to 2 can be seen as the ten elements list sorting problem in the model of computation where a number of allowed operations changes from one game to another one. Thus, in game 0, the fact that the pupils can see the values of the cards can be considered as the case where the model of computation (CM0) contains the operations of comparison, exchange, identification of the index of an element with a given value and identification of the value of an element with a given index. In game 1, the fact that a player can see if the cards were changed by the operator or not, correspond to the model of computation (CM1) with the available operations of comparison, exchange, identification of the indexes of elements that have been exchanged and the operation that provide the response "yes" or "no" to the question: "Was there an exchange of the cards during the last comparison?". The goal of game 2 to sort the cards of three persons at the same time was retained in order to prevent a player to use the information about the cards' exchanges in order to put him in the model of computation (CM2) with only available operations of comparison and exchange that corresponds to the list sorting problem formulated in the previous section.

Expected solving strategies

The game 0 aims at familiarizing pupils with the manipulatives and the rules of the games. In particular, the pupils need to understand the meaning of the three allowed operations and the actions that are forbidden (for example, to glide the cards on the grid). It is expected that the pupils will memorize the values of the cards and their positions in order to sort them (strategy S_m in Figure 1).

Thus, the strategies that can appear will be rather the instance algorithms (that allow to sort only particular cases of the cards placement).

In game 1, due to the change of rules, the pupils cannot see the values of the cards, but they still can observe if there were exchanges or not. The strategy of memorisation of the positions of cards that were exchanged is tedious. Therefore, it is expected that the pupils will engage themselves in the research of a more economic strategy. Between the possible strategies we can imagine those that use the information about the exchange S^e during the last comparison of two cards and those that don't S^g. In the first category, it is possible to distinguish the family of strategies S^e_{st} that use the information about exchanges as a condition for termination and the family S^e_{ch} where the information about exchanges is used for choosing the next pair of cards to be compared but the termination of the strategy is determined by the end of the systematic process of comparisons. For example, to the first category belongs the strategy S^e_{lr} that compares cards two per two from left to right and backwards until there are no more exchanges and $S^e_{rdm}$where cards pairs are chosen randomly until there are no more exchanges. As examples of strategies that belong to the category S^e_{ch}, we can think of S^e_{in} that is based on the idea to create a subset of the cards with installed local order (constituted of one card at the beginning) that will extend at each step by insertion of one card from the non-sorted part. The insertion is made by comparing a card from the non-sorted part with all cards of the sub-set starting from the most right one until a card with which there is no exchange. Another example of the strategy of the family S^e_{ch} is quick sort S^e_{qs}.

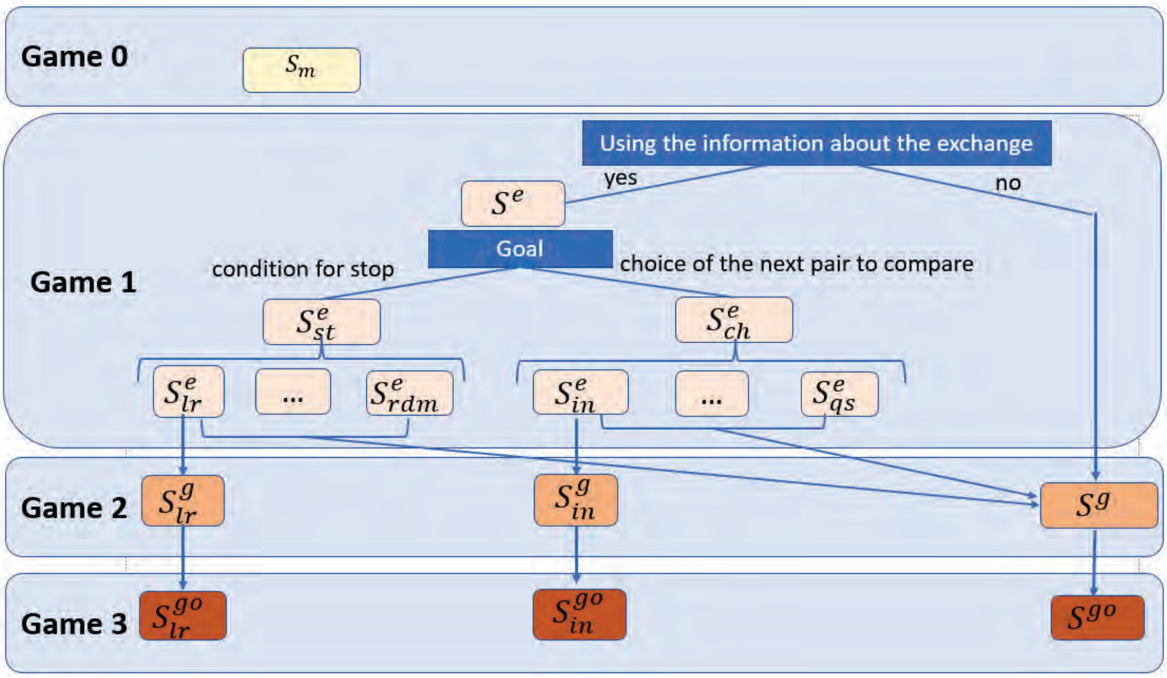

Figure 1: Evolution of expected pupils' strategies during problem-solving

If pupils don't use the information about the exchange, they are *de facto* placed in the next problem situation (game 2) with CM2. The strategies of the class S^g in this case could be based, in particular, on the idea to bring one card by one on their definitive positions considering the global order (as in the selection sort, for example).

For pupils who elaborated the strategies of the class S^e in game 1, game 2 introduces in the *milieu* the question about the worst case of cards placement. Thus, it is expected that certain of these strategies will evolve, the others will be abandoned and replaced by strategies of class S^g. For example, the strategy S^e_{lr} is susceptible to become the cocktail sort algorithm and the strategy S^e_{in} can be evolved into the insert sort algorithm. The strategy S^e_{rdm} (that becomes too costly in the game 2) will be abandoned as well as quick sort algorithm (which cannot be executed in CM2).

Game 3 aimed to introduce in the *milieu* the question about the possibility to use the strategies elaborated in game 2 for a bigger number of operators. It was also expected that the challenge to use the minimal number of comparisons possible would allow pupils to pass from the simple observations that the strategies work to analysing their properties. This may result in an optimization of the strategies (which we showed on Figure 1 using superscript "go") or their replacement by more efficient ones from the point of view of the number of comparisons needed to solve the problem.

We hypothesize that the set of developed problem-solving situations could be used at different school levels for promoting pupils' algorithmic activity. In this paper, we are interested in the implementation of the lessons sequence at the upper primary school level drawing the following research question: "Does and to what extent the tasks design favorize the emergence of algorithmic activity of pupils of this level?"

Lessons sequence and its implementation in the class

On the basis of the developed set of problem-solving situations, we elaborated the lesson sequence in collaboration with a teacher associated with the research. It included three lessons that were implemented in the class of 5-th grade (that corresponds to pupils' age of 10–11 years) in the city centre of Lyon, France. In the first lesson of one hour, the pupils played in the games 0 to 2 according to the rules described above. The developed strategies were formulated only at the private level (pupils described them on the paper after game 1 and 2) in order to give enough time for all pupils to do their research and to elaborate the strategies without influencing on this process by ideas produced by others. The teacher didn't not intervene in the pupils' problem-solving.

At the second lesson of two hours, the teacher introduced a new challenge: to sort the cards of all pupils of the class at the same time. The pupils were asked to think in groups about the strategies to apply in case of seven cards on a grid and to count the number of the comparisons needed to solve the problem. Thus, it suggests that the assignment given in the class differed from the initial formulation of game 3 presented above. The attempt of each group to sort the cards of all pupils of the class was followed by the general discussion led by the teacher who invited pupils to explain why the proposed strategy worked (or why they thought that it would work) and if it could be optimized from the point of view of the number of comparisons. The third lesson of two hours was devoted to the following analysis of elaborated strategies. In particular, pupils may explore the possibility to sort more than 10 cards (11, 12, 50, 100, any number of cards) using the developed strategies as well as to discuss the termination of the elaborated algorithms.

Data collection

We collected the videos of three lessons filmed by one camera at the back of the class, videos of work of three groups of pupils at each lesson, pupils' written descriptions of developed strategies. All videos were transcribed and analyzed as well as the pupils' productions.

Data analysis and findings

Due to the space restrictions, we report only about a part of the results that concern strategies development at first two lessons. The *a posteriori* analysis of the game 0 and 1 showed the consistency with the *a priori* analysis. In game 1 we noticed the appearance of the strategies of the two families S^e and S^g. The first family was represented, in particular, by the strategies S^e_{lr}, S^e_{in} and S^e_{rdm} described above. The family S^g was represented by a selection sort algorithm developed by the pupils who didn't use the information about the exchange of the cards. Comparing the anticipated strategies with those that appeared in the game 2, we point out new elements not envisaged in the *a priori* analysis. This concerns the case of one pupil named Arthur that we present in the following.

In the result of all games, three groups proposed the selection sort algorithm (one group used 42 and two groups used 21 comparisons to sort seven cards). In one of these groups, we also noticed the appearance of the bubble sort. Moreover, one group proposed the insert sort with 21 comparisons, one group stopped their research on the strategy S^e_{lr} with 43 comparisons and two groups didn't succeed to develop general algorithms.

Analysis of Arthur's case of strategy development

Arthur in the game 1 elaborated the strategy S^e_{in} described above. When the rules of the game 2 were announced by the teacher, Arthur resisted to abandon the usage of the information about the cards' changes and took the decision to apply simultaneously the strategy switching from one pupil to another (which means that every pupil executed the same strategy three times). Thus, Arthur generalized the strategy in a trivial way. However, from his actions we can infer that Arthur anticipated that implementing the strategy only one time is not sufficient and that execution of several times the same strategy will not change the order of already sorted cards.

The new challenge to sort the cards of all pupils of the class lead Arthur to understanding that his strategy would be too costly from the point of view of the number of needed comparisons. He took the decision to try to sort the cards of the pupils of his group with closed eyes. Arthur's tentative to come off the information about the cards' exchanges eventually helped him to generalize his strategy in CM2 in a non-trivial way and to obtain the insert sort strategy with 21 comparisons.

For the teacher's question if the strategy will work for the whole class, Arthur gave the positive answer referring to the experience with three pupils and added the following:

Arthur: In my head … it is logical. We make the cards number 4 and 5 … imagine that one person doesn't exchange, there are other people that could exchange … because we don't know what they have … therefore it is necessary to come back to the beginning of the grid. Because, if, for example, here [shows the place number 4 on the grid] there is an ace … it should be brought back to the beginning.

In this excerpt, Arthur explains the decisions ta.ken during strategy development. He refers to the cards number 4 and 5, but the chosen cards are used only as means to illustrate the "local" worst case (when an ace is placed on the right extremity of a subset of cards) identified by the pupil. The given example has a general character and used by the pupil to validate the elaborated strategy.

Conclusions and perspectives

The *a posteriori* analysis showed that the designed set of tasks supports to a large extent the development of sorting algorithms by pupils of upper primary school level. The identified individual cognitive path enriched *a priory* analysis. The generalisation in the game 2 could be made trivially, but the goal to sort the cards using the minimal possible number of comparisons in game 3 puts a pupil in a situation where he should search for a more efficient way to generalise the developed strategy in CM2. This case also permitted to point out the ways to improve the design for the next cycle of the design experiment. For example, the assignment of the game 2 could be modified by asking the operators to make manipulations with cards (exchanging or not exchanging) under the table or use the method of "closed eyes" for a player used by Arthur.

Besides, we revealed several mechanisms that emerged during implementation of the lessons sequence. The process of strategies development involves conjecturing, taking decisions and generalization. Artur's case showed the capacity of pupils of this level to consider the "local" worst case of the cards' placement that is crucial for evolving S^e strategies in general sorting algorithms.

In most cases, the pupils' experience to sort cards of three operators in game 2 seems to be decisive for retaining the strategy as the one that would work for the whole class in game 3. The arguments about strategies validity produced by pupils in the private level has mostly a pragmatic character and are highly anchored in the actions made during strategies development. More research needs to be carried out to identify the favorable conditions for fostering the algorithms validation process. Future work is also likely to compare the results obtained from the experimentations at different school levels in order to study the impact of "external" conditions (age, pupils' knowledge repertoire, etc.) on the pupils' algorithmic activity in the developed situations.

Teachers' beliefs on computational thinking in school mathematics

Martine Rekstad[1] and Nils Henry Williams Rasmussen[2]

[1] Western Norway University of Applied Science, Norway; mrek@hvl.no

[2] Western Norway University of Applied Science, Norway; nhwr@hvl.no

Keywords: Computational thinking, mathematics teachers, compulsory education.

Introduction – positioning and focus

In this poster proposal we present an aim to investigate which aspects of computational thinking that emerge in teachers' beliefs on computational thinking in school mathematics. Several researchers have commented that there is a lack of empirical research on programming and computational thinking in didactic practices (Forsström & Kaufmann, 2018; Grover & Pea, 2013; Weintrop et al., 2016). Forsström and Kaufmann call for a discussion regarding the influence of the role of the teacher in students' learning processes in activities such as programming (2018). By analyzing reports written by 12 lower-secondary and secondary school teachers from Norway who planned, implemented, discussed, and reflected upon a classroom session in mathematics involving computational thinking, we want to reveal insight in which aspects of computational thinking that are prominent in teachers' beliefs on computational thinking in school mathematics. This research will have a teacher perspective.

An OECD report links the intention with computational thinking in school mathematics to expectations of a more general understanding of the role of technology in society (2019). The OECD report also refers to a report on computational thinking that provides a comprehensive overview and analysis of recent research findings on computational thinking in compulsory education. This report summarizes concepts and skills of computational thinking and presents a framework for computational thinking in compulsory education (Bocconi et al., 2016, 2018).

Results from an analysis in the first author's master's thesis show that there is a relationship between aspects of computational thinking that emerge in activities, and what three teachers state about computational thinking. However, the research in the master's thesis reveals that there is no apparent correspondence between the intention of computational thinking in school mathematics, and what emerges through activities in mathematics and in the three teachers' beliefs of what is important in computational thinking in school mathematics. These results indicate that the three teachers focused more on skill development than problem solving. Based on this, two new dimensions of computational thinking emerge. One dimension emphasizes the development of skills, and the other dimension highlights problem solving. These dimensions do not exclude each other, but rather show what is emphasized (Rekstad, 2021).

Methodology

In order to illuminate which aspects of computational thinking that emerge in teachers' beliefs on computational thinking in school mathematics, we have collected data from 12 mathematics teachers who are enrolled in a teacher development program. The data consists of reports about their developmental work on computational thinking in their own classrooms. The teachers are to plan and implement classroom activities that develop computational thinking, and afterwards place the activity in the framework of Bocconi et al. (2016, 2018).

We plan to apply content analysis where we evaluate and code the teachers' reports and beliefs. The analysis will afterwards be discussed according to the framework of Bocconi et al. (2016, 2018). This framework addresses core skills, approaches, and dimensions of computational thinking with or without technology, in which computational thinking are used.

Implications

We have gathered data, but not yet carried out the analysis. There are two elements that might be interesting to see. Firstly, it will be interesting to see which aspects of computational thinking are prominent in the teachers' planned session, reflections, and discussion about their own experiences with teaching computational thinking. Secondly, it is interesting to look at whether the activities mentioned in the teachers' reports fulfill the criteria of the problem-solving or skills-development dimension of computational thinking. Based on the results from the masters' thesis, we expect to see more of the dimension that emphasizes skills development.

Advantages and disadvantages of using loops in algorithms: conceptions of pre-service primary teachers learning Scratch

Christof Weber[1, 2]

[1]University of Teacher Education Lucerne, Switzerland; christof.weber@phlu.ch

[2]University of Applied Sciences Northwestern Switzerland; christof.weber@fhnw.ch

The purpose of this paper is to explore pre-service primary teachers' conceptions of loops for drawing squares in their early stages of learning Scratch. Twenty-six pairs of student teachers, all with some experience in teaching mathematics at primary school level, explain the advantages and disadvantages of using loops in Scratch. Qualitative content analysis of their written explanations revealed three categories: (1) the higher efficiency of loops is seen as a clear advantage, (2) their narrower range of applicability as a clear disadvantage, and with regard to (3) the cognitive demand of loops, the responses are contradictory. In addition to some misconceptions, we could identify a key fact that student teachers must know in order to competently handle loops in Scratch, that is different outputs may occur from the same instruction if the instruction is inside a loop.

Keywords: Algorithmic thinking, loops, pre-service teachers, primary mathematics, Scratch.

Introduction

In computer science, imperative programming is a programming paradigm that uses sequences of instructions to control the flow of a program. The *loop* construct is a specific instruction type used to manage and control flow: it denotes a sequence of instructions—the loop body—that are specified once but may be carried out several times in succession. The purpose of this study is to find out how pre-service primary teachers who are novice programmers think about loops and how they use loops for solving a geometrical problem. Although loops are indispensable for algorithms and thus essential for algorithmic thinking, empirical research shows that the use of loops is challenging to novices. So, how do pre-service primary teachers think about the value of the concept of loops?

In contrast to the traditional approach of examining the loop programs of novice programmers, we examine their responses to a question which asks about the advantages and disadvantages of the loop concept in Scratch. For this purpose, our student teachers had first learned how to develop an algorithm that draws a square using the programming environment Scratch. We chose this approach because our interest is a better understanding of primary teachers' thinking in loops, with an aim of better understanding algorithmic thinking more generally. Second, drawing regular polygons such as a square is a common task in primary school textbooks. Third, due to its block-based and visual nature, Scratch seems to be appropriate not only for representing algorithms, but also for introducing primary school children and their teachers to programming. Furthermore, Scratch's instruction "repeat (number)" for count-controlled loops does not require a loop counter variable (which is difficult to master for novice programmers, see Cetin 2015 or Lagrange 2020). In a self-paced learning unit designed for primary teacher training, our student teachers had to solve several geometric problems and represent their algorithms using flowcharts (on paper) before realizing them using Scratch (on the computer). As a result, they should learn some central concepts of algorithmic thinking such as thinking in loops. The learning materials contained several tasks, and also metacognitive reflection questions on their learning. In the last task of the learning unit, they were asked to set up an algorithm to draw an arbitrary regular *n*-gon (*n* is to be entered as input). Consequently, to solve this general geometrical problem, they had to use loops not with a fixed number of repetitions (e.g. 4) but with a variable upper loop bound. Since generalization and algebraic thinking is beyond the scope of this paper, the corresponding results cannot be investigated and discussed here.

In this study, we address the following question: *What are primary student teachers' perspectives on the advantages and disadvantages of the loop concept, after they have been introduced to it?*

Thinking in loops as a constituent element of algorithmic thinking

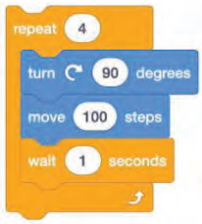
As theoretical computer science shows, a system of data-manipulation rules which follows the imperative programming paradigm must offer three constructs so that all theoretically computable problems can actually be solved by an algorithm: sequence, repetition (loops), and selection (conditionals) (Böhm-Jacopini-theorem, see Curzon et al. 2019, p. 525). In addition, two types of loops are distinguished, count-controlled loops (modeled by "repeat (number)" in Scratch or "for" in other programming languages) and event-controlled loops ("repeat until (condition)" or "while").

Since algorithms are mathematical objects that solve computable problems, *algorithmic thinking* is a specific way of dealing with algorithms, namely the design and analysis of algorithms. To do this at a sufficiently explicit level, algorithms must be accessible in a suitable symbolic representation, such as in a programming language. For example, as Lagrange points out, if "[...] formal notation for algorithms [...] is a vehicle for abstraction rather than for execution on a computer" (2020, p. 45), then algorithmic thinking is involved in the development of an algorithm that draws a regular polygon, but not in its implementation in a programming language. *Since loops are a constituent element of algorithms, thinking in loops can also be considered as a constituent element of algorithmic thinking*. Accordingly, to introduce students to algorithmic thinking, we can familiarize them with the loop concept and have them solve tasks such as drawing a regular polygon. In the corresponding algorithm, only the simple loop type of count-controlled loops is needed, because the number of iterations is already explicitly known at the time of entering the loop.

As some authors point out, algorithmic thinking is quite important for primary school mathematics (e.g. Benton et al. 2018; Gleasman et al. 2020). Therefore, primary teachers should be able to introduce their pupils to early algorithmic thinking by, for example, teaching topics such as multiplication as repeated addition or place value through programming. At the same time, many studies have shown that loops cause various difficulties for novice programmers, and not only when variable is involved in iteration or when loops are nested (for loop errors in text-oriented programing languages see Cetin 2015, for loop misconceptions of school students working with Scratch see Grover & Basu 2017, for a systematic overview see Swidan et al. 2018).

Context and method

A total of 52 primary student teachers participated in the study, 43 (82.7%) are female and 9 (17.3%) are male. All participants had some experience in teaching mathematics, but no one had prior knowledge of programming or computer science. All of them were enrolled in two primary teacher education classes in Switzerland and had chosen mathematics as their individual focus towards the end of their studies. As a part of this program, I have offered a course called “Standard Written Algorithms and other Algorithms”. One of its components was a self-paced learning unit called “Algorithmic Thinking in Mathematics: Introduction to Scratch” (approx. 6 to 8 lessons). By working through a series of activities in which several geometric figures (squares, further specific convex and non-convex regular polygons, etc.) had to be constructed using Scratch, the student teachers were gradually introduced—by the learning unit material, not by me in person—to different representations of algorithms (flowcharts and code) and to the three control concepts of algorithms (sequence, iteration, and selection). Thus, to learn the concept of loops, one of the first activities was to examine the effects of a piece of code (see Figure 1, left). In the following activity, the concept of loops was introduced by a (fictional) pupil who proposed to replace the four sequences of repetitive instructions with the (new) loop instruction. The task then asks the student teachers to explain the advantages and disadvantages of using loops (see Figure 1, right). This kind of task has been shown to be highly effective for learning especially for building comprehension-based, conceptual knowledge, whether used retrospectively or, as in this case, integrated into learning materials (Bisra et al., 2018). Since the the advantages and disadvantages of loops were not discussed in class while working on the unit, we can analyze these students’ explanations to get a fuller picture of their conceptions of the loop concept than if we were to examine their loop programs for errors.



Activity “Introduction to the loop concept”:

A pupil of your class suggests that instead of using the script on the left, use the script above: What advantages and disadvantages do you see in this so-called loop?

Figure 1: An activity to introduce the loop concept

In order to obtain high quality responses, all 52 participants worked through the activities of the learning unit in pairs (Gleasman et al., 2020; Robins et al., 2003). Since they had to write their answers for each activity, the data set consisted of 26 written responses, each listed several advantages and disadvantages of loops. In view of the research question, these responses will be analyzed here. Since our goal is to generate hypotheses about the algorithmic thinking of primary teachers, we did not to compare or weight them in our analysis such as by counting frequencies. Rather, we have analyzed the answers according to the qualitative content analysis (Mayring 2015). Three main categories, *efficiency* of loops, *cognitive demand* of using loops and *applicability* of loops were inductively reconstructed by repeatedly summarizing the answers with descriptive terms.

Results

We present two main findings. First, three main categories of answers emerged when the students reflected on the advantages and disadvantages of using loops (see Table 1). While some of the sub-categories relate to the process of programming, others refer to the final program. Second, a key fact was identified that must be known for the successful mastering of loops, as well as two learning misconceptions. We will now provide details on each of these findings.

Table 1: Categories of advantages and disadvantages primary student teachers list when learning loops

Category 1: Efficiency of loops …		
… in terms of programming	Using loops allows *fewer programming actions*. As a consequence, it requires *lower expenditure of time* for writing a program.	Seen as advantages
… in terms of the program	Using loops allows *fewer lines of code*, and is thus more *space-saving*. As a further consequence, the size of the square is controlled via *a single instruction*.	
Category 2: Cognitive demand of using loops …		
… in terms of programming	The use of loops *increases* or *decreases the cognitive demand* on the *writer* of the program.	Mostly seen as disad-vantages, sometimes as an advantage
… in terms of the program	The use of loops *increases* or *decreases the cognitive demand* on the *reader* of the program.	
Category 3: Applicability of loops …		
… to problems to be solved	*Not every problem* can be solved with the use of loops.	Seen as a disadvantage

Types of characterizations

There were three main student teachers' characterizations of the advantages and disadvantages of loops: (1) the *efficiency of loops*, which students related to the process of programming or to the final program, (2) the *cognitive demand of loops*, which students again related to programming or to the final program and (3) the *applicability of loops*, in terms of what kind of problems can be solved using loops. For an overview of these main categories with their subcategories, see Table 1.

Category 1: Efficiency of loops

All student teachers expressed unanimously that loops bring a gain in efficiency. We can identify two subcategories of answers, depending on whether efficiency refers to the programming process or to the final programming output.

Subcategory 1.a) A first sub-group of student teachers' answers relates efficiency to the act of pro-gramming, that is, to the process and the effort to move it forward. The student teachers argued that using loops results in fewer programming actions (such as "drag the block from the block palette into the code area") or leads to a lower expenditure of time for writing a program. The following two statements illustrate this first sub-category:

> The moves and rotations need to be programmed only once, instead of four times. (P17)

> The loop is a useful tool to speed up the programming of repetitive sequences. (P01)

A few students mention both effects, that fewer actions and less time are needed thanks to loops:

> One advantage is that it takes much less blocks to program the script. One is thus faster. (P12)

Subcategory 1.b) Quite differently, some student teachers related efficiency to the final program, that is, to the product and its length. They suggested that the use of loops results in fewer lines of code. Some answers of this sub-category conclude that the runtime of the program will be shorter:

> The efficiency of the algorithm is increased, since fewer instructions need to be executed, therefore the square can be drawn faster. (P20)

Other student teachers saw that the program therefore requires less space, and sometimes mentioned in the same breath that the shorter length also makes the program clearer:

> The proposed loop makes the script more compact. Due to its compactness, it takes up less space and is therefore clearer. (P26)

Unexpectedly, a group of student teachers formulated another advantage resulting from the reduced number of instructions, namely that the size of the square can now be manipulated more easily:

> The length of the sides of the square can be modified at a single instruction. (P17)

With Cetin, this answer might indicate that its authors see loops as a whole, as a new object, and thus have reached the level of the "object conception of loops" (2015, 159). This would mean that they no longer see the loop as a step-by-step arrangement of four individual sides, but as a single, integral object depending on one parameter (the size of the square) only.

Subcategory 1.c) A third group of answers relate efficiency to the criteria of both sub-categories, i.e. to the programming process as well as to the final program. For example:

> The advantage of a loop is that it must be set only once and will still be executed four times. Thus one saves time when programming. Since one does not have to enter the instructions several times, the program is shorter and therefore clearer. (P07)

Category 2: Cognitive demand of using loops

As the statement "less space […] therefore clearer" (P26, see above) shows, some students also considered the intellectual challenge that the new concept poses to them, or its cognitive demand. While most student teacher pairs found an adequate use of loops more demanding than the use of sequences of instructions, there are also few who stated that loops place less cognitive demand. Again, we can identify two subcategories which refer either to programming or to the program.

Subcategory 2.a) A first group of answers concerns the process of using loops and the associated cognitive demand, which student teachers judge partly as higher, partly as lower. To illustrate, here is an answer that explains how loops are a challenge:

> An additional block [the “repeat ()”-instruction, see Figure 1, C.W.] is introduced, making programming more complex. When a mistake happens, it happens everywhere (on all sides of the square) and it is more difficult to determine the origin of the mistake. (P18)

This statement reveals a challenge that one must master in order to competently handle loops: The *one-to-one relation between output* (in the ‘stage’ window) *and instruction* (in the code area) *must be broken*. This fact applies because while instructions that are not part of a loop body show (at most) one effect on the output side, any instruction within a loop can have multiple effects (at most as many effects as often the loop is run). Therefore, in the case of an unexpected output, it is not straightforward to determine from which instruction(s) of the loop body it originates.

A rather contrary, but positive view on the cognitive demand is expressed in the following answer:

> Fewer errors can happen because you program fewer instructions. (P03)

Subcategory 2.b) A second group of student teachers’ statements refers to the final program, as they comment on the cognitive demand of reading loops. Again, it was not considered unanimously within the data set. A corresponding response is as follows:

> One disadvantage is that with loops it is harder to see what exactly is being repeated. In contrast, with the full script you can follow every step. (P02)

The following response illustrates even better why loops can be demanding:

> It is more difficult to follow the individual operations or steps. You can't see the individual steps that make up the square. (P06)

As already mentioned, one student teacher pair surprisingly found it easier to understand instructions located in the loop body and gives the following argument as an advantage of loops:

> For schoolchildren: It is more difficult to follow when the various program steps are one after the other, instead of within a loop. (P17)

This is the only response that looked at the cognitive demand of using loops for their future pupils.

Category 3: Applicability of loops

In the responses for this category, student teachers looked at the problems that can be solved with the use of loops. They expressed that instructions inside a loop do not allow as much modification or variation as those outside. In this respect, the use of loops does not allow to solve all possible problems. The following response shows this perspective very clearly:

> Not all changes can be made to the shape, for example, you cannot change the thickness of each side. The loop repeats the same thing 4 times. This means that it is not possible to change anything in every single repetition that is made. The loop causes that the same instructions are repeated, so modifications in between are not possible. (P13)

Here the instructions of the loop body are considered fixed and cannot be modified. As a result, some shapes are judged to be non-drawable (which is sometimes true, but sometimes not):

> A disadvantage of loops is a lower flexibility: if a rectangle or an irregular triangle is to be drawn, a loop is of no use. (P21)

The following response is somewhat more nuanced, pointing out that an instruction of the loop body may well have different consequences, at least to a certain degree ("regular" differences would be possible, others not). It focuses not on a mathematical but on a design aspect of the shape:

> The thickness of the sides can be increased or decreased, but this is done regularly. If we want the sides to be of different thicknesses, we can't do this with loops. (P15)

The following response suggests how this issue could be overcome with the help of variables:

> The sequence in the loop is fixed. In this case the instructions are repeated four times stubbornly and cannot be varied so easily. With the help of variables, that would be possible. (P01)

Unfortunately, this statement is not further elaborated or illustrated it with an example.

Discussion

The study is related to the question of what constitutes algorithmic thinking in mathematics and the assumption that thinking in loops is a constituent element of algorithmic thinking. It explores learning to use count-controlled loops in 26 pairs of pre-service primary teachers solving a geometrical problem utilizing Scratch. Unlike previous studies (Cetin, 2015; Grover & Basu, 2017; Swidan et al., 2018), we are not interested in student teachers' errors in their loop programs, but rather in how they explain the advantages and disadvantages of the loop concept. The reconstructed categories relate to *efficiency*, *cognitive demand*, and *applicability*. Although the student teachers involved had just been introduced to the loop concept, they recognize its efficiency as a first advantage. However, they only refer to surface features (fewer instructions are needed, the program is shorter), which is characteristic for novices. Second, as future specialists in teaching and learning, students address the cognitive demand of the new concept for solving problems. However, not every student pair assesses it the same: While most students found it more difficult of keeping track of the interaction of an instruction within the loop and its effect on the output, some find it easier to follow sequences of instructions structured by loops. The statements referring to the third category, the applicability of loops, mention this aspect only as a disadvantage. At this early point of their learning process, students still feel constrained by the construct, again in terms of surface features (design possibilities, possible shapes of the figure). Since loops with variable upper bounds were only brought up at the end of the learning materials, it is not surprising that no student took the expert point of view yet (only thanks to loops, a geometric problem like drawing arbitrary regular *n*-gons can be solved).

The analysis of our data set also provides two misconceptions: The claim that "[…] fewer instructions need to be executed, therefore the square can be drawn faster" is not correct, since a smaller number of instructions does not necessarily lead to a shorter runtime (instructions in the loop body can be executed several times). Also the claim "if a rectangle or an irregular triangle is to be drawn, a loop is of no use" is a misconception, since iterative elements are also present in polygons such as rectangles. In addition, a key fact was identified that students must be aware of: they need to consider that instructions within loops can have not just one but multiple effects on the output, so that two different outputs do not necessarily refer to two different statements. *In this way, thinking algorithmically would mean not only seeing the advantages and disadvantages of loops that go beyond surface features, but also breaking the one-to-one relation between output and instruction*.

We are aware of the limitations of our study, such as the small number of students involved, the type of tasks they had to do, the programming language employed, or the analysis of written responses without subsequent in-depth interviews. However, under these limited conditions, the study provides some qualitative results that complement and extend previous studies (Cetin, 2015; Grover & Basu, 2017; Swidan et al., 2018). Since the category system makes preliminary hypotheses, it might contribute to developing a theory of learners' thinking in loops and therefore of their algorithmic thinking. For example, future research could address the following questions: To what extent would our category system predict the advantages and disadvantages that student teachers of higher grade levels would see? Could our category system even serve as an empirically supported description of the learning trajectories in learning to use loops to solve a mathematical problem?

Developing algorithmic thinking without programming by designing instructions for encryption

Carina Zindel

University of Cologne, Germany; carina.zindel@uni-koeln.de

Algorithmic thinking is an important part of digital literacy, enabling learners to navigate the digital world with confidence. As part of a Design Research study with 22 learners in grades 5 and 6 so far, it was investigated to what extent the children learn to think algorithmically when they discover an encryption algorithm without use of a programming language. It was found that some learners can intuitively and independently develop certain algorithmic thinking ideas (such as sequencing and loops) when writing instructions (=developing an algorithm). Hurdles show up in the degree of precision and the degree of generality of the instructions.

Keywords: Algorithmic thinking, algorithms, encryption, design research.

Introduction

Digital literacy is important in order to be able to navigate the digital world in a responsible manner. Many IT systems in the world around us can only be used in a responsible manner if the basic ideas behind them are understood. Wing (2006) coined the term "computational thinking" in this context, "that represents a universally applicable attitude and skill set everyone, not just computer scientists, would be eager to learn and use" (Wing, 2006, p. 33). Computational thinking includes processes such as "solving problems", "using abstraction and decomposition when attacking a large complex task", or "thinking recursively" (ibid, p. 33). Hence, computational thinking is a different skill than programming, as "programming" relates to concepts regarding the syntax and semantics of programming languages. As one example, the "CS Unplugged" project (Bell, Rosamond, & Casey, 2012) presents several resources developed to promote computational thinking without a computer.

Up to now, there have been very few learning opportunities on this topic for children in Germany, as computer science is not a compulsory subject throughout the country or even offered at all (cf. Pasternak, Hellmig & Röhner, 2018). This is due, among other things, to the way education is promoted. Computer science is often only offered as an elective subject from grade 9 onwards. Digital literacy is politically regarded as a task for all subjects, and thus especially for mathematics education. Therefore, it is also due to the general conditions that, due to the general educational aspects, algorithmic thinking should be promoted in mathematics classes as well. Besides, the opportunities should be used that exist due to the topics that are covered anyway.

Theoretical background

Although Wing (2006) proposes the term *computational* thinking, this type of thinking should not to be considered as restricted to dealing with computers. Instead, Wing (2006) stresses that computational thinking is an activity of humans, not of computers. It is a foundational type of thinking that allows humans to attack problems in a way so that they can ultimately be solved using a computer.

Such considerations are not unknown to mathematics. Here, the idea of algorithm proves to be much older than that of computer (Möller & Collignon, 2019). Many algorithms are part of the mathematics curriculum, although their algorithmic nature often remains implicit. That is, certain algorithms are made a topic of discussion (e.g., written arithmetic procedures or solving equations), but it is rarely made explicit that this is an algorithm. This also leads to the fact what constitutes an algorithm is not defined and ideas such as "explicit sequence of steps to solve a problem" or similar have not been an explicit learning object in mathematics education so far.

In order to reduce the complexity of computational thinking as a learning subject, and at the same time to emphasize more the role of the algorithm, this study proposes to use the term *algorithmic thinking* (AT) for capturing the kind of thinking that is necessary when designing and reflecting algorithms (in contrast to technical programming). There are different conceptualizations for specifying what is required for students to possess algorithmic thinking. Following Harlow et al. (2016, p. 340), five algorithmic thinking ideas are distinguished in this paper:

- "**Sequencing**: Creating an ordered list of instructions to complete a task"
- "**Breaking down actions**: breaking an event into smaller parts"
- "**Looping**: Repeating a set of instructions multiple times"
- "**Event-driven programming**: identifying how one circumstance triggers another"
- "**Message passing**: coordinating actions across code or characters"

This paper examines the extent to which AT ideas can be developed. One promising way to promote the development of algorithmic thinking is to engage students in writing instructions for self-discovered algorithms. After all, writing is not only a learning goal in its own right, but also an important thinking tool (learning to write and writing to learn, cf. Morgan, 1998). Austin and Howson (1979, p. 167 f.) also already dealt with the connection between language and concept formation. Heller and Morek (2015) distinguish three different functions of academic language (AL) both oral and written: (1) "AL as a medium of knowledge transmission (communicative function)"; (2) "AL as a tool for thinking (epistemic function)"; (3) "AL as a ticket and visiting card (socio-symbolic function)" (ibid., p. 175). This suggests that writing promotes deeper engagement with the content and thus fosters deeper understanding. At the same time, instructions for algorithms can be conceived as a separate text genre that students need to learn (similar to geometric construction texts, cf. Rezat & Rezat 2017).

In this paper, the idea is to develop algorithmic thinking by inventing an encryption algorithm without directly focusing on programming (similar to the examples of Bell et al., 2012). Encryptions are suitable because, on the one hand, they are an important topic in everyday life. On the other hand, they are suitable because even without programming, the algorithm must be described very precisely and accurately so that someone else can understand or reverse it. The basic idea of a symmetric encryption procedure can be experienced and learned by reinventing the Caesar Cipher, which is described in more detail in the design section below. In reality, of course, this is currently even more complex. However, since the teaching-learning arrangement should be suitable for grades 5/6, the Caesar Cipher was chosen as an example.

This leads this study to the following research question:

> RQ: To what extent do children in grades 5/6 show AT ideas when writing down instructions (algorithms) for encryption and decryption? What hurdles are encountered?

Methods

The methodological framework of this study is design research (Gravemeijer & Cobb, 2006), whose aim is on the one hand the development of a teaching-learning arrangement in several cycles and on the other hand the analysis of the learning processes initiated by the teaching-learning arrangement, i.e., in particular typical learning pathways and hurdles. In this paper the first results of the first cycle are presented.

So far, 22 learners in grades 5 and 6 have participated (a total of about 1600 minutes of video material). The design experiments were videotaped and passages relevant for the analysis were transcribed.

To select relevant passages, those involving writing the algorithm were identified. To show the range of written products, four cases, some of which are very different, are contrasted below. For data analysis, a qualitative content analysis (Kuckartz, 2019) of these products was conducted and the reconstructed AT ideas were marked by ||...||. For this purpose, a deductive-inductive procedure drawing on the categories from above (||sequencing||, ||breaking down actions||, ||looping||, ||event-driven programming||, ||message-passing||) was chosen to reconstruct which AT ideas learners address when it comes to the elements of instruction (algorithms) and which learning trajectories and hurdles occur.

Design

The learners have been working with the Caesar Cipher (cf. Allen, 2017). In this process, letters are shifted forward in the alphabet by a fixed key (Table 1). For example, the plaintext "hello" and key 3 provides the ciphertext "khoor", as every character is shifted by 3 characters.

Table 1: Clear- and walking alphabet to illustrate the Caesar Cipher (here with key k=3)

plaintext	a	b	c	d	e	f	g	h	i	j	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z
ciphertext	d	e	f	g	h	i	j	k	l	m	n	o	p	q	r	s	t	u	v	w	x	y	z	a	b	c

Table 2: Letter number table

a	b	c	d	e	f	g	h	i	j	k	l	m
0	1	2	3	4	5	6	7	8	9	10	11	12
n	o	p	q	r	s	t	u	v	w	x	y	z
13	14	15	16	17	18	19	20	21	22	23	24	25

When numbers are assigned to the letters of the alphabet as in Table 2, the encodings can also be expressed mathematically by the basic arithmetic operations or modulo calculations. The encoding of a plaintext letter can thus be represented by the calculation $y = (x + t)\ mod\ 26$ where $x, y \in \{0, . . . ,25\}$ is the number of the plaintext and ciphertext letters, respectively, and $t \in \{1, . . . ,25\}$ is the key number. As an alternative to the modulo computation, a bifurcation could also be considered: if $x + t < 26$, then set $y = x + t$, otherwise set $y = x + t - 26$. Formulas for decryption using this method are obtained analogously. The plaintext letter is obtained from the ciphertext letter using the calculation $x = (y - t)\ mod\ 26$, which can alternatively be described by the branching "if $y - t > 0$, then set $x = y - s$, otherwise set $x = y - t + 26$".

The teaching-learning arrangement consists of three sessions of 45 minutes each. Here, the focus lies on the learners' instructions they wrote down at the end of the first and the beginning of the second session. In the first session, the learners are first confronted with an encrypted message that they need to decrypt. However, they are not given explicit instructions on the Caesar Cipher, but rather discover the procedure by themselves. Afterwards, the learners are tasked with writing down instructions for their discovered procedure, for encrypting as well as for decrypting messages. The writing assignment demands a lot of precision, or even the ability to commit. This is different from oral language, where it is sometimes rather fleeting and children may contradict each other in the next sentence. By writing it down, a commitment is demanded, and the AT ideas in the learners' instructions are made explicit.

In addition, two design principles were implemented to initiate AT ideas. The design principle "Using your own instructions again" was implemented in such a way that at the beginning of the second sessions the children were asked to encode and decode again according to their own instructions from the first design experiment session and then to reflect on whether they had really only used their instructions. The design principle "confrontation with algorithms (instructions) of other children" was implemented in such a way that they were then confronted with another instruction from another group that addressed other aspects in order to sensitize them to this and to encourage the learners to sharpen their instructions again.

Empirical insights

Four of the instructions written down at the end of the first session are presented below (Table 3). They were chosen because their differences prove instructive for illustrating the range of written products.

Florian and Aaron ||sequence|| their instructions by making several steps explicit ("pick a number," "move each letter in your text by its respective place," "as soon as the alphabet ends, start over"). Moreover, they perform ||breaking down actions|| in the process, as they sequence into several substeps. It should also be emphasized that they are one of the few who also intuitively implement ||looping|| directly ("as soon as the alphabet ends, you start again from the beginning", "then continue with all the letters like this until they make a meaningful sentence"). Finally, they also show the idea of ||event-driven programming|| by formulating conditions ("when you have figured out the number of shifted digits").

Karin and John also show the idea of ||breaking down actions|| by aptly describing the shifting pattern of encryption and decryption ("In encryption you go letters forward", In decryption you always go letters back"). Thus, they also address a step of ||sequencing|| at the same time, but fold the steps less widely than Florian and Aaron. No ||loops|| or ||conditions|| are explicitly formulated. The instructions of Anna and Rebekka are very similar. They too focus on the central shift pattern and thus address ||sequencing|| and ||breaking down actions||, respectively. Unlike Karin and John, however, they do not formulate the instructions in general terms, but for a specific key, namely key 2. Marcel and Jonas, on the other hand, do not address the algorithm per se, but rather focus on the input-output idea by stating that "you have to give the other person the key and then you can write the text". This most closely addresses the AT idea of ||message-passing||, although the statement remains very general.

Table 3: written products for instructions on encoding and decoding of three learner pairs (literally translated from German) and reconstructed AT ideas.

	Encryption	Decryption	AT ideas
Florian & Aaron	Encryption: Pick a number from 1-25 and move each letter in your text by that number. *As soon as the alphabet ends, start again from the beginning.	Decryption: Look first how the letter is called if you shift it by all possible places. When you have found out the number of shifted digits (then continue with all letters) until they form a meaningful sentence.	||sequencing||, ||breaking down actions||, ||looping||, ||event-driven programming||
Karin & John	In the case of encryption, you move letters forward.	When decrypting, you always go back letters.	||sequencing||, ||breaking down actions||
Anna & Rebekka	You get the encrypted letter by moving two letters to the right.	You get the decoded letter by moving two letters to the left in the alphabet.	||sequencing||, ||breaking down actions||
Marcel & Jonas	You give the key number to the person you want to write to and then you can write the text.	You should drag the first word through all 25 possibilities and then use the correct principle to decode the other words.	||message-passing||

In summary, algorithmizing works quite well for two written products (||sequencing||, ||breaking down actions||). However, only one instruction also contains the idea of looping and ||event-driven programming||. The third treatment is more on the surface or usage level and, apart from the ||message-passing|| aspect, does not really address the algorithm itself. So, there are some ideas available as resources among the learners. However, not all AT ideas are activated by all learners by themselves. In addition, with ||sequencing|| also - when it occurs - the degree of precision needed is partly unclear.

The lack of precision also becomes clear when looking at the learners' oral statements about it. When asked by the teacher how John and Karin proceeded with an encoding task, John answers "We have always gone one further" (#2) and, when asked again by the teacher (#3), justifies this with "Because when you encrypt you always go forward" (#4).

1	Teacher	Can you briefly describe how you proceeded?
2	John	We have always gone one further.
3	Teacher	Ok, can you still explain why you always went one further?
4	John	Because when you encrypt you always go forward.

With regard to ||sequencing||, John remains as general as they have formulated it in their instructions by only mentioning the step of going one character forward. So, he does not name any further steps verbally either. Afterwards, the teacher gives the order to work on the decoding task “EQTQPC” (plaintext is “CORONA”). John suggests in #10 to try everything from 1 to 25 and starts directly with the first letter of the ciphertext ("E"), which he moves to a "D".

10	John	Ok. Then we would actually have to try out everything from 1 to 25. Then one back from E the D.
11	Teacher	You can write in there again and take notes.
12	John	Ah, yes. D. Ah I didn't click on it. D. Then back from Q, that's P. Then back from T one, that's S. Then back from Q one, that's P again. But that doesn't give a real word (laughs) You can see that now.
13	Teacher	Mhm. What could you do now?
14	John	Then two back, three back and then four back and then 5 back.
15	Teacher	Karin, what would you do now? What is your idea?
16	Karin	I've already tried a few combinations and I'm just about to try A, so. (long drawn out) A. (long drawn out) M. N.
[…]		
22	Teacher	So describe what you're doing right now. What exactly are you really doing now?
23	John	The letter back and try that until it makes a correct word.

In #12, John further unfolds this process using the example. By performing the shift in steps for each individual element, he basically performs a ||loop||. This is also reflected in #14 when, after shifting one place in the alphabet, he now suggests as a further procedure "then two back, three back, and then four back, and then 5 back" (#14). This is a change from the written product, as ||loops|| were not made explicit in the instructions before. This shows that he uses the idea of ||loops|| intuitively as a structured procedure, but that he does not yet describe this process in general. Possibly he lacks appropriate linguistic means for this. A possible linguistic device would be "do … until …". He uses this in #23 to indicate the termination condition for the algorithm as a whole: "until it results in a correct word".

The following is another brief look at what situational potential the design principle of "confronting instructions from other children" can have. Anna and Rebekka formulated their own instructions in an example-based manner. After Anna is confronted with Florian and Aaron's instruction, she notes that the instruction is "much more general" (#101).

101	Anna	This instruction is also much more general. So, I think we understood it last time in such a way that we should really formulate instructions for this example. So, with the right instruction you really come from each task also really to the solution. Both encryption and decryption. And ours is more related to a specific example.

In summary, it can be stated that hurdles can be reconstructed in the *degree of precision* of the instructions or in the *degree of generality*. Under certain circumstances, as seen in the two scenes, these can be resolved by a renewed reflection on one's own instructions by executing them on another example or by a contrasting comparison with instructions of other children.

Discussion

Algorithmic thinking is important for mathematics education and first ideas can be initiated in grades 5/6, as shown here. The initial results of this Design Research study show how diverse the starting points for possible learning processes for algorithmic thinking are. Learners intuitively activate different AT ideas. It should be emphasized that the learners develop AT ideas in a setting that does not draw on any ideas of programming, but rather on the general discovery and description of algorithms. The empirical insights illustrate possible working mechanisms of the design principles investigated in this study, namely “Using your own instructions again” and “confrontation with algorithms (instructions) of other children”, which are suitable for eliciting further AT ideas

The results presented here also make a first contribution to the discussion whether algorithmic thinking or programming should be learned first. It is possible that learners develop AT ideas even without programming, which are thus starting points for further learning processes. It would therefore be wasted potential to simply prescribe the programming language and so without first giving the learners the opportunity to develop the AT ideas themselves. This could provide a promising starting point for the developing of algorithmic thinking, although it is likely that some aspects of algorithmic thinking require programming to become fully developed. The results show that general principles (such as looping) could possibly first be learned in a general way, and then be applied to different programming languages or programming environments such as Scratch. The idea behind this is that the children learn and understand not only the specific handling of a tool, but the principles behind it.

What is challenging is to find an appropriate level of precision and generality when writing instructions for algorithms. Algorithms could indeed be thematized without programming. However, until learners understand how a computer works, they lack a kind of alphabet of what is allowed as ingredients for creating an algorithm. So, it is not trivial to find or name the smallest building blocks that are considered valid for describing an algorithm. Here, learning opportunities are needed. The design principle "confronting with algorithms of other children" has revealed situational potential in this respect. Based on this, the children developed AT ideas on their own.

In the next step, it will be examined to what extent implementing the instructions with Scratch building blocks promotes the degree of precision and to what extent further AT ideas are sharpened or developed. In addition, it is conceivable to check for other (mathematical) topics to what extent AT ideas can be developed in the respective area.

Acknowledgment

I thank my Master student Mr. Nima Khazaei, whose work on his master thesis has supplied the data investigated here.

Introduction

History of mathematics *in* mathematics education, and history *of* mathematics education continue to receive much attention. Although empirical research and coherent theoretical/conceptual frameworks within this area have emerged relatively recently, there exists an increasing interest in these lines of work. The purpose of this CERME TWG is to provide a forum to approach mathematics education in connection with history and epistemology.

TWG12 welcomes both empirical and theoretical research papers, and posters proposals related to one or more of the following issues – although any paper or poster of relevance to the overall focus of the group is taken into consideration. All educational levels can be considered, from early-age mathematics to tertiary education and teacher training:

1. *Design of teaching/learning materials using the history of mathematics, preferably with conclusions based on empirical data.*
2. *Research on the existing uses of history or epistemology in curricula, textbooks, or classroom practice.*
3. *Research on the history of mathematics education, on local, national or international level.*
4. *Connections between mathematics education, history of mathematics, and history of mathematics education: Theoretical and methodological issues.*

Even though the inception of this TWG is fairly recent – it started in CERME6 (2009) – it has deeper institutional roots within the mathematics education research community. The *History and Pedagogy of Mathematics* (HPM) study-group (http://www.clab.edc.uoc.gr/hpm/about%20HPM.htm) was created at the 1972 ICME conference; it has been organizing satellite conferences to the ICME meetings since 1984, and has several active regional branches (HPM-Americas, European Summer Universities).

In CERME12, TWG12 accepted 13 papers and 1 poster. One paper was withdrawn due to financial problems, one participant could not present because of illness. The Covid pandemic was the reason that CERME12 was delayed until 2022, however, even in 2022 all sessions were on-line. Thanks to the excellent virtual platform created by the Free University of Bolzano and the effort and enthusiasm of the organization and participants, TWG12 was again a success, though with participants from a more restricted range of countries than in previous years

Before going into any details, it should be stressed that TWG12 has four general but distinctive features which give these meetings their specific flavour. Firstly, its topic lies at the intersection of different fields of research – mathematics education research and history of mathematics – which requires versatility and methodological vigilance (Fried, 2001; Chorlay & Hosson, 2016). Secondly, the strength of the historical and the HPM community varies greatly among countries, and these meetings play a crucial role for researchers working in relative isolation, and with difficult access to resources in the field. Thirdly, the scope of TWG covers both history in mathematics education and history of mathematics education, which are two significantly different research topics (TSG 27 and 55 in ICME14); connecting the two lines of investigations is a constant challenge. Fourthly, since the topic of TWG12 is neither specific to one level of the educational system (from primary education to teacher-training) nor to any single mathematical topic (be it fraction concepts, algebra, proof, etc.), the work in TWG12 intersects that of most other TWGs. It should be noted that, as in former editions of CERME, there was little intersection with what was covered in TWG8 (Affects and the teaching and learning of mathematics), TWG10 (Diversity and mathematics education), in spite of the fact that it is not uncommon for outsiders of the HPM research community – among which most policy-makers and curriculum-designers – to ascribe such goals to the historical perspective in teaching.

These four features make these meetings not only useful but also challenging and exciting. As the final discussion made clear, the general feeling among the participants was that one of the main outcomes of this meeting is that we actually learned a lot from the one another, both from their papers and from the lively discussions.

Some significant features of the 2022 conference

From an organizational viewpoint, due to the relatively small number of contributions, the TWG12 team decided to offer three work formats for the sessions. In addition to the two traditional formats – oral presentations of a paper (talk) and discussions of topics of general interest – we also organized two 1h30-hour workshop sessions (with two parallel presentations each). A distinctive feature of TWG12 is that it potentially covers all mathematical topics, all historical periods, and many different research perspectives (history of education, historical roots of a given concept or practice, analysis of teaching resources and curricula, task design, analysis of teaching practices, training design etc.), usually making it difficult for the participants to make the most of short oral presentations and 8-page papers. The workshop format enabled some of the participants to actually share some material, and discuss both research questions and methodological issues. Out of the 13 contributions four were found particularly suitable to be presented in a workshop: two contributions on history *of* mathematics education (Hamann & Schmidt-Thieme, Goemans & De Bock) and two on history *in* mathematics education, either at the secondary level (Spies & Junker) or in teacher education (Arnal-Bailera, Beltrán-Pellicer & Oller-Marcén). The participants of TWG12 agreed that the new format was enjoyable and should be kept for upcoming CERME conferences, whenever possible.

As to content, there was a general balance between the two main lines of investigation: 6 papers on the history of mathematics education, and 7 papers on history in mathematics education. Let us highlight a few features of the Bolzano edition of CERME, without aiming for a thorough survey.

As far as history of mathematics education is concerned, a significant share of the papers bore on the New Maths movement in Europe, thereby shedding light on this complex historical phenomenon from a variety of perspectives: connections with advanced mathematics (in terms of content and of interactions among different social groups and stakeholders); controversies at the time of the reform and long-term effects (if any); impact on curricula, teaching resources, and actual teaching practices; specifics of different countries (Belgium, Nordic countries) and of different segments of the education system (e.g., vocational training).

As far as history in mathematics education is concerned, the "traditional" line of work on task design was represented by several papers (Surroca, Spies, Oswald). In spite of differences in terms of mathematical contents and segments of the educational system at stake (from primary to tertiary education), these papers illustrate how the HPM perspectives requires that researchers combine inputs from two different fields of research, mathematics education and history of mathematics. They also showcase a practice which lies at the heart of the HPM perspective: the use of original historical sources in the classroom (Chorlay, 2016).

Over the last decade, teachers have become a central topic of interest for researchers working in the HPM community, with inputs from many theoretical frameworks. Teacher education was the main focus of the papers presented in CERME 12, with analyses making use of a variety of theoretical constructs and frameworks from mathematics education: the "four S"-model (van den Bogaart), Zhang's the ADTRE model, and Godino's "epistemic configurations" (in the paper of Oller-Marcén et al.). By contrast, the analysis of "ordinary" teaching practices in primary or secondary education is still an emerging topic, with one paper in CERME 12 (Chorlay), with theoretical inputs from the Documentational Approach to Didactics (Gueudet, Pepin, Trouche) and the Didactic and Ergonomic Double Approach (Robert, Rogalski, Vandebrouck).

Challenges for the future

The number of papers and posters presented in TWG12 was modest, and half of the participants of this edition of TWG12 were first-timers. This reflects the fact that, in spite of the fact that the HPM community has a stable international basis and ramifications in many countries, it remains somewhat marginal within the mathematics education community. Some of the reasons accounting for this situation are structural and beyond the scope of our actions, such as the modest role of history of mathematics in curricula, and the necessity for researchers in this field to be knowledgeable in two different areas (history and mathematics education). However, the importance of the inclusion of history of mathematics in teacher training seems to be gaining more recognition in many countries, thus providing opportunities to further and disseminate research. Also, the fact that research carried out from an HPM perspective touches on virtually all mathematics education topics should pave the way for exchanges and collaboration. While this is true at a theoretical level, it remains a challenge to strengthen and stabilize these connections. In the spirit of CERME's three Cs (Communication – Cooperation – Collaboration), it is one of the aims of TWG12 to reach out and generate fruitful interactions.

A suitcase full of logs – an experiment with the use of history of mathematics in teacher training

Desiree Agterberg

Amsterdam University of Applied Sciences, the Netherlands; d.a.agterberg@hva.nl

A group of students in a Dutch teacher-training-program were given a collection of fragments from different textbooks, to devise a lesson-plan for the introduction of the concept logarithm. Some of the fragments in the collection contained information on the history of mathematics. The lesson-plans were analyzed to determine how the history of mathematics was incorporated. Some students only used biographical information on the inventor of logarithms, others used exercises and a logarithmic table to enhance the comprehension of the concept.

Keywords: History of mathematics, logarithms, lesson design, empirical study, teacher training.

Introduction.

This paper describes an empirical research activity that I carried out as part of a larger study. In this study the way history of mathematics can be used by teachers to improve mathematical cognitive demand is investigated. In this paper I will focus on an assignment on the history of logarithms. The research question is: in what ways do in-service teachers use the history of mathematics in a lesson design for the introduction of the concept of logarithms?

The structure of the paper is as follows. First, I will shortly present formats for presenting history of mathematics in curriculum materials. Then I will describe the design and results of a teaching experiment at a teacher training program at the Amsterdam University of Applied Sciences (AUAS), where participants were asked to design a lesson plan for the introduction of logarithms, using a collection of preselected fragments. Finally, I will discuss the results of the teaching experiment and make some remarks on how this is embedded in the larger study.

The 4S formats.

The history of mathematics (HoM) can be used in mathematics education in many ways. Both Tzanakis et al. (2000) and Jankvist (2009) have written important texts on how this can be done and reasons for doing so. In a recent article (Agterberg et al., 2021) we describe a categorization of ways how HoM can be presented in curriculum materials or classroom activities. This categorization is meant to be used as a tool in what we call a design-oriented approach. With the help of this tool, teachers should be enabled to select and adjust curriculum materials that use HoM or even design classroom activities themselves. We distinguish between four formats for presenting HoM in curriculum materials. We chose format names that all start with the letter S: *speck*, *stamp*, *snippet* and *story*. The term speck was chosen to indicate the smallest format. The word stamp refers to the notion of a small, separate box of information, alongside the main text. The term *snippet* is used for the average size piece of historical information with substantial relation to the text in which it is incorporated. The fourth and last format story relates to larger historical packages that transfer a story of mathematics. Table 1 summarizes the main characteristics of the formats. A complete description of the formats can be found in (Agterberg et al., 2021).

Table 1: Four formats for presenting HoM in terms of size, content, location and functions

Format	Speck	Stamp	Snippet	Story
Size	Very small	Small	Medium	Large
Content	Text only	Text with or without illustrations	Text with or without illustrations, related to instruction or task	Text with or without illustrations, related to instruction or task
Location	Arbitrary location in curriculum material	Arbitrary location in curriculum material	Particular location in curriculum material	Particular location in curriculum material
Goal	Transfers historical aspects of the discipline	Transfers historical aspects of the discipline	Can transfer historical aspects of the discipline	Can transfer historical aspects of the discipline
Tool	Primarily affective, motivational	Primarily affective, motivational	Primarily support of learning of mathematics itself	Primarily support of learning of mathematics itself

In the next section I will show some concrete examples of these formats from Dutch mathematics textbooks. These examples were used in the teaching experiment that is mentioned earlier and will also be described in the next sections.

A suitcase full of fragments.

In February 2021 I taught a course on history of mathematics at the mathematics teacher training program at the AUAS, together with two colleagues. The students that participated in this course are all in-service teachers. They had already finished a teacher training program for lower secondary education and are working as mathematics teachers. The course on history of mathematics is part of a part-time teacher training program for higher secondary education. The goals of the course are to increase the participants' knowledge on history of mathematics and to teach them how to use history of mathematics in the classroom. Due to Covid-19 the class was taught completely online.

In the first session the students were instructed to do an assignment we called 'suitcase assignment'. For this assignment we used a virtual suitcase, containing fragments from three chapters from different Dutch mathematics textbook series, in which the concept of logarithms was introduced. Figure 1 shows one of the pictures that was in the suitcase (coded P2). It is a photo of some handwritten long multiplications, used in the original chapter to illustrate how calculations were done back in the 16th century. No wonder that Napier wanted to create a shortcut, seems to be the message of this picture. In didactical terms one could say this picture can be used to demonstrate the usefulness of logarithms, so the history of mathematics serves as a tool for understanding why a certain concept is developed. In terms of the formats described in the previous section, this picture can be regarded as a stamp: a small piece of historical information that can be placed at relatively arbitrary position in a chapter on logarithms.

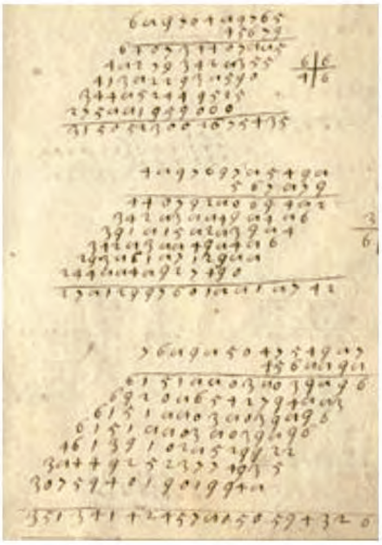

Figure 1: handwritten multiplications (cTWO, 2011, p. 21)

Figure 2 is a translated text from another chapter, stating some information on John Napier, the inventor of logarithms. In the original chapter the text is accompanied by a picture of a statue of Napier, which was left out in the suitcase assignment. This fragment contains only biographical information and does not give any mathematical information on why or how the logarithms were invented. This fragment can also be categorized as a stamp.

John Napier, also known as John Neper (Edinburgh, 1550-1617), was a Scottish mathematician who made his name mainly with his invention of logarithms. John studied for some time at St. Andrews University but also spent considerable time in other European countries. He was a convinced Protestant and particularly passionate about theology. In 1593, he published a religious work entitled Plaine Discovery of the Whole Revelation of St. John, which was translated into Dutch, French and German, so that he also became known on the continent. He practised mathematics mainly as a hobby.

Figure 2: translated text on John Napier (Wageningse Methode, 2015, §7.2)

Figure 3 is a translation from an exercise from the same chapter as picture P2 (figure 2). In this exercise the pupil learns by some examples how to use a logarithmic table to calculate specific multiplications, through some examples. The pieces of the logarithmic table that are necessary for performing this calculation are also shown on the right-hand side. In the original chapter, there is a full logarithmic table available as well. This table was also put in the suitcase, as picture P4.

How can you use these tables to approximate 456 ×12,3?

1. Search the table for the number closest to 4,56 → 4,574
2. Find out which power of 10 equals 4,56 → $10^{0,66}$
3. Find out which power of 10 equals 456 → $10^{2,66}$
4. Search the table for the number closest to 1,23 → 1,230
5. Find out which power of 10 equals 1,23 → $10^{0,09}$
6. Find out which power of 10 equals 12,3 → $10^{1.09}$
7. Find out which power of 10 is the answer: $10^{2,66} \times 10^{1,09} = 10^{3,75}$
8. Find out which number this is: 5,623 ×1000=5623

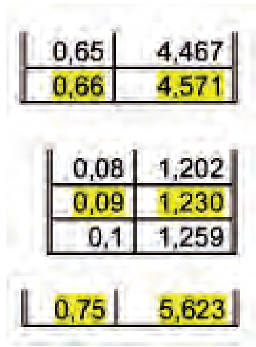

Figure 3: translated exercise on the use of the logarithmic table (cTWO, 2011, p. 22)

Table 2 lists the complete contents of the suitcase and specifies the contents of all historical fragments. All pictures, texts and exercise were separated from the original structure in the chapter and put together randomly in a table. The texts were retyped and renumbered, with identical fonts, colors and layout, so the fragments that belonged together in the same chapter could not be recognized on external features.

Table 2 Contents of virtual suitcase with fragments of chapters on logarithms

Type of fragment	Number of fragments	Historical fragments	Name of fragment	Contents of fragment
picture	4	3	P1	face of Napier
			P2	handwritten long multiplication
			P4	logarithmic table
text	8	3	T2	short biography of Napier
			T3	reason for developing logarithms
			T5	explanation of logarithmic table
			T8	long biography of Napier, including mathematical content
exercise	10	3	E5	use of logarithmic table to find specific powers of 10
			E8	use of logarithmic table to convert numbers into powers of 10
			E10	use of logarithmic table for multiplication and division

The students were given time to read all the fragments in the suitcase, then select the fragments they wanted to use in their lesson plan and adjust them if they wanted. Finally, they arranged the fragments in an order of their choice and wrote an explanation of their choices and purposes. They were instructed to select at least one fragment that contained, in their opinion, something related to the history of mathematics.

Results.

Twenty students handed in a complete lesson plan after the session. Their designs were scored on what historical fragments they used. The results are in table 3.

Table 3 Amounts and combination of selected historical fragments in suitcase assignment (P=pictures, T=texts, E=exercises, #=frequency)

#P	#	selection	#	#T	#	selection	#	#E	#	selection	#
0	1	-	-	0	1	-	-	0	8	-	-
1	10	P1	5	1	9	T2	4	1	8	E5	4
		P2	1			T3	1			E8	4
		P4	4			T8	4	2	4	E5 & E8	3
2	7	P1 & P4	5	2	8	T2 & T8	2			E8 & E10	1
		P2 & P4	2			T3 & T8	3				
3	2	P1, P2 & P4	2			T5 & T8	3				
				3	5	T2, T5 & T8	2				
						T3, T5 & T8	3				

Almost all students chose to incorporate at least one piece of biographical information. Three students did not include it at all (and four students chose both texts T2 and T8 that contained biographical information). The logarithmic table P4 was chosen thirteen times, but two of those lesson plans did not contain an explanation and/or exercises to accompany it. This way it was merely used as an illustration, a bit like illustration P2: an ancient long multiplication, showing how arithmetic was a tedious activity back in those days. The reason for developing logarithms is mentioned in fragments T3 and T8. Six students chose neither of them (among them two of the students that also did not incorporate any biographical information).

Twelve students selected one or more historical exercise. One of these students did not include the logarithmic table (P4) in his lesson plan, so it is questionable if this student really understood the exercises himself. From the eight students that did not select any historical exercise, four only selected fragments that contained biographical information (only T2 and/or P1) and the other four also incorporated some historical mathematical information (at least one of T3, T8, P2 or P4).

The way the students incorporated the fragments in their lesson plan was also categorized according to the 4S formats. The smallest format speck was not found amongst the lesson plans. The fragments in the suitcase were not that small and no student deliberately adjusted a chosen fragment in a way that reduced it to a speck. The eight lesson plans that did not incorporate exercises were all categorized as stamps. The remaining twelve lesson plans were mostly categorized as using history of mathematics in one or more snippets. Two students arranged their chosen fragments with history of mathematics to a complete story. The results of all twenty lesson plans are shown in table 4.

Table 4 Lesson plans categorized according to 4S formats

Format	**Frequency**
speck	0
stamp	8
snippet	10
story	2

Discussion.

In the previous section the research question "in what ways do in-service teachers use the history of mathematics in a lesson design for the introduction of the concept op logarithms" was answered with regards to type of fragment (picture, text, exercise), contents (biographical, mathematical) and finally format (speck, stamp, snippet, story).

The choice of fragments and design of lessons by the students will certainly be affected by the constraints of the suitcase assignments: limited time for reading, selecting, arranging and reporting, the assignment was completed during a (virtual) classroom session instead of a homework assignment, unfamiliarity of students with the fragments from different series of textbooks. The concept of logarithms can be presented in different ways (Kuper & Carlson, 2020). The students could possibly have had problems with the concept of logarithms themselves.

The historical development of logarithms is complex, but also provides promising opportunities to use it in class (Panagiotou, 2011). Even if the explicit historical information is left out, the geometric and arithmetic sequences from Stifel, Napier and others can be used for constructing logarithms through covariational reasoning (Ferrari-Escolá et al., 2016). The teacher can use this as an approach for constructing the concept during instruction, or have the pupils develop it themselves through a form of guided reinvention.

The students that did the suitcase assignment had received some instruction on how to use history of mathematics in their classrooms prior to this course, but this depended on the classes they took in previous years of teacher training. The fact that most of the students had little prior knowledge of the history of logarithms has probably also affected their choices considerably. Finally, knowing that the lessons were only planned and did not have to be enacted in class, could also have impacted the design. If the lessons had to be performed with a group of pupils, the students might have altered their plans.

The course on history of mathematics will be taught again in the beginning of 2022. The suitcase assignment with fragments from textbook chapters on logarithms will remain in the course, as a starting point for discussing the possibilities of using history of mathematics in the classroom. We intend to have the students enact the lessons they designed and reflect on this during the course.

This will surely provide us with a lot of interesting information from the classroom perspective, that we can learn from, to improve the course on history of mathematics itself and incite new research activities.

Acknowledgments.

I would like to thank my AUAS-colleagues Peter Lanser and Lidy Wesker-Elzinga. We taught the history of mathematics course, in which the suitcase assignment took place, together. They are very supportive to my research activities and it is inspiring to work with them.

The suitcase assignment is one of three assignments that were carried out by our students during the course on history of mathematics. In each assignment the students designed a lesson plan and they also filled out questionnaires on what they think about using history of mathematics for classroom activities. All lesson plans and questionnaires are collected as data and I am analyzing them as part of a larger study. I want to thank my PhD-supervisors Ron Oostdam, Fred Janssen and Bonne Zijlstra, who guide me in this research project.

The effect of a reading of Clairaut on prospective secondary mathematics teachers' instructional design

Alberto Arnal-Bailera[1], Pablo Beltrán-Pellicer[1] and Antonio M. Oller-Marcén[2]

[1]Universidad de Zaragoza, Spain; albarnal@unizar.es

and pbeltran@unizar.es

[2]Centro universitario de la Defensa de Zaragoza, Spain; oller@unizar.es

The use of original sources in teacher training is a rather well established research topic in the HPM domain. However, analyzing its explicit impact on classroom practice is still a relatively unexplored topic. This work addresses this topic by analyzing the tasks designed by 21 prospective secondary mathematics teachers just after participating in a series of activities structured around a fragment of Clairaut's Éléments de Géométrie. The possible effect of their reading of Clairaut is assessed in two ways. First, comparing the participants' epistemic configurations with that of Clairaut. Second, determining the steps of instructional design in which they considered to have been influenced. To do so, we use some elements of the onto-semiotic framework as well as the ADTRE instructional design model to analyze the tasks designed by the participants and their answers to an open ended question.

Keywords: Original sources, teacher training, epistemic configuration, instructional design.

Introduction and objectives

Over the last decades the use of history of mathematics in the context of Mathematics Education has become an intensive worldwide area of research (Clark et al., 2018). From early-age mathematics to tertiary education and teacher training, there are many reasons and many ways to introduce a historical dimension in mathematics education (Jankvist, 2009).

Regarding the use of history of mathematics in mathematics teacher training, Clark (2019, p. 49) proposes the following question as worth exploring: "Are the outcomes of teachers' study of history of mathematics seen in their classroom practice in explicit ways, and if so how? If not, why? Are the implicit ways equally meaningful?" In the particular case of original sources, the previous question is clearly related to the use of history as a resource by the teachers.

Consequently, the following research question naturally arises: Does the reading of original sources have an effect on teacher's professional practice? This question does not seem to have received much attention in the literature (Arnal-Bailera & Oller-Marcén, 2020), so this work aims to partly address this research question by analyzing the activities designed by a group of prospective secondary mathematics teachers after their work around a fragment of Clairaut's *Éléments de Géométrie*. In particular, our main objective is to determine the possible impact of their guided reading of Clairaut on their subsequent instructional design decisions.

Theoretical framework

Instructional design is an essential component of teachers' professional competence. There exist different instructional design models but all of them involve, at least, task analyzing and designing. In Figure 1 we show the elements of the so-called ADTRE model (Zhang et al., 2018).

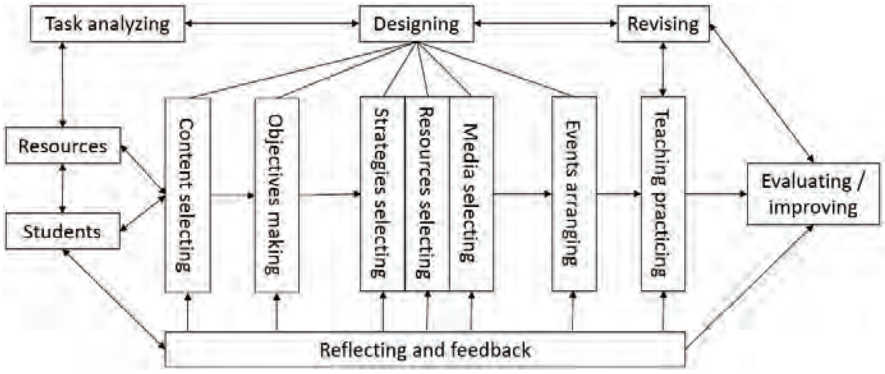

Figure 1: The ADTRE instructional design model. Adapted from (Zhang et al., 2018, p. 1078)

In the analyzing phase "instructional tasks are determined as a result of textbook and related curriculum material analysis and learner analysis" (Zhang et al., 2018, p. 1077). Even if these authors do not consider it explicitly, it seems clear that this phase may eventually involve reading and analyzing relevant historical texts or original sources.

Every theoretical framework dedicated to the knowledge and competencies of mathematics teachers considers how complex it is to define what makes a good teacher. These frameworks tend to agree on the fact that knowledge alone is not enough to do so, and for that reason the notion of competency is introduced. For example, a teacher should be aware of what is happening in the classroom from a specialized mathematics point of view, and act in consequence. Godino et al. (2017, p. 100) call this "competence for analyzing and managing didactical configurations." Didactical configurations take into account different aspects of instruction (epistemic, cognitive, affective, etc.).

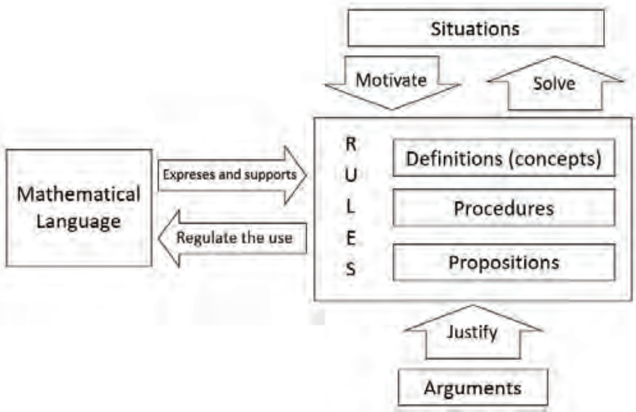

Figure 2: Components and relations of an epistemic configuration. Adapted from (Font & Godino, 2006, p. 69)

The Onto-Semiotic Approach to Research in Mathematics Education (OSA) assumes a pragmatic definition for the meanings that emerge within a system of mathematical practices (Godino et al., 2007; 2019). These meanings are established in terms of epistemic configurations (Figure 2), involving a set of primary objects: situations, languages, concepts-definitions, propositions, procedures, and arguments. Font and Godino (2006) show that the epistemic configuration is also a useful theoretical construct in order to analyze mathematical texts. In fact, these authors consider that mathematical texts can be seen, in some sense, as a system of mathematical practices.

The notion of epistemic configuration is central to the OSA and it has been extensively used in the research carried out from its perspective. This includes works focused on teacher education, in which this notion is used, for instance, to analyze teachers' practice or task design (Giacomone et al., 2018; Hummes et al., 2019).

Method

The experiment was carried out with 24 participants (13 men and 11 women) of the Masters' Degree in Secondary School Teaching. In particular, it took place within the course "Design, organization and development of activities for the learning of Mathematics" during the academic year 2018–2019. It consisted of three different activities:

1. A guided reading of a fragment by Clairaut (1741, pp. 125–128) in which the participants, working individually, had to complete a series of five tasks. In them, the participants had to identify relevant mathematical contents and processes, discuss them, and provide their personal point of view about different aspects of the text.
2. A classroom session in which the participants worked in pairs in two tasks, arising from certain claims by Clairaut and essentially related to the definition of tangent to a circle.
3. A homework individual task in which the participants were asked to design a 50 minutes session for grade 8 students, using GeoGebra, and related to the mathematical contents covered in Clairaut's text.

The selected fragment by Clairaut (which will be analyzed in detail in the next section) deals with the definition of the tangent to a circle at a point and the proof of what we call nowadays "alternate segment theorem". The interesting features from the point of view of Mathematics Education of Clairaut's work, and of this fragment in particular, were discussed by Barbin (1991) and Chorlay (2015), respectively. A complete description of the first activity, and the obtained results within the MKT framework can be found in (Arnal-Bailera & Oller-Marcén, 2020). In this paper, we focus on the third activity.

As we have already pointed out, the third activity was related to instructional design. In particular, the participants had to provide:

- The objectives of the session.
- The definitions of the mathematical concepts that they would introduce.
- Methodological indications including the intended use of GeoGebra.
- A sequence of tasks with an estimated timing.
- A GeoGebra file to be used in the session.

In addition, the participants were explicitly asked about the influence (or not) on the design resulting from their work with Clairaut's text.

Only 21 out of the 24 participants completed the activity. Each of them submitted a written document and at least one .ggb file. In this work we focus on the written productions. Taking into account the objective of the paper, our work was organized into three steps.

1. We carried out an *a priori* analysis of Clairaut's fragment.
2. We analyzed the participants' session design.
3. We analyzed the participants' answer to the question about the influence of Clairaut's text.

For the first two steps we have used the epistemic configuration as an analytical tool in order to compare the participants' configurations with Clairaut's, looking for possible similitudes or differences between them. For the third step we have adopted a deductive content analysis approach to the answers using elements of the ADTRE model as a tool.

Epistemic configuration of Clairaut's fragment

As a first step in our work, we used the notion of epistemic configuration (Font & Godino, 2006) in order to analyze the selected fragment of Clairaut's *Éléments de Géométrie*.

- Situation.
  The text aims to prove that, in any circle, an angle between a tangent and a chord passing through the point of contact is equal to half of the central angle defined by the chord.
- Concepts-definitions.
  In the fragment, Clairaut explicitly defined for the first time the following concepts:
  - C1: Tangent to a circle at a point, which is defined as a line touching the circle at a single point.
  - C2: Alternate-segment angle, which is defined as an angle between a tangent to a circle and a chord passing through the point of contact.
- Procedures.
  For a given inscribed angle, the chord opposite to its vertex is fixed, and then the vertex is "moved towards" one of the endpoints of the chord.
- Propositions:
  The so-called inscribed angle theorem (an angle inscribed in a circle is equal to half of the central angle that subtends the same arc on the circle) is explicitly stated in the text. In fact, it is introduced and proved just before the considered fragment.
- Arguments.
  Clairaut's proof relies on two arguments. The first one is explicitly stated, whereas the second one is just implicitly assumed:
  - A1: When the vertex is "moved towards" one of the endpoints of the chord, the inscribed angle becomes the alternate-segment angle because the secant line turns into the tangent.
  - A2: The alternate-segment angle is equal to the inscribed angle because during the process, the "moving" angle remains constant.
- Mathematical language.

- Graphic: The text is accompanied by a figure which is to be found in a sheet at the end of the book. This diagram suggests movement and supports a dynamic reading of the configuration, which is congruent with dynamic geometry.
- Symbolic: Points are represented by capital letters (A), angles, arcs and circles are represented by three points (ABC), segments and straight lines are represented by two points (AB).
- Verbal: There are two levels. The “main” discourse and marginal notes that are used to remind or to emphasize ideas.

The Participants’ configurations

Firstly, we analyze the participants’ epistemic configurations and compare them with the configuration underlying Clairaut’s fragment, which was described in the previous section. Due to space restrictions, we will particularly focus on the elements which, we think, are more innovative in Clairaut’s text: the procedure and the arguments (see the previous section).

First of all, 4 participants followed exactly the same procedure found in Clairaut’s text, considering a chord, and moving one of its endpoints. In the case of 5 additional participants, the dragging of points in GeoGebra played an important role in the procedures included in their proposals, even if it was not used to construct the tangent line as Clairaut does.

Regarding the arguments, the idea that the secant lines ultimately become the tangent line as a result of a dynamic process (A1) was clearly identified in the design of 8 participants. However, argument A2, which essentially involved considering the continuous limit of a constant magnitude, was found only in 4 of the designs.

The participants’ point of view

Now, we turn to the participants answers to the open question about how Clairaut’s work influenced their design. Only 4 out of the 21 participants who completed the activity answered that Clairaut’s text had not had an impact on their design. One of them did not provide any explanation. The remaining three participants provided arguments related to difficulties reading the text or to not finding the contents of the text useful for their purposes. In Table 1 we provide two examples of statements made by some of these students.

Table 1: Arguments of students for not being influenced by Clairaut

Participant A	“… since it was easier to me to see it in my way […] I think it is the same for others. The text is cumbersome…”
Participant B	“… [the text] is interesting to teach history of mathematics […] as a pedagogical object [sic] I didn’t like it.”

Now, the other 17 participants declared that the text had had some kind of influence over their decision making process. After categorizing the participants’ answer according to the elements of the ADTRE model, we provide in Table 2 the frequency of the identified ones.

Table 2: Elements of ADTRE model identified in the participants’ answers

Content selecting	Objectives making	Strategies, resources and media selecting
14	4	15

As we can see, many participants perceived an influence over their decisions about content selection. As an example, one of the participants stated that:

> Clairaut’s text was useful for me in order to introduce the concepts, in the way he did so

Also, a good number of participants informed about an influence over their strategies, resources and media selection. The following are two illustrative examples

> The criterion to choose this definition [Clairaut’s] was that it was easily implemented in GeoGebra

> We used the same idea as in Clairaut’s text […] we used an interactive software allowing to modify the angle […] this avoids the students to make the abstraction required when reading the text

However, very few participants made explicit a possible impact over their decisions regarding objectives making. One such example is the following:

> It served to me to […] involve the students in aspects related to proof in mathematics

Finally, it was particularly noteworthy that no mention to aspects related to the arrangement of activities was mentioned.

Conclusions

The direct influence of the activities carried out by de participants around Clairaut’s text was less important or, at least, less clear than we expected in advance. In fact, a few participants even explicitly claimed to not have been influenced at all. In addition, taking into account their own perceptions, the eventual influence was mostly related to content and strategies selection (see Table 2). Note that these elements require, in principle, a lower level of re-elaboration by the participant because contents and strategies can be more easily reproduced. This tendency to reproduction over more elaborated ways of making use of the text was already noticed by Arnal-Bailera and Oller-Marcén (2020).

Some authors (Biza et al., 2008) point out that the students’ initial conceptualizations of the tangent line in a Euclidean Geometry context have a deep impact on their understanding in more general contexts, such as Analysis. We have seen that Clairaut’s text, which in some sense brings together both contexts (Chorlay, 2015), has promoted among some of the participants the use of definitions, procedures, and arguments in their design that can be more easily transferred from a static geometrical setting to a more dynamic analytical setting.

It is noteworthy that about one half of the participants did not include Clairaut’s dynamic procedure and arguments in their proposals. In some cases, they seem to consider these arguments to be too complex for their students (see participant A in Table 1, for instance). Since this statement is merely based on the participant’s opinion, it illustrates the important role of beliefs in this type of activities, and the need to address them in some sense. In other cases, the participants' designs do not provide explicit information about the mathematical arguments that they would use in the classroom.

Even if scarce, the arguments provided by the participants that did not feel influenced by Clairaut's text were rather rich. Some of them contained elements related to the difficulties inherent to reading original sources (Jahnke et al., 2000), while others can be related to the fact that those participants did a shallow reading of the text in their previous work with it (Arnal-Bailera & Oller-Marcén, 2020). There were also some comments reminiscent of ideas exhibited by Siu (2007). It is noteworthy that no participant considered the possibility of including the explicit use of the original source in their session design.

Finally, we found some interesting comments that may foster further research. For example, one participant stated that:

> The classroom discussion […] was useful to focus the first part of…

This comment suggests that the role of the teacher educator is crucial when implementing this type of activities and has an impact over their outcome. Using original sources in a teacher training content is different from doing it in a school context (Jankvist et al., 2020) so the practice of the teacher educator might also be an interesting object of study.

On the other hand, statements such as

> The text made me reflect about which definitions and activities were more adequate to present the concepts at this level

point out the fact that the work with original sources might promote the prospective teachers' self-reflection about elements related to their didactic-mathematical competence (Breda et al., 2017). This opens an interesting line of research that we plan to explore in the near future.

Investigating the potential of a historical document for task-design

Renaud Chorlay

LDAR1 & Sorbonne Université, Paris, France; renaud.chorlay@inspe-paris.fr

Abstract: This paper is a progress report which presents the context, the outline, and the starting point of an ongoing research project. In the context of a reform of the French high-school curriculum, teachers were unexpectedly required to use history of mathematics in the classroom, without being instructed how to, and with almost no standard resources – such as official guidelines or textbooks – to work with. This provides an opportunity to study the work of teachers as designers of teaching material. We set out a research protocol in which five teachers agreed to (independently) design teaching sessions starting from the same document, namely an extract from Euler's Elements of algebra on the numerical approximation of square roots. This paper aims to establish the relevance of this document in this research context.

Keywords: History, task-design, teacher as designer, cognitive demand.

Rationale

This paper is a preliminary report which aims to present the rationale and starting point of an ongoing research project which lies at the intersection of several important yet under-researched (or hitherto independently researched) topics in mathematics education.

First, research on the use of history of mathematics in the mathematics classroom have convincingly argued that, from both cognitive and didactical viewpoints, tasks based on historical sources are particularly suited for non-routine mathematical work (Fauvel & van Maanen, 2000; Jankvist, 2009; Chorlay, 2016). However, whether or not this *potential* for cognitively demanding classroom activities translates into practice calls for empirical studies on actual classroom practices. Such studies are still quite rare in the History and Pedagogy of Mathematics research community.

Second, the interaction between teachers and resources for teaching are studied from a variety of perspectives (Adler, 2000; Remillard, 2013; Choppin, McDuffie, Drake, & Davis, 2018), but mostly in contexts where teachers deal with ready-made teaching material such as textbooks. Arguably, contexts in which teachers and researchers jointly engage in *task design* have also been studied (Jones & Pepin, 2016), but contexts in which teachers work as *autonomous* designers are largely understudied, with some exceptions usually related to the use of ICT (see, for instance, (Trouche et al., 2018)).

Third, in the wake of Mary K. Stein's work on cognitively demanding tasks and the distinction between low-level (or routine) tasks and high-level tasks (seen as characteristic features of "doing mathematics"), many papers have studied how actual teaching practices maintain or lower the demand-level of tasks (Henningsen & Stein, 1997; Boston & Smith, 2009). To the best of our knowledge, these theoretical tools have not been used to study tasks

[1] Laboratoire de Didactique André Revuz, Universités de Paris, Artois, CY Cergy, Paris Est Créteil, Rouen.

designed on the basis of historical documents, along with their actual classroom implementation.

In what follows, we will explain how a recent reform of the French educational system provided an opportunity to set out a research protocol enabling us to empirically study how teachers interact with historical sources and engage in task design. Among the many features of the teachers' work as autonomous designers (and implementers) of tasks, we will focus on the observables pertaining to the level of tasks actually selected by the teachers (i.e. cognitive demand), and to the level of uncertainty which they are willing to leave room for in the classroom (Zaslavsky, 2005).

Outline of the research project

Institutional context: A new high-school curriculum (2019)

The French educational system has a national syllabus which the Ministry of Education changes approximately every eight years, for reasons which are usually not explicit, and as the result of a non-transparent process. In 2019, new high-school syllabi were implemented in all subjects, in the context of a large structural reform of high-school (grades 10 to 12). As far as history of mathematics is concerned, this new syllabus stood in sharp contrast with former syllabi. In 2010, for instance, the previous syllabus for science majors (grades 11-12) mentioned history of mathematics in passing, in an introductory paragraph on the varieties of forms of students' engagement with mathematics.

On the face of it, the 2019 syllabus deepened the same ideas:

> It can be judicious to enlighten the content of the mathematics course by a historical, epistemological or cultural contextualization. Indeed, history can be seen as a source of problems which clarify the meaning of some notions. The passages labelled "History of mathematics" point to some possibilities along this line. Teachers can implement them by relying on the study of historical documents (MEN, 2019. Our trans.)

In both syllabi, history of mathematics is seen as a tool rather than a goal (Jankvist, 2009); historical activities should be weaved in the general fabric of the course (should they be considered). Although this tool is versatile, the main goal is to foster conceptual understanding and meaning-making, rather than – for instance – motivating students, finding real-life or extra-mathematical applications of mathematics, or showing that school mathematics reflect the cultural heritage of humanity as a whole (with inputs from many cultural areas) etc. (Jankvist, 2009). Also, the use of historical sources in the classroom is not mandatory. The difference between the 2010- and the 2019-syllabi does not lie in the general intentions, but in the strength of the "recommendation" that teachers select and study historical problems – and, possibly, historical documents – with their students, as one of the many ways to support students' engagement with mathematics. In the 2010-syllabus, the above quoted short passage was the only mention of this topic in a 7-page document, making it a rather elusive suggestion. By contrast, the 2019-syllabus is lavishly peppered with paragraphs explicitly labelled "history of mathematics", which makes this topic one of the few guiding threads of the whole syllabus (along with "proof" and "algorithmic thinking and programming"). Some of these paragraphs are carefully worded and give specific suggestions, as in: "The history of probability theory provides a framework to explain the mathematization of chance. An instance is given by the correspondence between Pascal and Fermat on the problem of points – also known as Méré's problem –, along with the ensuing works of Pascal, Fermat, and Huygens. The problem of the Duke of Tuscany, or Leibniz's works on games of dice can also be mentioned." (Grade 10). Other paragraphs are rather pithy, leave much room for interpretation, and do not even hint at specific means of implementation; as in: "One can mention the slow elaboration of the notion of function, from Antiquity up to today's codification by Dirichlet, by foregrounding some important stages: Newton, Leibniz, Euler. The importance of the algebraic notation should be stressed." (Grade 10)

These features of the new syllabus came as a surprise to both teachers and teacher-educators, and the long list of rather cryptic yet heavy-handed historical "suggestions" understandably bewildered most. Moreover, the traditional resources on which teachers usually draw to meet the requirements of a new curriculum were wanting: firstly, up until the 2010 reform of teacher-training, very few teachers had any academic background in the history of mathematics, nor any experience of its inclusion in the classroom. Secondly, the syllabus to be implemented as from September 2019 was published shortly before, leaving very little time for commercial publishers to develop textbooks (there are no official textbooks in France). Since the historical suggestions were rather new, unexpected, and required that some textbook authors be well-versed in history (which is not usually the case), many textbooks failed to meet the challenge. Thirdly, when a new syllabus is published, it is customary for the Ministry of Education to publish guidelines for its implementations along with on-line teaching resources. In 2019, such resources were published to scaffold the implementation of the "proof" and "algorithmic thinking and programming" transversal features of the syllabus, but none regarding the historical suggestions.

Research protocol

The publication of the 2019-syllabus came as a somewhat pleasant surprise and unexpected endorsement for the IREM network (Institutes for Research in Mathematics Education). Indeed, these state-funded structures in which academics (mathematicians, mathematics educators, and, occasionally, historians of mathematics), teacher-trainers, and teachers collaborate to develop resources for teaching and teacher-training has a subcommission focusing on history and epistemology of mathematics. Since the 1980s, both in the French national context of the IREM network, and in the international context of the HPM Study Group, this subcommission has been working along the exact same general lines mentioned in both the 2010 and 2019 syllabi, arguing that many historical documents provide opportunities for a genuine engagement in mathematics, i.e. to "do mathematics". Moreover, it has accumulated a significant collective experience of resource development (Fauvel, 1990; Chorlay, 2016, Barbin, 2018). This subcommision reacted to the publication of the 2019 curriculum by launching the collective development of a book meant to provide high-school teachers with a range of thought-through and empirically tested (at least once!) classroom activities based on historical documents and compatible with the new curriculum.

This collective project is the context of our study. A study which involves two types of participants – five high-school teachers and a researcher in history of mathematics and mathematics education. A study which weaves together two distinct projects: one is the development of a classroom session, with a view to contributing a chapter to the new IREM book; one is a research project, carried out by the researcher and bearing on the work of the five teachers as they engaged in the resource-development project. It was agreed from the outset between each teacher and the researcher that both projects were distinct but compatible. The following protocol was agreed upon:

1. The researcher would select one historical document which he thought fit for the resource-development project. All teachers would be given the same document.
2. A first meeting would take place between the researcher and each teacher, individually. The historical document would be read together; its mathematical content would be discussed; possible connections to the curriculum would be discussed, in a "brainstorming" mode. The goal of this session was to generate a shared understanding of the didactical potential of the document. "Shared" meaning: shared between the researcher and each of the teachers; and similar for all teachers, even though they did not communicate with one another. In this meeting, no specific choices of implementation would be made or even discussed. The meeting would be recorded.
3. Each teacher would work independently from both the other teachers and the researcher in order to design some teaching session compatible with the resource-development project. For research purposes, teachers were asked to endeavour to keep a record of their work: personal notes, draft versions of the final documents, etc.
4. Each teacher would implement the session(s) she/he designed. The sessions would be recorded, either in audio or in video form.
5. Two short interviews would take place: (1) shortly before the actual session(s), the researcher would carry out a semi-guided interview bearing on (a) the teacher's self-recollection of the design process, (b) the choices which the teacher made along the way, (c) the goal(s) of the session(s), (d) the expected or possible difficulties, to be experienced either by the students, or by the teacher. (2) shortly after the session(s), an informal debrief would focus on topics (c) and (d).
6. This would be the end of the research project. The resource-development project would enter new phases: exchange of information among the teachers; possible engagement in a new task-design cycle (alterations, then implementation of the altered sessions); writing of a chapter for the IREM book. These new phases would involve both the teachers and the researcher in a collaborative way.

Let us underline a few specific features of this research protocol. First, in the research phase (stages 1 to 5), there was no communication among teachers, so we are not studying an instance of collective or collaborative task design. Second, the nature of the teacher-researcher interaction was of the "clinical partnership" type (Wagner, 1997). Consequently, this should not be considered an instance of teachers and researchers working as "partners in task design" (Jones & Pepin, 2016). Third, we are not studying how teachers interact with curriculum *material* such as textbooks: the two documents which set the stage for the teacher's task design activity are the national syllabus on the one hand, and a historical document on the other hand. Whether or not the teachers would look for and use other documents in the task design process is one aspect of their engagement in this process that would be studied.

A priori analysis of the didactical potential of the historical source

We selected a three-page extract from the 1774 French edition of the first volume of Euler's *Elements of algebra*. The teachers were told that this book is not a research treatise but rather a didactic work, covering algebraic topics ranging from the very elementary (operations with fractions and directed numbers) to the rather advanced (solutions of algebraic equations up to the fourth degree). The extracts were taken from the final chapter. The teachers were given a three-page document, but the researcher explained that they would focus on the first part consisting of paragraphs 784 and 786, the rest being provided mainly for context. The document below is taken from the 19th century British edition, which we altered slightly both to stick to the mathematical notations used in the 1774 French edition and to restore a numerical error which got corrected in later editions:

Document 1: Extract from (Euler, 1828, pp.677-680)

CHAP. XVI. Of the Resolution of Equations by Approximation.

784. When the roots of an equation are not rational, and can only be expressed by radical quantities, or when we have not even that resource, as is the case with equations which exceed the fourth degree, we must be satisfied with determining their values by approximation; that is to say, by methods which are continually bringing us nearer to the true value, till at last the error being very small, it may be neglected. Different methods of this kind have been proposed, the chief of which we shall explain.

(…)

786. We shall illustrate this method first by an easy example, requiring by approximation the root of the equation $xx = 20$.

[Footnote by J. Bernoulli: This is the method given by Sir Is. Newton at the beginning of his Method of Fluxions. When investigated, it is found subject to different imperfections; for which reason we may with advantage substitute the method given by M. de la Grange, in the Memoirs of Berlin for 1767 and 1768.]

Here we perceive, that x is greater than 4, and less than 5; making, therefore, $x = 4 + p$ shall have $xx = 16 + 8p + 16 = 20$; but as pp must be very small, we shall neglect it, in order that we may have only the equation $16 + 8p = 20$, or $8p = 4$. This gives $p = \frac{1}{2}$, and $x = 4\frac{1}{2}$, which already approaches nearer the true root. If, therefore, we now suppose $x = 4\frac{1}{2} + p$; we are sure that p expresses a fraction much smaller than before, and that we may neglect pp with greater propriety. We have, therefore, $xx = 20\frac{1}{4} + 9p = 20$, or $9p = -\frac{1}{4}$; and consequently, $p = -\frac{1}{36}$; therefore $x = 4\frac{1}{2} - \frac{1}{36} = 4\frac{17}{36}$.

And if we wished to approximate still nearer to the true value, we must make $x = 4\frac{17}{36} + p$, and should thus have $xx = 20\frac{1}{1296} + 8\frac{34}{36}p = 20$; so that $8\frac{34}{36}p = -\frac{1}{1296}$, $322p = -\frac{36}{1296} =$

$-\frac{1}{36}$ and $p = -\frac{1}{36\times 322} = -\frac{1}{11592}$; therefore $x = 4\frac{17}{36} - \frac{1}{11592} = 4\frac{4473}{11592}$ value which is so near the truth, that we may consider the error as of no importance.

The goal of stage 2 of the research protocol was to reach a shared understanding regarding some critical features of the text. In the list of features below, we italicized those contents which are explicitly mentioned in the high-school curriculum. Although the notion of *didactical potential* of a document calls for a more refined delineation, for now we will consider that connections between the content of the document and explicit curriculum goals testify to this potential. Consequently, this potential is not a property of the document *per se* but is highly context-dependent. Below, we also added (and italicized) the grade(s) in which these goals are mentioned (except for the "algorithmic thinking and programming", for which the same goals hold across all three high-school grades).

- This text provides opportunities to carry out routine calculation (*grades 8-10*): expansion of $(4+p)^2$, calculation with fractions, solving first degree equations, solving equation $x^2 = 20$. Even though the procedures are routine, the numerical values involved quickly become difficult to operate upon by pen and paper calculation only.
- This provides opportunities to carry out comparisons of specific numbers, either by comparing the successive approximations 4, $4\frac{1}{2}$, $4\frac{17}{36}$ … to a numerical approximation of $\sqrt{20}$; or by comparing the squares of 4, $4\frac{1}{2}$, $4\frac{17}{36}$ … with 20. These are all *grade 10* goals.
- The text weaves together two *genres* of mathematical texts: the exposition of an algorithm, and a heuristic argumentation providing some warrants for claims regarding key steps of the calculation.
- The meaning of the main warrant ("*pp* must be very small, we shall neglect it") is ambiguous, and the text does not provide any proof-type justifications for it. Several interpretations are possible. A static interpretation: $|p|$ being less than one (a claim which also calls for warrants!), p^2 is less than $|p|$ (*grade 10*), also less than $|8p|$ etc. But Euler wrote that, as the algorithm unfolds, one is *ever more* justified in neglecting p^2, thus possibly pointing to an asymptotic interpretation such as: when p is less than 1 and tends to 0, not only is $|p|$ less than p^2, but it becomes infinitely less since the ratio $|p|/p^2$ tends to $+\infty$.
- The text mentions or points to several topics in number theory. First, the introductory paragraph mentions a classification of numbers (some are "rational" while some other necessarily involve "radical quantities"), and, implicitly, $\sqrt{20}$ belongs to the second category (*grade 10*). Second, number-theoretic considerations provide an answer to a key question regarding the algorithm: it will not stop, should the condition to be met be the production of the exact value of $\sqrt{20}$. Indeed, starting from a rational input (such as 4), the algorithm will yield only rational numbers, thus leaving $\sqrt{20}$ beyond reach.
- The text displays the first steps of a method, but the claims as to the scope of this method are implicit. Is Euler claiming that the four values from (4 to $4\frac{4473}{11592}$) are

increasingly better approximations of $\sqrt{20}$ (*grade 10*)? That an iterative interpretation of the algorithm leads to a sequence of numbers with limit $\sqrt{20}$ (and with a strictly decreasing distance between the sequence and its limit) (*grade 12*)? That this "method" works for *all* square roots? Or even for all polynomial equations?

- Jean Bernoulli's footnote reminds the reader of the fact that Euler is merely expounding Newton's method (actually in Raphson's version (Bailey, 1989; Ypma, 1995)). To the expert reader, this should bring to mind the topics of tangents and derivatives; topics which, on the face of it, do not play any part in the text. However, the linearization of the equation amounts to considering a tangent instead of the curve, and the relevance of these ideas (algebraic or geometric linearizations) reflects the relevance of the concept of derivative as provider of local linear approximations. It so happens that, when one deals with polynomial functions only, derivatives can be defined and worked out purely algebraically. Hence Euler's text can be seen as presenting a very interesting special case (theory of derivatives in a polynomial context) of a very important general concept (the derivative as provider of local linear approximations) (*grades 11 and 12*).
- The text illustrates the first steps of what is clearly an iterative algorithm. Identifying this text as presenting an iterative algorithm, extracting the algorithm by editing out the heuristic parts of the text (parts which may also contain algorithmic steps, e.g. expand $(x_n+p)^2$, solve linear equations), and, possibly, implement it in a programming language, all these are tasks which fit exactly the "algorithmic thinking and programming" strand of the whole high-school syllabus.
- In *grade 10*, other algorithms for the approximation of the solutions of numerical equations – such as bisection – are to be studied and implemented. Since Euler presents a different method, it could be interesting to compare these methods in terms of efficiency. In *grade 12* it can be proven that the convergence of Newton's method in the case of square roots is quadratic, hence much faster than the linearly convergent dichotomy. Also, implementing Newton's method requires that a first rough approximation of a solution be taken as starting point (here $\sqrt{20} \approx 4$), which, in itself, calls for another (maybe more elementary) algorithm.
- Euler's text can be criticized, or at least questioned, as to rigour. In particular, he used the same letter x to denote different numbers; same for p. At least two reactions could be mathematically and didactically relevant: one could either realize the fact that this iterative method generates recursively defined sequences, and introduce notations such as $x_{n+1} = \frac{1}{2}\left(x_n + \frac{20}{x_n}\right)$ (*grade 11*); or consider that the letters represent programming variables and not mathematical variables (*grade 10*). In this second context, some of the "=" symbols should be read as value-change operators and not as mathematical equalities.

The research protocol (stages 1-5) was implemented in the 2020-2021 school-year, with five teachers; the data are being processed. The goal of this initial progress report was to establish that the historical document selected by the researcher has the potential to generate cognitively demanding classroom sessions, and leaves considerable leeway for the teachers to engage in task design and implementation.

The reception of modern mathematics in Belgian technical education: Adhering or resisting?

Dirk De Bock

KU Leuven, Leuven, Belgium; dirk.debock@kuleuven.be

Belgium was one of the first European countries to be involved in the modern mathematics movement of the 1960s. The reform was led by a university professor (Georges Papy), supported by a number of enthusiastic teachers of general secondary education. The reformers showed almost no interest in technical education. In the mid-1960s, however, it became clear that also the mathematics programs of technical secondary education would be modernized. We examine the diverse reactions of stakeholders of technical education to the announced reform. Emile Ridiaux and like-minded teachers prepared and attempted to use modern mathematics for technical applications. Others, e.g. inspector Charles-François Becquet, resisted the upcoming reform, but his organization called MATEC, could not stand up to the well-oiled machine of Papy and his disciples. Consequently, from September 1, 1969, modern mathematics was generalized in all technical secondary schools in Belgium.

Keywords: Belgium, MATEC, modern mathematics, reform movement, technical education.

Introduction

Belgium was a pioneering country in the modern mathematics movement of the 1960s. A first experiment with modern mathematics began as early as 1958, one year before the landmark Royaumont Seminar. The experiment was carried out with prospective kindergarten teachers and was led by Frédérique Lenger and Madeleine Lepropre (De Bock & Vanpaemel, 2018). For technical assistance with follow-up experiments, the experimenters enlisted the help of Georges Papy, a professor of algebra at the University of Brussels. However, Papy did not limit himself to consulting: From 1959 he started his own experiments and would completely dominate the movement. In May 1961, he founded the Belgian Centre for Mathematics Pedagogy that grouped the country's most prominent modern mathematics enthusiasts. The Centre coordinated all aspects of the reform movement: It edited new curricula, set up experiments, developed course materials, retrained teachers, established local working groups, etc. The interpretation of modern mathematics was quite radical. Sets, relations, and algebraic structures formed the basis; logic, deductive reasoning, and proof were central. With appropriate political support, Papy's modernization efforts would lead to a mandatory implementation of modern mathematics in the general sections of secondary schools from September 1968.

Papy and his team members, who typically had an academic or general education background, showed little interest in technical education. No experimental programs or experiments were anticipated for this type of education. From official directives of the mid-1960s, however, it became clear that technical schools would also be involved in the modernization of the mathematics programs, a reform that prioritized intellectual formation over practical utility. A circular letter issued by the *Nationaal Verbond van het Katholiek Technisch Onderwijs* [National Association for Catholic Technical Education] on November 15, 1966, stated that every mathematics teacher in technical education should urgently inform himself about modern mathematics. To this end, these teachers were strongly advised to attend the classes given at the initiative of the Belgian Centre for Mathematics Pedagogy, and school boards were asked to give their teachers the opportunity to do so. (Holvoet, 1968). We find a similar recommendation in the 1966 mathematics program of the *Enseignement technique et professionnel féminin de l'État* [Technical and professional education for women in the state], as cited in Holvoet (1968): "All teachers are strongly advised to increase their knowledge by all means and in particular to attend regularly the courses organized by the Belgian Centre for Mathematics Pedagogy[1]" (p. 101).

In this paper, we search for answers to the following research question: "How have teachers and other stakeholders in technical education responded to an announced reform that seemed diametrically opposed to the goals of mathematics in technical education?" To answer this question, we have analyzed the available reform documents and all Belgian journals for mathematics teachers from that period: *Mathematica & Paedagogia*, *Nico*, and *Matmo* (see below). Moreover, we systematically searched *BelgicaPress*, a digital database of historical Belgian newspapers up to 1970[2]. This study is part of a line of research on the history of the modern mathematics movement in Belgium that recently led to the book *Rods, sets and arrows: The rise and fall of modern mathematics in Belgium* (De Bock & Vanpaemel, 2019). However, the reform in technical schools and the role of key actors in it remained underexposed. The present study aims to fill this gap in the existing literature on the Belgian modern mathematics movement. The scope of this type of research is, however, not just "purely" historical: Researching mathematics education of the past can provide historical insights that support the future, or as Van Bendegem (2021) stated it:

> This research is not merely historically interesting but is also relevant to understanding what present-day STEM (and I would add STEAM) initiatives are really about and what the potential pitfalls and dangers can be, and what the underlying educational aims and goals are (or should be) vis-à-vis society at large. (p. 604)

Ridiaux's actions to welcome modern mathematics

Emile Ridiaux (1924–2006), trained as an engineer, was a mathematics teacher in the secondary technical section of the *Université du Travail* [University of Labor] in Charleroi, an important industrial center in the French-speaking part of Belgium. With a view to preparing mathematics teachers in technical schools for the arrival of modern mathematics in their classrooms, Ridiaux founded a new teachers' journal, titled *Matmo*, a reference to "modern mathematics", and subtitled *Revue des ensemblistes du secondaire* [Journal for enthusiasts of sets in secondary schools]. *Matmo* was published between 1964 and 1968. A total of thirty issues appeared: Ten in the first volume (1964–1965), ten in 1966, five in 1967, and five in 1968. Layout and style of the journal were very

---

[1] All translations were made by the author.

[2] Collections of the Royal Library of Belgium (https://www.belgicapress.be/). Keywords used: "Becquet", "Matec", "Matmo", "Papy", "Ridiaux".

basic and each issue had only 16 stapled pages. The journal did not question the upcoming reform as such, on the contrary. In the first *Editorial* (September 1964), we read:

> We do not claim to be scholars! We know the scholars, because they have come down to us, to our teaching! At the secondary level, even at the primary level, we want to apply their advice, because we have confidence, and, with them, we have hope in a much better mathematical future.

Browsing through the different issues of *Matmo*, one notices that most of the contributions were written by Ridiaux himself and some of his colleagues. Mainly lesson ideas for lower (technical) secondary education are presented, on "modern" topics such as sets, relations, and structures (inspired by Papy's proposals), but also "classical" topics from algebra, higher arithmetic, and geometry are considered from a modern point of view. Sometimes student reactions are included in the lesson plans, showing that the lessons had already been trialed. Attention is also paid to applications of mathematics, especially from physics (e.g., electrical circuits), but also from chemistry and biology. *Matmo* regularly informs its readers of new developments related to mathematics education, both in Belgium and abroad (e.g., with echoes from France and the USA). Specific Belgian reform initiatives, in particular the in-service courses of Papy's Centre, receive ample attention. The emergence of an opposition movement in 1966 (see the next section) is also reported and limitedly documented, but already in the first issue of 1967, Ridiaux writes that although he welcomes remarks and criticisms, "We would like to avoid a quarrel between the ancients and the moderns, especially among teachers..." (in capitals, no pagination). After that, *Matmo* will not include any news about the opposition movement…

It is worth mentioning that in 1969 Ridiaux published a textbook on a remarkable method in which arrow graphs, one of the favorite representational tools of Papy and his collaborators, were used to transform algebraic formulas (Ridiaux, 1969). This technical skill was not considered important by modern mathematics reformers, but it was fundamental to (technical) applications of mathematics. In Ridiaux's method, a path of arrows, representing operations, is drawn from a variable to be found to a given variable. By tracing the inverse arrows, which represent the inverse operations, the requested variable can be calculated (see Figure 1). Sometimes, Ridiaux also visualized the different steps in this process via film strips, a didactic tool known from Papy's *Mathématique Moderne* (De Bock & Vanpaemel, 2019). In Ridiaux (1970), the author explained how this method can also be used to solve (systems of) linear equations. Ridiaux's method is no longer used in Belgian schools today, but it is still recommended, albeit in a modified form, by some mathematics educators of the 21st century (see, e.g., Noël, 2003). The case illustrates how Ridiaux tried to didactically modernize mathematics for technical education, his way of conforming to reformers' expectations.

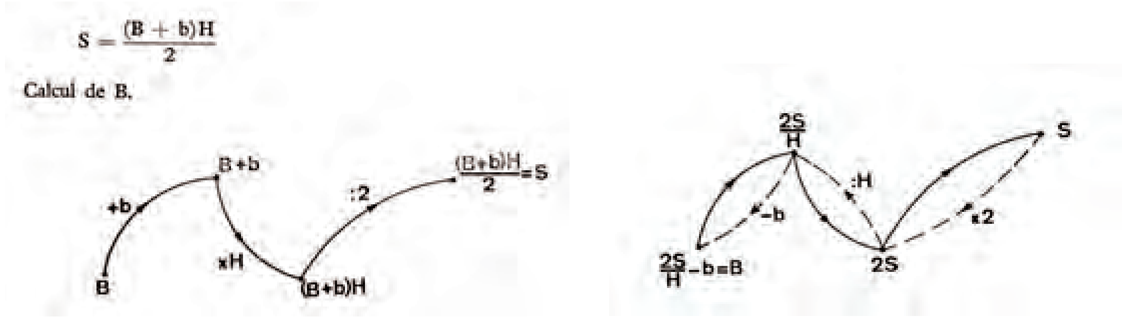

Figure 1: Example of Ridiaux's method for the transformation of formulas using arrow graphs; the variable *B* has to be calculated from the given formula (Ridiaux, 1969, p. 18)

Becquet and the action of MATEC

From Charles-François Becquet (1915–1987), a totally different sound was heard. Becquet was a master of mathematics (University of Liège, 1940), a teacher and later an inspector of technical secondary education organized by the state. In addition, though less relevant here, Becquet was a political author and militant in the Walloon Movement during and after World War II. In July 1963, Becquet had published an article entitled *Réformons les mathématiques* [Let's reform mathematics], in which he argued for a reform but one different from that proposed by Papy and his Centre (Schwilden, 1968). More specifically, Becquet advocated an approach that "makes better use of intuition, repetition, and new methods, such as those used in programmed courses". Becquet did acknowledge, however, that it would be desirable "to integrate the useful parts of new theories, taking into account the various levels and objectives of education" (Schwilden, 1968, p. 7). He also insisted that the reform be carried out slowly and gradually, and that the old not be swept away at once:

> Basically, the first phase would be focused on setting the traditional in order and the second phase on implementing the new theories. In this way, there would never be a deep conflict in the continuity of the curriculum, but a slow and secure evolution. The teachers themselves would not feel like pawns, like toys in the hands of curriculum developers. (Becquet in Schwilden, 1968, p. 7)

As early as September 1963, Becquet and some like-minded mathematics teachers at schools for technical education launched their own experiment to modernize the mathematics curricula for 12- to 18-year-old students in these types of school (Gadeyne, 1968). Eventually, 35 schools would follow Becquet's experimental method (Vermeulen, 1968). Becquet considered his experiment successful: A survey of participating teachers revealed that the method better established basic knowledge and facilitated understanding of mathematics. As a result, fewer students failed mathematics than before (*Le Soir*, April 24, 1968). In support of his actions, Becquet had founded a new teachers' association, *Mathématique et Technique* (MATEC) [Mathematics and Technique], in the first half of 1966. *Matmo 04/66* recorded a short press release about the initiative:

> About 30 school principals and teachers belonging to the various networks of technical education met, under the presidency of Mr. Inspector Becquet, at the *Institut d'Enseignement Technique de l'État*, in Namur, to constitute an association Mathematics and Technique, whose aim is the

> defense of technical education and its illustration in the framework of mathematics. (no pagination)

A Board of Directors was elected consisting of Becquet (president), J. Loomans (general secretary), and G. Benoit (administrative secretary), the latter two being principals of a technical school of, respectively, the official and Catholic network. Nine working groups were also established, each to address a specific problem related to the mathematics programs, and the relationships between technical education, on the one hand, and other forms of education and industry, on the other (*Matmo 04/66*, *05/66*). At a session on October 12, 1966, MATEC's Board of Directors adopted the following resolution:

> The Board of Directors of the teachers' association Mathematics and Technique expresses its strongest reservations regarding the consequences for the future of students in technical education resulting from the introduction of systematic teaching of set theory in the lower grades of technical and vocational secondary education. (*Matmo 10/66,* no pagination)

MATEC thus explicitly opposed the systematic introduction into the lower grades of technical secondary education of set theory, "a gateway to philosophy and logic but not to technical calculation", as Becquet had declared in an interview in *Le Soir*, a leading newspaper in the French-speaking part of Belgium (*Le Soir*, April 24, 1968, p. 6). But what did the technical schools fear would be lost, and what specifically did they propose as an alternative? The main concern, perhaps, was that in Papy's curriculum proposals mathematics would not be helpful to and would even isolate itself from other courses in technical education. In a letter dated November 1966 from Becquet addressed to the principals of the technical schools we read:

> The technicians insist on the practice of calculation. A solid knowledge of the fundamental operations involving integers, decimal numbers, and fractions is essential. The study of the metric system and its elementary applications, initiated in elementary school, must be continued. [...] Vocational training, the practice of technical drawing, and the technology course require real aptitudes in the above-mentioned subjects. […] In technical schools, the first-year drawing program includes geometric drawing and, already, an introduction to industrial drawing through the representation of simple parts. Teaching recipes alone would have no educational value. […] The drawing activity must therefore, in principle, be based on a prior knowledge of geometric notions acquired by experimental or intuitive means in the course of mathematics. It should be noted that the first-year geometry course should, more than in general education, introduce students to the knowledge of the common plane forms and solids and train them to see in space, because these notions and this skill are indispensable for the drawing of parts in the wood and iron workshop. It follows that the preservation of an elementary practical teaching of geometry, but always with a formative character, is essential. (*Matmo 10/66,* no pagination)

As an alternative, MATEC proposed that the lower grades of (technical) secondary education would study arithmetic, both calculation techniques and problem solving, the metric system, the basics of algebra (first degree algebra and the roots of a quadratic equation), plane geometry, trigonometry with right triangles (perhaps extended to non-right-angled triangles), and the first elements of solid geometry. Becquet did not oppose, at some later stage, the integration of some elements of vector and matrix algebra in schools for technical education. As stated by Noël (1993) and evident from the above listing, MATEC considered mathematics primarily as a technical tool and not as gymnastics of the mind. In the textbooks for Becquet's experiments, developed under his supervision by a group of teachers from technical schools involved in these experiments, the difficult chapters were split into two parts to separate the meaning of operations from the practice of calculation. Needless to say, the work of MATEC was strongly criticized and even ridiculed by Papy ("Mr. Becquet, the courses of Belgian Centre for Mathematics Pedagogy are open to you. Learn! You will be forgiven a lot", Papy, 1968, p. 34).

Vain hopes and math wars in the late 1960s...

The political decision to mandatorily introduce modern mathematics in the first years of secondary education from September 1, 1968, was made by Henri Janne, Minister of Education in an outgoing government, and announced in a circular of May 14, 1965 (Janne, 1965). Janne was a former rector of the University of Brussels, a socialist and political friend of Papy. On April 11, 1968, Janne's decision was confirmed by Frans Grootjans and Michel Toussaint, the Ministers of Education at the time, but their decision only concerned the general sections of secondary education (Grootjans & Toussaint, 1968). Thus, no formal decision was yet made about modern mathematics in technical secondary education. Moreover, on June 17, 1968, a new government was formed with two new Ministers of Education: Piet Vermeylen and Abel Dubois. The newly appointed Ministers soon allowed some schools of general secondary education "not yet ready to implement the new curricula" to postpone the introduction of modern mathematics by one year (Noël, 1993). Could the decision of Grootjans and Toussaint be reversed? A time of uncertainty followed for Papy's partisans, a time of hope for his opponents. This uncertainty led to a fierce math war in 1968–1969, especially in French-speaking Belgium (De Bock & Vanpaemel, 2019).

During that war, MATEC, which in the meantime had grown to a grouping of more than 400 school principals and teachers (*Le Soir*, April 24, 1968), further developed into a more or less structured opposition movement against Papy and the Belgian Centre for Mathematics Pedagogy. Already in 1966, it united forces with the *Association des Docteurs et Licenciés en Sciences Mathématiques sortis de l'Université de Liège* [Association of Doctors and PhDs in Mathematical Sciences from the University of Liège] (*Matmo 10/66*). Toward the end of the 1960s, an umbrella organization of mathematics teachers opposed to Papy's reform was established—the *Association des Professeurs de Mathématique de l'Enseignement Secondaire* [Association of Teachers of Mathematics of Secondary Education] (Derwidué, 1969). In reaction to this opposition, a group of teachers who supported Papy's reform project for the secondary level was created—the *Comité pour la Promotion de l'Enseignement Mathématique* [Committee for the Reform of Mathematical Education]) (Genaert, 1969). In 1968–1969, both organizations mobilized all those involved in the reform, including parents, for large-scale information meetings, hearings, and colloquia held in major Belgian cities (Figure 2).

Figure 2: Invitation flyer for a gathering of parents in Liège on June 23, 1969

The headlines of articles in the Francophone press of the period were telling: “La guerre des maths aura-t-elle lieu?” [Will the maths war take place?] (*Spécial*, March 6, 1968, p. 16), “Sur le front des maths” [On the maths front] (*Pourquoi Pas?*, August 29, 1968, p. 105), “Des cobayes pour les Papystes” [Laboratory animals for Papy’ists] (*Spécial*, April 9, 1969, p. 15), “À quand un cessez-le-feu et une commission d’armistice? Le pénible spectacle offert par la ‘guerre des math’ ” [When will there be a ceasefire and an armistice commission? The painful spectacle offered by the “math war.”] (*Le Soir*, April 27–28, 1969, p. 7), “Nouvelles maths: pour ou contre?” [New maths: for or against?] (*La Libre Belgique*, June 12, 1969, p. 5). The leftist press was mostly sympathetic to the reform initiated by Papy and his Centre, not only because Papy was a socialist, but also because there was a vague belief in the emancipatory power of the project.

The war was eventually won by Papy and his proponents. Minister Dubois, also a socialist, stuck to the decision of his predecessors. In an address delivered at the teaching college in Nivelles on April 27, 1969, he stated:

> The new curriculum is the Belgian version, very pragmatic and very adaptable, of a mathematical conception which is now being introduced in all industrialized countries; ... it constitutes a clear obligation for all schools run by the state; no one, my predecessors nor myself, has ever envisaged reconsidering it. (Dubois, 1969, p. 3)

When from September 1, 1969 all students of the first years of secondary education, both in the general and in the technical sections, without any exception, were subjected to modern mathematics, the late 1960s math war ended quickly. The official programs of the technical sections were similar to those of the general sections except for a few details. For Dubois, this was a deliberate decision, even a matter of principle, viz. an occasion to eliminate, maximally, divisions between different types of education (and thus to upgrade the status of the technical schools).

It would be unacceptable if not [the same programs were applicable] and that, with the introduction of the new program, the harmful division between general and technical education, each in their respective fortresses, would be continued. (Dubois, 1969, p. 3)

Conclusion

In the Belgian modern mathematics movement of the 1960s, technical secondary education entered the picture relatively late. The technical schools did not ask for the reform, but when it became clear that they would be involved, reactions were mixed. Ridiaux and some like-minded teachers adhered and tried to make the best of it, explaining in a newly founded journal *Matmo* how to incorporate modern elements into mathematics for technical education; others, such as Inspector Becquet and the members of MATEC, chose to resist. After a bitter math war in 1968–1969 between supporters and opponents of Papy, especially in French-speaking Belgium, modern mathematics was also implemented in technical secondary education, one year later than in general secondary education but with an almost identical program.

Future research could clarify the specificity of the Belgian modern mathematics movement in an international context. However, despite increasing scholarly interest and some single analyses with a specific scope (e.g., Kilpatrick, 2012; Vanpaemel & De Bock, 2019), comparative research on the international "New Math" phenomenon is still in its infancy.

The “best” axiom system for teaching geometry to secondary school students: A source of controversy in the early 1960s

Wendy Goemans and Dirk De Bock

KU Leuven, Belgium; wendy.goemans@kuleuven.be

Jean Dieudonné’s “Euclid must go!” provoked controversy among participants at the 1959 Royaumont Seminar. Although Dieudonné’s outcry led to misunderstandings, many contemporaries shared his view that geometry education needed to be modernized. On how to proceed, there was less agreement. At international meetings after Royaumont, no clear and supported solution could be proposed. For Dieudonné and other (Bourbaki-oriented) mathematicians, linear algebra was the royal road to geometry, but even then opinions differed widely. The controversy peaked in 1964 with the publication of Gustave Choquet’s L’Enseignement de la Géométrie and, shortly thereafter, Dieudonné’s Algèbre Linéaire et Géométrie Élémentaire. We carefully analyze these two seminal books and the role they played in the debates on modern mathematics in the early 1960s. Key differences are revealed and put into perspective with the similarities identified.

Keywords: Axiom system, geometry education, Gustave Choquet, Jean Dieudonné, modern mathematics.

Introduction

The 1959 Royaumont Seminar is widely recognized as a turning point in the history of the modern mathematics movement of the 1960s (Bjarnadóttir, 2008; Skovsmose, 2009). The Seminar brought together American and Western European reformers for the first time, and it also marked the start of this movement in several countries not previously involved. Although in recent years several researchers have argued that very diverse positions were taken at Royaumont, for example about the role of applications (De Bock & Zwaneveld, 2020) and of systematic psychological research (Schubring, 2014a, 2014b), in the collective memory of mathematics educators, Jean Dieudonné’s sharp attack on the traditional teaching of (Euclidean) geometry, for which his battle cry “Euclid must go!” was symbolic, continued to resonate.

A lot of ink has also been spilled about the exact meaning of Dieudonné’s slogan. Whence this vehement attack on “Euclid” while he deeply admired the achievements of the Greeks to mathematics (“I consider their creation of geometry perhaps the most extraordinary intellectual accomplishment ever realized by mankind”, Dieudonné, 1961, p. 35)? First, Dieudonné criticized what he considered a fossilized (French) educational tradition in geometry education, or as Hans Freudenthal (1967, p. 745) formulated it:

> The inventor of the slogan “A bas Euclide” a follower of Euclid? It looks odd, but it does so simply because few slogans have been misunderstood as badly as this one. Partly, it was Dieudonné’s own fault. When he cried “A bas Euclide,” he actually meant “A bas ‘Euclide’,” (viz. the Euclid of French lycée textbooks), but in oral discussions it is a hard thing to pronounce quotation marks.

Almost everything to which much attention was paid in this tradition, in particular “the triangle”, had, according to Dieudonné (1961), “as much relevance to what mathematicians (pure and applied) are doing today as magic square or chess problems!” (p. 36). However, Dieudonné was clearly in favor of an axiomatic approach to geometry, but not the old one of Euclid with its fuzzy distinction between “axioms” and “postulates”, but of a “modern” one based on linear algebra. Dieudonné’s views caused “sharp controversy” among the Royaumont participants, yet all agreed that a modernization of geometry education was needed. There was, however, less unanimity on how that modernization should be achieved. In a number of follow-up meetings in the early 1960s, the international mathematics education community attempted to come to some form of agreement, though without success. The debate quickly rigidified into the search for the “best” axiom system for secondary school geometry, and further hardened with the publication of Gustave Choquet’s *L’Enseignement de la Géométrie* and Jean Dieudonné’s *Algèbre Linéaire et Géométrie Élémentaire*, both in 1964.

In this paper, we first provide a brief overview of the development of the geometry debate in the first half of the 1960s. Second, we carefully analyze the aforementioned books by Choquet and Dieudonné in order to unravel the differences and commonalities in vision of these two scholars. To this end, inspired by the topic model for discourse analysis of Jacobs and Tschötschel (2019), we first manually compiled a list of topics (such as for instance “droite” [straight line], “symétrie” [reflection], …) that appear in the books, and this page per page. Then, we counted (using the freely available online tool of browserling on https://www.browserling.com/tools/word-frequency), how many times a topic is mentioned in each book. We compared how the topics that ranked highest in this count were dealt with in the two books. In comparing the manipulation of the different topics, we paid specific attention to the differences caused by the axiom system chosen. In the final section of this paper, we discuss how it came to a settlement, at least between Choquet and Dieudonné.

The geometry debate in the aftermath of Royaumont

The first half of the 1960s was particularly rich in international activities on the modernization of school mathematics. In addition to the annual meetings of the International Commission for the Study and Improvement of Mathematics Teaching (CIEAEM), important international meetings were held in, among other places, Aarhus, Denmark (1960), Zagreb-Dubrovnik, Yugoslavia (1960), Bologna, Italy (1961), Budapest, Hungary (1962), Athens, Greece (1963), and Frascati, Italy (1964). These meetings were initiated by one of the following international bodies, either in partnership or not: The International Commission on Mathematical Instruction (ICMI), the Organization for European Economic Cooperation (OEEC; in 1961 joined by nations outside Europe to form the Organization for Economic Cooperation and Development, OECD), and UNESCO. A detailed discussion of the objectives and conclusions of these meetings is beyond the scope of this paper and for that we can refer the reader to, for example, Furinghetti and Menghini (to appear). To indicate the international context and “climate” in which the polemic between Choquet and Dieudonné occurred, we discuss in a nutshell some key elements related to the debate on geometry education.

Although the 1960 Aarhus meeting was intended to have a broader scope, the debates concentrated on "Modern teaching of geometry in secondary schools with particular emphasis on ways of treatment opened up by developments lately, in particular by the algebraization of mathematics" (Behnke et al., 1960, p. ii). No less than five different proposals for "new" axiom systems for secondary school geometry were presented, including by the Royaumont lecturers Dieudonné and Choquet. Dieudonné reiterated his position that geometry education should be approached from the study of two- (or three-) dimensional vector spaces over the field of real numbers, equipped with an inner product. Choquet proposed his axiom system for affine and metric plane geometry that he would adopt in *L'Enseignement de la Géométrie* (1964). Although views differed, there seemed to be a consensus that Euclidean geometry was too difficult for 12–13-year-olds, even in the form of *Bewegungsgeometrie* [motion geometry], a German approach rooted in the work of Felix Klein and proposed at Royaumont by Otto Botsch. There were timid attempts, by Freudenthal, Willy Servais, and Tullio Viola, to include psychological aspects in the debate on school geometry, but this led to no less than a quarrel between Freudenthal and Dieudonné, with the latter stating, "*la psychologie, je m'en fiche*" [psychology, I don't care] (Behnke et al., 1960, p. 104).

In Zagreb-Dubrovnik (1960), a group of experts was commissioned to work out a detailed synopsis for modern secondary school mathematics "in the spirit of Royaumont". The experts agreed on the introduction to set theory, algebra, analysis, probability theory and statistics, but regarding geometry education, the outcome was an ambiguous compromise. For the final years (15–18-year-olds), an axiomatic and structural approach—heavily influenced by Choquet's vision—was recommended, while in the early years (11–15-year-olds), the emphasis would be put on a more intuitive approach (OEEC, 1961). The attention to intuitive geometry was largely due to the intervention of the Belgian Paul Libois, a lifelong advocate of intuition-based geometry teaching, but a dissident voice in the 1960s debates (Vanpaemel & De Bock, 2017).

The 1961 meeting in Bologna was intended to discuss the results of Aarhus and Zagreb-Dubrovnik, which had not led to any form of agreement. The discussion in Bologna led to some kind of compromise around a proposal by Emil Artin to define the Cartesian plane axiomatically as a vector space of dimension two with an inner product, but Freudenthal, Libois, and Viola partly disagreed. According to the first, the geometry programs proposed in Aarhus and Zagreb-Dubrovnik were based on an "anti-didactic inversion", expressing that an end product of mathematical activity, the most recently composed structure of mathematics, is taken as a starting point for mathematics teaching (Freudenthal, 1963).

At the meetings in Budapest (1962), Athens (1963), and Frascati (1964), results of early experiments with modern mathematics could already be presented. In particular, the audacious approach of the Belgian Georges Papy, combining mathematical rigor with an innovative pedagogy, received considerable attention and appreciation.

Two notable books shaping the debate of the mid-1960s

When reading Choquet's *L'Enseignement de la Géométrie* and Dieudonné's *Algèbre Linéaire et Géométrie Élémentaire*, one immediately notices the points of agreement in the objective Choquet and Dieudonné aim to achieve with their work; similarities in their views on the teaching of geometry are already apparent in the introduction to their books. Indeed, both authors state that they mainly target secondary school teachers. Moreover, they agree that the teaching of geometry for young children (age less than 13) should be based on observation and experiments, while in the last two or three years of the secondary school, linear algebra should be the basis of geometry. Between these two age groups, children should be gradually familiarized with deductive reasoning.

As (pure) mathematicians, Dieudonné and Choquet were "*Bourbakists*". *Bourbaki*'s approach to mathematics was axiomatic-deductive, formal, and uncompromisingly rigorous, deliberately excluding diagrams and external motivations. Both our protagonists were convinced that the *Bourbaki* model for structuring mathematics as a science was also the "best" model for structuring mathematics education, in casu geometry education, with the axioms of linear algebra as a fundamental model.

Before presenting their "best" axiom system for teaching geometry to secondary school students, Choquet and Dieudonné digress on how it should not be done, both referring to colleagues along the way, anonymously or not. Choquet seeks to minimize the number of axioms:

> mais je ne pense pas qu'il soit désirable, comme l'ont préconisé certains professeurs, de prendre au départ de très nombreux axiomes [but I do not think that it is desirable, as some professors have advocated, to take very many axioms at the start[1]] (Choquet, 1964, p. 10)

Dieudonné denies the claim that the axioms of linear algebra are too abstract, and refers to Choquet on the way:

> partir d'un *autre* système d'axiomes, […] le plus connu est sans doute le système d'axiomes proposé récemment par Choquet, d'une remarquable ingéniosité qui témoigne du grand talent de son auteur, mais que je tiens pour parfaitement inutile et même nuisible. [starting from another system of axioms, […] the best known is undoubtedly the system of axioms recently proposed by Choquet, of a remarkable ingenuity which testifies to the great talent of its author, but which I consider to be perfectly useless and even harmful.] (Dieudonné, 1964, p. 17)

However, both authors agree on the fact that the "best" axiom system should separate affine and metric notions, or as Dieudonné phrases it:

> Je pense surtout ici à la distinction (clairement sentie depuis Poncelet) entre propriétés géométriques de nature « affine » et propriétés de nature « métrique ». Il est particulièrement choquant, du point de vue logique, de voir mélanger en une incroyable salade ces deux types de propriétés dès le début de la traditionnelle « Géométrie euclidienne », mettant exactement sur le même plan des notions aussi différentes que celle de parallèle et celle de perpendiculaire [I am thinking here above all of the distinction (clearly felt since Poncelet) between geometric properties of an "affine" nature and properties of a "metric" nature. It is particularly shocking, from a logical point of view, to see these two types of properties mixed together in an incredible salad from the very beginning of the traditional "Euclidean geometry", putting exactly on the

[1] All translations were made by the authors.

> same level notions as different as that of being parallel and that of being perpendicular] (Dieudonné, 1964, p. 13)

Likewise, both Choquet and Dieudonné first treat the two-dimensional geometry of the plane before generalizing the concepts to the three-dimensional geometry of the space.

Faithful to his opinion that geometry should start off with a limited number of strong axioms, Choquet immediately sets off with axioms on a straight line and on a set of straight lines. He defines the *plane* as a set, equipped with a structure, induced by a set of subsets, called *straight lines.* Then he defines *parallel* straight lines and he states *axioms* on the existence of a unique straight line connecting two different points in the plane, and on a unique straight line parallel to a given straight line and passing through a given point of the plane (the so-called *parallel postulate*). Being parallel is an equivalence relation on the plane, leading to the concept of the *direction of a straight line* as the equivalence class to which the straight line belongs.

Dieudonné, however, first dedicates some pages to the necessary basic properties of real numbers and to the axioms of Euclidean geometry. He defines the *plane* as a set on which there exist three operations: addition of two elements, scalar multiplication of an element with a real number, and scalar product of two elements. Assuming the former two operations satisfy the necessary conditions, he calls this plane as soon as possible a *vector space*. Dieudonné then defines a *straight line* as an affine subspace with its *direction* fixed by the corresponding linear subspace (i.e., a straight line through the origin). Two straight lines are *parallel* if they have the same direction (that is, if they are both affine subspaces resulting from the same linear subspace). From these definitions, and using the properties of the underlying vector space, the proposition that there exists a unique straight line through two different points, and the *parallel postulate*, are proved.

In conclusion, because of the different choices for the axiom systems in the two books, properties that are put forth as axioms by Choquet can be proved as corollaries by Dieudonné, and vice versa.

In the further treatment of affine geometry in the books by Choquet and Dieudonné, their different starting points lead to only minor or mere formal differences. Noteworthy however, is the topic of the *addition* of two vectors. In Dieudonné's exposition, this addition is inherent to an operation on the elements of a vector space. Choquet, however, defines this operation by making use of parallelograms: The addition of two points x and y is the point z such that the origin, x, y, and z form a parallelogram. It illustrates Choquet's statement from his introduction, expressing how vectors are naturally at the foundation of geometry:

> L'axiomatique d'Euclide-Hilbert est basée sur les notions de longueur, d'angle, de triangle. Elle cache à merveille la structure vectorielle de l'espace […]. Le fait qu'un triangle soit la moitié d'un parallélogramme n'a pas empêché qu'on mette l'accent pendant plus de vingt siècles sur l'étude détaillée […] des triangles […]. On voyait le triangle, mais non le parallélogramme qui aurait pu conduire aux vecteurs. [The axiomatic system of Euclid-Hilbert is based on the notions of length, angle, triangle. It hides wonderfully the vector structure of the space […]. The fact that a triangle is half of a parallelogram has not prevented one to put emphasis for more than twenty centuries on a detailed study […] of triangles […]. One saw the triangle, but not the parallelogram which could have led to vectors.] (Choquet, 1964, p. 10)

Continuing with the definitions of an affine transformation, a translation, a homothety, and a dilatation, there are some differences in the order in which these concepts are treated and in the importance that is given to them. Loyal to his choice of the axiom system, Choquet first defines a translation as an operation on a straight line, before extending this definition to the plane. Dieudonné first defines these transformations as mappings on the vector space, even before defining a straight line. The definition of a dilatation is in Dieudonné's book left for the exercises, which should not be a surprise, since a dilatation is either a translation or a homothety.

Entering the world of Euclidean geometry, the consequences of the different choices for the axiom system, seem, at first sight, to manifest themselves again more firmly. At this point, Choquet first mentions briefly that only basic and well-known properties of real numbers will be used. He then posits in an axiom the concept of *distance* as a structure on a straight line. Later, in his chapter on the axioms of the *metric structure*, he first states an axiom on when two straight lines are *perpendicular*, followed by the definition of *perpendicular projection*. Only then, the notion of distance is used to define the *norm* of a vector. This concept of norm, together with the perpendicular projection, finally leads to the definition of the *scalar product* of two vectors.

Dieudonné reverses this order more or less completely. Since he starts with a vector space as underlying structure of the Euclidean space, he disposes immediately of the *scalar product* of two vectors. Similar to Choquet, however, he restricts this scalar product as an operation on a straight line. Applying the scalar product, the definition of a *norm* of a vector and the *distance* between two points, follow immediately. Only then, the notion of two *perpendicular* vectors is defined, again using the *scalar product* of these two vectors.

In his chapter on the metric structure of Euclidean space, Choquet mentions that the axioms he presented allow to show that the concept of distance that he introduced is equivalent to the concept of distance that is associated to the scalar product (which is the way Dieudonné defines distance), summarized in a Theorem:

> Théorème 96.3. Pour tout point $o \in E$, on peut définir sur E, de façon unique, une structure d'espace vectoriel d'origine o, muni d'un produit scalaire, dont les variétés affines de dimension 1 et 2 sont les droites et plans de E, et dont la distance associée au produit scalaire soit identique à la distance donnée sur E. [Theorem 96.3. For any point $o \in E$, one can define on E, in a unique way, a structure of a vector space with origin o, equipped with a scalar product, whose affine subspaces of dimension 1 and 2 are the lines and planes of E, and whose distance associated with the scalar product is identical to the distance given on E.] (Choquet, 1964, p. 148)

The treatment of the Euclidean transformations or isometries (i.e. translations, rotations, and reflections) is very similar in the books of Choquet and Dieudonné. Of special interest is that both authors first define a rotation, and then use the group of rotations to present a definition of an angle. As Choquet formulates it, a substantial part of geometry can be constructed without the use of angles:

> remarquons que nous avons pu construire commodément une grande partie de la géométrie sans parler jamais d'angles: La structure affine de Π, le théorème de Pythagore, la théorie des similitudes, ont été établis sans utiliser, ni angles, ni cas d'égalité des triangles. [note that we

> could conveniently construct a large part of geometry without ever talking about angles: The affine structure of Π, the Pythagorean theorem, the theory of similitudes, were established without using neither angles, nor similar triangles.] (Choquet, 1964, p. 97)

Only in a later stage they write about trigonometry and trigonometric formulas and about measuring angles. Both Choquet and Dieudonné end their exposition on the "best" axiom system by looking beyond secondary school geometry by examining in the appendices some extra topics, such as angles from a different viewpoint, non-Euclidean geometry, and quaternions and rotations.

A settlement between Choquet and Dieudonné

Papy's didactic approach, as elaborated in his *Mathématique Moderne* (Papy, 1964–1967), soon enjoyed considerable prestige in circles of mathematics educators, particularly in France (see, e.g., Walusinski, 1963). Also Dieudonné (1964) had praised "the remarkable and promising trials of our Belgian neighbors" (p. 17). Papy's approach to the teaching of geometry basically consisted of two stages. In the lower grades (12–15-year-olds), a system of (synthetic) axioms for affine plane geometry was gradually introduced, leading to the structure of the vector plane, an approach showing strong parallels with Choquet's. In the third year of secondary school (14–15-year-olds), this structure was equipped with an inner product, leading to the so-called Euclidean vector plane. At the beginning of the upper grades (15–18-year-olds) then followed what Papy called a "*retournement psychologique*" [psychological reversal]: The achieved goal of the first stage—the Euclidean vector space structure of the plane—was taken as a new and "unique" axiom for the second stage, i.e. the further development of geometry (of the plane and of higher dimensions) from a purely algebraic perspective.

At a meeting of the CIEAEM in Milano Marittima, Italy in 1965, and titled "The place of geometry in modern mathematical teaching", André Revuz tried to reconcile Choquet's and Dieudonné's points of view (Revuz, 1965). Revuz, who was esteemed by all parties, presented a statement about the role of geometry in the education of 12- to 18-year-olds, based on Papy's two-stages approach which was agreed upon by the CIEAEM members present. In the same year, on the occasion of an ICMI colloquium in Echternach, Luxembourg, this proposal was solemnly approved by Choquet and Dieudonné (De Bock & Vanpaemel, 2019).

In conclusion

Excesses of modern mathematics of the 1960s, such as the one described in this paper, have likely contributed to the current divide between the mathematics community and the mathematics education community, a divide that is unhealthy for both (Fried & Dreyfus, 2014). As concluded by Kilpatrick (2012), although modern mathematics is considered a failure, it did change mathematics education and the way it is treated by its stakeholders. Likewise, the books discussed in this paper were criticized (Freudenthal, 1967) and presumably not often used in secondary education, but they did stir the debate on geometry education in the 1960s and afterwards, geometry education did not return to the state it had before Dieudonné initiated the debate. Although the outcome of this debate on geometry education is in large likely due to the diplomatic qualities of Revuz, further research on the role of Papy's approach in this settlement could be of interest.

Notabilia Arithmetica: a Jesuit mathematics school book

Tanja Hamann[1] and Barbara Schmidt-Thieme[1]

[1]University of Hildesheim, Germany;

hamann@imai.uni-hildesheim.de and bst@imai.uni-hildesheim.de

In this paper we take a look at an arithmetic textbook from 1703 called Notabilia Arithmetica that belongs to the holdings of the old school library of a former Jesuit gymnasium in Germany and that was edited there, too. We analyse the book in regard to its content and possible integrated methodical aspects in order to find out more about mathematics education in Jesuit schools in the early modern period. The book shows us that – even though mathematics played a minor role in Jesuit education and was basically limited to Euclid in the general teaching rule – practical arithmetic must have been taught to a considerable degree, so that an arithmetic textbook was a necessary means for teachers.

Keywords: Arithmetic, Textbook research, Educational history, Jesuit education.

Introduction

Notabilia Arithmetica is the title of a small, pocket-sized book from 1703 that belongs to the stock of the Josephine library, that is the library of the former Jesuit gymnasium *Josephinum* in Hildesheim, Germany.

The research presented in this paper is part of an interdisciplinary research project aiming at a broad account of the library stock. So in the first place the focus is a local one. In the second place, though, we aim at embedding our findings in the history of classroom practice. Existing literature on Jesuit mathematics education has been thoroughly reviewed by Diaz (2009). However, research on mathematics education in Jesuit schools in Germany is extremely scarce. Furthermore, Diaz states a lack of research on classroom practice and that the "reality of teaching practices and curriculum […] need[s] […] further scholarship to understand the praxis of the Jesuit system." (2009, p. 65)

Following the presumption by other authors (e. g. Schubring, 1987) that teaching practices are determined by textbooks, we find the *Notabilia* a unique source. What makes it stand out from most other books in store of the library is that it has been edited by Hildesheim Jesuit mathematicians themselves. We may therefore start from the premise that the book was really used in classroom context and that it therefore serves as a source on actual Jesuit mathematics education.

In this paper we take a closer look at the *Notabilia Arithmetica* in regard to possible implications about mathematics instruction in a Jesuit gymnasium. We start by giving some general information on Jesuit education as well as on the history of the *Josephinum* and its library. Following this, we introduce the *Notabilia* itself. We describe its content and take a closer look at indications of purpose and methodical aspects, using the hermeneutic approach. Finally, we contextualize it by drawing comparisons to what other sources tell us about Jesuit education.

The Jesuits’ role in education

Following reformation and – as a consequence thereof – decline of Catholicism in the 16th century, the Jesuits drew on education in order to regain ground. Having officially been founded in 1540, the Jesuits soon started settling throughout Europe and the rest of the world and establishing colleges with associated *gymnasia*. Their education was characterized by a firm und uniform order, which was written down in the *Ratio atque Institutio Studiorum Societatis Jesu* in 1599. The Jesuit educational system became very influential and served as model for schools run by other religious orders, making it a relevant subject of research concerning mathematics education in the 16th and 17th century.

The *Ratio Studiorum* contains rules for the professors of the different subjects, and it is understood that it is due to the major influence of the famous Jesuit Christoph Clavius that mathematics has been taken up as a regular subject in there at all (Diaz, 2009). It was part of a two-year philosophy course, which comprised the subjects of the *quadrivium* and which followed on the grammar course and preceded the theology course. There was a clear focus on religious education whereas mathematics and the natural sciences did not play an important role within the curriculum (Hammerstein & Müller, 2005). This shows in the *Ratio*, as well: the paragraph containing rules for the professor of mathematics comprises less than one page, stating that three quarters of the physics course should be spent on Euclid and some geography or either astronomy in addition. Every month or every second month a mathematical problem shall be presented and discussed with a larger audience, and once a month the contents dealt with in recent lessons should be reviewed.

Generally, the primary aim of education was to have students who were capable of using their acquired knowledge on practical problems. Therefore, repetition, practice and rote learning were important and common parts of scholasticism. Typically, a new subject was first presented in a *lectio*, then further treated in different *quaestiones* and finally memorized and repeated in written exams and *disputationes*. The students’ achievements were regularly publicly displayed and rewarded with prizes. There was a catalogue of textbooks that were supposed to be used in the Jesuit gymnasiums and which were preferably written by Jesuits, too. Hammerstein & Müller (2005) name some of these standard textbooks but none for mathematics.

The *Gymnasium Josephinum* in Hildesheim

A short history of the *Gymnasium Josephinum*

The history of the *Gymnasium Josephinum* goes back to the year 815 when Louis the Pious – son of Charlemagne – founded the diocese of Hildesheim. It started out as a cathedral school located in the dome court, responsible for elementary education and being of high importance in the Middle Ages.

In 1587 the first Jesuit priest came to Hildesheim and by 1595 the Jesuits had established a residence and started a new gymnasium alongside the old cathedral school, first only teaching lower grammar classes. In 1601 the residence became officially a Jesuit college. Due to the Thirty Years’ War the Jesuits were expelled from Hildesheim in 1634 but returned already in 1643 and in the following years the school grew further. It is not before this time that we have knowledge of teachers for mathematics and the natural sciences. Around 1660 a vicar bestowed money explicitly meant for the constitution of four teaching positions for philosophy and mathematics and by 1664 there was at least one specialist teacher for mathematics (Gerlach & Seeland, 1950; Pilz, 1995). By the end of the 17th century the school had been given the name *Gymnasium Mariano-Josephinum*.

Since the Jesuit order was disbanded in 1773 the gymnasium was assigned to the diocese of Hildesheim again and it is still an episcopal secondary school located next to the dome today.

As to the students, already around 1700 there was what we would nowadays call a heterogeneous student body, regarding the region they came from as well as their estate. Besides students from noble or bourgeois origin there were also the poor ones, the *pauperes*, who obtained free housing and who especially the Hildesheim Jesuits were said to take a lot of care of (Pachtler, 1894).

The school library

As early as 1595, the year that schooling was taken up, the Jesuits of Hildesheim also took up establishing an associated library. When they were forced to leave Hildesheim they had to leave the books behind, as well, and when they returned in 1643 they found the library had been marauded in the meantime. They restored it and started collecting books again. Due to donations, gifts and inheritance the stock grew considerably up to about 20,000 volumes. The library got again endangered during the Second World War and indeed the old school building that had housed the library was destroyed in 1945. Luckily, most of the books had been evacuated before to a church outside of Hildesheim. They were only retrieved in the late 20th century, which is why their revision is still ongoing. Today the remains of the Josephine library comprise about 13,500 volumes, a considerable part of which dates back to Jesuit times. The library has been incorporated into the dome library and up to now only about 5000 volumes have been catalogued (Schmidt-Thieme, 2020).

Several mathematical textbooks are part of the stock, not least because Peter Heckenberg bequeathed his private collection to the library upon his death in 1695. Heckenberg who was a vicar and librarian of the Josephine library in the 17th century was himself the author of some of these mathematical textbooks (for further detail see Schmidt-Thieme, 2020). Nevertheless, we do not know the number of these books yet nor what role they played for practical mathematics education.

Standing out, though, are two booklets, both of them pocket-sized and especially noticeable as they were edited by mathematicians of the Hildesheim Society of Jesus themselves, leading to the assumption that these were produced for classroom work and therefore played a role in teaching practice. These are an arithmetic textbook by the name of *Notabilia Arithmetica* from 1703 and an edition of Euclid (*Elementa Euclidis*) from 1704. The latter still needs a closer look at. For what we found so far, it is most striking that we are dealing with an edition of Euclid’s Elements that lacks all the proofs (*sine demonstrationibus* is part of the full title) but all the propositions are basically reproduced. However, this paper deals with the *Notabilia Arithmetica* that seems to be an original work promising to give us further insight into the Jesuit mathematics classroom.

The *Notabilia Arithmetica*

General description

The book's full title is *Notabilia Arithmetica quae Omnem Arithmeticam, ejusque varium usum, cum in aliis multis, tum maxime in Geometricis operationibus succincte proponent* (Notable arithmetic that propounds briefly the complete arithmetic, its various uses, both in many other [things] and in most geometric operations), there is no author mentioned, but named as editors are mathematicians at the gymnasium of the Hildesheim Jesuit society. It has been printed in Hildesheim by Johannes Leonard Schlegel in the year 1703 and comprises 144 pages and 8 further uncounted sheets. Two of these added sheets differ slightly in the two copies that we worked with, so they might be drawn instead of printed. The *Notabilia Arithmetica* is written in Latin. The copy from the Josephine library shows a hand-written note, "biblioth paup 1709", on the title page, suggesting that it has been incorporated into the *bibliotheca pauperum*, the library for the poor students.

The book begins with a foreword dedicated to lecturers (*lectori*) and ends with some further suggestions for lecturers (*monitio ad lectorem*), so it is quite clear that it was written for teachers rather than for students even though it became part of the students' library. It is explicitly called a *compendium* in the foreword, containing only what is necessary, so it was supposedly not meant for the introduction of new topics. The reason given for the booklet's special format (approx. 8 cm x 13 cm) is that this facilitates compiling it with other mathematical textbooks, namely especially some of those written by Peter Heckenberg[1].

The copy found in the Josephine library is not the only copy that has persisted, there are at least seven more: three in the dome library in Hildesheim, one in Hannover as part of the private library of Gerhard Molanus[2], two in Münster and one in Trier, both of the latter being former sites of Jesuit colleges, as well.

Structure and content

Before we go into some focal points, we give an overview of how the book is structured and what mathematical subjects it contains. The content of the *Notabilia* is divided into four parts, each of which comprises several topics, rules and algorithms.

The first part deals with integers and their basic arithmetic operations. It starts with *numeratio* – that is introducing figures and their names – and goes on with introducing meaning and procedures of addition, subtraction, multiplication and division, followed by rabdology, which is calculating with the use of Napier's bones.

---

[1] We have not found any books written by Heckenberg that share the same format yet, the remark might be an explanation, though, why the *Notabilia* and the *Elementa Euclidis* were both edited in this special format.

[2] Gerhard Wolter Molanus (1633–1722) was a professor of mathematics at the University of Rinteln, later abbot of the monastery in Loccum and acquainted with G. W. Leibniz, with whom he exchanged books from his private library.

The second part deals with fractions, starting again with *numeratio*, being followed by the rules for cancelling and the basic arithmetic operations for fractions.

The third part is about arithmetic rules and contains a vast variety of subjects. It starts with a relatively long chapter (*Cap. 11*) on the so-called golden rule, also known as *regula de tri* (rule of three), and goes on with a much longer chapter (*Cap. 12*) comprising 16 common and widespread rules (*Aliae regulae Arithmeticae in vulgari usitate*), such as the *regula falsi* (method of false position), but also rules on arithmetic (e. g. the so-called Gauss sum) and geometric progressions and some combinatorics. The latter indicates Athanasius Kircher[3] as source. The common rules are then followed by some shorter chapters on decimal fractions, some geometric rules (including trigonometry, measuring, planimetry and stereometry), astronomy, chronology (first of all *computus*), algebra (including extracting roots) and bookkeeping.

The fourth part contains various things and we could describe it as comprising miscellanea. It starts with the definition of a number as a manyness composed of unities and some more definitions of special numbers (e. g. odd, even and perfect numbers), which are followed by an overview of population figures (*Cap. 19*). Next are surveys containing currencies, measures of capacity and length, square measures, some geography and chronometry (calendar). For all kinds of measures the local Hildesheim measures are included.

These four main parts are followed by a synopsis of the whole book, condensed in *XII. Propositiones Arithmeticae* and twelve arithmetic paradoxes. The propositions are preceded by a short insertion that seems to be an announcement of a *disputatio* in the school. The booklet ends with an alphabetic index and the aforementioned hints for lecturers. Appended are three arithmetic tables and a geometric one, the latter alongside an explanation.

Quite some things are noticeable about the mathematical content of the *Notabilia Arithmetica*.

First of all it shows a vast variety of subjects, exceeding pure arithmetic by including topics like geometry, metrics, astronomy and geography. The inclusion of the latter can be explained with regard to the *Ratio Studiorum*, where astronomy as well as geography are explicitly named as possible subjects of lesson. As to geometry, there is no reference to Euclid but instead those areas are included that are less theoretical but have a relevance to practical applications. It appears that the same can be said about all the other topics and about the arithmetic chapters, as well. Especially chapters 11 and 12, which are the ones that deal with the rule of three and the other common rules and which therefore have a major relevance for everyday calculations, take up a big part of the whole work (altogether the two chapters comprise 20 pages). It appears that usefulness and applicability have been main criteria in choosing what subjects to include in the *Notabilia* and consequently – as it is called a compendium for teachers – in the mathematics classroom.

Having grown out of a cathedral school and with a religious order being in charge of the school, one could have expected the arithmetic course to stand in the tradition of medieval Christian education,

[3] Athanasius Kircher (1602–1680) was a German born Jesuit mathematician and seems a convenient source regarding that textbooks used by Jesuits should preferably be written by Jesuits, as well.

more precisely to refer to Boethian number theory. As we can see, this is not the case. The only exceptions are chapter 19, which includes some short definitions that resemble those we find in the works of Boethius, and chapter 11 on the rule of three where certain kinds of proportions are defined. Both parts added together comprise no more than five pages and especially chapter 19 stands out from the rest. Instead the content rather strongly resembles the content of the arithmetic books written by Renaissance reckoners.

This prioritization of content seems again plausible with regard to the aims of Jesuit education as mentioned above, namely the ability to apply knowledge and solve practical problems. In comparison to the *Ratio Studiorum*, though, it is striking that arithmetic is not scheduled there at all, let alone to such an extent. The existence of the *Notabilia Arithmetica* therefore serves as a proof that Jesuit mathematics education – at least as far as Hildesheim is concerned – has exceeded the standards by including arithmetic and further practical knowledge to a considerable extent.

Methodical references

Due to the *Notabilia* being a sole compendium, we cannot draw conclusions about the introduction of new mathematical concepts, procedures and propositions from it. But nevertheless, there are features that are interesting from a methodical point of view.

One thing that is noticeable is that several cross references can be found within the main parts of the book so we may assume it was one aim of the author(s) to write a book that was user-friendly. The existence of the alphabetic index and the comprehensive propositions at the end support the impression that the book was meant for practical use and possibly to serve as a reference book that was easy to use.

Another thing that attracts attention is that for some topics, e. g. the rule of three and calculating with fractions, we find guidelines regarding how to do exams and what theory needs to be proven. One example that we will now take a closer look at is chapter 11, the chapter on the rule of three. After different variations of the rule are presented a paragraph follows that is captioned *Regula aurea Examen & Theoria* (p. 40-41). As to exams it is said that the rule should be examined in all its variations, but with an emphasis on the simple rule in opposite to the *regula composita*. Regarding theory, we find standards that are to be followed. First, it is explained for the basic rule, how the figures that are involved in the calculation are interrelated by referring to their proportionality. The proportionality is then used to show how and reason why the fourth figure can be calculated from the other three. The passage ends with *Quod erat demonstrandum*, before the same argumentation is done for the inverted rule. As for the *regula composita* it is stated that it leads to the same problem already treated, a fact that will please the students. This bit creates the impression that a certain students' pleasure is granted. Finally, it is indicated that the majority of the common rules following in chapter 12 can be derived and proven from the rule of three and that it therefore suffices to learn the former.

In this paragraph we find confirmed that there are rules that are to be followed by all (at least all Hildesheim professors), even for an area that is not covered by the *Ratio*. We also find confirmed that exams are an important part of the curriculum, otherwise they would hardly be mentioned in a booklet that comprises only what is most necessary. The emphasis on the simple rules leaves several possible explanations. In the first place, one could take it as evidence for the minor significance attributed to mathematics within the Jesuit curriculum. It might just as well be an expression of time shortage, which is something we must assume considering the small amount of time that the *Ratio* allows on mathematics, even more as it is already exceeded by the variety of arithmetic topics. The explications also suggest another reason, namely the subject's internal material logic that allows us to deduce special rules to basic rules respectively to trace them back vice versa. Altogether the *Notabilia Arithmetica* shows us that despite the emphasis on practical knowledge Jesuit arithmetic education went beyond the pure memorization of algorithmic procedures. Even though a lot of the content reminds us of the Renaissance reckoning books, in this regard there is a considerable difference.

One thing that does not become clear from the remarks on demonstrations is whether they reside only with the teachers or are presented by students, as well. Exams were usually written but another part of the book gives us further insight, namely the aforementioned announcement of a *disputatio* (p. 136), which stand out in a curious way. There are no further comments about it and there is not even space between it and its adjacent sentences. We are only told that the disputation took place on the 5th of September 1702 in the school's public auditorium. Participants are named as *Domin[i] Antonio Fondeux* and *Leo[n]ardo Fischer* and as opponents *Joanne Robeck*[4], *Andrea Antonio Neuhaus* and *Johan. Angelo Schwartz*. We have no further information about the actual event but the announcement tells us that disputations on arithmetic were conducted at all. We may assume that these were events where students were meant to present propositions, proofs and explanations that they memorized from their teacher's demonstrations. The fact that the announcement is exposed in the *Notabilia* might nevertheless be a hint that we are dealing with an outstanding event and that arithmetic disputations did not take place regularly.

Conclusion

We find that the *Notabilia Arithmetica* has been written for teachers of mathematics, as a compendium of the topics from arithmetic lessons and as a reference book for necessary arithmetic knowledge. The *Notabilia* does not serve as a methodical manual for the introduction or development of mathematical procedures or concepts but it does include guidelines on what contents should be proved and how this reasoning was supposed to be done. In addition, it includes instructions on what was to be reviewed in exams. Even though the book was meant for teachers, it became placed at the poor students' disposal. Seemingly, some teacher or librarian regarded it as useful for them, too.

As for the content, the *Notabilia* shows a strong emphasis on practical applicability and computational abilities. This corresponds with the general aims of Jesuit science education but exceeds the standards for the professors of mathematics as we find them in the *Ratio Studiorum*, concerning both extent and topics. We may assume that there was a general need for usable arithmetic knowledge which was satisfied by the Jesuit educators or either a strong reckoning

[4] Johann R. Robeck (1672–1735) from Calmar, Sweden, was a philosopher who is best known for a treaty on suicide for theological reasons.

tradition going back to Renaissance reckoning masters. In any way, Jesuit mathematics education covered much more than Euclid's Elements and it can be assumed that the *Notabilia Arithmetica* arose from practical need for an arithmetic textbook that presented the subject matter in short and that served as a kind of teaching aid for lecturers, just as the *Elementa Euclidis* did for Euclidean geometry. This assumption is supported by the apparent absence of a standard textbook for mathematics and especially elementary arithmetic in the catalogues of such standard books. The fact that the book seems to have found its way into other Jesuit colleges, as well, might be another instance showing us that a textbook that summarized arithmetic was required for teaching practice.

This paper is just a starting point from which much more research on the topic needs to be done. Such future research must include analysis of and comparison to further books from the Josephine library and locating our findings in the broader context of Jesuit education. The latter comprises the more general context as well as special ideas concerning mathematics education, in particular those of Christoph Clavius (for more details on the role of Clavius see Diaz, 2009).

Initiate reflection by original sources – Conception and empirical evaluation of a teaching project in calculus class

Rosmarie Junker[1] and Susanne Spies[2]

[1]Gymnasium Netphen, Germany; junker@gymnasium-netphen.de

[2]University of Siegen, Germany; spies@mathematik.uni-siegen.de

One effect of working with original sources in mathematics classes that is repeatedly mentioned is the stimulation of reflection on mathematics and, as a result, a change in the students' mathematical beliefs. In the context of the teaching project presented here on working with Bernoulli's first textbook on calculus, this could be impressively confirmed empirically by means of a qualitative study. The article is dedicated to the conception of the teaching sequence, as well as first results of the empirical evaluation, and also poses the question of the conditions for dealing with original sources in a digital setting in a reflection-stimulating way.

Keywords: Beliefs, Calculus, Original sources, Reflection.

Working with original sources as a unique tool

The integration of the history of mathematics can not only contribute to the acquisition of process-related competencies and deeper understanding of the role of mathematics in the world as required by the curriculum, but also promises meaningful experiences with mathematics. Potential opportunities as well as difficulties depend strongly on the type of historical references used and also on the method chosen. Therefore, with regard to the teaching project discussed here, we first take a special focus on the motivations and problems specific for working with historical sources. Working with historical sources not only makes it possible to learn something about the history of the subject, but, if the source is chosen appropriately, it also offers the rare opportunity to gain insights into real (historical) research work in mathematics lessons. Thus, authentic insights into the thinking and working of researching mathematicians become possible. The ICME Study (2000) in this context lists three motivational fields: "replacement," "reorientation," and "cultural understanding" (Jahnke et al. 2000, p. 292). Thus, especially the work with historical sources is said to have the possibility to complement the learners' beliefs of mathematics by the aspect of mathematics as a process and human cultural achievement and thus to contribute to a more comprehensive picture of mathematics among the students. This initially theoretically expected outcome could also already be confirmed in various empirical studies and traced back to experiences within the history of mathematics (cf. e.g. Jankvist, 2015, or the approaches referred to in Bütüner, 2015). Furinghetti et al. (2006) implicitly take up this and add two further aspects to the three prominent points mentioned above: In addition to the opportunities for deeper understanding they also address potential problem areas. On the one hand, a historical text cannot be completely grasped on the first reading, and the interpretation is not clearly right or wrong, unlike what we are used to in mathematics classes. On the contrary, a hermeneutic, discursive approach like known from humanities is required here, which is clearly different from the ordinary experience in mathematics classroom and to which both the learners and the teachers must be prepared. This is also true for the different levels of language, which have to be switched between, if mathematics from the source is to be connected with today's school mathematics. The differences are to be made fruitful as an irritation that promotes understanding. The language competence necessary for this is certainly a high hurdle for many students, to which appropriate assistance must be provided. However, if these hurdles, created by the difference of mathematical representation in historical texts, are taken up and (at least partially) overcome, it is precisely these differences that offer the opportunity to reflect on the mathematics we have known so far and to enter into discussion:

> "Sources from mathematics history that defamiliarize the familiar arouse epistemic curiosity and trigger reflections in the classroom in a natural (intrinsic), effective, and performance-enhancing way." (translated from Glaubitz, 2010, p. 30)

This thesis particularly emphasizes the role of the source as an occasion for reflection on mathematics at various levels (see below).[1] To summarize the motives outlined here, mathematics history especially by working with original source-texts does not function first as a “tool” (among others) for learning mathematics (cf. Jankvist, 2009), but rather as a (possibly unique) tool on the way to a valid image of mathematics and to meaningful experiences in mathematics education.

With regard to teaching practice, at least two research questions are following: Is there empirical evidence for the claim that working with historical sources leads to increased reflective competence? And if so, which conditions for success can be named? In order to answer these questions, we will first present a project in calculus classes in a digital setting and after that discuss the empirical evaluation of student products with regard to different levels of reflection. Finally, first conditions for success for a reflection-oriented (digital) use of historical sources in mathematics lessons will be derived from this project.

A teaching project on Bernoulli's differential calculus

We are convinced that the opportunities described will not happen by themselves. Rather, good methodological framing is necessary.[2] This is especially true if the use of sources does not take place in face-to-face lessons, but must take place in a digital setting. How this can be done successfully is shown by the project presented below, in which the source work was rather closely guided and methodologically accompanied. As meant by the hermeneutic approach to original sources (cf. Jahnke, 1991) the project was organized as the ending of the “normal” calculus series in Q1 (Grade 11 in German Gymnasium) in an mathematics course of a manageable size with 18 students. The course is characterized in particular by the fact that almost all students have at least average mathematical competencies. Only three students deviate downwards in this respect. In addition, the course as a whole shows a high willingness to perform and a readiness to engage with unusual content and methods. In contrast to the teaching project on Bernoulli's differential calculus

---

1 Reflection on mathematics and its relationship to environment, and the individual is repeatedly seen as a contribution to general mathematics education (cf. Bauer, 1990, Skovsmose, 1998 or Lengnink, 2006).

2 For a discussion on possible methods for introducing and reading historical texts in general see Junker & Spies (2020).

presented by Jahnke (1995), our project started by a specific introduction to the historical context of the source dealt with. In addition, hermeneutic reading of the source was guided to a greater extent than was intended by Jahnke. Due to the corona-related school closure, the project ultimately took the form of a digital guided source study in which the focus was on a sort of “interrupted reading” (cf. Metz et al., 2007) of the source excerpts flanked by work assignments.[3] These consisted of reproducing the newly learned historical procedures and tasks aimed at tracing Bernoulli's argumentation in detail and clarifying the unfamiliar historical terminology. This was accompanied by writing assignments. Due to the fact that there was no possibility for direct interaction while working, the formulations of the assignments were very small-guiding and pointing the students to the criucial points explicitly. Students were required to submit their assignments and each received individual feedback on their results. Questions regarding the content could also be directed to the teacher at any time via e-mail. At the end of each work block, explanations and answers were provided for everyone in various digital formats in response to questions asked and uncertainties observed. In this way, questions and uncertainties of individuals could be answered and at the same time productively turned around for the other students. By this at least indirectly the group was addressed despite the isolated way of working at home.

The project was introduced with a podcast that was supposed to introduce the students to the mathematical-historical situation around 1700 related to the beginnings of differential calculus and the scientific debate between Johann Bernoulli and his colleague Marquis de l'Hospital. The podcast did not yet contain mathematically relevant details, but served mainly to give the students an insight into the possibilities of scientific exchange and to point out the special situation between Johann Bernoulli and l'Hospital (cf. Jahnke, 1999). The format of a podcast was chosen in order to preserve, in the spirit of “StoryTelling”, the character of oral storytelling and its advantages over a read story (cf. Alchin, 2011 or Heering, 2016), even in digital format. Furthermore, the constellation described in the podcast could be taken up again at the end of the series by asking the students themselves to enter into a scientific exchange with Johann Bernoulli as l'Hospital. In order to prepare the students for the unusual fact that Johann Bernoulli did not use the representation of functions in a coordinate system to introduce the differential, an excursus was made on the possibility of constructing parabolas without a coordinate system. In several explanatory videos, the students were given the opportunity to reproduce such a parabola construction using only compass and ruler and to repeat relevant mathematical content (Thales' theorem and the geometric mean theorem). This was followed by an initial view in Johann Bernoulli’s Text - an excerpt in German translation from the work "Die Differenzialrechnung" (Schäftlin, 1924), which dealt with the introduction of the postulates fundamental to his work as well as the derivation of the differential of the quadratic function. In a small-step, task-guided analysis of the short source excerpt, the students should interpret the derivation of the "rule of derivation" for parabolas geometrically. On the one hand, this rather small-step approach to Bernoulli's geometrical way of reasoning is due to the experience that even advanced mathematics students showed great problems in leaving the context

3 Due to limitation of space we can’t present the tasks and materials in detail here. An english translation of some of the used texted in and classassignments is available online via https://www.uni-siegen.de/fb6/phima/mu/schulprojekte.html

of 'function, coordinate system, function graph' and following the geometrical arguments when working with this source (cf. Spies & Witzke, 2018). On the other hand, even in high school students usually have little experience in approaching a mathematical text independently, which is especially true for historical mathematical texts. The questions posed in the tasks thus exemplify to the learners how such a text can be approached, how deep one has to turn to each character with 'pen and paper' in order to really understand the mathematical argument. Through the questions asked, the repeated reading and the repeated comparison of what is read with one's own - in this case elementary geometric - (pre-)understanding, i.e. the reading in the hermeneutic circle is instructed.[4] This example shows, however, that the difference between "mathematical reading" and the reading of texts in the humanities or fiction, for example, can be experienced at least implicitly in the intensive examination of historical texts and thus a reading competence is trained that is indispensable for later (mathematics) studies. Because for Bernoulli's work, the notion of differential is of central importance, this initial source work was concluded with the task of writing a fictional entry for Diderot and d'Alembert's Encyclopedia of Knowledge on the meaning of the term differential. The genre of the encyclopedia article calls for the formulation of thoughts in an educational language, thus leaving behind both the level of (historical) technical mathematical language and individual linguisticization in the process of understanding. The change of language level not only initiates reflection on content, but is also considered an educational goal in mathematics education (c.f. Jahnke, 1991, p. 8). Besides, this task also points to the encyclopedia as a work that shaped the science of the Enlightenment and, with Diderot and d'Alembert, at least to two other greats of the time. In order to bring the students to a common level of learning for the following tasks, an explanatory video was created afterwards, in which the problems of understanding that had become apparent in the processing of the tasks, especially with regard to the concept of the differential, were taken up and attempted to be solved. Following the derivation of the differential, the first task from Bernoulli's textbook was to be reproduced, namely the construction of the tangent line to a parabola point. Here, too, we decided on a small-step, question-guided analysis of the source aimed the independent construction of a tangent to any parabola point. The tasks in this block are intended to sharpen the eye for the peculiarities of a geometrically reasoning calculus: While in school lessons, in which the slope of a tangent at a given point x0 is searched for or the derivative function is to be determined, Bernoulli solves the classical ancient, geometrically formulated tangent problem for a conic section. Thus, a second point is to be constructed for an arbitrary curve point in order to be able to construct the tangent line in this point on the basis of Euclidean geometry. The term "subtangent" mentioned Bernoulli‘s solution is an example of a mathematical term that was mathematics-common at the time and in the context of Bernoulli's argumentation, but which is unknown in (school) mathematics today. Here the students can also experience a development of mathematical terminology. By asking the students to construct the tangent line on their own at the end, it was at least possible to ensure that those students who were able to do so had a rough understanding of the theory. Just as after the first

4 For the students in the project it was the first time to deal with historical sources in mathematics classroom. Perhaps there is no such small-steped guidance necessary if there is more experience in hermeneutic reading and if the teacher has the possibility to interact directly with her students.

source work, an explanatory video was after this block, too, which was supposed to answer questions of the students that arose during the processing of the source work and which tried to solve problems of understanding that appeared in the students' results.

To conclude the project, the students should now take on the role of l'Hospital themselves and enter into a fictive scientific exchange with Johann Bernoulli. In a letter, they were to address their questions regarding Bernoulli's procedure for the determination of differentials and the construction of tangents to Bernoulli, by comparing their newly acquired knowledge with their previous ideas of differential calculus.[5] This task also served the purpose to ask last open questions for understanding. It is noticeable that the letter form was well received. Most of the students kept the letter form given at the beginning in their own texts and obviously enjoyed writing down their thoughts in this style. The questions and reflections touched on a very wide range of topics: They ranged from questions about concrete conclusions in the source excerpt read, to astonishment about the geometric method of constructing and discussing curves and the validity of Bernoulli's postulates, to the question of why this type of calculus is not part of the curriculum. At the end a response from the teachers again as a letter on behalf of Johann Bernoulli addressed all of these issues and collected questions from the students to address and clarify. Obvious misconceptions were addressed and could be cleared.

Levels of reflection within the students letters – Qualitative content analysis

The students' letters to Johann Bernoulli are written testimonies that in a certain sense document first effects of the source project. The "scientific exchange" in the letter format also leads to relatively open and personal formulations of the thoughts. The students' documents thus allow conclusions about the extent to which the source work actually led to reflections on mathematics. In order to examine the students' letters in a structured way the documents were read following the method of qualitative content analysis (Mayring, 2002). The units of analysis thereby resulted from the sections of meaning within the letters. Guided by the expectation to find testimonies of personal reflection on mathematics, the levels of reflection also formulated by Glaubitz (2010) following Bauer (1990) were first used as deductive categories: the object level, which contains both the reflection in the mathematical work and the reflection on the object, directed "to the essence of the discipline". Furthermore, there is the level of meaning, which includes the reflection on the meaning of working with mathematics as well as the reflection on the meaning and limits of mathematical thinking itself. And finally, the level of self-reflection, which contains the reflection about the effects of the occupation with mathematical contents on the possibilities of the own thinking and acting as well as the reflection about the role of mathematics for the own person and the own self-conception. As a result of a first review of the material, the object level was again divided by us into three levels and thus the category catalog was inductively expanded. On the one hand, there is the level in which mainly a comparison of different mathematical methods and approaches is made (level I). Furthermore, we distinguish here a level in which thinking about a transfer of mathematical approaches and methods to obvious questions and problems beyond the treated mathematical problem takes place (level II). And as a third level we have singled out the level that

5 While the previous are past-related tasks, this writing task is a present-related task in the sense of Schorcht (2018).

involves reflection on the question of the genesis of mathematical content and problems (level III). These sub-areas of the subject level correspond at the same time to different requirement areas of mathematical tasks. With this subdivision, we thus map the very different levels of object reflection that are visible in the letters. The analysis of the letters based on these categories show that each category can be found in several examples[6]. So one can be justified in hoping that the treatment of also historical perspectives and contents in mathematics lessons can reach the most diverse levels of reflection. Almost all of the students' letters contain expressions such as "exciting," "surprised," "impressed," or "interesting,". This shows that the confrontation with historical mathematics also had an emotional effect and that, similar to the reflection on aesthetic experiences with mathematics (cf. Müller-Hill & Spies, 2015), meaningful experiences are documented here as well. Furthermore, these are all clear indications that most of the students were able to use the series of lessons to restructure their own understanding of mathematics and its meaning, to add new aspects, and to expand their repertoire of ways of thinking about mathematical questions. Through the analysis of the letters to Bernoulli, we can thus assume that the students' engagement with the mathematical content was stimulated at various levels, some of which were high, and also at structurally different levels. This provides further empirical evidence for the theoretically assumed effectiveness of historical sources in mathematics education.

Suggesting conditions of success (not only) in a digital setting

The evaluation of the final letters shows that the students were stimulated to reflect deeply on a wide variety of levels through their intensive engagement with the historical source material. This finding is nevertheless astonishing, since often in particular the direct exchange about the readings of the learners among themselves and with the teacher as well as the openness of the task in the context of the hermeneutic method is described as a special moment, which stimulates the reflection in the first place. However, precisely these aspects of the source work had to be omitted in the digital implementation of the project. Therefore, in conclusion, some methodological conditions will now be discussed here, which allow historical source texts to become an occasion for reflection in mathematics lessons even in the digital setting.

Working with original sources requires a framework that can both convey a sense of the historical context and motivate work with the historical text (which is usually outside the curriculum). In a digital setting, this might be done with the help of a podcast, a historical documentary, or an introductory text. Depending on the format chosen, a more or less differentiated picture of the historical context is drawn. A deeper understanding of the source continues to be a necessary basis for successful reflection. This in turn requires that on the one hand the professional as well as the historical preconditions are given in order to be able to do something with the historical mathematics. In the project described, a first important step was to introduce the students to the geometric construction of the parabola in order to be able to recognize the geometric-analytical arguments in the source text as such. So the alienation effect of the source does not become a barrier to understanding. In a digital setting, such an introduction can take place, for example, via an

6 Cf. Junker & Spies (2020) for exemplary quotations for each category

explanatory video or a text flanked by tasks. On the other hand, a more in-depth individual engagement with the text is necessary. As described above, we believe that this cannot be initiated by a simple reading assignment, at least in a digital setting, but requires questions that guide the reading, encourage repeated reading, and draw attention to the central parts of the argument. Although such guidance in face-to-face classes can, of course, happen in individual exchanges, one advantage of the digital course emerged here: All students could (and had to) work intensively on the sources on there own. Thus, the work was done at the individual pace and each individual had the chance to experience that he or she is able to work out a completely unknown content and to comprehend the unfamiliar mathematical way of reasoning, since there was simply no possibility to have a contact person immediately in case of difficulties in understanding or to wait until the issue is clarified in the plenary. Even if the experience of competence and deeper understanding is certainly an important basis for a successful reflection, the direct exchange is naturally missing in a purely digital setting, which in turn would have led to fruitful discussions and reflection about the subject matter. In order to move from an in-depth reading of the source excerpt to reflection on what has been read, the mathematical argumentation must be left behind and the meta-level must be taken up. This also needs to be instructed. In the digital setting, this step can be stimulated, for example, by writing assignments, as it was done in the project presented here by the encyclopedia entry on the differential and the concluding letter. It is important to choose a form that stimulates the change of language levels in a natural way and also encourages the students to connect the historical argumentation with their previous knowledge. Again, the advantage of the purely digital setting is that own thoughts have to be formulated individually. On the other hand, there was no need for communication about the individual results, which would certainly have led to fruitful discussions, since ideas can be taken up directly, thought through further and then formulated together. The experiences in the presented project show that source texts can also become an occasion for reflection in a purely digital format if the discussed conditions for success are met. Above all, the experience of (guided) individual engagement with the text and writing about mathematics turned out to be important factors for successful reflection. The missing exchange about what was read could at least in part be taken up by direct feedback and interposed explanatory videos, even if here of course the potential can only be exhausted in real communication about historical mathematics. It can therefore be assumed that a combination of digitally guided intensive individual source work and the exchange about it in face-to-face lessons with a subsequent writing task to be worked on individually would be a format that could strengthen the observed effects and that the "foreign and bulky" of the source texts could be used productively in class.

Concurrence of two mathematics worlds in the Netherlands, 1600 and beyond

Jenneke Krüger

University of Utrecht, Netherlands; j.h.j.kruger@uu.nl

In the early 17th century at the University of Leiden, mathematics courses in the Liberal Arts and a mathematics course for surveyors and engineers in Dutch language existed peacefully next to each other, with some pathways between them. The reasons for this unique situation, the relation between the different mathematical courses and the characteristics of the Dutch language course are discussed. The design of the Dutch language course has some aspects in common with modern curricula. Two questions arise. Did this course influence the mathematics education in the next centuries? Was the Dutch language course a first step towards the development of mathematics as a school discipline? The second part of the paper attempts to find answers to these questions.

Keywords: History of mathematics education, mathematics for practitioners, engineering school, mathematics as school discipline, mathematics teachers.

Introduction

Towards the end of the 16th century two different worlds of mathematics and mathematics teaching may be distinguished in North-western Europe. One was the learned world of mathematicians at universities, at other institutes of learning, or working independently, whose object of study was the mathematics of the Greek mathematicians, their translators and commentators. It was a world of theory, in which an increasing number of ancient works became available for study, encouraging the development of mathematical theory. The language of communication was Latin, obligatory at all universities, the language of the men of learning. Mathematics teaching formed a part of the Liberal Arts, the general education as a foundation for the higher faculties. The students followed at least lectures on pure mathematics (number theory and Euclidean geometry), sometimes followed by mixed mathematics, subjects such as astronomy, mechanics, and cosmography.

The other world was the practical world of the common people, practitioners who didn't know Latin and who used some mathematics as a tool in their working life. Their grasp of mathematics might be extensive, but often it was very limited, without much theoretical background. In this practical world of surveyors, bookkeepers, building masters, military architects, traders, navigators, etc. there were as yet no teaching institutes. Private instruction by reckonmasters, self-instruction and learning at work were the main avenues to mathematical knowledge. The mathematics taught was primarily practical, without much attention to mathematical theory, confined to routines that seemed to work in a specific situation.

This changed in Leiden around 1600, at the university, which was established in 1575 as the first university of the northern Netherlands. The mathematics lectures, in Latin, in the Liberal Arts faculty were taught by Rudolph Snellius, while from 1600 a Dutch course for surveyors and military engineers flourished, under responsibility of the University and taught by university professors. This last course became known as Duytsche Mathematique (*Dutch Mathematics*). The reasons for this unusual situation, some characteristics of and the relations between the two mathematics form the subject of the first section of this paper. Two questions arise.

1) Are influences of the characteristics of Duytsche Mathematique recognisable in mathematics education in the Netherlands during the 17th and 18th century?
2) Was the engineering course an isolated incident or a first step towards mathematics as a school discipline?

Following (Chervel, 1988; Cardon-Quint & d’Enfert, 2017) a school discipline is taken as a subject taught in institutes, with specific teaching and learning goals, development of specific content partially independent of academic mathematical sciences, dedicated teaching methods, learning means, tests and examinations and taught by a body of professional subject teachers.

Mathematics teaching at Leiden University in the early 17th century, an innovation

The governors of the new Leiden University did their utmost to invite humanistic scholars with a good reputation to become professor in Leiden. As was the case in the older renowned universities, the theoretical framework for the faculties consisted of the works of Greek and Arabic authors, such as Aristotle, Euclid, Ptolemaeus, Hippocrates, Galenus, Avicenna and Averroës (Otterspeer, 2008). Justus Lipsius, Joseph Scaliger and Claudius Salmasius were some of the more famous scholars who came to Leiden, in return for a very good salary, free living and exemption of the obligation to give public lectures. Their names warranted quality of the university; they were expected to attract many students.

The first appointments were in the three main faculties: Theology, Law and Medicine, followed by Literature and Languages (classical and eastern) and Philosophy. Mathematics had a low priority; during the first years there was no professor for the undergraduate mathematics courses. In 1581 Rudolph Snellius (1546-1613) was appointed, a graduate in the Liberal Arts of the Calvinist University of Marburg. In Marburg he became an enthusiastic follower of Petrus Ramus (1515-1572), the French humanist and educational reformer. Ramus had proposed a shorter, well-structured curriculum, which combined theory with practical exercises. For mathematics he proposed to teach only those parts of Euclid and other authors which were useful to the students and to combine theory and practice (Wreede, 2007).

Snellius was not the only follower of Ramus at Leiden University, moreover he favoured teaching a variety of authors, both the ancient and modern. Some of the authors he taught were Ramus, Valerius (*Physica*), Euclid (*Elements*, *Optics*), Maestlin (a follower of Copernicus) on cosmography and astronomy, and classical authors such as Aratus, Proclus and Plinius (on geography). Being a Ramist meant he would be inclined to value mathematics used for practices on its own merits. Around 1605 Rudolph gave lectures on geometry, geography and optics, his son Willebrord assisted him with lectures on arithmetic and astronomy. Willebrord Snellius (1580-1626) was taught by his father, he also was a student of Ludolf van Ceulen (see below) and of Joseph Scaliger. He went on to become a highly praised and very productive mathematician, who succeeded his father in 1613 (Wreede, 2007).

Towards the end of the sixteenth century the commanders of the Dutch army, Maurits van Nassau (1567-1625) and Willem Lodewijk van Nassau (1560-1620), realized they would need many more mathematically trained engineers and surveyors to maintain their military advantage over the Spanish army. There were a few mathematically knowledgeable military engineers such as Adriaan Antonisz. and Samuel Crop and some practitioners such as Ludolf van Ceulen, who based their practices on sound theoretical mathematical knowledge, without knowledge of Latin, but they were few. Maurits, son of Willem van Oranje[1], had been a student at Leiden University, where he met Snellius and a fellow-student, Simon Stevin (1548-1620). Stevin, a good mathematician and engineer, became the tutor, quartermaster-general and principal advisor of Maurits. Together they convinced the curators of the University of Leiden to establish a separate course in Dutch language for surveyors and military engineers, the Duytsche Mathematique. It started officially in January 1600 with a curriculum prescribed by Stevin in the *Instruction*. Stevin designed an efficient curriculum, with the content, teaching methods and work forms prescribed. Theory preceding and alternating with practice; a method of study very much favoured by Stevin (Krüger, 2015). The course itself, the use of a written curriculum and the teaching language were an innovation.

The first professors who taught Duytsche Mathematique were Ludolf van Ceulen (1540-1610) and Simon Fransz. van Merwen (1548-1610). Simon Fransz. Van Merwen was a surveyor and burgomaster of Leiden. Ludolf van Ceulen was a respected mathematical practitioner, who taught mathematics and fencing and served on some committees advising the government. He didn’t know any Latin but was very accomplished in geometry. He is best known for his calculation of the first 35 decimals of π. Van Ceulen passed away in December 1610, whereupon his former student, assistant, surveyor and army engineer, Frans van Schooten, continued the lectures and the practice sessions in the field. At first as a temporary lecturer, from 1615 as professor Duytsche Mathematique (Krüger, 2018). His extensive and well-illustrated lecture notes[2] (BPL 1013) provide information on the content, structure, and didactic approach of the course. Van Schooten followed broadly the *Instruction,* with some adaptations and with deliberate didactics. In BPL 1013 calculations of roots, using decimal numbers is followed by some geometry and the principles and practice of surveying. This is followed by advanced surveying techniques, advanced geometry, calculations of volumes and wine gauging. Students who had come this far could take an exam to become an admitted surveyor, Rudolph Snellius had been an examiner on behalf of the university. The second part of the lecture notes is about fortification, defined by Van Schooten as the art to build and defend fortifications as well as the art to attack and conquer fortified places.

In 1646 Frans van Schooten Sr. was succeeded by his eldest son, Frans van Schooten Jr., a very talented mathematician, who edited a new edition of Viète’s work and translated Descartes’ *Geometry* into Latin. He used the lecture notes of his father, but also gave lectures on logarithms, algebra, and sundials (Dopper, 2014). Though Frans Jr. was more a scholar than a practitioner, he

[1] Willem van Oranje was the leader of the Dutch revolt against the Habsburg rulers, until his murder in 1584.

[2] BPL 1013, University Library Leiden, special collection

maintained contacts with surveyors and engineers, even if he was not himself a surveyor and engineer as his father had been.

Ludolf van Ceulen, Simon Stevin, Willebrord Snellius and Frans van Schooten Sr. all served as examiners for the admission of surveyors in the province of Holland (Krüger, 2014). In the academic lectures the professors taught the theory of mathematics as developed by Greek and Arabian scholars and their interpreters, with Latin as teaching language. The Duytsche Mathematique on the other hand taught which mathematics to use and how to use it in specific practical situations, with Dutch as teaching language, in interaction with practitioners. In Leiden, during the first half of the 17th century these two mathematics programmes, with different aims and content, existed peacefully together with links between them through the actors involved. Many factors, political, social, personal, were at the basis of this unusual situation.

Mathematics education during the 17th and 18th century

In 1681 the Duytsche Mathematique was abolished. It was reintroduced in 1701, as a theoretical university course, taught by a lecturer and it never regained the fame it had in the 17th century. Until well into the 19th century mathematics remained a rather unimportant part of the undergraduate program. However, the interest of university professors in technical applications increased. For example, civil architecture, hydraulics, steam engines, windmills, optics, navigation, and fortification were at one time or another subject of lectures at the universities of Leiden, Franeker and Utrecht (Krüger, 2014).

In society the notion that mathematics was relevant for many crafts and professions gained acceptance. In primary schools there was a gradual improvement in the position and quality of arithmetic teaching. Virtually every village and town had at least one primary school, for which the local government was responsible. In the more ambitious towns mathematics formed part of the comparative examinations for a teaching post, a mathematics journal for teachers was published from 1754 (Krüger, 2019). Between primary education and university education the contours of on the one hand general education, on the other hand vocational education became visible.

General education as a preparation of boys for university took place in Latin schools and Illustrious schools. In so-called French schools general education prepared the sons and daughters of well-to-do citizens for their position in society. Latin schools offered no mathematics or sciences, Illustrious schools offered a range of subjects in Latin, but some mathematical topics were taught in Dutch. Examples are fortification and navigation at the Illustrious school in Amsterdam from 1743-1762; geometry, arithmetic, algebra, and fortification were taught at the Illustrious school in Deventer from 1690-1727. The mathematics taught in French schools depended on the headmaster-owner. In all these institutes the content was mainly determined by the teacher and was theoretical, though teaching applications. There was no formal curriculum for any type of school.

The perceived relevance of mathematics for many professions and crafts was reflected in the relative abundance of textbooks being printed and in the existence of many small private schools and teachers offering private mathematics lessons (geometry, navigation, fortification, bookkeeping, etc.). Naval colleges were established to teach mathematical skills to navigators and from the late 18th century drawing schools and lessons in mathematics and drawing in orphanages became more common. Both in vocational training and in general education, mathematics teaching was haphazard, depending on initiatives and skills of individuals, with no written curriculum nor a system of examination. Neither was there a group of professional mathematics teachers (Krüger, 2019). However, from 1756 onwards the three institutes of the Foundation of Renswoude were comparable to the Duytsche Mathematique. In these institutes, in The Hague, Delft and Utrecht, talented orphans received a combination of professional training, based on mathematical subjects, and general education. From the start governors and mathematics teachers formulated a curriculum with subjects, aims, theory preceding practice and alternating with practice, examinations, textbooks, and other materials for the students. The first mathematics teachers had good contacts with many different practitioners, there were also contacts with professors at the Universities of Leiden and Utrecht (Krüger, 2013).

Unlike the situation in some other countries (Karp & Schubring, 2014) the Dutch government did not establish primary, secondary, or vocational institutes, until the end of the century (Krüger, 2019a).

Mathematics: a school discipline in general education

During the 18th century, under the influence of French authors, mathematics gradually was considered as formative for the development of the mind, to learn to reason clearly and with use of logic. As a result, when around 1800 education became the responsibility of the national government, mathematics was on the agenda. Primary education was regulated first, in 1806; arithmetic became a compulsory subject. Moreover, all teachers had to pass exams, including arithmetic, to be allowed to teach and the inspectorate became rather important in the acceptance of modern ideas with regards to content and methods. From about 1820 the development of mathematics as a school discipline becomes noticeable: textbooks specifically for use in (extended) primary schools, specialized journals, teachers specializing in mathematics and authors discussing teaching methods (Krüger, 2019). The authors might be teaching at the Royal Military Academy, at French schools and other private schools, at naval schools and other similar institutes or they belonged to the group of primary school teachers in the highest rank, who had specialized in mathematics. Those who became proficient in mathematics could improve their position (Smid, 2019). The regulation of secondary education had to wait until 1863. At least until then there existed a patchwork of private and council schools, extended primary schools and vocational institutes, all teaching some or quite a lot of mathematics, with textbooks written by some of the teachers.

From the start of the 19th century mathematics was seen by regulators, inspectorate and others as belonging to general education, with a formative value in sharpening reasoning faculties. On the other hand, for many people the main aim of teaching mathematics was to prepare for crafts and professions. In their opinion the emphasis of teaching mathematics ought to be on mathematics used in professions and how to use this. Tensions between these aims surfaced occasionally, as in the case of Jacob de Gelder, a highly praised mathematician and teacher, author of many textbooks (Beckers, 1999). In 1819 he left the School for Artillery and Military Engineers after serious disagreement with the director, a military man, about the amount and level of mathematical theory which was taught (Krüger, 2019a). Another example is the appearance of an arithmetic journal aimed at crafts men and farmers, as the calculations at primary schools were deemed to be too exact and rigorous for daily practice (Krüger, 2019). Indeed, most pupils would enter the workforce after leaving primary school and learn a craft. The development of mathematics as a school discipline, visible in the first half of the 19th century, received a strong impulse through the regulation of secondary education in 1863. For general education two new types of school were introduced, of which the Hogere Burger School[3] (HBS) would become the most influential (Krüger, 2014). At the HBS the students were taught a range of subjects, with sciences, mathematics and modern languages taking up many hours in the timetable. The school had as one of its aims preparation for the Polytechnic School, also established in 1863, the successor of the ailing Academy for civil engineers (Krüger, 2019a). In the early years of the HBS mathematics included subjects such as mechanics, use of technology, cosmography, and line drawing, next to arithmetic, algebra, geometries, and trigonometry. The development of a group of professional mathematics teachers got a strong impulse through the HBS. Gradually topics such as mechanics and cosmology disappeared from the mathematics curriculum. From the last quarter of the 19th century there were discussions about the content of the curriculum, the teaching methods, examinations and the merit of various textbooks. The teaching was theoretical, the use of mathematics in practice was delegated to the final years of Engineering Studies. At first, many mathematics teachers had a background in military or civil engineering, gradually most mathematics teachers had a degree in mathematics, but no experience with the use of mathematics in practices.

Discussion

Are influences of the characteristics of Duytsche Mathematique recognisable in mathematics education in the Netherlands during the 17th and 18th century?

As described in the second section, during the 17th and 18th century there was a growing awareness of the relevance of mathematics for numerous practices. Illustrious schools, small private schools and private teachers offered the teaching of mathematics to use in practices, or as part of general education. Mostly these programs or schools lasted at most a couple of years and details of the content are unknown. The only known example of a programme which showed some of the characteristics of the Duytsche Mathematique is the curriculum of the Foundation of Renswoude. The three institutes of this Foundation resemble Duytsche Mathematique in the combination of theory and practice, the structure of the programme, the interaction with practitioners and the relative success; moreover, professors at the universities of Utrecht and Delft occasionally served as examiner for the Foundation in Utrecht and Delft (Krüger, 2014).

Another sign of the awareness of relevance of mathematics for practices is the publication of numerous books on mathematical subjects, both the fundaments and the practices. Books on practices offered some mathematical theory; further research is necessary to determine the relevance and the depth of the treatment of mathematics in these books.

[3] *Higher Burgher School,* meant for the sons of middle- and upper-class citizens

Was the Duytsche Mathematique an isolated incident or a first step in the evolution of mathematics as a school discipline?

The engineering course, the Duytsche Mathematique, at Leiden University was at the time innovative, due to the teaching language, and the way it was designed. A written curriculum, prescribing content, teaching methods, work forms, theory preceding practice and alternating with practice, is reminiscent of mathematics as the present-day school discipline. However, while the teaching method as seen in the manuscript by Frans van Schooten Sr. shows strong didactics, directed towards the needs of the students, the content was mostly aimed at the practices of surveying. Not all of it, there are geometry examples which do not seem relevant for surveying or engineers but are mathematically interesting. Also, there are indications that the practice somehow disappeared from the course, Frans van Schooten Jr., an excellent mathematician, seems to have concentrated on teaching and expanding the theory of the subject, with theoretical exercises about the practice of surveying, application of theory, as opposed to exercises in the field, using mathematics. One could say that Duytsche Mathematique showed some characteristics of a future school discipline, however it may also be seen as a forerunner of Engineering Studies.

The first example of a possible development of mathematics as a school discipline in the 18th century is given by the Foundation of Renswoude. The programmes of the three institutes started coordinated, with some contact between the teachers in the three towns, with theory as the basis for practice. Interaction with practitioners was relevant for the programme, which could be described as a combination of general education with vocational training.

General education, with mathematics as a permanent factor, gained terrain from the start of the 19th century, in the form of primary education. This was followed in the second half of the century and in the 20th century by secondary education and the first years of vocational training. General education is theoretical, mathematics is about theory of the school subject, formulated in its own language and applied to theoretical examples. The use of mathematics, which mathematics to use and how to use it, is rarely or not at all experienced in general education and there is no interaction with professional users of mathematics.

Was the Duytsche Mathematique a first step in the evolution of the school discipline? Yes and no. It was more an example to follow than a first step; the Dutch society was not yet ready for more or less autonomous school subjects. A hundred years would pass before schoolteachers started to specialize in mathematics and another hundred years before a recognizable body of mathematics teachers became visible. They formulated opinions about the mathematics teaching programme, produced teaching materials and contributed to the formation of the school discipline, losing the interaction with professional users of mathematics in the process. Meanwhile the two worlds of mathematics from 1600 blurred and branched in many different ways, developing into a rich and varied universe of mathematics.

‘Maths knows no races or frontiers’: the history of mathematics for an antiracist education

Erika Luciano[1] and Elena Scalambro[1]

[1]Università degli Studi di Torino, Mathematics Dep. “G. Peano”, Italy;

erika.luciano@unito.it and elena.scalambro@unito.it

Keywords: Antiracist education, Inclusive school, History of the Shoah.

Towards an antiracist education

While the awareness towards the Shoah had always been prerogative of humanities in educational context, only in recent years it emerged as unspoken potential of scientific disciplines. Hence, we would discuss the opportunity and the impact of introducing these issues in schools starting from a different perspective, the one of the history of mathematics and science. The national guidelines *Per una didattica della Shoah a scuola* (2017) identify the interdisciplinary and transcultural approach as the root cause that makes the didactics of racism one of the most complex educational challenges, since it involves different skills and specializations. Conversely, the cross-cultural dimension invoked is typical of the multidisciplinary approach of the history of STEM disciplines. Believing that the education to live together in diversity is everyone’s task, research in the history of STEM can become an important component of the contrasting action on modern racisms (Segre, 2018). A good teaching of the history of scientific disciplines can contribute to counter the cognitive-essentialist bias which underlies the racist views of new generations (Rutherford, 2020). Moreover, historical-scientific research becomes an educational tool aimed at ‘disarming’ false arguments, stereotypes and slogans which are often puerile but simple, and therefore effective. The plots of the internal history of STEM can make the future generations aware of the instrumental use that was made of such disciplines, which are usually considered – by their very nature – impervious to ideological conditioning.

A response to local needs

Unfortunately, the chronicle of many European countries, and specifically in Piedmont, has recently recorded many serious acts of racism and anti-Semitism, which bring back in vogue the most forbidden Nazi-fascist stereotypes. The perception that these intolerable facts are not isolated and the consequent concern about the surfacing of forms of hatred that make the past dramatically close, are reflected in the statistical data: from January 1, 2018, to the end of February 2019, 118 acts of racism were reported in Piedmont, 36% of which in Turin and its metropolitan area. In 8% of cases, they occurred in a school context. On the other hand, according to IRES Piemonte annual report for 2020, only 13.67% of the population considers racism and other forms of discrimination to be of concern and, due to Covid19 emergency, this percentage dropped to 9.5% in 2021. This is even more regrettable considering that the Piedmontese scientific community was among those most dramatically affected by the racial laws of 1938 (Luciano, 2020).

Educational activities in schools

Hence the idea to design educational activities and training courses in order to sensitize teachers and students of secondary schools to Memory, starting from the critical re-reading of some aspects and moments of research and teaching of mathematics and science during the fascist dictatorship (ideologization of mathematics, teaching of racism, etc.). For instance, the analysis of textbooks of the period is proposed in order to raise awareness of the instrumental use of theoretically ‘neutral’ subjects such as mathematics. At the same time, such interventions aim to promote integration and social and cultural inclusion of students from fragile backgrounds. During the school year 2020-21, three schools were involved in this project.

- At the IC “U. Foscolo” (Turin) two classes (grade 8) delved into the personal trajectories of scientists who were victims of racial laws, reading and commenting on the correspondence of that ‘dark’ period. To make them accessible to a wide public, they created a freely navigable multimedia content published on the school website (https://www.icfoscolo.org/wp-content/uploads/2021/01/MOOC_Giornata-della-Memoria.pdf) on the 2021 Holocaust Memorial Day.
- At the IIS “Santorre di Santarosa” (Turin) three classes (grade 11 and 12) with biochemistry study address opted to focus on the eighteenth-century debate on polygenism and racism and on the exploitable use of mathematics (statistics, demography) and science (biology, anthropology, medicine) to justify colonialism, racism and anti-Semitism, in modern and contemporary times.
- At the Liceo “G. Peano” (Cuneo) the Mission Memory path was pursued: teachers and students (grade 11 and 13) rediscovered the life stories of their colleagues who were persecuted for racial reasons, with particular attention to the local context: they focused on the reconstruction of the biography of Ugo Levi (1903-?), who taught mathematics and physics in Cuneo in the historical period considered, also interviewing some of his former students.

In conclusion, history of STEM becomes a resource for improving students’ consciousness: actually, “history is something that can make us aware of who we are, and how we have come to be the individuals that we are” (Radford, 2014, p. 89). We claim that history of mathematics and sciences provides an important means of combating ignorance, with the goal of defeating racial discrimination and intolerance, and contributes to identify appropriate antiracist resources to incorporate into school curricula. We hope that the ideas, insights and experiences illustrated can form a basis for new educational actions in this direction, which are especially needed in our society, crossed by currents of racial hatred and contempt for diversity.

Concepts introduced in Norwegian textbooks before, during and after the New Math period

Hilde Opsal[1] and Bjørn Smestad[1]

[1]Volda University College, Volda, Norway; hilde.opsal@hivolda.no

bjorn.smestad@hivolda.no

For a nuanced discussion on the legacy of New Math, detailed knowledge of the content of mathematics before, during and after New Math is needed. In this article, we mirror a study of Icelandic textbooks, studying at what ages certain New Math-connected concepts were introduced in 14 Norwegian textbook series for age 7-15 published in the 1950s, 60s, 70s and 80s. As was the case with Iceland, set-theoretical concepts appeared with New Math and were mostly gone by the 80s, while axioms of the number field and the study of number were to a large extent present throughout the period studied. These were introduced at an earlier age in the 70s. We find that some New Math-related concepts were introduced in textbooks before New Math entered on a full scale, unlike Iceland. Like Iceland, many other concepts were introduced in the 70s and stayed in textbooks.

Keywords: New Math, textbooks in mathematics, mathematical concept

Introduction

New Math was an international movement that began in the mid-twentieth century. It has been strongly associated with the set concept. Since the set concept lost its place in textbooks quite soon, it is tempting to believe that the long-term impact of New Math was small. As Schubring (2021) points out, many believe that New Math affected all countries similarly. For informed discussions on this period within the history of mathematics education, more nuanced pictures of the legacy of New Math in each country are important. In this article, we present such a picture for Norway, mirroring a similar study for Iceland by Bjarnadóttir (2017).

In 1966, an international meeting for experts on mathematics teaching at the primary level was held in the UNESCO Institute for Education in Hamburg. In the report from this meeting, a list of basic topics was proposed that should be included in primary school. These included concepts from set theory (Williams, 1967, p. 47). However, set theory was just one of several topics in mathematics that were introduced to students either as a new topic or for younger students. According to Kilpatrick (2012), internationally many of the ideas of New Math are still part of school mathematics.

In this paper, our research questions are: Which concepts related to New Math were introduced in the textbook series for compulsory school from age 7 in Norway and to what degree did they survive into the 80s?

The starting point for New Math

The Royaumont seminar in 1959 was “the starting point for the coordinated international efforts to reform mathematics teaching based on the conception of ‘modern mathematics’” (Schubring, 2014,

p. 89). Teachers, school leaders and researchers from many countries, including Norway, Sweden and Denmark attended this seminar (OEEC, 1961). The starting point for New Math was a desire to teach mathematics that corresponded to modern society with its tremendous acceleration in technical, economic and social development (Christiansen, 1967). According to Christiansen, the curriculum in mathematics was previously narrow and the primary focus was to practice formal skills, while mathematical concepts and the interaction between these were often less emphasized.

The conclusions from the Royaumont seminar stressed that one must move away from memorizing facts and procedures to experimenting, discovering and making mathematics with physical objects. "This experimentation must lead to the abstraction of the quality of a set called number" (Schubring, 2014, p. 93). In the beginning one should focus on the ideas and later the mathematical concepts sets, subsets, mapping etc.

At the Royaumont seminar, it was also outlined how one could reform mathematics teaching in school. Regional cooperation was recommended. The authorities in Norway, Sweden, Denmark and Finland were positive about Nordic co-operation and in 1960 the Nordic Committee for the Modernization of Mathematics Education (NKMM) had its first meeting (NKMM, 1967). In 1967 a report was published on the work of this committee, providing a description of the current situation in the four countries, followed by goals for the schools' mathematics teaching. Several experimental texts for textbooks at different grade levels were developed and experimental teaching was carried out. The report also includes a proposal for a concrete curriculum for first to twelfth grade.

For the first three school years, two experimental texts were developed by NKMM, one Swedish and one Danish-Finnish, written by Bundgaard and Kyttä. "The basic ideas are the same in the two series, but they differ in many details" (Håstad, 1967, p. 99). For grades four to six, NKMM had trouble finding a suitable writing team and therefore they decided to translate the experimental texts published in the United States in the large project School Mathematics Study Group (NKMM, 1967, p. 108). For grades seven to nine, NKMM developed experimental texts in geometry and algebra.

Iceland did not participate in the Nordic collaboration, nevertheless the result of the collaboration influenced Iceland through, for example, the choice of a Danish-Finnish textbook series. The Bundgaard-Kyttä textbooks series was translated to Icelandic (Bjarnadóttir, 2017), together with textbooks for age 10-12 written by Agnete Bundgaard alone. We will call the combined series the Bundgaard series. Bjarnadóttir (2017) has studied how students in Iceland were introduced to certain mathematical concepts, often related to New Math, and at what age they were introduced to these concepts. In her study, the content of this textbook series is compared with the content of other series in use in Iceland before, during and after the introduction of New Math. In Iceland, there was just one textbook series in mathematics from 1939 to 1966 (Bjarnadóttir, 2017). The results of her study are that the topics that were new in the Bundgaard series were "the use of set theoretical concepts and the notation for building up the number concept and understanding of operations through repeated reference to the axioms of the number field" (p. 58). Negative numbers were not mentioned in it. Bjarnadóttir concludes that this textbook series went far in meeting the requirement that "mathematicians" had for mathematics in primary school. Here, she is most likely referring to those mathematicians who participated in the Royaumont seminar in 1959. The topics that survived in textbooks after the New Math period were primes and divisibility, mental arithmetic and approximation and estimation. The topics that did not survive were replaced by an introduction to statistics, probability, the use of variables and solving simple equations. These were new topics when the Bundgaard series was replaced by an Icelandic textbook series in the 70s.

Bjarnadóttir's study shows that there were more than set theory concepts that were introduced to the students with New Math. Some of these were also introduced for students in the textbooks in the period after New Math, not necessarily for the students at the same age.

Norway participated in the cooperation and was therefore naturally affected by this participation. But unlike Iceland, in Norway there were many publishers of textbooks for primary schools. After a temporary curriculum in mathematics with New Math was introduced in 1971, several textbook series were published with content adapted to this new curriculum. Soon, mathematicians as well as parents of school children protested. In the final curriculum in mathematics, which was approved in 1976, New Math content was greatly reduced (Gjone, 1985, p. VII:31; Solvang & Mellin-Olsen, 1980, p. 1:18).

"The residue of the new math era may be difficult to see in today's school mathematics, but it is there" (Kilpatrick, 1997, p. 956). Kilpatrick mentions inequality as a subject that came in with New Math in USA and has remained in school mathematics.

Method

As outlined above, Bjarnadóttir (2017) studied the content of textbooks that were published in Iceland before, during and after the introduction of New Math. Based on Bjarnadóttir's study, we have done a similar study of when students encounter the various concepts for the first time in Norwegian textbooks.

Bjarnadóttir first developed tables with mathematical concepts based on literature on New Math, then she analysed how and when students were introduced to these concepts in Icelandic textbooks. Bjarnadóttir chose the following categories *set theoretical concepts and notation; structure of the number field;* and *study of numbers.* We have chosen to use Bjarnadóttir's categories to be able to compare the Icelandic and the Norwegian situation.

The two authors of this paper have each studied each textbook series separately and noted where the students are first introduced to the various concepts. When in disagreement, we have studied the textbooks together and come to an agreement on where the students meet the concept for the first time. We have noted both the first implicit treatment of a concept and the first explicit one. For reasons of space, in the tables in this article, we only include the first explicit introduction. If the concept is only introduced implicitly, we have marked this by putting parentheses around the age. We exemplify what we mean by an implicit introduction of a concept through the commutative law for addition. When several examples and tasks in a row have the same numbers (as for example 2+3 and 3+2), without the commutative law being mentioned, we conclude that there is an implicit introduction to this concept.

After preparing tables that show the age at which students are introduced to a topic for the first time, we have analysed these tables to compare different periods, which also makes it possible to compare the result from Norway with the situation in Iceland.

In this study, we analyse the content of textbooks that were published before, during and after the period of New Math, that is the period 1950 to 1980s. Early in the 1970s, several textbooks with New Math were published. We have chosen to include all known series from this period. In the period before and after New Math, we have chosen series from Aschehoug and Cappelen, as these published textbook series for the whole period. They have partly the same authors as the books that were published in the 1970s. We also conjecture that they were used by many schools in Norway, although there exists no statistics to determine this. We have also included Tanum, during and after the introduction of New Math (see Table 1), to include one more textbook series for the 80s. None of the Norwegian textbook series published in the 1970s were directly linked to NKMM's experimental texts.

Table 1: Textbooks included in our analysis. Textbooks from 1970s are marked for clarity

	Publisher	Year	Age	Title	Author
A1	Aschehoug	1953-	7-13	Nå regner vi	Aam, Johannesen, Slaatto, Paulsen
A2	Aschehoug	1964-	7-15	A. regneverk for folkeskolen	Paulsen, Slaatto
A2+	Aschehoug	1971-	7-9	A. regneverk, mengder og tall	Paulsen
A3	Aschehoug	1980-	7-12	Vår matematikk	Harboe
A4	Aschehoug	1987-	7-15	Regnereisen	Venheim, Breiteig m. fl.
C1	Cappelen	1962-	7-15	C. regneverk: matematikk	Bue
C2	Cappelen	1971-	7-15	C. matematikkverk	Bue, Gjerdrum
C3	Cappelen	1980-	7-12	Jeg regner	Gjerdrum, Bue
D1	Dreyer	1972-	7-12	Grunnskolens matematikk	Eicholz, Arneberg
E1	Eli	1972-	7-15	Ny regning	Dentrup, Kjeldberg, Kjeldberg
G1	Gyldendal	1972-	7-12	Matematikk for grunnskolen	Myrmo, AAs, Grymer, Ridar
N1	NKI	1973-	7-12	Tal og teikn	Rudjord, Bjørklund, m.fl.
T1	Tanum	1970-	7-12	Min matematikk	Viken (red.)
T2	Tanum	1980-	7-12	Min matematikk	Viken

Dreyer (D1) was based on a US textbook series, adapted to Norwegian conditions. Eli (E1) was based on a collaboration between Norwegian and Danish teachers. Gyldendal (G1) refers in the teacher manual to NKMM's report but does not claim to build directly on it. Tanum (T1) was based on a Swedish textbook series and refers also to NKMM. The other textbook series (A2+, C2 and N1) were modernizations of previous Norwegian textbook series. A2+ was written as a supplement to an existing textbook series to introduce students to set theory. This supplement was only for students aged 7 to 9, older students used A2 textbooks. In our analysis, we have first analysed A2 (under the heading A2), then the combined series of A2 and A2+ (under the heading A2+).

When comparing our results with the findings of Bjarnadóttir (2017), we need to keep in mind that the two textbook series before New Math in her analysis were used in the periods 1922-37 and 1927-80. The textbooks we have studied were published much later. In addition, the Icelandic textbook series before New Math were for students from the age of 10 because children were expected to learn some mathematics at home before starting school at age 10.

Results

We will follow the structure of Bjarnadóttir (2017), looking first (briefly) at concepts from set theory, then axioms of the number field and finally what Bjarnadóttir calls "topics of number".

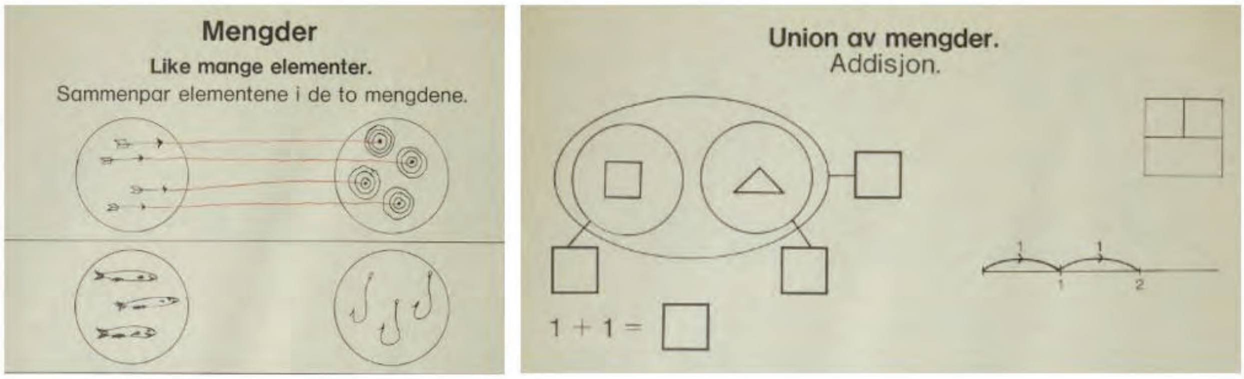

Figure 1: A section from A2+ from 7-year-olds. To the left with introduction to Sets (p. 10) and to the right with introduction to Union (p. 30)

Our analysis shows, not unexpectedly, that set theory entered the textbooks in the 1970s for the students aged 7 (see Figure 1 for the introduction in a textbook series) but were not included in the textbooks that were published after the New Math movement had passed. This is similar to what Bjarnadóttir found in Iceland.

For axioms of the number field (Table 2), the picture is different. Most of these were present in the 60s or even in the 50s, but in the 70s series, they were presented to younger students. In the 80s, it is more complicated – some of the axioms are left out, some are presented later, while some are even presented earlier.

The commutative law of addition is introduced implicitly for 7-year-olds in all time periods, from the 50s to the 80s. However, there is variation in when students are introduced to this law explicitly, from age 8 to age 13. It also varies when students are introduced to the commutative law of multiplication. If the law is first introduced implicitly, then it happens when students are 7 or 8 years old. It is often explicitly introduced when students are 9 years old. The same applies to the distributive law, but it tends to be introduced explicitly in the 70s (under New Math). The associative laws of addition and multiplication are introduced explicitly at the secondary level (from 13 years) in the 60s and at the primary level (under 13 years) in the 70s. The associative laws appear implicitly or not at all in the textbooks of the 1980s.

The additive identity is implicitly included for 7-year-olds throughout the period, and explicitly included later. Only in the 80s is it mentioned explicitly to 7-year-olds. The fact that addition/subtraction and multiplication/division are inverse operations is included in almost all textbook series, either explicitly or implicitly. But it varies when students are introduced to these connections. It seems that students were introduced to these connections at a younger age in the 70s.

In the 50s, the role of 0 in multiplication is introduced to 9-year-olds. In the 60s, this has been moved to when the students are 13-14 years old, and in the 70s and 80s it is again in most of the textbook series for 8-9-year-olds. The role of 0 in division is not mentioned in the 50s and 80s. In the 60s, it is mentioned in the same textbook as 0 in multiplication, and in the 70s it is mentioned at a higher grade level if at all.

Table 2: The age-groups of students for which axioms of the number field are presented

Topic\Textbook	**50s**	**60s**		**70s**							**80s**			
	A1	**A2**	**C1**	**A2+**	**E1**	**C2**	**D1**	**G1**	**N1**	**T1**	**A3**	**A4**	**C3**	**T2**
Commutative law of addition of multiplication	 (7) 13	 13 14	 9 9	 13 9	 9 9	 8 8	 8 9	 (7) (8)	 10 9	 (7) (8)	 (7) 11	 14 9	 (7) 9	 (7) 9
Distributive law	(9)	14	13	9	9	(9)	9	(9)	9	(10)		14	(8)	(8)
Associative law of addition of multiplication		 13 14	 13 13	 8 9	 9 9	 8 9	 7 9	 9 10	 10 10	 7 (9)			 (8) 	 (9)
Identity -additive -multiplicative	(7) (10)	(7) 14	14 14	(7) 9	13 13	(7) 	10 8	 8	12 12	(7) (8)	7 	7 9	(7) 	(8) (8)
Inverse -additive -multiplicative		13 	14 13	13 	12 15			(12) 12	(10) (12)	 12		13 15		
0 in multiplication 0 in division	9 	14 14	13 13	9 14	 (15)	8 	8 9	8 	9 12		9 	9 	8 	
Negative numbers		12	12	12	11	11	12	12	10	11	12	12	11	10
Inverse operations add./subt. mult./div.	 13 10	 14	 9 13	 13 9	 (9)	 (9) 10	 9 9	 9 (9)	 8 8	 10		 7 11	 (8) (9)	 (10) 10

Within study of number (Table 3), most topics were present already in the 60s. However, many of these were introduced far earlier in the 70s. Again, the picture is mixed as we enter the 80s.

While the number line is not included in the series from the 50s, it is included in most later series from the age 7. In some textbooks, especially in the 80s, it appears a little later. The connection between even numbers and odd numbers was introduced earlier with the New Math: for 7-8-year-olds students in the 70s as compared to 12-14-year-olds in the 60s. We see that the early introduction lasts into the 80s.

It varies how old students are when they are introduced explicitly to primes, factorization and divisibility (from 8 years to 14 years), but these concepts are often introduced simultaneously.

Students are introduced to bases other than ten in some of the textbooks in the 60s and 70s, but not in any of the textbooks in the 80s. Modular systems is never a topic in the textbooks studied.

In the 60s and 70s, students were introduced to equations at the age 7-9, while in the 80s they were introduced to equations at the age 10-12. This is different from the variable concept. It appeared in the textbooks for 11-12-year-olds in the 1960s, for 7-9-year-olds in the 1970s and again for 11-12-year-olds in the 1980s (except in one textbook series where students were introduced to this concept when they were 9 years of age).

Statistics is not included in the textbook series from the 50s, later, students are introduced to statistics between the ages of 8 and 11. In only two of the textbook series do we find probability, one of them in the 70s and one in the 80s.

Table 3: The age-groups of students for which topics on numbers are presented

Topic\Textbook	50s	60s		70s							80s			
	A1	A2	C1	A2+	E1	C2	D1	G1	N1	T1	A3	A4	C3	T2

Discussion and conclusion

Set-theoretical concepts were not included in the textbook series in primary school in the 50s and 60s in Norway, entered with New Math in the 70s and partly disappeared again in the 80s. As such, we can distinguish a clear "New Math" period in Norwegian textbooks. Several other concepts (for instance associative laws) were introduced to students at a younger age in the 70s than before. Of these, some of the concepts stayed in the textbooks for the same age group in the next decade, while others returned to textbooks for students of a higher age. While textbooks series vary, there is a tendency for more of the terms be introduced explicitly earlier in the 70s.

Our study gives a somewhat different picture of New Math's role than Bjarnadóttir's (2017) study. As there were no new textbook series in Iceland for decades before New Math, the change was abrupt. In Norway, on the other hand, several textbook series were published in the decades before New Math took hold. This contributed to a more gradual change. One major difference was that in Norway, many New Math ideas entered textbooks in the 60s, but New Math (including set theory) came in full force in 1971, with a new temporary curriculum. In Iceland, New Math (including set theory) was implemented in the 1960s, but some New Math ideas (such as statistics) only entered primary school in the 1970s as other New Math ideas waned.

Although New Math has been partly derided and ridiculed in later years, we do see that many concepts which are now taken for granted as a part of school mathematics, were introduced in the 1960s and 1970s. This applies, for example, to statistics, approximation and estimation, as Bjarnadóttir also concludes in her study.

When it comes to the textbook series that were published in the period of New Math, in Iceland and Norway, we see that there are some similarities in when students in the two countries are introduced to the different concepts. However, we also see large variations between the different textbook series published at about the same time. This variation is more apparent in our analysis than in Bjarnadóttir's, as there were fewer competing textbooks in Iceland.

Taken together, the detailed analyses provided by Bjarnadottir for Iceland and by us for Norway, provides a foundation for a more nuanced discussion on the legacy of New Math in the two countries. If such analyses are done for more countries, we may see even more what is special with how New Math has been implemented in different countries.

Mathematic-historical example for university teaching of mathematics - how can methodical knowledge be taught as well as the culture of mathematics be made accessible?

Nicola Oswald[1]

[1]Universität Würzburg, AG Zahlentheorie, Würzburg, Germany; nicola.oswald@mathematik.uni-wuerzburg.de

In our presentation, we introduce a teaching unit for university mathematics teaching, which is based on historical documents. Specifically, these are two articles by David Hilbert (1862-1943) and Adolf Hurwitz (1859-1919) on proofs of the transcendence of the number e and an accompanying letter exchange between the two authors. We illustrate that these archival finds are suitable to deepening students' understanding of both mathematical methods and mathematical culture.

Keywords: Historical documents, Proofs of transcendence of e, David Hilbert and Adolf Hurwitz, Mathematical culture

Introductory reflections on history of mathematics in university teaching

Incorporating the historical development of mathematics can be used as a didactic element in teaching mathematics. In textbooks, monographs and lectures, it may help mathematicians to classify the mathematics dealt with and thus at the same time enables the reader a systematic approach to the mathematical content.

In a case study on the use of so-called knowledge maps in a history of mathematics course in university teaching (Khellaf et. al, 2018), we found that students develop very individual and confident ideas and cross-references about the development of mathematical thinking. Figure 1 illustrates different examples of student views on structuring mathematical development steps.

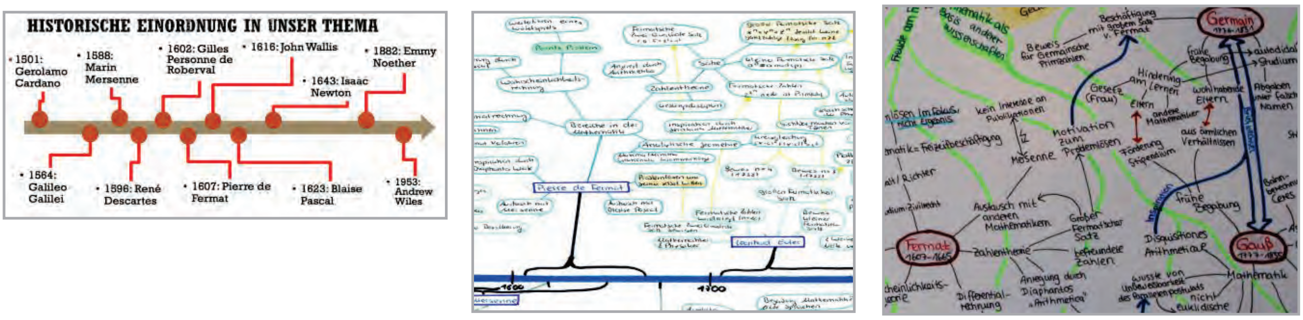

Figure 1: Excerpts from a lecture and two knowledge maps by students, created in the seminar "Development of mathematical ways of thinking“ (University of Hanover).

The importance of mathematics history in university teaching has been discussed at various points in the past. The mathematician Max Dehn (1878 - 1952), for example, took a particularly firm standpoint. In a statement on the teaching of mathematics at the University of Frankfurt in 1932, he named the history of mathematics as fundamental subject matter in addition to "the structure of analysis", "axiomatics in geometry, the foundation of arithmetic". He justified his view by writing that the treatment of mathematics history ensures "[...] to consider again and again the multiple connections between [mathematical topics], and this is more important than to bring no matter how [new] original results.“ (Dehn, 1932, p. 72) In addition, Dehn underscored the high value of a mathematics-history seminar, which was aimed particularly at faculty members, as a "kind of continuing educational class".

The mathematics didactician Gregor Nickel argues in his article “Zur Rolle von Philosophie und Geschichte der Mathematik für die universitäre Lehrerbildung“ (Nickel, 2015), translated "On the Role of Philosophy and History of Mathematics for University Teacher Education“, that mathematics history must be understood not as an accessory but as a "subject of teaching in its own right."

> "The historically reasonably adequate presentation of a topic from the history of mathematics certainly cannot be done incidentally, but requires time and attention, on the part of the teacher a certain mathematical-historical professionalism, and on the part of the students a solid prior mathematical experience." ((Nickel, 2015, p. 216) translated from German by the author)

In the following we show a practically oriented teaching unit on transcendence proofs of Euler's number e, which on the one hand is thematically suitable for the current teaching material in early university semesters (after two basic lectures on analysis), and which on the other hand can be built on a limited corpus of mathematics-historical documents.

Historical material for the construction of a teaching unit

The transcendence proofs of e of Adolf Hurwitz (1859-1919) and David Hilbert (1862-1943) from 1893, which are the subject of this work, can be juxtaposed with an exchange of letters between the mathematicians, which shall make both the genesis of the proofs themselves and the contemporary context tangible and raise questions about the "culture of mathematics". In the following, we will first discuss excerpts of this correspondence, then give a sketch of the proofs’ main ideas.

Correspondence between David Hilbert and Adolf Hurwitz

The correspondence in question essentially comprises five letters written by David Hilbert and Adolf Hurwitz between October 1892 and February 1893. The life and work of these two mathematicians was characterized by enormous and groundbreaking developments within the research and teaching of mathematics as well as the institutional conditions in the German-speaking world (see some aspects below in the introduction of the teaching unit).

Hurwitz and Hilbert (as junior scientists and professors in Königsberg, Zurich, and Göttingen) took an active part in developments of mathematics and exchanged views on them in a correspondence comprising a total of at least 198 postcards and letters, which is now kept in the Göttingen State and University Library (under the directories Cod_Ms_D_Hilbert_160 and Cod_Ms_Math_Arch_76). They had met when Hurwitz was appointed associate professor in Königsberg in 1884, where Hilbert attended his lectures as a committed and ambitious mathematics student. Since then they had an ongoing collegial friendship, which was maintained through regular written exchanges, especially after Hurwitz's call to the ETH Zurich (then still Polytechnikum). In their letters the topics ranged from general remarks on the situation in higher education and personal matters to very concrete research results and, where appropriate, mutual references and suggestions for improvement. In the latter sense, for example, the exchange of letters on new proofs of transcendence of the number e quoted below was written. This begins with a letter in which Hilbert presented his simplification of a known proof (by Thomas Stieltjes). In the following we will quote some relevant passages of the letters, which are mostly three to five pages long. The focus at this point will be on the nature of the communication regarding the proofs.

A new development of the proof was communicated by Hilbert in his letter of December 31, 1892:

> "Concerning my proof of the transcendence of e, I realized very soon after I wrote to you that one can still considerably shorten the same by omitting the whole Stieltje pointe. [...]"
>
> - The proof follows, in particular the choice of the polynomial f(z), see next section. -
>
> "[...] You see that hereby the proof also contains a different conclusion at all, in that not from the integral sum II but from the integer I the dissimilarity from 0 is shown. The use of this conclusion also gives the proof of the transcendence of π a simplification which seems to me not inconsiderable."

Hurwitz replied on January 10, 1893, again with a new proof and an idea:

> "Your scientific communication concerning the number e has, as you can imagine, interested me very much. [...] The matter did not let me rest and I discovered a further simplification, [so] that one can now bring the proof in the first hours of a lecture on differential calculus. [...] Have you already edited your proof? If so, please write me whether you have already sent it to Klein. I would then have the above further simplification printed in a short note behind your work. I would prefer it if we chose the Göttinger Nachrichten. [...] So please answer me quickly, even if only by card. That your punch line can also be applied to π is clear; but I haven't quite thought it through yet."

Within three days Hilbert replied (on January 13, 1893):

> "I have already worked out my proof for e and π during the Christmas vacations, and in the process - especially in the part dealing with π - a number of advantageous and simplifying things have emerged, so that the whole thing will now take up 4 - 5 printed pages, and my presentation is by no means brief. In your proof, of course, the integral is avoided; but whether the presentation of the proof becomes shorter and clearer is not yet quite clear to me. [...]. But it is my conviction that the proof with the help of the integral will always remain the clearest and most capable of development [...]"

Hurwitz wrote about a month later (on February 08 or 13, 1893):

> "For a long time I wanted to answer your dear letter of 13/I, but - as it goes - the answer was postponed from day to day. Today, as a guiding impulse, your transcendence note arrives, which I immediately typed into a café. You have written the note with Gaussian classicism. I hope that you will agree with the short note (2 printed pages presumably) in which I will make the modification of your proof, [...]. Felix Klein submitted it to the Göttingen Society on 4/II. As an advantage of my modification I see that it becomes clear in the proof that only the addition theorem and the differential equation [...] The idea of modifying your proof by replacing the integrals by limit values had also occurred to me. However, there still seem to be difficulties [...]"

The letters already clarify the core of the proof differences: The preference of integral or differential calculus, which still lay the foundation of every analysis course today. It is interesting that Hilbert and Hurwitz emphasize the respective greater "simplicity" of their proofs (and remain in disagreement).

Two proofs of transcendence of the number e

In the following, we will give a sketch of the two proof lines, published in (Hilbert, 1893) and (Hurwitz, 1893). We mainly limit ourselves here to the mentioned crucial difference in the approach of the proofs (the „differential analogue“), which is illustrated by excerpts from a lecture by students in a seminar (see more details in the next section).

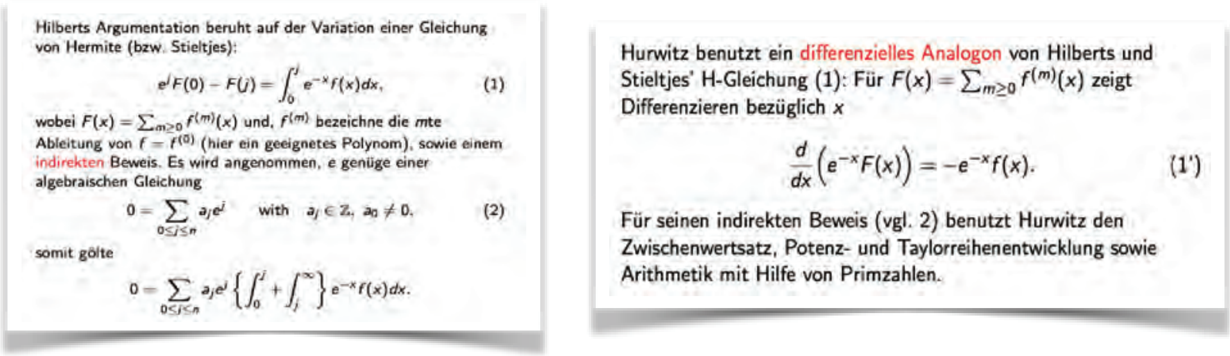

Figure 2: left: Excerpt from an introductory seminar lecture "Basic Idea Proof Hilbert, right: Excerpt from an introductory seminar lecture "Basic Idea Proof Hurwitz"

Figure 2 describes that Hilbert's argument is based on a variation of equation (1), where F(x) is defined as given and f^(m) describes the mth derivative of f^(0). Hilbert then goes on to give an indirect proof by estimating the individual integrals, respectively their arithmetic properties, and leading equation (2) to contradiction. In contrast, Hurwitz argues with a "differential analogue," see equation (1’). For his indirect proof Hurwitz further uses the intermediate value theorem, power and Taylor series expansion, and arithmetic of primes. We cannot go into detail through all the mathematical steps here, however, we want to state that the proofs are non-trivial, but quite short, and all methods are usually discussed in the first two analysis lectures of a university course.

In favor of the two proofs as well as on the corresponding historical documents for practical teaching purposes is the fact that the basic idea of the proofs provides an application of the fundamental theorem of integral and differential calculus. An integral proof is contrasted with a differential proof. Students thus learn, using a concrete example from modern history, that the methods and foundations experienced in their first university semesters are sufficient to understand and discuss seminal mathematics. In addition, the parallel use of original proofs and accompanying correspondence allows a variety of cultural aspects of mathematics or the mathematical community to be reflected, see next section.

Implementation in a teaching unit

Based on the historical documents, we constructed a teaching unit, which was so far conducted in two different seminars: A seminar on selected topics in analysis (10 participants; University of Würzburg) and a mathematics-history seminar on developments in mathematical ways of thinking (13 participants, University of Hanover). In both seminars (each 90 minutes per week), the content was divided into three parts: Mathematics-historical context and the letter exchange, the proof of David Hilbert, and the proof of Adolf Hurwitz before the background of the correspondence. The introduction was done by the lecturer, the proofs were presented by one student each. Time (about half an hour) was then allowed in each lesson so that the content presented could be discussed. In the following we will refer to the analysis seminar. The students were all in their third or fifth semester (Bachelor Mathematics or Computational Mathematics).

In the introduction, we first gave a brief historical contextualization of the seminal period of the late 19th century for mathematics in the German-speaking world: The first International Congress of Mathematicians was held in Zurich in 1897, journals and publishing houses were founded or changed their direction, lecture notes of mathematicians were published, polytechnics gained importance, interdisciplinary fields (for example, geometry of numbers, algebraic number theory, and algebraic geometry) were discussed and evolved, teacher training was professionalized - to name only a few contemporary aspects, some of which still influence our teaching and research practices in mathematics today. We then introduced the mathematicians Hurwitz and Hilbert, and their correspondence, which spanned a total of several decades. Finally, the letters referring to the proofs of transcendence of e were presented in detail. In the discussion that followed, the students were particularly interested in the influence of the mathematicians Charles Hermite (1822 - 1901) and Felix Klein (1849 - 1925). Furthermore, we focussed the way of discussing mathematics and developing proofs by letters - in contrast to today's mathematical culture and speed (e.g. by zoom meeting).

All students were given preparatory questions for the seminar sessions, and the presenting students in particular were asked to integrate these into their presentations. As an example, we show here the questions which especially refer to the difference integration-differentiation:

In your presentation, address the following questions:

(I) Historically, integral or differential calculus – what came first? Since when were these related to each other? Treat these questions discursively and be critical in your literature review.

(II) Fundamental theorem of differential and integral calculus: prove that Hurwitz's approach is indeed the „differential analogue" of Hilbert's approach.

(III) Partial integration: prove the Hermite equation. What is the differential analogue to partial integration?

The presenters were encouraged to prepare together to some extent. The questions served as a guideline. They were deliberately kept both general and concrete. Question (I) was directly stimulated by the correspondence and the question whether differential calculus or integral calculus should be studied first and why. Especially in their search for sources, the students became active: The discussion led us to different protagonists of the history of mathematics (from Archimedes to Newton / Leibniz) and their influence on our mathematics today. Questions (II) and (III) were more specific to the respective lecture. By differentiating Hilbert's integral, question (II) could be addressed; the differential analog (question (III)) to partial integration is the product rule used for Hurwitz's equation (1).

With all students we summarized: Both proofs so far rely essentially on the differential equation exp = exp' for the exponential function (or, equivalently, the integral equation for exp). This kind of reproduction property appears in the proof of Hermite's identity (1) as well as in its differential counterpart (1'). The similarity of the proof ideas is due to the main theorem of integral and differential calculus. The real differences of the two proofs lie mainly in the mathematical methods and tools used in the estimation of the arithmetic properties. Together with students, we have decomposed the proof into individual steps, see a summary of the results of the proof analysis in Table 1.

Table 1. Comparison of the steps of the proofs, highlighted with frames: integration-differentiation difference (blue), differences concerning mathematical tools (red)

Steps of the proof	Hilbert	Hurwitz	Background & Application
Basic starting point	Integral equation (1) Partial integration	Differential equation (1') Product rule	Duality in fundamental theorem of analysis Exponential function exp = exp'
Assumption	Algebraic equation = 0 (2)	Algebraic equation = 0 (2)	Concept of the proofs: Proof by contradiction
Defining ingredients	Definition of a polynomial f	Definition of the polynomial (7)	Comparing the polynomials: only slight differences due to prime numbers
Construction	Combining (2) and (1) (algebraic equation)	Combining (2) and (1') (algebraic equation)	Similar basic construction: Integration of equation (1) resp. (1') in algebraic equation (2)
Mathematical Tools	Investigation of Arithmetical Properties: Elementary formula (3) Arithmetical estimation (integers)	Investigation of Arithmetical Properties: Mean value theorem to receive equation (6) binomial theorem / Taylor series expansion Arithmetical estimation	Different proof lines: Tricky methods, Tools in principle elementary / understandable, Execution sophisticated
Conclusion	Assumption not possible	Assumption not possible	Conclusion: e is transcendental

In addition to the mathematical facts, further facets of mathematics were addressed. Especially with regard to students in their first semesters, a lack of understanding of the "culture of mathematics" is often thematized. This fuzzy term is used for very different aspects of the subject: For example, technical skills such as writing down a mathematical conclusion or the correct use of operators are addressed, or an understanding of the difference between examples and a rigorous proof is named. Especially the discussion of proofs is treated repeatedly and with different perspectives: The fact that mathematical facts can be proved in many ways (and by methods of different subdisciplines) and that it is ultimately a matter of perspective and context which proof lends itself or even "prevails" at which point is an integral (and challenging) part of understanding mathematics as an inquiry-based discipline. Looking at the related process of the creation of mathematics, its culture certainly includes the negotiation of the content itself: How is mathematics discussed and circumscribed, and by whom? Here again there is the possibility of taking different perspectives. In addition to the very concrete question of the use of terms and attributes themselves, it is also possible to look much more indirectly at the way in which results are published and thereby made known. Even science, which seek to be as objective as possible, is determined by subjective people.

One aim of the teaching unit was to initiate a process of understanding, that the culture of mathematics carries this richness of facets within itself and thus, despite the immanent formal rigor, can be thought much more creatively than perhaps suspected. Respective aspects were directly or indirectly addressed: Proofs in general, the need for variations of proofs, formal language and notations, mathematical methods and tools, meta-level: when is mathematics "simple"? or the evolution of mathematics in general.

Some conclusions concerning the culture of mathematics

In some concluding remarks we want to take up two of the mentioned aspects that have met with a particular response from students with reference to our teaching unit.

Proofs and variations of proofs

The fact that proofs represent a fundamental difference between school and university didactics and thus form a decisive hurdle for students, especially first-year students, has been noted in numerous works. Students in particular have difficulties "acquiring an understanding of the culture of proof and argumentation in scientific mathematics." (Jahnke & Ufer 2015, p. 350) Yet proofs represent the heart of mathematical culture (cf. (Grieser, 2015)), they should themselves be able to be seen as a means of developing knowledge and understanding. Georg Pólya already stated that "beginners [must] be convinced first of all that learning proofs is worthwhile, that they have a purpose, that they are interesting." (Pólya (1967, p. 195)) The question here is how appropriate motivation can happen. In some cases it is underlined that just an "upstream exploratory phase for understanding an assertion" [helps] in the "eventual formation of a need for proof and is indispensable for making out a proof idea." Accordingly, the need is expressed to give students "ample opportunity to develop problem awareness.“ (Grieser, 2015, p. 662)

Our thesis is that by including the letter exchange of Hilbert and Hurwitz in the formation of the two proofs of transcendence of e (as „exploratory phase“), this process of proof development may be made more comprehensible and tangible. In addition, we assume that a reflection process on proof variations in general can be triggered. In a qualitative survey in the seminar on selected topics of analysis, students gave preliminary feedback on this. Here, we give some excerpts from the answers to the questions about the meaning of variations of proofs (connected with the correspondence) and about their own perception of the discussed proofs of transcendence of e against the historical background: Proof variations were described by students as "representing developments within mathematics" and as "very important, especially that they become easier and more understandable", "through the correspondence the [...] background" was recognized and it became apparent that "through discussion (competition) [of Hilbert and Hurwitz] development" occurs. All students found the historical or personal reference to mathematicians interesting, and some even motivating. Students highlighted that the "writing became more understandable" and "clearer why [...] some methods were used". One student, who found the letter exchange interesting and motivating, evaluated that the proofs, however, did not become easier to understand. In two additional oral discussions with the students (each at the end of the respective seminar presentations), it became clear that it was precisely the comparison of the two proofs by the authors in the letters that made them reflect. One student, for example, brought up the general difference between "elementary" and „simple" mathematics, another remarked that Hilbert's integrals seem rather "scary", though mathematically more "universal". Together we then noted that in fact Hurwitz's more "elementary" proof was more often used in textbooks, while Hilbert's proof was more likely to be used or developed in more advanced research. Overall, students rated the difficulty of the mathematics as adequate for their prior knowledge (from lectures on analysis) and felt Hurwitz's proof was easier. Although we are of course referring to a small number of students and have no quantitative study to show, consequently, we see a tendency that our teaching unit has triggered an interesting thought process among students regarding the role of proofs and variations of proofs. Naturally, not all students have a strong interest in history of mathematics, e. g. only some indicated in the survey the wish to have a dedicated course on history of mathematics, however, all indicated they would like to see more mathematics-historical aspects in their studies (which is not provided for in their regular curriculum).

In summary, we would like to conclude that a teaching unit based on historical documents is able to broaden the students' horizons both from a mathematical as well as a cultural point of view. The documents presented above in excerpts are suitable for this purpose, since they allow not only a mathematical depth but also evolutionary access to the development of mathematics itself.

Exploring a property of mixed product in the middle school inspired by Bézout's use of units

Andrea Surroca Ortiz[1] and Christine Chambris[2]

[1]Université de Paris, France; andrea.surroca.o@gmail.com

[2]CY Cergy Paris Université, Laboratoire de didactique André Revuz (EA 4434) (UA, UPD, UPEC, URN), France; christine.chambris@cyu.fr

In his arithmetic treatise, Bézout teaches arithmetic as grounded on quantities and units. It is from this perspective that we consider a property of a "mixed product", involving a multiplication on sets of quantities. In this note, we present the main lines of some didactical research on the use of this property with students of years 7 and 8 (12–14 years old). We focus mainly on the conception of units and related notions, as the multiplicative relation between units of the same kind.

Keywords: Bézout, quantities, unities, multiplication, mixed product.

Historical introduction.

Étienne Bézout (1730–1783) is well known in algebraic geometry for his theorem on the number of intersection points of two plane algebraic curves. However, we are interested here in his « Cours de mathématiques à l'usage des gardes du pavillon et de la marine», first printed in Paris, in 1764[1]. The French Royal Academy of Sciences praised his particular way of presenting the different notions in his « Éléments d'arithmétique »: "so M. Bezout has often treated these objects in a way which is absolutely his own & which makes them surprisingly simple." (Histoire de l'Académie Royale des Sciences, 1764, p.97). His success did not diminish until the end of the 19th century (Alfonsi, 2011).

In his treatise on arithmetic, Bézout presents an application that we find of great didactic potential. It is a multiplication in which the unit of measurement is made to appear. The property could be stated as follows: multiplying a quantity (the multiplicand) by a multiplier is equivalent to multiplying the number of units of the multiplicand by the multiplier, and is also equivalent to multiplying the unit of the multiplicand by the multiplier. This particular use of units was remarked upon by the Académie des Sciences as an innovation.

> These subjects, so often treated, become, by the manner in which he offers them, absolutely new & of the most luminous simplicity. We can put in the same rank what he says on the nature of the units in multiplicand, multiplier & product […] (p.98)

Bézout gives the following example:

---

[1] The references in this text point to the edition printed by J.B.G. Musier fils in 1779, identical to the first one (Alfonsi, 2011) and the oldest that is available in a digitized text. Any quotation is our free translation from French.

> 112. Let us ask, for example, what is the value of 5/7 of a pound? Since the 5/7 of a pound is the same thing (96) as the seventh of 5 pounds, I reduce the 5 pounds to pennies (57) and […]. If one were to ask for the 5/7 of 24 pounds, it is obvious that one could first take, as we have just done, the 5/7 of a pound, and then multiply by 24 what this operation would have given but it is more convenient to multiply 5/7 by 24 pounds, which gives 120/7 pounds (107), and then to evaluate this last fraction which will be found to be worth 17 pounds 2 pennies 10 denarii 2/7. (Bézout, 1779, item 112. Our free trans.)

He also gives the following example involving fractions:

> 96. For example, in 4/5, 4 can be considered as representing any four things, 4 pounds, for example, which must be divided into five parts; for it is obvious that it is the same thing to divide 4 pounds into five parts in order to take one of these parts, or to divide one pound into five parts in order to take 4 of these parts.

Bézout doesn't justify this property in his manuscript. Nevertheless, he gives a meaning thanks to the use of the different kind of units and stressing the multiplicative relations between units of the same system. It is also through the use of units that Bézout gives meaning to the different numbers, including decimal numbers and fractions, and also gives theoretical justifications to the algorithms of arithmetic operations and meaning to the rules of calculation and to the properties satisfied by the numbers under consideration.

The heritage, in the sense of Grattan-Guinness (2004), of Bézout's work, and in particular his use of units as a didactic tool, and even as a theoretical tool, is part of the inspiration for the research of which we present some of the results in this paper.

Mathematical perspective.

From a contemporary mathematical point of view, the property quoted above is a *mixed product,* which involves two multiplications in different sets. First, the *external law,* which acts on the set of quantities, and secondly, the *internal law of composition* on the set of numbers considered (*e.g.* integers or rationals).[2] Nowadays, and contrary to Bézout's usage, we would write the first step of the calculation of the example (112) (before dealing with sub-units), using the multiplication and equality signs and parentheses, which provides 3 equalities, as follows:

$$5/7 \text{ x } (24£) = 24 \text{ x } (5/7\ £) = (24 \text{ x } 5/7)\ £.$$

In order to be demonstrated rigorously in some generality, it requires mathematical arguments that were out of use in Bézout's time (the modern axiomatics developed in the nineteenth century), and which are beyond the scope of the teaching curriculum of middle school today.

Theoretical framework and didactical motivation.

In this former example, the initial quantity is 24 £, in the term (24 x 5/7) £ the number of units is scaled, and in the term 24 x (5/7 £) is the unit itself that is scaled. We consider both the possibility

[2] This is different from considering only the multiplication in the set of rational/integral numbers with the commutativity and associativity properties of it, disregarding the set quantities (and the units).

of varying the number of units considered and the one of scaling the unit itself. We have three different expressions for the same quantity, so in each concrete case we can choose to use the first or the second way of proceeding, depending on what would, for example, simplify the calculations. This is one of the (technical) interests of this property. However, what motivates us was to better understand what competencies are the ones reflected when using the unit-scaling strategy. We also stress that the reasoning involved can be used to conceive multiplication involving fractions, as, *e.g.*, in item (96)[3]. Indeed, Behr et al. (1997) consider the rational number as an operator acting, either on the number of units, or in the unit itself of the operand. In their experiment, the students (preservice teachers) were reluctant to scale the unit as if this strategy were "cognitively more demanding" (p.65). The unit-scaling perspective relies on quantities and measures, and differs from the more studied one about "unitizing" and "composite units", as in Lamon 1996. Indeed, although she defines *unitizing* as the "cognitive assignment of a unit of measurement to a given quantity" (p. 170), it seems to us that her examples refer rather to a grouping notion. Nevertheless, she states that "The ability to form and operate with increasingly complex unit structures appears to be an important mechanism by which more sophisticated reasoning develops" and pointed out that this perspective has been shown to be successful in several mathematical teaching domains. Behr et al. (1997, p.50) also agree with the relevance of conceptual units in learning. See the references in therein.

We hypothesize that a perspective based on quantities with a broad approach to units, could support the development of the unit-scaling reasoning, as well as could perform the multiplicative relations between units of the same family, since they refer to the size of the quantity, instead of referring to the number of unities composing of the quantity. We focus on these concepts (quantities, units, multiplicative relations between units, quantity-scaling strategies) and the relations between them.

Chambris, Coulange, Rinaldi, & Train (2021) pointed out some other deeper potentialities of the mixed product property, related to the multiplication of fractions, the equivalence of fractions (in terms of "compensation theorem"), and the knowledge about metric units. They previously identified this property (in terms of "multiplicative version of the compensation theorem"). They show that the understanding and the teaching, of it could rely on the knowledge of the "related units". Indeed, Chambris (2021) have introduced into didactic research the notion of *related units*[4], based on quantities as a foundation for numbers. We can interpret these units as obtained by enlarging or reducing, let's say, a *standard* unit (*e.g.* pound, gram)[5]. For instance, to justify his calculation in his item 96 quoted above, Bézout uses a unit, and in item 112, we can see 24 pounds as a unit.

[3] Let us remark that a cognitive gap of abstraction is involved when considering 4/5 as 4/5 of the unit 1.

[4] Previously named relative units, she actually calls them *related units*, whose meaning is shown in this example: both the sizes (the weights) of "1 gram" and of "250 grams" can be used as units, units that are related one to the other.

[5] We prefer this point of view, to that of considering a *related unit* as the unit *composed* by many equal standard units, a notion that lead to a *grouping* approach, and makes it more difficult to consider a *related unit* smaller than the standard one, and then making obstacles for the multiplicative relations (in both directions) between units of the same family.

In the same article, Chambris, Coulange, Rinaldi, & Train (2021) stress that the *related units* are an implicit knowledge, mostly missing in the French curriculum. Furthermore, the lack of this knowledge seems to be in connection to some recurrent difficulties in the students, as for example, conceiving the multiplicative relations between different units of the same family, *e.g.* the ten is ten times smaller than the hundred, and the hundred is ten times bigger than the ten. Indeed, when working with metric units and "numeration units" (Chambris, 2021), Chambris, Coulange, & Train (2021) noticed difficulties in the students and the teachers in managing the possible links between

- *related units* (metric and *numeration*),
- multiplicative comparison relations (*e.g.* 1 cm is ten times smaller than 1 dm),
- the composition of these relationships (*e.g.* ten times smaller than a tenth).

Observe that these items appear in Bézout's work (with a different point of view), even though he uses the partitive approach to define fractional units and fractions, instead of the "fraction as comparer approach", as named by Freudenthal (1983), which leads to a better mastery of the multiplicative relations between units (Cortina et al., 2014).

On an ongoing project, we therefore sought to go further in identifying the lack in the competencies that is reflected in the missing of the mixed product. We asked ourselves what treatment involving units are needed, or at least useful, to support the quantity-scaling strategies in a meaningful way. In this note, we outline some explorations thought the interview of a middle school student.

A didactical reading of the use of units and multiplicative relations in Bézout's treatise.

Through some citations, we show here that the units are at the base of Bézout's arithmetic treatise, using them as a tool, as well as means of meaning. At the beginning of his treatise, Bézout defines units as "a quantity that is taken (usually arbitrarily) to serve as a term of comparison for all quantities of the same kind." (item 3). He then adds "The number expresses how many units or parts of units a quantity is composed of." (item 5). Bézout makes the distinction between numbers, which he calls *abstract numbers* (*e.g.*"three or three times"), and numbers expressed in units, which he calls *concrete numbers* (*e.g.*"four pounds")[6]. His multiplicand of item 112 is as well, from which we took as our first example. Bézout defines the sub-units of the simple unit as parts of it. About tenths he writes the following:

> 21. In order to evaluate in decimals the parts smaller than the unit, one conceives that this unit [...] is composed of ten parts […]

This is a partitioning approach. Nevertheless, he considers these sub-units as units in their own right, and hastens to mention one of the multiplicative relationships between them and the simple unit: " they [the tenths] are ten times smaller than this one [the simple unit] (item 21)", which will make possible, later on, an explanation of the proposed calculation techniques and the exposed properties, including that of the mixed product. Indeed, to mention the multiplicative relations bet-

[6] We observe that what he defines as a *concrete number* seems to be, nowadays, rather (the measure of) a quantity in a given unit.

ween units of the same system is recurrent is Bézout’s treatise, in particular when introducing the tens, hundreds,… and the decimal place-value system: “a number followed by two others, [...] marks a number a hundred times greater than if it were alone” (item 11); “ as one moves from right to left, the units of which each number is composed are ten times larger” (item 15); “these new units, ten times smaller than the tenths, will be one hundred times smaller than the main units” (item 22).

Furthermore, we find it interesting from a didactical point of view that before introducing decimal numbers, he first introduces another system of units, in which the ratio between one unit and the next is *not* division by ten. Indeed, the first example proposed is that of the pound (as a currency), “the pound is divided into 20 parts, which are called pennies, the penny into 12 parts, which are called denarii.” (item 17). He then quotes the ounces, the toise, the day and the marc, which were common units of volume, length, time and currency at the time, before introducing the divisions and subdivisions by decimals, the convenience of which he praises. A multiplicative relation is also quoted to explain the meaning of multiplication of fractional numbers, “multiplying the denominator 3 by 5 changes the thirds into fifteenths, *i.e.* into parts five times smaller” (item 106).

To describe the process of multiplication, Bézout uses the notion of unit twice. Firstly, in the multiplication algorithm itself, to name the different digits of the multiplicand and the multiplier “[...] and retain the tens, which are hundreds, to add to the next product which will also be hundreds.” (item 50). Secondly, he uses the units to give meaning to this technique (“[...] because the number by which I multiply is a number of hundreds.” (item 51).

The notion of unit, and in particular that of *unit fractions*, remains fundamental in Bézout's treatment of fractions. He then considers a second definition, based on division, with a “unit” point of view, “Another way of looking at a fraction is to consider the numerator as representing a certain quantity that must be divided into as many parts as there are units in the denominator.” (item 96), and uses the property of the mixed product to interpret it. We quoted the end of item 96 in our introduction.

Didactical exploration. The problem type. Interviews.

We want to explore whether, in specific problems where the didactic variables encourage it, the unit-scaling part of the mixed product property is used. We also look for the skills that are involved in it. The first author began her experimental approach with an interview between directive and semi-directive, with an interview guide with questions in a precise order, but left the possibility of asking other questions, depending on the interviewee's answers. On the one hand, we tested some knowledge on notions of units, conversion of units and measures, which are part of the curriculum. On the other hand, we checked the state of mastery of a certain point of view on units, less present in the teaching, such as the multiplicative relations between units of the same family. We finish with two problems, whose written productions we have collected. The two problems proposed aim to observe whether students are leveraging units to use the mixed product property by scaling the quantity and make calculations easier. Among the knowledge potentially involved in solving the problems this way, we sought to test which ones are mastered by the students, which ones are not, and then we wanted to know if the students use this property to solve the two problems.

The basic problem we propose to study is the following. Given a quantity of a certain magnitude whose measurement is expressed by the number **a** relative to a quantity **u** taken as a unit, multiply this magnitude by a number **k.** The situations to which the learner is exposed highlight the various multiplications **(k** x **a**, and **k** x **u**), as well as the fact that a unit, like any quantity, can be enlarged (the scalar **k** is greater than 1) or reduced (the scalar **k** is smaller than 1).

In our starting example,“Rice pudding at the Indian festival”, the initial quantity is enlarged.

Problem (Rice pudding). For an Indian festival, it has been decided to make rice pudding. The rice is sold in packets of 250 grams and 1 kilogram. We calculated the quantity of rice needed, according to the number of guests. We need 7 packages of 250 grams. Then we say that there will be 4 times as many guests. How much rice is needed in total?

This is a special case, because the initial quantity (7 times 250 grams) is measured in relation to another quantity, **u**, which is 250 grams, taken as a unit (here 7 stands for **a**). To take 4 times this initial quantity, we could proceed by multiplying 7 by 4, then computing 250 grams 28 times. More simply, we can also choose to first enlarge our unit by 4 times, which gives 1000 grams, and then take 7 times 1000 grams.

We chose to interview students from the Collège International de l'Esplanade, Strasbourg, during the school year 2020-2021, one in year 8 (13 years old) and four in year 7 (12 years old). Here we briefly present part of the analysis of the interview with the 8 year student, which lasted 18 minutes.

Analysis of Persephone's interview

After analyzing the interview, we present here some evidences on the skills of the student. We have sought to highlight whether the mathematical knowledge existed for the student, whether the student had to find it by herself, with some adaptation or not. We also point out some knowledge that seems to be lacking in her studies, or some competencies that are not fully developed.

Indeed, she knows several families of units with their different units (*e.g.* “meters, kilograms” (A019), “hectograms decagrams decigrams” (A021)), knows what quantities they measure (*e.g.* “meters distances” (A025)), and knows how to convert between units of the same kind: to the interviewer's question in A106, “one meter equals how many centimeters”, she answers “one hundred” (A107), then adds that “one millimeter equals zero point one centimeters” (A115). She also masters the ratio between units of the same kind: the researcher : “how do you go from ten to a hundred?” (A078), the student : “by doing times ten” (A079).

The student knows the multiplicative relations between hours and minutes (“[the hour is] sixty times [larger than a minute]”, in A087) and “[a minute is] sixty times [smaller than the hour]”, in A089), although she does not state them spontaneously. We can ask ourselves whether this is due to a lack of practice in these manipulations because she has not been taught, for example, that a minute corresponds to a unit sixty times smaller than an hour, that it is one sixtieth of an hour.

The student knows that one hour is sixty minutes (A081). In contrast, the opposite conversion appears more difficult to the student. To the question “one minute is how many hours?” (A082), she starts to answer with an order of magnitude that is right “one minute is / zero decimal point” (A083), then she hesitates, then makes a mistake. The question seems to be out of reach at this point for the student.

The interview also shows that the student is more comfortable with families of units whose ratio between them is ten (so are every example of units given by the student). The dozen seems to be more remote to her ("by tens it is much easier" (A057)), and she may not consider the ten as a unit ten times larger than the single unit, or the hundred as a unit ten times larger than the ten. Sub-units, such as the tenth, are not named, and naming the multiplicative relations between units of the same species, when this relation is less than one, is also more difficult for her as shown in what follows.

A118	Interviewer:	the centimeter is larger / and how many times larger than a millimeter?
A119	Student:	since there is a decimeter / zero decimal point // by no means / is bigger / ten times uh a hundred times

With questions about the change in the measure when the unit have been changed, the student succeeds in giving the right answers. However, when the researcher asks "had you ever thought about that?" (152) , she replies "yes, but it's still paradoxical" (A153), then adds "I wasn't taught that, we weren't told about that no / on the other hand it's still visible" (A155).

The student doesn't succeed to correctly solve the « Rice pudding problem ». Despite an initial impulse to enlarge the unit in the first problem, she abandons this strategy, and does not use the unit-scaling part of the mixed product property yet leading to simpler calculations. The student begins by answering the question about the quantity of rice needed:

A181	Student:	it will take um a kilogram of rice because we make two hundred and fifty times four so there are four times more and so twenty-one um not at all / twenty-eight packets of um rice of two hundred and fifty grams

Note that she starts by multiplying 250 grams by 4. Then she multiplies 7 times 4, which would be too much. Then she keeps this second product, giving as a result twenty-eight packets [...] of two-hundred-and-fifty rice, which is right, and does not take into account her first multiplication, that is 250 times 4, and which should have been multiplied by the number of initial packets, that is 7, to obtain a right final result. The researcher unsuccessfully tries to get her back to the first multiplication.

A194	Interviewer:	at one point you had multiplied the four here / by four times as many guest
A195	Student:	yes
A196	Interviewer:	by the two hundred and fifty grams of rice / and you got a kilo / isn't that another way of calculating?
A197	Student:	well, if you wait (silence) well, we don't know if it's the packets or if it's the grams // is that it?

Conclusion on Persephone's interview

The student interviewed has mastered all of the concepts related to the units taught in primary school and at the beginning of middle school. In contrast, the student does not manage to solve the problems correctly. In between, we identified some notions that are not completely out of reach, but that they don't appear as a solid background, and not taught at the school. We hypothesize that these are the notions that are lacking, or are at least useful, to give the mixed product a ground that can bring it meaning. This study shows that a broader view and knowledge about units and at least the following notions are lacking: families of units whose ratio between them is *not* ten, multiplicatives relations -in the two directions- between units of the same family, fractional units, as well as considering the metric units and *numeration units* as units in their own right. It seems to us that a point of view that Bézout gives in his treatise, where the conception of units is based on quantities and that the relations between their sizes are highlighted, could support the conceptualization of quantities into units and make closer the competency to apply it in a given task by using the quantity-scaling strategy.

Perspectives.

The aim of the interview was to test the knowledge of the students in the concepts involved in the application of the mixed product when *enlarging* or *reducing the unit*, as well as the ability to apply it. After a deeper analysis of the tasks, we sought to assess some of the involved concepts more precisely, before implementing a teaching experiment with students of year 7 (the results of which will appear in a forthcoming article). Indeed, the teaching experiment is based on the idea of better identifying the concepts at stake in the mixed product, by testing the students before and after exposing them to didactic situations with the aim of supporting them in the development of the missing competencies (including those highlighted in the interview), and in particular, the multiplicative relations between quantities of the same kind, as units of the same family and fractional units, through a "fraction as comparer approach" (Freudenthal, 1983), as well as handling tasks.

Standing on the shoulders of Giants
– looking at the teaching subject “conics”

Ysette Weiss

Johannes Gutenberg University Mainz, Mathematical Institute, Mainz, Germany;
yweiss@uni-mainz.de

Why do we teach parabolas? One possible answer is because they are in the curriculum. How does content get into the curriculum, whose responsibility was and is the design of curricula and textbooks in Germany? The history of conic sections as a subject reveals a rich and varied teaching tradition that not only calls into question ideas about “invariability” of teaching subjects, but also enables greater openness and joy in the design of mathematics curricula.

Keywords: Conic sections, curriculum development, Neuere Geometrie, Meraner Reform, history of mathematics education

Why should math teachers in Germany study the history of German math curricula?

How did the current curriculum of secondary school mathematics come about? Over the past millennia, a large number of (still-valid) mathematical truths have been discovered, discussed, and proven. Who chooses what to teach in class and on what grounds is such a decision taken? To what extent does the development of modern mathematics effect curriculum development? Students obtaining a teaching profession should ask themselves these questions also in order to recognize their own prospective responsibility in mathematics curriculum development.

However, the study of the historical development of curricula in Germany is complicated, as these differ in the different federal states. The pronounced federalism in the German cultural and educational system has a long tradition. Until 1871 Germany consisted of many independent feudal states and free commercial towns. These small states had their own cultural and educational policies. Even with the establishment of the German Reich in 1871, the competencies were not centralized, the states remained responsible for education and culture. The promotional principle continued during the Weimar Republic. Under the rule of the National Socialist regime, education and culture were centralized. The accompanying ideologization of science and culture through racial theories, as well as the indoctrination of young people in schools, can also be demonstrated in the maths curriculum and maths textbooks (Mehrtens, 1989). The ease with which the Nazi regime was able to influence schools and universities in the centralized system led to a special appreciation of the federal division of responsibilities after the end of the Second World War. This principle was also used by the allied victorious powers of the Second World War when developing administrative structures in the western zones of occupation. In the Soviet occupation zone, however, after the founding of the GDR in the 1950s, the federal structures were dissolved and centrally standardized curricula and textbooks were developed. As early as 1956, the guidelines for the mathematics curricula for the upper level in the GDR show a strong reduction in the treatment of conic sections to spheres and calculations using methods of analytical geometry and analysis[1], while the mathematics textbooks for the the upper secondary schools in the FRG still were based on the methodology to the Weimar Republic. The *EOS* (extended general education polytechnic high school) in the GDR began with the 9th grade, the upper level had only 2 years compared to the 3 years of upper secondary classes of the Gymnasium in the FRG. Accordingly, in the justification of the guidelines for the teaching of mathematics in the *EOS*, content reduction and pre-employment focus on calculation methods are in the foreground. After reunification, federal principles were also established in education policy in the new federal states. Today, according to the federal principle, educational policy in Germany is a matter of the federal state. Accordingly, curricula, textbooks, school types differ in the different states. Standardizations and coordination are planned and implemented by the *KMK* (Conference of Ministers of Education) and relate to specific structures, such as Exam formats. The educational standards set nationwide for Germany in 2011 provide guidelines on what students should be able to do and when; these requirements are based less on content than on skills. The shift from input-oriented content requirements for the main subjects and foreign languages in the form of educational plans and curricula to output-oriented standards is one of the measures of a general turn towards output orientation and the definition of central standards in Germany. Conic sections are no longer obligatory. The introduction of central exams had a strong influence on the content of mathematics education at the Gymnasium. After 2000, a new, nationwide trend towards the *Zentralabitur* (centralised A-level-examination) began, partly with reference to the PISA studies and the unexpectedly poor performance of German students. The ideologised and scandalized debate about central exams did not refer to existing experiences with central exams in the federal states of the former French occupation zone, nor to the central examinations of the GDR and the majority of the new federal states.

The discussion of educational policy, educational institutions, mathematics curricula and exam formats in Germany, including the time of the Nazi regime, the post-war period and the special features of the GDR's educational system, is of particular importance with regard to right-wing populist developments. The growing centralization efforts in the context of the digitization of schools, which are presented exclusively as an answer to new global challenges, also require cultural and historical contextualization. For the latter, the study of mathematics education is particularly suitable due to its algorithmic subjects (Weiss, 2019). The preoccupation of mathematics teachers with the history of mathematics teaching and the development of selected content as a subject can also be motivated pragmatically in Germany at present. In some federal states there are opportunities for schools to have more autonomy, e.g. through internal school curricula that are developed by the school's teaching staff. The content-related discourses are often restricted by current pedagogical trends, such as discovery learning or project teaching. Dealing with historical teaching materials gives one the opportunity to be inspired by alternative presentations and task formats without coming into conflict with current educational theories.

Why should math teacher students in Germany study the history of conic sections as a teaching subject in German mathematics curricula?

During their university studies, the student teachers are confronted with the values of various communities of interest and common practices and thus various reasons for different selections of mathematical subjects and its concept developments. Most of the time, however, this happens implicitly through the enculturation in various communities of practice. The appearance and the disappearance of conic sections in mathematics teaching offer ample opportunities to prospective mathematics teachers to look into their own traditions. Dealing with different value systems from the historical perspective enables the prospective mathematics teachers to develop their own points of view and to structure and classify different value and norm systems without personal conflicts with actors of the different communities in their own environment.

In the following considerations we limit ourselves to the teaching practices of three communities that are or were important for the university education of German *Gymnasium* mathematics teachers: the community of researching mathematicians, the community of mathematics educators and educational scientists and that of historians and philosophers of mathematics. We also limit ourselves to the teaching of conic sections. Of course, there are lecturers and teachers who belong to several communities. Fundamental principles such as the historically determined close connection between research and teaching and the freedom of research and teaching in German university education are represented by the norms and values of all three communities. In the present article, however, the main focus will be on tensions and contradictions between these communities and their historical contextualization. For this reason, we also put contrasting values of the different communities in the foreground.

The teaching subject “conics” in the teaching practice of researching mathematicians

The education of Gymnasium math teachers in Germany is closely linked to the education of mathematicians. The mathematics diploma was only introduced in Nazi Germany.[2] To contrast the different communities, we refer in the following to university locations in which only teachers for upper secondary schools like the Gymnasium are educated (e.g. the universities of Bonn, Göttingen and Mainz). The separation of teacher education for Gymnasium teachers from that for the primary, elementary and secondary schools[3], corresponds also to the historical development. In the university education of mathematics teachers for Gymnasium, math courses are held by researching mathematicians and are usually shaped as common lectures with students studying only mathematics. The teaching activities of the community of researching mathematicians and mathematics lecturers are very much motivated by the care for the next generation of mathematicians. The value system of this community is characterized by the promotion of mathematical achievement. In many ways, values and norms result from the role of mathematics as

2 Information about the historical development of German mathematical institutes one can find in (Schubring, 1985)

3 Grundschule (from school year 1 to 4), Hauptschule (from school year 5 to 9) and Realschulen (from school year 5 to 10)

a competitive sport. The mathematics lectures focus on learning modern mathematical language and modern methods to solve open and important problems.

Conic sections appear in the mathematical lectures of math teacher students, if mentioned at all, in group-theoretical or projective contexts, but not associated with the elementary mathematical object "conic". Analytical geometry is taught in the form of linear algebra in which conic sections are used for classification implicitly. Mathematical research is highly specialized; the recognition of what counts as important knowledge is regulated by the appreciation of the international community. The predominant teaching method so far is the deductive, axiomatic. In the last few decades there have been efforts to introduce additional mathematical courses for student teachers that deal with elementary mathematical content. Such courses are usually designed by researching mathematicians.

The teaching subject "conics" in the teaching practice of historians of mathematics

The teaching and research area History of Mathematics has in Germany a long and worldwide recognized tradition (Purkert & Scholz, 2009, Weiss, 2020). In the GDR, courses on history, philosophical aspects, and the logical foundations of mathematics were compulsory in the curriculum for all students mathematics teachers (Schreiber, 1996). The extent to which mathematical-historical contexts are addressed in today's university education for student teachers depends on local conditions. In the community of mathematical historians, however, there is agreement that conic sections are a fundamental topic in the history of ideas in mathematics (see e.g. Struik, 2013). Both the Greek origins of the conceptual development of conic sections (e.g. Coolidge, 1968) and their outstanding role as a problem-solving method (e.g. Renn, Damerow & Rieger, 2002) were and are main topics of lectures on the cultural history of mathematics. However, there are also delimitations. The values and norms of teaching history of mathematics are linked to the use of historical scientific methods. The latter can differ from the use of the history of mathematics by mathematicians or math educators (Fried, 2001). Michael N. Fried and Sabetai Unguru demonstrate the explication of these contradictions using the theory of conics (Fried & Unguru, 2017). The possibility to limit oneself to conic sections when considering fundamental philosophical differences becomes apparent in Évelyne Barbins research on the philosophies or theories behind history and education (Barbin, 2015). The main examples for comparing the different methods and perspectives are conic sections (see also Barbin, 2012, Bartolini Bussi, 2015).

The teaching subject conic sections in the teaching practice of mathematics educators

In the context of subject matter didactics, the parabola, the hyperbola as examples of functions and the area and volume calculation of conics are topics of teaching. Here, too, it depends on local conditions whether connections to the content of higher mathematics or to topics of the history of mathematics are shown. As we shall see, the teaching history of conic sections is particularly suitable not only to show aspects of the historical development of the values and norms of the community of mathematics educators, but also their relationships to the other communities. In the 19th century, math teachers of the Gymnasium were simultaneously researching mathematicians and very often also historians. They developed the teaching of conics taking all three perspectives into account.

The history of teaching conics as a path to common traditions and values

Scientific development and the elementarization of mathematics

This contradiction between mathematics as a science and the exemplified elementary school mathematics was the basis of different fruitful discourses in the 19th century, which led to a transformation of the pre-university teaching that was to great extent shaped by Euclid's elements until then. The focus on the development of geometry teaching in the 19th century is especially illuminative since here the scientific development and the elementarization of mathematics happened parallel to each other at frequent intervals and often by the same people. The historian and maths teacher Max Simon for instance notes: "When you look at the elementary geometry of the 19th century, it is especially worth mentioning, how the great developments of science also come to light in elementary geometry." (Simon, 1906, translation by the author). These developments are among others descriptive geometry (Monge), Analysis situs (Carnot, von Staudt), geometrical constructions (Steiner), projective properties (Poncelet), barycentric coordinates (Möbius), linear algebra and algebra (Graßmann, Plücker), analytical geometry (Gergonne).

Flourishing teaching culture in *Neuere Geometrie*

Under the banner of *Neuere Geometry* (Newer Geometry), the research in geometry as a science and the educational reforms in mathematics teaching merge. "The New Geometry, seen from its genesis, is not as much in contrast to the geometry of the ancient than it is in contrast to analytical geometry… Analytical geometry as a subject is a continuation to the elements, but as a method, it is in contrast to the elements"(Pasch, 1882, S.1, translation by the author). The immediate junction of new developments in mathematics with teaching reforms is also fostered by the professionalization of the teachers, restructuring of the school system, development of new curricula as well as changes in the university system. In 1810, for instance, the examination of teachers for *higher schools* was introduced, which did not only require decent knowledge in philosophy and history but also in mathematics. In 1812, the deep knowledge of Euclid's books 1-6, 11 (spacial geometry) and 12 became a general requirement for the final examination (*Abiturprüfung*) at school.

With the so called *Süvernscher Normalplan* (1816) and a renewed lesson scheme for maths education, for instance the analytical approach to conic sections became a teaching subject in grade 10 and 11 (*Sekunda*, 16-17 years old) at the *Gymnasium*. While the conic sections were taken up in the curriculum, text books with different approaches to the subject appeared. For an impression about these different presentations, we recommend a look at the antiquarian or digitally available text books of this time. The theologist Johann Andreas Matthias (1813) for instance, chose the approach to conic sections along the Apollonian way. The mathematician Johann August Grunert (1824) however, used the analytical method to deal with conic sections in his teaching script with exercises and their demonstrated solutions. Also, the mathematician, philosopher, reform educator (*Reformpädagoge*), politician, school teacher (*Schulmann*) and founder of the Berlin Pedagogical Seminar, Karl Heinrich Schellbach, composed in 1843 a text book about conic sections (Schellbach, 1843). An impression of later teaching texts on the subject, which even took projective approaches into account, as well as a detailed analysis of the presentation of *Neuere Geometrie* is provided by

Sebastian Kitz in his dissertation on *Neuere Geometrie* as teaching subject for higher teaching institutions (*höhere Lehranstalten*) between 1870 and 1920 (Kitz, 2015). Examples of the appearance of modern mathematical developments in elementary geometry, as it was described by Max Simon, are also Hermann Hankel's (Hankel, 1875) and Jakob Steiner's (Steiner, 1876) synthetical treatises on conic sections.

The royal road to geometry

The expectations regarding the reforming power of *Neuere Geometrie* become apparent in Hankel's way to rephrase the well-known ancient anecdote: "There is no royal road to geometry. We, however, can add: The *Neuere Geometrie* is this royal road." (Hankel 1875, S.33, translation by the author). Despite these high expectations in the *Neuere Geometrie* and its rapid development as scientific discipline, the school reform initially experienced setbacks. The choice between synthetic and analytic geometry, between Euclidean and *Neuere Geometrie* was at first in the *Gymnasium* decided in favor of Euclidean geometry without the treatment of conic sections. Consequently in 1837, by a Prussian circular directive (*Preußisches Zirkularreskript, i.e. Runderlass*) of Johannes Schulze, the successor of Süvern, disposed a reduction of scheduled mathematics lessons and the removal of conic sections of the curriculum at the Gymnasium (Treutlein, 1911, pp. 37- 45).

Meraner Reform and *Anschauungslehre*

Only during the gathering of philologists in 1864 in Jena, it came to the foundation of a mathematical-pedagogical section and to the revival of the discussion on conic sections for the teaching at secondary school. In these discussions, the treatment of conic sections in analytical form was linked with the notions of variable and function and hence with the intentions of the *Meraner Reform* for the introduction of differential- and integral calculus (Schimmack, 1911). The proposals of the *Meraner Reform* did not only take those parts of the theory of conic sections with a direct relation to the notion of function into account, but also recommended to deal with conic sections in analytical and synthetical form – even with application to the elements of astronomy, albeit without exemplification of its implementation. Another source of the reformation of the Euclidean tradition of geometry teaching is the development of the *Anschauungslehre*, an education to an inner intuition and view. The geometry book in three volumes of Henrici and Treutlein (Henrici & Treutlein, 1981-1983) as well as Treutlein's *Anschauungslehre* (Treutlein, 1911) – called by Felix Klein "exceptionally noteworthy book" (Klein, 1925, p. 261) – give a good impression of a versatile pedagogically rich treatment of conic sections respecting the different approaches. Accordingly, Treutlein connects plane geometry with spatial geometry by geometrical transformations as reflections, creates references to applications and uses folding and models for the education of internal intuition and view (*Anschauung*) (Weiss, 2016). Also, descriptive geometry, that was only taught at *Realgymnasium* and *Oberrealschule* (secondary schools with a focus on science) can be found in the appendix of the third volume of the geometry text book of Henrici and Treutlein. Here we find (without exercises) an introduction in different projection methods and hence an integration of this approach. An other interesting textbook on the theory of conics, which implemented the perspective of geometric algebra, was the book by Hieronymus Georg Zeuthen (Zeuthen, 1882), a Danish historian and mathematician.

The dawn of conic sections

From the beginning of the twentieth century until to the New Math in the Seventies, one can find planimetric, stereometric, analytical, affine, perspective, projective up to group theoretical conceptions of conic sections, mostly close to the treatise of Walter Lietzmann's *Elementare Kegelschnittlehre* (Lietzmann, 1949). Until the end of the sixties, one can speak of a bloom of conic sections. The New Math brought conic sections in relation with differential and integral calculus as well as considerations with set-theory and geometrical transformations. Spherical geometry served as contextualization of contents and methods that were acquired in the theory of conic sections (Athen et al., 1967). Not well-known are the international endeavors in the New Math reform (De Bock & Zwaneveld, 2017) to strengthen the application side of New Math. Also, in general secondary schools of the GDR the basics of descriptive geometry where taken up in grade 7 and 8 when the school subject Technical Drawing was introduced. With the reform of the upper school in 1975 and unified examination requirements the conic sections were more and more reduced to linear structures in analytic geometry and in the analysis to the investigation of function graphs of parabolas (Schupp, 1988) and are nowadays reduced to the context of functions. The introduction of dynamic geometry software, in particular with the possibility of 3-dimensional dynamic representations, has not yet led to the high expectations placed on it with regard to the revival of traditional geometrical content. On the other hand, the new technical possibilities for visualizations and animations also arouse the interest of mathematicians who are teaching higher mathematics and perhaps open new doors for common practice.

Introduction

Thematic Working Group 13 focuses on the mathematics learning of 2–8-year-olds. We acknowledge that this learning may take place in kindergarten, preschool, primary school, and other less formal settings. We pay attention to how mathematics is approached implicitly and explicitly by children and teachers, and other responsible adults. A wide range of topics is covered in TWG13, spanning different areas of mathematics and different theoretical and methodological approaches. This wide span is a characteristic feature of TWG13, a feature that has been documented at other conferences as well (e.g., the POEM conferences, see Carlsen et al., 2020) and by Levenson et al. (2018).

Overview

Thirty-six participants from fifteen countries presented 22 papers and 3 posters in TWG13 during the CERME12 conference. These were organized into eight themes, namely: theoretical frameworks, toddlers' education, teachers' actions and training, curriculum and inclusion, analyses of children's activities, measurement in early years mathematics, literature overview, and prospective teachers' education. Each session was devoted to one of these themes and contained paper and poster presentations, followed by a discussion on the presentations, as well as a general discussion on questions related to the theme of the session. Next, we present the main questions related to each theme and the main outcomes of the discussions that took place.

Theoretical frameworks

Two papers were presented in this session, by Wernberg and Johansson, and by Kleven. The questions discussed were related to the possibility and the plausibility of a 'unified' theory, used to provide a holistic view of a learning situation. The discussion led us to acknowledge that theories cannot be static; they need to be continuously developed and adapted, e.g., by empirical studies. Especially when analyzing kindergarten activities, it is difficult to restrict oneself to only the children, the adult, or the activity, since they are all interwoven. Therefore, several frameworks can be useful to grasp this complexity; these frameworks could be the part of a network of theories.

Additionally, qualitative and quantitative methodologies could be used complementarily, in order to reach well-verified theories.

Toddlers' education

Three papers were presented in this session, by Cooke, by Palmer and Björklund, and by Vanegas, Giménez and Prat. The questions discussed related to the outcomes of studies on toddlers' mathematical learning and on the limitation of such studies. We firstly observed that studies on toddlers' mathematical learning are becoming more frequent in TWG13. Additionally, we agreed that the analysis of the mathematical activities of such young children raises questions on whether and what kind of mathematics is actually involved in those activities. By not having access to the verbal utterances of these children, the risk of over-interpretation may be high. We also agreed on the importance of engaging or collaborating with preschool teachers, since their expertise and experience might be crucial in understanding the toddlers' ways of expressing themselves.

Teachers' actions and training

Three papers were presented in this session, by Erfjord, Carlsen and Hundeland, by Barkai, Levenson, Tsamir and Tirosh, and by Anantharajan. The questions discussed were based on the premise that teachers in early childhood education must make many choices related to mathematical activities, materials (books), drawings, etc. These choices may be influenced by their beliefs or their curiosity to learn more about children's thinking. So, we discussed the factors that affect these beliefs and these choices and whether professional development can affect them. We concluded that teachers in early childhood education often have quite stable beliefs, much dependent on their subject-specific knowledge, e.g., beliefs about teaching and learning arithmetic may be different from those about geometry. Similarly, teachers with a problem-solving view on mathematics may highlight different counting strategies, while teachers with an instrumentalist view encourage fixed algorithms. Moreover, teachers' mathematics anxiety may occasionally lead them to resources with immediate use, e.g., a textbook or a worksheet.

Curriculum and inclusion

Three papers were presented in this session, by Henriksen, by Højsted and Rasmussen, and by Lange, Lembrér and Meaney. There was also a poster presented by Walla. The questions discussed were focused on the challenges and the benefits of comparing mathematics curricula from different countries, but also on achieving inclusion. We agreed that considerable differences concerning the role of curriculum in early years mathematics exist among different countries. Therefore, comparing curricula may be quite challenging. The same is the case with the use of textbooks, since most countries do not use textbooks in kindergarten. This, combined with a non-explicit curriculum on mathematics, may in turn lead to a reduction of mathematical activities in kindergarten. We also agreed that the issue of equity is not solely an issue for the mathematics classroom but affects all school subjects.

Analyses of children's activities

Three papers were presented in this session, by Baumanns, Pitta-Pantazi, Demosthenous, Christou, Lilienthal and Schindler, by Conceição and Rodrigues, and by Vogler, Henschen and Teschner.

There was also a poster presented by Pettersen, Volden and Justnes. The questions discussed were based on the premise that often, a narrow focus is needed when we analyze very young students' mathematical activity. So, we discussed the possibilities for triangulation and for generalization of our results. In our discussion, we acknowledged the context-bounded nature of most research on early years mathematics, which in turn leads to qualitative approaches. We also noted that the culture of assessment in the early years varies across different countries.

Measurement in early years mathematics

Three papers were presented in this session, by Robotti, by Pytlak and Maj-Tatsis, and by Hoth and Fricke. We discussed whether a more general measurement sense is useful, e.g., one that incorporates comparisons of objects, informal measurements, etc. We also considered whether the introduction of standard units or other measurement tools support children's first approach to measurement or their intuitions about measure sense. It was noted that in many countries there are learning trajectories beginning with comparisons and by using non-standard units, while there are also activities on measuring with meters or rulers. We agreed that the use of standard units relies on the ability to identify numbers, while the use of non-standard units relies on an experience which supports the discovery of measuring and contributes to construct the measurement sense. Thus, children's experiences of length comparison as a daily activity and the use of non-standard units give rise to the necessity of standard units.

Literature overview

Three papers were presented in this session, by Flaten, by Maffia and Silva, and by Tzekaki. We discussed what can be learned by literature reviews or syntheses. We also discussed the necessity of reaching consensus on our terminology, e.g., on playful learning, board games, and patterning. We agreed that the field of early years mathematics education is blurred, as is mathematics education in general. This is mainly due to the concepts and methodologies adopted from different research areas, such as psychology or sociology. Therefore, literature reviews and other systematic reviews are very helpful in planning and conducting research, since they allow us to systematize our own approach and to look at a given issue from different points of view. We also agreed on the necessity of consensus on our terminology, regardless of cultural differences. At the same time, we need to be aware that sometimes we observe the same terminology used to describe different aspects of mathematics education, but also different terminology used for the same aspects of mathematics learning. This makes it sometimes difficult to synthesize the results of empirical studies.

Prospective teachers' education

Two papers were presented in this session, by Sabo Junger, Ferme and Lipovec, and by Sala-Sebastià, Breda and Farsani. Given the fact that most, if not all, early years teachers do not have a solid mathematical background, and do not necessarily believe in the importance of problem solving, we discussed two issues concerning teacher training, namely how can prospective teachers' problem solving skills be enhanced and how can their attitudes towards problem solving be changed. In our discussion, we agreed that the terms 'problem', 'word problem', 'task' and 'modeling' should be clarified, in order to assist prospective teachers. We also agreed on the necessity of incorporating problem solving as part of prospective teachers' training, including the use of various heuristics. This in turn, may assist them in identifying and utilizing opportunities for spontaneous problem solving, which will appear during their teaching. Additionally, it can make them cautious before providing children with too much help during problem solving.

Future directions

From the summaries of each session above, we observe that, besides the growing interest in early mathematics education, there are a number of issues that need attention, also in the future. The various curricula, kindergarten systems, and school systems differ significantly across the European countries. These cultural issues cause difficulties for researchers when comparing, aligning, and reflecting on the research results from different countries. However, the discussions that took place in CERME12 were promising in the sense that a growing understanding and acknowledgement of these cultural differences were emerging. Related to the issue of cultural differences, researchers might focus more on early mathematics education in the family, by asking questions such as: How may parents and other responsible adults provide opportunities for young children to engage in mathematics at an early age? Another issue that emerged was the need for developing systematic research in our field, as a way to cope with the multiplicity of approaches and methodologies. Finally, few studies were concerned with affective issues related to early years mathematics. This might be another avenue for future research.

We look forward to further scientific discussions in future CERME conferences. Several of the participants of CERME12 have attended the Early Years Mathematics group several times in the past. We thus see the contours of a research community across country boarders.

Teachers’ curiosity about their own student’s counting over time

Madhuvanti Anantharajan

Stanford University, USA; madhuvan@stanford.edu

Using the novel construct of teacher-curiosity, this study extends the idea that teaching in early mathematics is effective when based on students’ mathematical thinking. The study examines how six early childhood mathematics teachers’ curiosity towards one of their own students’ thinking changes over five weeks, alongside professional learning (PL) to support teacher-curiosity. Findings suggest that teachers can stay curious and continue learning about students with whom they are familiar.

Keywords: Teacher-curiosity, Early childhood mathematics, Teacher-learning.

Introduction and literature review of teacher-curiosity

Attending to children’s mathematical thinking is a vital component of teaching early mathematics (Carpenter et al, 2017; Franke et al., 2001). A potential way to help teachers attend to children’s thinking is to support teachers’ curiosity about how students think. This study uses the framework of teacher-curiosity to examine changes of early childhood mathematics educators’ curiosity about one of their own students’ mathematical thinking. Teacher-curiosity is defined as an instance where “teachers recognize something as unknown, unfamiliar, puzzling, uncertain, or new in the context of teaching and learning, and feel motivated to initiate inquiry into that instance” (Anantharajan, 2020. p.31). This definition is based on a framework of teacher-curiosity (Figure 1) developed from literature in teacher-learning and mathematics education; philosophical work on curiosity; and studies of curiosity in psychology.

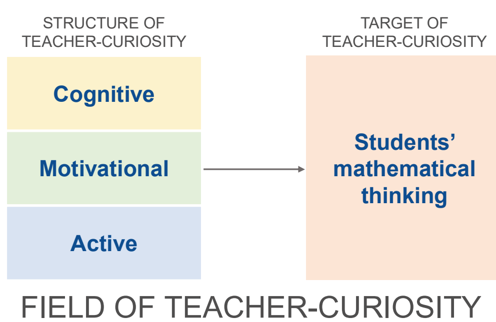

Figure 1: Framework of teacher-curiosity

The framework of teacher-curiosity comprises of cognitive, motivational, and active aspects (Anantharajan, 2020). Psychological studies describe the cognitive aspect of curiosity as experiences of surprise, ambiguity, puzzlement, or novelty (Berlyne, 1966; Kashdan, 2004; Lowenstein, 1994). In the current study, this involved teachers identifying something as surprising, ambiguous, puzzling, or new in student-thinking. The motivational aspect of teacher-curiosity involves what the teacher wants to learn about, from among elements that are surprising, ambiguous, puzzling, or new. Finally, the active aspect of teacher-curiosity involves the steps that teachers take to pursue their curiosity and learn more. The framework also relates curiosity to its target: knowledge. The target of teacher-curiosity in the current study is teachers’ knowledge of students’ mathematical thinking. This study focused specifically on children's understanding of counting: principles of counting like one-to-one-correspondence, cardinality, and number-sequence, and strategies such as grouping, skip counting and so on (Carpenter et al., 2017).

Approaching children's thinking with curiosity may help teachers identify what they wish to learn about, and teaching moves they can implement, which is often a challenge (Jacobs et al., 2010, van Es et al., 2008). The broader study in which the current paper is situated aimed to support teachers' curiosity about student-thinking through a PL. The current paper analyzes some potential transfer of teacher-learning from the PL context to the participants' classroom practice. The research question addressed in this study is: How does participants' curiosity about their individual focal student's mathematical thinking (FST) change over five weeks during which the participants take part in a professional learning module to support teacher-curiosity?

Research Design and Methods

The study was grounded in the early mathematics activity of Counting Collections. Children count collections of objects and teachers observe them count, not telling them what to do but asking students to explain their work. These interactions allow teachers to make sense of students' counting. The activity was a common element across the PL and participants' practice. The six participants taught grades TK[1] to 1 in three schools in the US, in California. Four participants taught multi-grade classrooms of K-1 and the participants' teaching experience ranged from one to twenty years. Participants implemented Counting Collections prior to the PL and were familiar with teaching based on children's thinking. They were paid a nominal honorarium to compensate them for their time in the study and the professional learning module.

The PL was informed by the research on teacher-learning (Borko et al., 2014; van Es & Sherin, 2008) and supporting curiosity (Kashdan & Fincham, 2004), and facilitated by the author. Participants were individually interviewed before and after the PL, during which they also responded to a video of a child counting. The PL included six weekly, after-school sessions of 90-minutes. One session was held after a two-week gap. Sessions included video-based discussions based on the teacher-curiosity framework, opportunities to engage in mathematics, and reflect on curiosity in practice. Participants also shared video from their own classrooms, recorded with a wearable camera during interactions with a student. Participants presented and posed questions about aspects of the clip they were curious about and received feedback from other participants. Of these multiple forms of data about the participants' curiosity, the current paper analyzes one specific data set described below.

Focal student documentation

At the start of the PL, each participant chose a focal student from their classrooms whose thinking they wished to understand better. Each week, the participant independently interacted with and documented this student's thinking during Counting Collections. The researcher did not observe this interaction. Participants used the focal student documentation tool (Table 1) each week to document their curiosity about the focal student. The tool progresses from noticing to the cognitive,

1 Transitional kindergarten (TK) is a grade level in the California public school system for 4-year-olds who turn five after September 2 of the school year. TK is followed by kindergarten.

motivational, and performative aspects of teacher-curiosity. Participants sometimes collected the student's work or took photographs of the student's counting, but only the weekly documentation tool was collected as data for this study. Participants did not share any identifiable details about the focal student. The effects of participants' curiosity on FST were not studied. During the last session of the PL, the participants also completed a focal student reflection tool, where they reflected on the previous six weeks of their own curiosity about the focal student. The data for the current analysis consists of the weekly documentation tool. Thus, each of six participants completed five instruments.

During the last part of the weekly PL meeting participants shared with a discussion partner what they learned about their focal student, what they still wished to learn, and asked for suggestions and feedback from their partners on next steps. Participants were paired with different partners each week, to enable a variety of feedback and suggestions based on their partners' knowledge and experience.

Table 1: Focal student documentation tool

Question/ prompt in documentation tool	Dimension of teacher-curiosity
What did you notice while watching this student count?	Target
What did you think this student understands or is able to do in terms of counting?	
List all the things that felt new, surprising, puzzling, unclear or unknown to you about the student's thinking.	Cognitive
Among these things, what interested or mattered to you to find out more about? Why?	Motivational
What next steps can, or did you take, to find out more?	Active
What can or did you do to record or keep track of the student's thinking?	
How can you confirm your understanding of the student's thinking?	

Analysis

The data was analyzed using a coding framework of *a priori* and emergent codes, in Nvivo (Table 2). Code 1 captured the *structure of teachers' curiosity about student-thinking*. The subcodes represent the dimensions of the teacher-curiosity framework, namely (1a) cognitive, (1b) motivational and (1c) active aspects of teacher-curiosity. The motivational aspect included subcodes to capture whether the participant wished to learn about something related to student-thinking (1bi) or not (1bii). Similarly, the active aspect of curiosity included subcodes to capture whether the participant's response to the student is meant to elicit student-thinking (1ci) or direct it (1cii). Code 2 captured the *mathematical ideas that participants noticed in student-thinking* based on principles and strategies of counting identified in the early mathematics research. Each of these sub codes was coded as a strong understanding or a partial understanding, and the participant's use of evaluative language to describe student-thinking. Inter-rater agreement was calculated for about 30% of interview data, as a combination of Kappa statistics at the parent code level, and discussion and consensus at the grandchild code level. The Kappa values ranged from 0.7-1.0. After reaching agreement on the interview data the two coders discussed the focal documentation data to confirm that the codebook could be applied to these data. The researcher coded the focal student data. The second coder independently proposed codes. Disagreements were discussed to reach consensus.

Table 2: Samples of coded data

Code	Sample of coded data
1a. Cognitive	I was happily surprised that she knew to count by tens this time. (Beth, wk 3)
1b. Motivational	
1bi. To learn about student-thinking	Would he be able to add any of his groupings together or would he revert back to counting by 1s [?] (Lillian, wk 2)
1bii. For other reason	Because she wasn't using counting by 2s to her advantage to help her double check. (Hannah, wk 4)
1c. Active	
1ci. Elicit student-thinking	"I asked her to show me how she made her rows again with more items from the collection. She continued to make uneven rows. I said I wondered why they had different amounts. She said they needed to get "bigger."" (Rita, wk 1)
1cii. Direct student-thinking	I asked her what 2 100 charts would make to see if she had the vocab & she did. So I guided her using the 100 charts as reference on how to count to 100. (Stacey, wk 5)
2. Mathematical ideas in student-thinking	
2a. Strong understanding	She has pretty good one-to-one correspondence. (Bella, wk 1)
2b. Partial understanding	"She counted by 10s and stacked the 10s into 10s (for the second time) But when counting she couldn't go past 100 by 10s." (Stacey, wk 5)

Participants' responses were organized into a table with responses to each question, each week. As each participant documented a different student no analyses was done across participants. Each participant's data from week 1 was a starting point. This initial data was compared with the combined data from weeks 2-5 for that participant. By comparing the week 1 data to the cumulative data over the subsequent four weeks, the analysis illustrates the participants' knowledge and curiosity about FST at the beginning of the PL (week 1), with what they subsequently learned and wanted to learn about the focal student over the next four weeks. The data from week 2-5 were combined because the iterative weekly changes for each participant were small and happened at different points. However, the cumulative change over the subsequent four weeks is clearer to perceive and acknowledges the overall magnitude of learning and effort by the participants. Combining the data from these weeks did not inflate what participants learned over that time but simply illustrates the change in what they learned or wanted to learn about their focal student from week 1.

Findings

Participants identified more mathematical understandings in FST

All participants noticed more strong and partial understandings from weeks 2-5, compared to what they started with in week 1 (Table 3). All participants also noticed the change in students' understanding of at least one mathematical idea over time. Participants were not prompted to follow the student's understanding of one idea. However, all participants did so, alongside other ideas. None of the teachers used evaluative language when documenting their curiosity about their own focal student during the five weeks of documentation.

Table 3: Changes in teacher-curiosity about FST

	Bella		Beth		Hannah		Lillian		Rita		Stacey	
	Wk 1	Wk 2-5	Wk 1	Wk 2-5	Wk 1	Wk 2-5	Wk 1	Wk 2-5	Wk 1	Wk 2-5	Wk 1	Wk 2-5
Mathematical understandings	3	12	3	13	3	17	4	15	3	17	3	9
What teacher found surprising etc.	2	7	1	4	1	4	2	4	2	10	1	7
What teacher wanted to learn more about	0	3	1	4	1	2	2	3	1	6	1	4

Participants identified more surprising, puzzling, ambiguous or new aspects of FST

Compared to the number of instances that participants found surprising, puzzling etc. about their respective focal students in week 1, all teachers record between 4 and 10 additional sources of surprise, puzzlement etc. about the focal student's counting, from weeks 2 to 5. (Table 3) As an example, Table 4 illustrates data from Rita's documentation.

Participants posed more questions about FST

At the end of five weeks, all participants identified more things about FST that they wanted to learn about, compared to week 1. From week 1 to 5, the number of things the teachers wanted to know about their students' thinking increased by between 2 and 6 (Table 3).

Participants implemented/ proposed multiple responses intended to elicit FST over five weeks

All participants proposed or enacted between 3 and 12 types of responses to elicit specific details of FST (Table 5). All participants mention certain types of responses: specific counting tasks to elicit

Table 4: Change in cognitive aspect of Rita's curiosity about her focal student

Week 1	Weeks 2-5
It was surprising that she would make rows with different amounts. I also wondered why she chose the large collection she did when she hadn't before.	I was surprised she began numbering the second row of objects at 1 again. I have seen her write her numbers 1-20, so I wondered why she couldn't in this instance. New: she matched color of beads to bowls Unclear: her plan for counting all Puzzling: why she thought matching colors would help. Why is she successful at grouping and adding when she uses one-color collection? How does she see this collection differently? Why did she work better by herself? I wondered how she made the connection to start grouping. I wondered if using the days-in-school chart supported this learning. I wondered what attracted her to use the same collection and how that helped her.

mathematical ideas, questioning and asking students to explain their thinking, and documenting or note taking about the focal student. Four participants indicated directive moves as part of their response. Of these, three participants indicated directive moves in the first week and not after that. One participant did not indicate directive moves till the fourth week. The documentation did not indicate a clear shift from directive to eliciting moves by the participants. Over the duration of the PL participants may have felt a conflicting need to learn about student thinking and have the student meet certain learning goals. This conflict may represent a challenge that teacher-curiosity poses in practice.

Discussion

Analysis of the focal student documentation provided a brief glimpse of how participants' learning in the PL transferred to their own practice over time. The results indicate that over five weeks, participants identified more understandings in their respective FST compared to week one, more aspects of FST that they found surprising puzzling, ambiguous or new, and more questions about FST. Finally, participants implemented or proposed multiple responses intended to elicit FST over the course of five weeks. Thus, the findings suggest that the PL and the teacher-curiosity protocol may help teachers perceive changes in, and develop a deeper understanding of, their students' thinking. The findings also suggest that, with consistent support, the participants' familiarity with their own students did not prevent them from identifying new, surprising, or puzzling things about the student. Rather, the results align with Loewenstein's (1994) notion that overcoming "manageable gaps" in knowledge and learning increases, rather than decreases a person's curiosity.

Participants likely drew on a wealth of implicit knowledge about the focal student and their class contexts, which informed what they noticed, found surprising, wished to know about, and how they responded. For example, knowing what mathematics the class had engaged with up to that point of time may have led participants to notice if the focal student struggled with something when others in

Table 5: Types of responses to focal student proposed by participants from weeks 1-5

Types of responses	No. of participants
Give tasks to reveal specific understanding	6
Question student or listened to student explain	6
Make notes or document student work	6
Have student record their counting	5
Observe student	5
Provide or suggest tools and other physical supports	4
Demonstrate to or direct student	4
Give group work and whole class activities	1
Give open-ended counting task	1
Give tasks to extend student thinking	1
Compare student work over time	1

the class did not. When focusing on the whole class, participants could likely only manage brief observations and conversations with the focal student, limiting the detail of what they were able to document. However, they had the opportunity to repeat their observations, which may have shaped participants' curiosity about their focal students. The fact that all participants followed their focal student's understanding of one mathematical idea over time suggests that the documentation process may have allowed them to consistently focus on a single idea. All teachers happened to observe a change in their student's understanding of grouping to count. This is likely a common mathematical idea at this grade level that the participants saw as an important part of curriculum. It is also possible that having more opportunities to interact with the focal student allowed participants to propose or try different responses with the student. The documentation tool included detailed questions regarding how they documented FST and how they might confirm what they learn. These questions suggested that responding to FST may involve multiple moves. The participants' suggestions to each other during PL meetings may have also motivated them to try different responses.

One concern may be that the comparison between week 1 and the combined responses of weeks 2-5 may misrepresent the participants' curiosity. However, rather than obscure details of weekly changes, this approach makes explicit that by actively engaging with FST over five weeks, participants were able to identify several aspects of their students' thinking that they did not fully understand and wanted to learn about. These additional questions may not have emerged for the participants if they stopped engaging with the student's thinking after one interaction. Overall, the findings suggest that actively supporting teachers' curiosity about their students can help them use their knowledge of their students to discover details of their students' mathematical thinking over time, rather than view their students as "known" entities. Classroom-based research on teacher-curiosity over a longer period is necessary to better understand how teacher-curiosity can be supported in PL and motivate practice.

This paper describes a course attended by 30 graduate students in mathematics education, non-preschool teachers, that aimed to promote participants' knowledge of young children's development of numerical competencies. Prior to the course, participants held high positive beliefs towards children's engagement with numerical activities, but their self-efficacy was low. Findings indicated that mastery experience, mostly by repeatedly analyzing videos, and repeatedly designing tasks, afforded participants a chance to see how they were progressing and increased their self-efficacy.

Keywords: Adults' beliefs, adults' self-efficacy, mastery experience, numerical competencies.

Introduction

In recent years, there has been a growing emphasis on early childhood mathematics education and the professional development of preschool teachers (e.g., Tirosh et al., 2019). While this is commendable, young children spend much of their time at home with parents, grandparents, and other responsible adults. As such, increasing adults' awareness of their roles in promoting early numerical skills is important. In a previous study (Levenson et al., 2021) we investigated 91 adults' beliefs (none were early childhood educators) regarding supporting children's engagement with various numerical activities. Findings indicated that in general, participants had positive beliefs towards early mathematics.

The current study builds on that previous study by investigating a small group of adults who participated in an intervention aimed at promoting their awareness to and knowledge for engaging children with numerical activities. In this paper, we describe the intervention and present findings related to adults' beliefs before and after attending the intervention. In addition, we investigate their self-efficacy for engaging young children with numerical activities. Even if adults believe in the importance of their involvement and the importance of engaging children with numerical activities, they might not believe they are capable of doing so, and thus might avoid such activities.

Background

Studies of adults' beliefs regarding early mathematics have mostly focused on parents. Those studies found that while parents tend to agree that mathematics can be and should be promoted in the years before first grade (e.g., Missall et al., 2015), they also believe that engaging young children with mathematical activities is less important than engaging children with literacy activities (Blevins-Knabe et al., 2000). Not surprisingly, in that same study, parents also reported reading to their children more often than engaging them with mathematics activities. Whether during everyday contexts, such as carrying out household chores, or during more structured contexts, such as direct teaching, parents reported helping their children learn language skills more than mathematics (Cannon & Ginsburg, 2008). Thus, it may not be enough to have positive attitudes and beliefs towards early mathematics.

In addition to a person's beliefs, studies have found that self-efficacy can also impact on a person's behavior (Bandura, 1986). Bandura defined self-efficacy as "people's judgments of their capabilities to organize and execute a course of action required to attain designated types of performances" (1986, p. 391). Self-efficacy was found to be related to the effort, persistence, and commitment one places in their actions (Allinder, 1994). Parents' self-efficacy to parent successfully was found to impact on their involvement in their children's academic domain (Hoover-Dempsey et al., 2001), even at the preschool level (Pelletier & Brent, 2002). According to Bandura (1997), there are four main sources for a person's self-efficacy: mastery experience, vicarious experiences, verbal and social persuasions, and emotional and physiological states. The most powerful source is mastery experience; when a person completes a task successfully and deems the effort to complete that task worthwhile, that person's confidence to complete similar tasks will rise. In studies of teacher self-efficacy, this source has been found to be very influential (Arslan & Bulut, 2015). After mastery experience, vicarious experiences also impact on one's self-efficacy. A person gauges their success at a task by comparing themselves to others with similar abilities or attributes, who have engaged in the same task. The third source, verbal and social feedback, is considered weaker than the first two, although people do tend to see themselves through the eyes of others. Finally, the last source of self-efficacy is based on how people interpret affective states such as anxiety and mood.

Related to this study is how interventions can impact on self-efficacy. In one study, parents' self-efficacy increased after participating in an intervention that helped them focus on their children's strengths, as well as their own parenting strengths, while practicing new parenting skills (Waters & Sun, 2016). In another study, parents and their preschool children attended a school-readiness program where parents interacted with their children and observed teachers interact with their children (Pelletier & Brent, 2002). Findings indicated that parents' self-efficacy related to their own ability to teach and motivate their child increased. Parents reported that having the opportunity to interact with their child along with teacher support, impacted on their self-efficacy. Thus, mastery experiences and social feedback were sources for self-efficacy. For pre-service mathematics teachers, a methods course that involved group work when learning how to implement challenging tasks, served as an intervention that raised participants' self-efficacy through vicarious experiences (Yurekli et al., 2015).

The current study and intervention were based on the Cognitive Affective Mathematics Adult Education (CAMAE) Framework (Levenson et al., 2021). The framework considers knowledge adults need for engaging children with playful mathematics, including knowledge of content and children (e.g., knowing that children aged three may not yet have acquired the cardinality principle of counting) and knowledge of activities that can promote numerical thinking. The framework also considers accompanying beliefs. In our previous study, we found that adults believed in the importance of their own intervention for promoting children's numerical knowledge, yet significantly less participants believed that they needed guidance to do so (Levenson et al., 2021). Furthermore, no differences were found between parents, adults who have some other connection with young children, and those who claimed to have no connection with young children. In that study, self-efficacy was not investigated. In the current study, we investigate the beliefs and self-efficacy of adults prior to and after participating in an intervention aimed at promoting their awareness and knowledge for engaging children with numerical activities. Our research questions are: (1a) To what degree do adults hold positive beliefs towards promoting numerical skills in early childhood and (1b) believe that adults' interactions with young children are important? (2a) What are adults' self-efficacy beliefs regarding knowing children's numerical skills and (2b) what are their self-efficacy beliefs regarding designing numerical activities for young children? (3) How might a course that aims to promote adults' awareness and knowledge for promoting young children's numerical skills impact on adults' beliefs and self-efficacy?

Method

Participants and setting

The setting for this study was an elective course entitled *Early childhood numerical thinking: Theory and research,* attended by students working towards their master's degree in mathematics education. There were 30 participants (not the same as in our previous studies), of which twelve were parents of children between the ages of three and six, 13 had some other relationship with children of that age, and five claimed to not have any significant relationship with children of that age. None were early childhood educators. We chose this context for our study, wishing to include at this point in our research only adults who we hypothesized would have a general positive disposition towards mathematics. The aim of the course was to raise participants' awareness of number competencies developed prior to first grade, and in accordance with the framework, to increase their knowledge of children's development of those competencies, as well as the tasks that might promote early number knowledge and competencies.

The course included 13, 90-minute sessions, and focused on three major numerical competencies: counting and enumerating, comparing sets, and number composition and decomposition. During the first and last session, participants watched and then individually analyzed a video of Omer, a three-year old boy and his grandmother Esther (the second author of this paper), engaging in various counting activities while baking cookies. Analysis of this video, as well as other video clips viewed during the course, focused first on the child's ability to carry out the activity (e.g., Could the child count the cookies on the tray, and what were his difficulties?), as well as the adult's role in the activity (e.g., What exactly did the grandmother ask her grandson to do? How were the cookies arranged on the tray?). We will relate to this video and its analysis as the first activity (1) of the course. The rest of the course consisted of a series of activities repeated for each competency: (2) read and discuss related research (e.g., Gelman & Galistel, 1978; Tsamir et al., 2015), (3) view and analyze together YouTube videos of preschool children practicing that competency, (4) individually design a task to implement with a preschool child aimed at promoting that competency, (5) discuss together proposed tasks and agree upon one common task that each participant would carry out, (6) implement the agreed upon task with a young child while videoing the activity, (7) individually analyze the child's knowledge and competency when carrying out the task, (8) view and analyze together participants' videos. In accordance with the aims of the course and the framework, for each element of the course, we discussed children's ability to carry out a particular skill, as well as how a task may be designed and implemented to focus on a specific skill. For example, when discussing Tsamir et al.'s (2015) study of children's strategies for decomposing numbers, we discussed which strategies were more advanced and appropriate and how the task challenged children or supported a specific strategy.

Tools

A two-part questionnaire was handed out during the first and last sessions of the course, the first part focusing on beliefs and the second part focusing on adults' self-efficacy. A six-point Likert scale (1 being the lowest degree of agreement) was used to rate participants' agreements with the belief and self-efficacy statements. There were six belief statements related to promoting early numerical skills (see Table 1) and twelve self-efficacy statements, of which six related to knowing children's conceptions (e.g., I am capable of identifying different arrangements of 8 items which children find difficult to count) and six related to building appropriate numerical activities (e.g., I am capable of building activities that will promote children's skill in counting eight objects). Each group of six self-efficacy statements was combined to give an average self-efficacy score (see Table 2). Cronbach's alphas for each of the two categories was .924 and .965 respectively.

About a month after the course ended, participants were contacted and asked if they would agree to be interviewed. Twelve participants agreed, five parents of young children, four who had some other relationship with children, and three who had no significant relationship with young children. A semi-structured interview was conducted with the aim of identifying elements of the course that impacted on participants' self-efficacy for engaging young children with numerical activities. Participants were asked: The course focused on young children's numerical competencies. Which of the following elements of the course (here, participants were shown the eight course activities listed above) impacted the most on your self-efficacy for knowing about children and their ability to successfully carry out various numerical tasks? Which elements of the course impacted on your self-efficacy for designing tasks to promote early numerical competencies? Interviews were recorded and transcribed.

Findings

As seen in Table 1, and as we hypothesized, participants' beliefs regarding young children's engagement with number activities were positive from the start. At the end of the course, participants were even more positive. The only significant difference was noted for question 5. At the beginning and at the end, not all participants believed that every activity has the potential to invite children to engage with numbers. Yet, participants' belief in this statement on the posttest was significantly greater than on the pretest, perhaps due to the focus on activities in the course.

Table 1: Beliefs regarding engaging young children with numerical activities

Belief questions	Pre M(SD)	Post M(SD)	t(29)	p
1. Children enjoy activities/games that deal with number aspects.	5.23(1.006)	5.47(.819	1.191	.243
2. Children's number knowledge can be promoted.	5.43(1.006)	5.77(.430)	1.836	.077
3. It is worthwhile to engage children with activities/games that deal with number aspects	5.70(.596)	5.87(.346)	1.306	.202
4. Activities/games that deal with number aspects can increase children's knowledge of number concepts.	5.67(.661)	5.70(.535)	.226	.823
5. Almost every activity/game can invite children to engage with aspects of number.	4.17(1.341)	4.70(1.264)	2.570	.016
6. Interaction between a child and an adult while engaging in an activity/game can increase the child's knowledge of number.	5.43(.774)	5.67(.547)	1.756	.090

While participants held positive beliefs towards children's engagement with numerical activities, their self-efficacy at the beginning of the course was less positive, although not definitively low (see Table 2). As Michelle (all names are pseudonyms) said during her interview, "Before the course I thought I was aware and had a way (of doing mathematics with my child) and it was important to me." By the end of the course, self-efficacy beliefs were significantly higher. Interestingly, their self-efficacy related to building numerical tasks was greater (although not significantly) than their self-efficacy for knowing children's competencies.

Table 2: Self-efficacy before and after the course

Self-efficacy	Pre M(SD)	Post M(SD)	t(27)	p
…related to knowing children's competencies	3.869(1.23)	4.869(1.008)	3.831	.001
… building numerical tasks	3.887(.802)	5.125(.802)	4.862	.000

Regarding elements of the course that impacted on participants' self-efficacy, it was difficult for many participants to separate their self-efficacy for knowing children's competencies and their self-efficacy for building numerical tasks. As they talked with the researcher, they intertwined both. This is not surprising as no significant differences were found between these two self-efficacy beliefs. Furthermore, building appropriate numerical tasks and knowing about students' competencies go hand in hand. As Shur stated, "When I choose a task, like counting to 30, I need to know the age of the child, if he is 3, 4 or 5, and then I need to make a task for that child, for what that child knows, at his age." Thus, below, we report in general how the various elements of the course seemed to impact on the participants' self-efficacy for engaging young children with numerical activities.

Nearly all the participants found the video of Omer and Esther interesting. However, interesting does not impact on self-efficacy. What did impact on their self-efficacy was viewing the video twice, once during the first lesson and once during the last lesson. As Levy stated, "In the beginning, the story of Omer offered a taste, but did not help me know about what might be easy or difficult for children. But at the end of the course, … then I could see how much I learned, that is, I could name the different competencies and say where he got stuck and where he didn't." Dahesh stated, "watching the video of Omer and Esther helped me see that maybe I could do those activities with cookies, and that I could build all kinds of tasks with different things." In Levy's case, we could say that the analysis of the video of Omer afforded him a mastery experience, seeing how much he had progressed at analyzing what a child can and cannot yet do. For Dahesh, it was a vicarious experience, seeing that someone else was able to do something led her to believe that she could do it as well.

There were several other activities where participants watched and analyzed videos – watching YouTube videos in class, watching videos they had made of themselves engaging children with numerical activities, and watching videos other participants had made of their activities with children. Regarding the YouTube videos, either participants did not mention this activity, or they specifically said that it made less of an impression than watching videos of themselves or of others in the course. Regarding the other two video activities, watching videos made of themselves was carried out individually as a home task, and watching others' videos was carried out in a group situation. Interestingly, it was the context of the activity, doing it alone or as a group, which seemed to make a difference to some participants. For example, Dave remarked,

> The main thing for me was the individual work, writing the summary of the activity carried out with the child…when you sit at home and watch your recordings, you concentrate much more… To me, the (numerical) activity seemed at first boring, and then you see that the child is having fun… I was always surprised that the child was having a good time.

For Dave, it was necessary to have the time and quiet to focus on a recording. Dave's feeling of surprise when he realized that the child was actually enjoying the numerical activities, hints at an affective impact. Salin emphasized the importance of the group setting, that it increased the opportunities to view different children engaging in numerical activities, "When you see each child that was videoed and the child's age, then I learned more what is easy or difficult for children." Michelle related to the discussion of the videos, and not just watching others' videos, "discussing the videos lets you see things from others' perspectives." All are relating to mastery experience, that is, their experiences in analyzing several children's engagement with numerical activities.

Another aspect of analyzing one's own videos was the fact that participants completed this task three times, one for each numerical content. Like Levy's comment that he was able to see the difference between his first and last analysis of Omer, Dave remarked on his analysis of his own recordings, "I could see my progress from the first analysis I did till the last. You can see it in the length of each analysis, that it increased…Each time I viewed the same recording and saw it again, that was real learning for me." Dahesh also referred to her progress when she analyzed each of her videos, "With each summary and analysis of the activity carried out with the child, there was improvement. The first summary was totally different than the last."

In addition to watching and analyzing videos, participants noted the activity of making up numerical tasks for children as an influential activity. This activity also had two parts, writing the task at home, and then discussing everyone's tasks in class and deciding together what to implement. Both parts seemed to impact on the participants. For Levy, building tasks and discussing with others their tasks, made him notice the specific components of various numerical competencies, which enabled him to address those components when building a numerical task, "In the beginning, I didn't know… that counting and enumerating are different competencies and they are different from composing and decomposing numbers, … [Now] it's easier to focus each task I build and think in which direction I want to take the task." For Neta, discussing different tasks also had an affective impact, "The discussion [of different tasks] … opened my mind to other ideas… and made me feel, wow, there are lots of important things [to consider]." Her exclamation of "wow," signifies an emotional response.

Less participants mentioned the importance of implementing the tasks with children. However, those that did stated that they were able to deal better with unexpected circumstances, such as asking a question in a different way when it seemed that the child did not understand directions. Neta stated, "such experiences increased my self-confidence to guide the child I was sitting with." She also stated that this part was "fun." The element least noted was reading research papers. Two participants asked to be reminded of which research papers were read during the course. It could be that as graduate students, participants had read so many papers and theories, that additional reading of research papers left less of an impression on them than other activities.

Discussion

As found in previous studies (e.g., Missal et al., 2015), participants in this study believed in the importance of promoting early number knowledge and believed that adults have an important role in this effort. Yet, before the intervention, adults' self-efficacy regarding knowing children's conceptions and building appropriate numerical activities was rather low. Perhaps this is one reason that previous studies (Cannon & Ginsburg, 2008) found adults engaged their children with more literary activities than number activities. That self-efficacy was rather low, contradicts finding from a previous study (Levenson et al., 2021), where adults believed their involvement was important, but did not necessarily feel they needed guidance. It might be that because all participants in this study were graduate mathematics education students, they realized, more than other adults might, that they did not have adequate knowledge for promoting young children's' mathematics knowledge. Further study is needed to investigate the self-efficacy of adults who do not have a mathematical background.

Regarding how elements of the course impacted on adults' beliefs and self-efficacy, in accordance with Bandura's (1997) theory, we found that mastery experience, mostly by repeatedly analyzing videos, and repeatedly designing tasks, afforded participants a chance to see how they were progressing. This finding leads us to conclude that short-term workshops may not be enough. One needs to accumulate positive experiences to feel that they have mastered a task and are able to carry out a task. We also found that it was not just one activity, but a combination of several activities, along with positive feelings of surprise and enjoyment, that resulted in higher self-efficacy. Previous studies have reported the benefits of supplying parents with mathematical activities to be done at home (Vandermaas-Peeler et al., 2012); this study has shown the benefits of having adults practice designing their own tasks to carry out with children. Furthermore, supplying activities might not be enough if adults do not have the self-efficacy to implement them. Watching videos of other participants' implementations and discussing those activities with one's peers, can lead to helpful vicarious experiences that may also boost self-efficacy. Further research is needed to investigate the impact of similar courses for adults who do not have a mathematical background.

For researchers and practitioners, it is important to identify students at risk of developing mathematical difficulties. The aim of this pilot study was to investigate whether it is possible to identify first-grade students who are at risk of developing mathematical difficulties (RMD) through online measures in arithmetic and pattern tasks. In our study, 54 first-grade students worked on 75 tasks in twelve sets on a computer screen. We also carried out a standardized mathematics test to identify students as RMD. We then investigated if error rates and response times as online measures allow to replicate the identification of students as RMD. Using a logistic regression model, we found that the error rates and response times allow identifying students as RMD with acceptable accuracy. We also found that tasks on symbolic number comparison, completing color patterns, and enumeration of small sets were particularly informative to identify students as RMD.

Keywords: mathematical difficulties, early identification, digital tools.

Introduction

Mathematical difficulties often begin early, before primary education and can—due to insufficient support—cascade into severe mathematical problems (Geary, 2013; Moser Opitz, 2013; Sasanguie et al., 2012). Longitudinal studies confirm that students who enter school with mathematical difficulties do generally not overcome these during primary school (e.g., Viesel-Nordmeyer et al., 2019). It is significant for teachers to be aware of such difficulties, be able to identify them, and to provide adequate support for students. Yet, identifying student difficulties at an early age is challenging—among other reasons, because young students often lack the ability to report their difficulties (Klein et al., 2010). There are numerous tests for identifying students at risk of developing mathematical difficulties at an early age (Hellstrand et al., 2020). These tests, some of which are conducted individually, require a considerable amount of time for both conducting the tests and evaluating results. Also, they are often not feasible to use by practitioners at school. A digital screening offers the possibility to identify, also in practice, a large number of children who are at risk to develop mathematical difficulties. Digital tools are particularly suitable as both the collection of data and its evaluation can be conducted on the same digital device. The Erasmus+ project DIDUNAS builds on this idea. It aims to develop an app, which incorporates tasks in the domain of early arithmetic and pattern tasks, that identifies first-grade students in need of support. For this identification, the app uses data such as error rates and response times.

This pilot study aims to investigate whether it is possible to identify first graders who are at risk of developing mathematical difficulties through online measures (response times and error rates) of students' work on tasks in the domain of early arithmetic and pattern tasks.

Related work

Early identification of students with mathematical difficulties

A variety of reliable and valid standardized tests are commonly used in identifying mathematics difficulties. To develop these tests, researchers focus on identifying variables that appear to be good predictors. Some tests assess speed and accuracy with which students can identify object sets (e.g., Geary et al., 2009). Early numeracy skills, such as quantity comparison, number identification, and counting, appear to have much predictive power for mathematical difficulties (Gersten et al., 2005). Most of these tests include tasks on: Object counting, number comparison, sequencing, connecting numbers to quantities, number recognition, and counting back and forth. Fewer tests include number calculations such as additions and subtractions with symbols or word problems. Even fewer tests include patterning tasks such as copying or extending a pattern or identifying the pattern unit. However, a growing number of researchers (e.g., Verschaffel, et al., 2017) argue that that for investigating mathematical abilities of young students, patterning tasks also need to be considered. Students' number sense and awareness of structure and patterns contribute substantially to students' later success in mathematics (Wijns et al., 2019). Pittalis et al. (2018) in a longitudinal study with first-grade students suggested that that the growth rate of algebraic arithmetic has a direct effect on the growth rate of conventional arithmetic, and subsequently the growth rate of conventional arithmetic predicts the growth rate of elementary arithmetic.

Error rates and response times as measures to identify mathematics difficulties

Several studies investigated differences in error rates and response times of students with and without mathematical difficulties. Some of these studies addressed students' enumeration ability and indicated that students with mathematical difficulties have longer response times within the subitizing range as compared to students without such difficulties (Moeller et al., 2009; Schindler et al., 2020; Schleifer & Landerl, 2011). Other studies addressed students' comparison of symbolic and non-symbolic numbers and found no significant differences in error rates and response times between children with or without mathematical difficulties (Mussolin et al., 2010). However, the slope of response times was significantly steeper for students with mathematical difficulties. Other studies found that response times and error rates for non-symbolic number line estimation are significant predictors of mathematical achievements (Sasanguie et al., 2012). These studies indicate that error rates and response times for suitable tasks can be a predictor of mathematical difficulties. Thus, we intend to investigate: *To what extent can error rates and response times of early arithmetic and pattern tasks be used to identify students that may be at risk of developing mathematical difficulties?*

Methods

Participants

The study was conducted with 54 first-grade students (age: M = 7.38; SD = 0.55) from two primary schools in Germany. In the German federal state that the study took place in, a social index classifies schools into levels from 1 to 9 which is based on factors such as child and youth poverty, family language, and special educational needs of students. Index 1 represents the most favorable conditions. The two participating schools had an index of 7 and 6 which means they tended to have a higher number of students in need of support. Of the students, 34.6% had German as their mother tongue.

Procedure and tasks

For the study we used two tests: (1) the standardized ZAREKI-K test to identify students at risk of mathematical difficulties and (2) a self-developed computer screen test with twelve sets of arithmetic and pattern tasks (75 tasks in total).

Standardized mathematics test: ZAREKI-K is a standardized test for identifying children at the transition from kindergarten to primary school of being at risk of developing mathematical difficulties (von Aster et al., 2009). The test battery is constructed as an individual procedure and consists of 18 subtests. For the present study, an adaptation of ZAREKI-K was used, which requires only six subtests: (a) Counting up to 30, (b) Numbers that precede or follow, (c) Word problems, (d) Visual calculation, (e) Number conservation, and (f) Writing numbers. This adaptation has been shown to yield excellent prediction rates for identifying students at risk of developing mathematical difficulties (Walter, 2020). The students took an average of 14.6 minutes to complete the ZAREKI-K.

Early arithmetic and pattern tasks: The students worked on twelve sets presented on a computer screen (Fig. 1). Every set had an example task to get the students acquainted with it. For sets (1), (4), and (5), students were to determine the number of objects. For set (2), students were asked to determine a number on a number line. Set (3) asked for the number behind the sun. Set (6) asked how many dots needed to be added or subtracted to make it equal to the number shown on the right. In set (7), the largest number was to be determined. In set (8), the number of persons' legs behind the wall was to be determined. In set (9), students were to determine the number of bricks of the tower behind the white blob. In set (10), the result of an addition/subtraction problem was to be determined. In set (11), the students were to compare quantities. For set (12), a color pattern was to be completed. Students could skip a task if they found it difficult by saying "next". There are no identical tasks between these sets and ZAREKI-K. However, both include cardinal and ordinal aspects of numbers. Additionally, set (12) is a pattern task from early algebra, which is not included in ZAREKI-K.

Students answered by tapping on the computer screen. The answers to each task were given with a single tap on the screen. For sets (1)–(10), a number field with the buttons labeled with 1 to 20 was shown at the bottom of the screen. Set (11) had a yellow, a blue, and an equal ("=") button for answering. Set (12) had a yellow, a blue, and a red button for answering. It took students an average of 20.8 minutes to complete these tasks (including all instructions, explanations, and trial tasks).

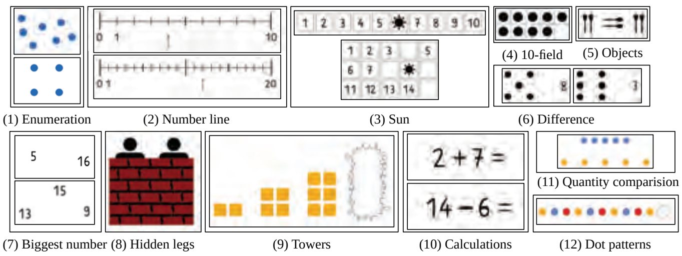

Figure 1: Example tasks of the twelve sets

Measures

We use the following data sets:

(1) **Identification of mathematical difficulties at risk:** ZAREKI-K identifies whether a student is at risk (RMD) or not at risk (¬RMD) of developing mathematical difficulties. We used an Excel spreadsheet provided by Walter (2020) for entering the students' individual points achieved in each subtest, which then calculated the risk of students to develop mathematical difficulties. Of the 54 students, ZAREKI-K identified 18 as RMD and 36 as ¬RMD.

(2.a) **Error rates:** Mean error rates were calculated for all 75 tasks in total as well as each of the twelve sets separately. We considered tasks, where the students answered wrongly or did not answer at all, as being not solved correctly. We considered all tasks, which were not being solved correctly, as error.

(2.b) **Response times:** For each task, the time from when the stimulus was first shown to when the student typed the response on the computer screen was measured. Only response times of correctly answered tasks were taken into account, since tasks that were not understood by the students sometimes were quickly skipped and since students partially rashly guessed wrong answers. Mean response times were calculated over all tasks that were answered correctly as well as for each of the twelve sets separately.

Statistical analysis

We followed the guidelines of logistic regression analysis and reporting by Peng et al. (2002). Logistic regression was performed using SPSS 27 in order to calculate a probability value between 0 and 1 for each student using mean error rate and mean response time over all tasks. For different cut-off values p between 0 and 1, students are identified as RMD or ¬RMD. A ROC (receiver operating characteristic) curve was then plotted, which indicates the sensitivity (true positive rate) and specificity (true negative rate) for all cut-off values p as an indicator of the overall classification accuracy. The area under this curve (AUC) is a measure of the classification quality.

Next, we ask which of the twelve mean error rates or the twelve mean response times are most informative for identifying students as RMD, according to ZAREKI-K. We thus carried out a backwards selection, subsequently for both mean error rate and mean response time for all twelve task sets in early arithmetic and patterns using our multiple-logistic regression model.

Results

We conducted a t-test to compare mean differences of error rates and response times between students identified as RMD and students identified as ¬RMD. Using the Shapiro-Wilk test, the normal distribution of mean error rates ($W(54) = .974$, $p > .05$) and mean response times ($W(54) = .967$, $p > .05$) was checked. Using the Levene test, the homogeneity of variances of mean error rates ($p > .05$) and mean response times ($p > .05$) were checked. Thus, variance homogeneity exists between the groups. With regard to the mean error rate, the 18 students identified as RMD had a significantly higher mean error rate ($M = .29$, $SD = .12$) as compared to the 36 students identified as ¬RMD ($M = .19$, $SD = .09$; $t(52) = –3.48$, $p < .05$). With an effect size of $r = .43$, this is a medium effect. With regard to the mean response time, the 18 students identified as RMD did not have a significantly higher mean response time (M = 7.04s, SD = 1.63s) as compared to the 36 students identified as ¬RMD (M = 6.65s, SD = 1.29s; $t(52) = -.957$, $p = .34$, $r = .13$).

The Likelihood ratio test indicates that the logistic regression model is significantly more effective than the null model (constant only) ($\chi^2(2) = 11.67$, $p < .05$). Goodness-of-fit was assessed using the Hosmer-Lemeshow test, indicating a fit of the logistic model ($\chi^2(8) = 5.15$, $p > .05$). Wald test indicates that mean error rate of the 75 tasks is a significant classifier of RMD ($\chi^2(1) = 8.53$, $p < .05$). The mean response time is not a significant classifier in this regard ($\chi^2(1) = .987$, $p > .05$).

The logistic model calculates a probability value between 0 and 1 for each student based on the error rates and response times. The cut-off value p then defines at which probability value a student is identified to have RMD or ¬RMD based on the logistic regression model. Choosing cut-off values of p thus means to trade off sensitivity (true positive rate) and specificity (true negative rate) as they change diametrically. Table 1 shows the sensitivity and specificity for different cut-off values p. The total accuracy is computed as the number of all correctly identified results in relation to all results.

Table 1: Sensitivity, specificity, and total accuracy of the model for different cut-off values *p*

Cut-off value *p*	.05	.1	.15	.2	.25	.3	.307	.35	.4	.5	.6
Sensitivity (%)	100.0	100.0	88.9	83.3	72.2	72.2	72.2	61.1	61.1	55.6	33.3
Specificity (%)	5.6	13.9	25.0	44.4	61.1	69.4	72.2	77.8	80.6	91.7	94.4
Total accuracy (%)	37.0	42.6	46.3	57.4	64.8	70.4	72.2	72.2	74.1	79.6	74.1

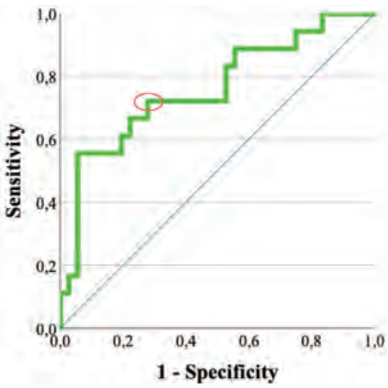
For the identification of students at risk of developing mathematical difficulties at an early age, a high sensitivity is often desirable even at the expense of a decreased specificity. A high sensitivity would ensure that only a few students with mathematical difficulties at risk are missed. However, this has the consequence that the specificity decreases and students with mathematical difficulties at risk are not detected. For the cut-off value $p = .307$, a reasonably high sensitivity of 72.2% is achieved at a still high specificity of 72.2%. Table 2 displays the classification of the students identified to be RMD and to be ¬RMD through the participants' error rates and response times compared to the students identified as RMD and ¬RMD from the standardized ZAREKI-K for cut-off value $p = .307$.

Table 2: Classification table[a]

		Identification		Percentage correct	
		¬RMD	RMD		
ZAREKI-K	¬RMD	26	10	72.2%	specificity
	RMD	5	13	72.2%	sensitivity
Overall percentage				72.2%	

[a]cut-off value $p = .307$

The ROC curve (see Figure 2) is the generalization of a single classification table (see Table 2). Each point of the ROC curve indicates sensitivity and (1–specificity) for a given cut-off value p. The drawn diagonal would be expected if the classification was purely random. A measure of the classification quality of the model is the area under the ROC curve (AUC). Following Hosmer et al. (2013), the classification accuracy can be considered "acceptable" with an AUC = .761.



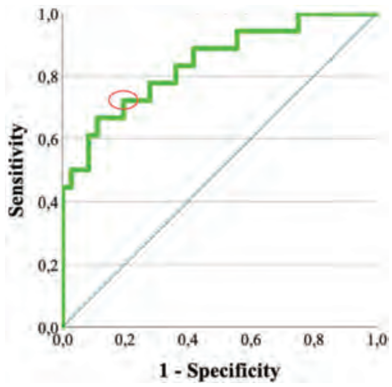


Figure 2: ROC curve of the general model (left; AUC = .761; ellipse marks cut-off value p = .307) and the reduced model (right; AUC = .841; ellipse marks cut-off value p = .351)

To identify those sets whose error rates and/or response times are particularly good for the identification of students at the risk of developing mathematical difficulties, logistic regression was performed through backwards selection. This backwards selection is first done with all twelve mean error rates of the sets. Step by step, the twelve mean error rates are removed from the model, starting with the one that has the lowest significance for predicting the ZAREKI-K outcome. All variables that are significant to replicate the classification based on the ZAREKI-K outcome at the $p < .1$ level remain included according to the Wald test. At the same time, the Likelihood ratio statistic is used to check whether the model would improve by adding another variable. After eleven steps, the mean error rates of sets 7 (symbolic number comparison) and 12 (completing color patterns) (see Figure 1) remained. For the response times, the mean values of set 9 (completing growing number patterns) could not be included, since the number of incorrect answers were too high for which response times were not considered. After eleven steps, only the response time of set 1 (enumeration of small sets) remained. Applying logistics regression onto these three variables identified through backwards selection, Likelihood ratio test indicates that the logistic regression model is significantly more effective than the null model (constant only) ($\chi^2(3) = 22.99$, $p < .05$). Goodness-of-fit was assessed using the Hosmer-Lemeshow test, indicating a good model fit; $\chi^2(8) = 3.58$, $p > .89$. Furthermore, Wald test indicates that the mean error rate of set (12) ($\chi^2(1) = 6.88$, $p < .05$) and the mean response time of set (1) ($\chi^2(1) = 6.91$, $p < .05$) are significant classifiers of developing mathematical difficulties. The mean error rate of set (7) is not a significant classifier in this regard ($\chi^2(1) = 3.256$, $p > .05$), but since $p < .1$ it remained in the model. Following Hosmer et al. (2013), the classification accuracy can be considered "excellent" with AUC = .841. With a cut-off value of p = .351, this model has a higher specificity of 80.6% compared to the previous model at a sensitivity of 72.2%. The total accuracy of this model is 77.8%.

Discussion

The results of our study should be viewed and interpreted against the backdrop of the following limitations: Logistic regression requires sufficiently many training samples, i.e., RMD and ¬RMD cases. Having only 18 students identified as RMD and 36 students identified as ¬RMD limits the certainty of the learned logistics regression model. A larger sample could provide further certainty. In addition, we optimized the classification threshold for the logistic regression model on a single data set and did not evaluate the classification accuracy on an independent test set. In practice, the classification threshold needs to be learned on a training set, which would likely decrease the classification accuracy on independent data.

This pilot study addressed the question to what extent error rates and response times of correctly solved tasks as online measures in early arithmetic and pattern tasks can identify students that may be at risk of developing mathematical difficulties (RMD). Using logistics regression, we found that the mean error rate across all 75 tasks is a strong classifier of RMD, whereas the mean response time was a weaker classifier. Combining error rates and response times in our study yielded an acceptable discrimination of the model of AUC = .761. Furthermore, we investigated to what extent the error rates and response times of twelve sets can be used separately to identify students' RMD. We found that the error rates of two sets (symbolic number comparison, completing color patterns) and the response time of one set (enumeration of small sets) appeared to be particularly informative. The influence of the set about complementing color patterns is especially noteworthy since the standardized mathematics test focused on early arithmetic, not patterns. Combining error rates of symbolic number comparison and completing color patterns with response times of small set enumeration yielded a discrimination of the model of AUC = .841.

Since the DIDUNAS project aims to develop an app that identifies first-grade students in need of support, what can we learn from these results regarding the app development? In our pilot study, we found that it is possible to use online measurements of certain tasks or a set of them (here: symbolic number comparison, completing color patterns, enumeration of small sets) to achieve a reasonably reliable identification of students at risk of developing mathematical difficulties in grade 1. This is promising for future developments. In the future, we will build on these results for developing the DIDUNAS app, which then can be used by teachers around the world to help identify students with risks of mathematical difficulties early on. As the app will require less effort in the conduction and evaluation, compared with some standardized mathematics tests, the app will enable a resource-saving use for teachers. The study presented in this paper is an important first step in that direction.

First grade students' decomposition of 3D shapes: the interconnection between spatial reasoning and spatial structuring

Joana Conceição[1] and Margarida Rodrigues[2]

Assuming 3D decomposition as a form of spatial reasoning, in this paper, it is our aim to understand how 1st grade students decompose 3D shapes and how these decompositions are related to spatial structuring. Data were collected during a learning experiment where students were asked to decompose three 3D shapes, in two different ways, without disassembling the models, and draw each part. We categorize 21 first graders strategies and analyze more deeply the records from three students that are representative of the different strategies. Results show that students decompose shapes by establishing local relationships, when they recognize, for instance, composites, but cannot yet coordinate them to form the whole; or global relationships, when students coordinate different composites, relating them with the whole, and apparently, have a previous mental model that is coherent with the structure of a shape.

Keywords: Spatial reasoning, spatial structuring, decomposing 3D, early grades.

Introduction

Recent studies show the importance of spatial reasoning (e.g. Mulligan, 2015; Sinclair & Bruce, 2015), especially its relationship with mathematical achievement and with success in STEM disciplines, being these of great demand in the 21st century. Jones (2001) defines spatial reasoning as "the process of forming ideas through the spatial relationships between objects" (p.55). Also, to Davis et al. (2015), spatial reasoning involves two interconnected parts, (mental) *understanding* and (physical) *transforming*, in which composing/decomposing shapes constitute a form of spatial reasoning associated to *understanding*. In early grades, decomposing shapes contributes to a better understanding about shapes' structures. This is also important in more advanced grades, where students have shown difficulties (Duval, 1995; Duval, 1998; Spiegel & Ginat, 2017). Spiegel and Ginat (2017) describe some aspects where 7th and 8th grade students struggle concerning decomposing and recomposing shapes, in geometry problem solving. These researchers relate these difficulties to lack of fluency and flexibility, within this type of spatial reasoning, since "decomposition requires careful fluency analysis, of possibly overlapping elements. Recomposition requires flexible manipulations with elements and resources" (p. 215). This points to students understanding of how to coordinate different parts of the shapes by spatially structuring the shape. That means that students need to understand how the shape is composed, which relationships can be established within the shape and how these work together. In what concerns early grades, Hallowell et al. (2015) describe 1st grade students' difficulties in relating 2D shapes with 3D solids, through composing and decomposing, suggesting the importance of providing adequate experiences. Previous learning experiences seem to influence students' performance in tasks involving decomposition and recomposition (Spiegel & Ginat, 2017). As Sinclair and Bruce (2015) argue, even though 3D shapes have a strong presence in early grades' classes, there is still little research about the way students learn about these shapes.

Clements and Sarama (2014) propose two learning trajectories for composition of 2D and 3D shapes, based on relationships between components and composites and among components, composites and the whole, similar to Battista and Clement's (1996) construct of spatial structuring. Considering composing and decomposing shapes as a type of spatial reasoning, it seems to be relevant to understand and characterize the relationships 1st graders establish while decomposing 3D shapes, that is, how do they structure 3D shapes.

For that purpose, we have designed a learning experiment where we seek to understand how students spatially structure 2D and 3D shapes, through composing and decomposing shapes. This paper aims to answer the following questions: How do 1st grade students decompose 3D shapes? How the decompositions are related to the way students spatially structure those shapes?

Spatial reasoning and spatial structuring

Spatial reasoning is often associated to the process (Jones, 2001) or the ability (Battista, 2007) to create spatial images, and manipulate those images to generate new information. In order to create images, students need to understand objects' structures and by understanding their structures they will be able to manipulate them, physically or mentally.

Spatial structuring is defined by Battista and Clements (1996) as the mental act of constructing a mental representation for an object or set of objects. It consists in identifying units of composition (components), establishing relationships among those components forming composites and establishing relationships among components, composites and the whole. In 3D shapes, built with cubes, components are the cubes while composites are organized sets of cubes. Through this process, students go from seeing a shape as a whole to identifying its parts and establishing relationships among them, into a deeper understanding of shapes' structures. Decomposing and composing shapes, as a form of spatial reasoning, (Davis et al., 2015) seem to be straightly connected to understanding the shape's structure, as it contributes to establishing different relationships among the parts and between these parts and the whole. As students decompose or compose shapes, they establish relationships that allow them to build a mental model for that shape, to find new paths to construct the shapes, to find more sophisticated relationships within the shape. Also, working with different representations for the same shape, as it happens when students draw a 3D shape or when they interpret a 2D depiction of a 3D shape, fosters students understanding of the structures and its codes of representation. As such, we assume a interconnectedness between spatial reasoning and spatial structuring in composing and decomposing 3D shapes.

Spatial structuring shapes can be local or global (Battista & Clements, 1996). Local structuring is related to recognizing components or to establishing relationships among components into composites without yet establishing relationships among components, composites and the whole. Global structuring, in its turn, is evident when students relate components, composites and the whole in a way that makes a previous mental model correspond to a shapes' structure. For global structuring, the operations of coordination and integration are fundamental.

Coordination operation involves establishing interrelationships between different parts considering spatial relationships between them (Battista & Clements, 1996) and eventually with the whole. The operation of integration is linked to a previous existence of a mental model that represents a shape in a way in that each part of this mental model corresponds to a part of the shape, considering its relationship with the whole. The coordination operation is of great importance to the integration operation since it allows to interrelate the different parts of that mental model and also to relate different forms of representing the shape. Both operations are also involved in spatial reasoning processes like creating mental images and models.

Composing and decomposing shapes is important in understanding shapes' properties, but it extends to other domains in mathematics, such as part-whole relationships and fractions, among others (Clements & Sarama, 2014).

Method

The research presented in this paper is part of a teaching experiment focused on first-graders' spatial structuring processes. The teaching experiment was organized in three sequences of tasks where students are asked to explore relationships in 2D and 3D shapes and also the relationships between 2D and 3D representations for the same shape. Each task was implemented in a 60 minutes weekly session.

In the task reported here (12^{th} task), students were asked to decompose three 3D shapes in two different ways (Figure 1) and to draw these forms of decomposition (2D). 3D multilink cube models were available for each shape. Students could manipulate the models without disassembling them. Some of the students' solutions for decomposing 3D shapes were presented and discussed in a whole-class discussion, after they solved the task.

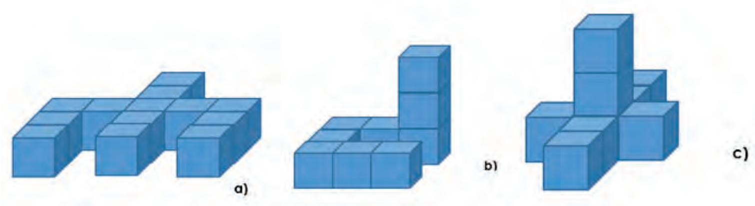

Figure 1 – Shapes presented to students

All the three shapes require the students to coordinate different parts. Shape a) has only one layer, as it can be fully placed on a plane base. Shapes b) and c) have different layers and require the coordination in three dimensions. Additionally, shape c) has a hidden cube that students might not be aware of, when the shape is in the position depicted in Figure 1.

Data were collected in a class with 21 students and their teacher, with great experience, of a public school in Lisbon. All students' names are pseudonyms. We have collected and analyzed all students' drawings. In this task, we have found five different strategies. For this paper, we present drawings from three students, Bruno, Carolina, and Duarte, which are representative of the whole range of strategies.

Data analysis

We started by noticing and categorizing students' strategies as presented in Table 1:

Table 1 – Categorization of students' strategies in both forms of decomposition (*n*=42)

	Decomposes into a smaller piece and a bigger piece	Decomposes by separating into shapes' composites	Decomposes using symmetry	Decomposes into equal or quasi-equal composites	Decomposes into components	No answer or incomplete
Shape a)	12 %	43 %	17 %	14 %	9 %	5 %
Shape b)	12 %	35 %	5 %	25 %	12 %	12 %
Shape c)	9 %	24 %	0 %	29 %	14 %	24 %

Since our focus was on spatial structuring, we built an analytical framework based on local and global structuring (Battista & Clements, 1996) for analyzing the strategies above, being these two progression levels for structuring. The strategies presented above point to different types of relationships established that can be associated to local or global structuring, depending on the ability to coordinate components and composites. Thus, a thoroughly analysis of these strategies led us to include progression sublevels for each level, as presented in Table 2. For each sublevel, we include a brief description of the strategies as aspects emerging from data analysis that we call Indicators/strategies. "No answer or incomplete" was especially due to a matter of time, which might explain, at least partly, its increasing. The categorization we propose here is hierarchic, thus each level includes the previous. We considered the children's difficulty of representing 3D shapes in a sheet of paper. However we assumed the duplication or omission of cubes as essential indicators of lack of coordination.

Table 2 – Analytical framework for decomposing 3D shapes

Level	Sublevel	Indicator/strategy
Local structuring	**E1-** Identifying components	Decomposes shapes into components (cubes).
	E2- Establishing relationships among components	Decomposes into two composites, being one of them almost the totally of the shape and the other a small part. Relates components when representing each of the composites.
	E3- Establishing relationships among composites	Decomposes, establishing relationships among composites (e.g., through symmetry).
Global structuring	**E4-** Establishing relationships between components, composites, and the whole by coordination.	Decomposes shapes into equal or quasi-equal composites. Coordinates position and orientation of components and composites with the whole, recognizing cubes that are part of more than one view.
	E5- Establishing relationships between components, composites, and the whole by integration.	Decomposes shapes, recognizing hidden cubes

Results

In the previous section, we have presented a distribution of student's strategies (Table 1). We use our framework to analyse these strategies, assuming that the same strategy may be allocated either to local structuring or global structuring, depending on the relationships students establish.

We start by analyzing Bruno's drawings (Figure 2).

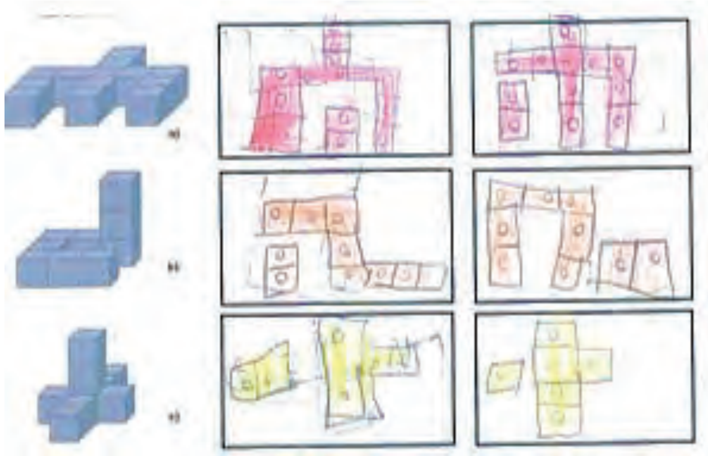

Figure 2 – Bruno's drawings

Bruno decomposes all three shapes into two composites, separating a small composite made of one or two cubes from the rest (level E2). Bruno presents two different decompositions for each shape. These forms of decomposing seem to be anchored in visual aspects. We can also observe that Bruno duplicates cubes that serve more than one composite instead of coordinating both composites. This was the case of the first decomposition for shape a) and b). In shape c), Bruno seems to miscount cubes. We infer that this could be related to the fact that he may not recognize the hidden cube, placed on the bottom of the central composite, and to the difficulty of representing, in a 2D sheet of paper, cubes from the second and third levels, while observing from above.

Carolina's drawings, presented in Figure 3, seem to show that the student establishes equal or quasi-equal composites which are used as complex units for decomposing the shapes.

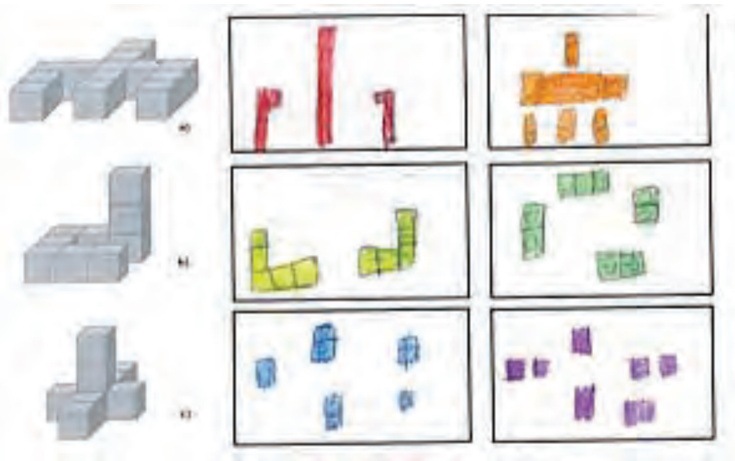

Figure 3 – Carolina's drawings

For the first shape, Carolina seems to consider a larger composite and several smaller composites, in both decompositions. However, for the first decomposition, Carolina apparently establishes a relationship of symmetry within the shape and uses it to decompose the shape, duplicating cubes. For shape b), Carolina presents two different decompositions. In the first, she decomposes the shape into two quasi-equal parts, apparently recognizing two complex symmetrized composites. Nevertheless, Carolina duplicates one of the cubes that is part of both composites, drawing 5 cubes for each. Thus, this student seems not to be able to coordinate the composites properly, while drawing. In this way, both composites seem to be drawn, in the worksheet, as being the reflection of each other. This could also be the way Carolina found to represent the cubes from the levels above, in a 2D paper. For the second decomposition, in shape b), apparently the student chooses to decompose using equal or quasi-equal composites, being able to coordinate them, almost like iterating the smaller one. For construction c), Carolina decomposes it into small parts, apparently without considering the hidden cube, since she draws only eight cubes, in both forms of decomposing. Therefore, Carolina's work could be included in level E3, since the student seems to relate several composites, without yet coordinate them consistently.

Carolina´s forms of decomposition seem to show that the student uses composites that are, apparently symmetrical, in some cases, and, in other cases, are quasi-equal. Hence, this form of structuring is more complex than those showed by Bruno.

Duarte's drawings, presented in Figure 4, seem to indicate that this student decomposes the shapes using equal or quasi-equal composites made of two or three cubes, with exception of the last where he uses a larger composite.

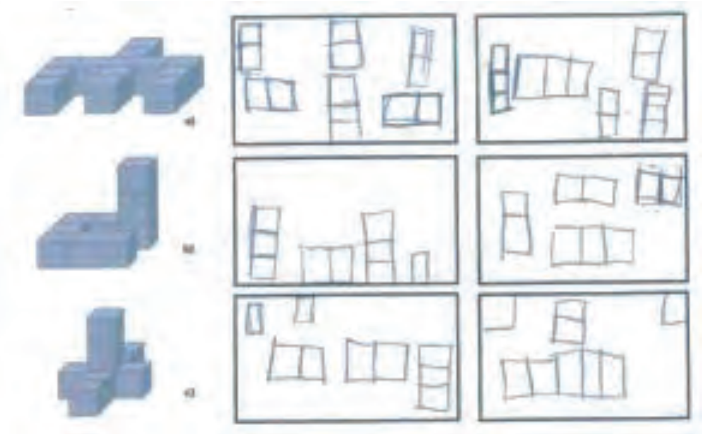

Figure 4 – Duarte's drawings

The horizontal or vertical orientation the student uses to draw each composite seems to be close to its orientation in the 3D shape. Duarte's drawings seem to show that he unitizes shapes using composites as complex units, repeatedly, to decompose shapes. He seems to coordinate the composites adjusting the number of cubes in each composite so that their size fits the shape. Duarte also shows to be able to coordinate different composites that he uses do decompose shapes, not duplicating cubes that are part of more than one view. Moreover, Duarte is the only student, from this group of three, that recognizes the hidden cube in shape c), by drawing it and mentioning it while presenting his strategy in whole-class discussion: "We made the top part with the square [sic] below". This seems to show that his mental model is coherent with the shape. Hence, we consider that Duarte’s work could be included in sublevel E5 from global structuring level.

Conclusions

This paper aimed to understand how 1st grade students decomposed 3D shapes and how these decompositions are related to spatial structuring. As suggested by Battista and Clements (1996), we observed two levels for spatial structuring in students’ work while decomposing three different 3D shapes: local structuring and global structuring. For the former, local structuring, students seemed to maintain a bigger composite and take apart one or several smaller composites. Another strategy for decomposing was establishing symmetrical composites within the shape’s structure and drawing these symmetrical composites as complex units. In most of the strategies, where structuring seems to be local, students showed a tendency to duplicate cubes, while drawing, meaning this that they struggled in coordinating composites when they had overlapping cubes in the corners (Spiegel & Ginat, 2017). Also, for local structuring, students seem not to recognize hidden cubes within the structure. Therefore, local structuring comprehends different levels of sophistication according to the complexity of the relationships that are established. That is, students recognize different kinds of complex units for structuring a shape, using different kinds of relationships, like repeating or symmetrizing composites. In local structuring, students show difficulties in coordinating composites.

For the latter, global structuring, one student showed to be able to coordinate properly different composites, as well as to recognize hidden cubes. This student used consistently quasi-equal composites, as units, to decompose all three different shapes, but he also showed ability to adjust the number of cubes in each composite to fit the shape. Global structuring implies that students have previous mental models that represent accurately the shape, its components and composites and that these parts are properly coordinated.

Either in local structuring or in global structuring, students were capable of suggesting two different forms of decomposition for each shape. However, it is only in global structuring that we can admit that students are able to coordinate in properly all the elements, considering overlapping elements, as mentioned by Spiegel and Ginat (2017), revealing a deeper understanding of shape’s structures. By establishing different relationships, students had the opportunity to deepen spatial relationships. However, we must also consider as a limitation the fact that the students did not have any previous lessons about how to draw a 3D shape.

Through this work, we expect to contribute to a deeper understanding of spatial structuring in geometric contexts, where spatial reasoning processes such as decomposition of 3D shapes play an important role. Also, we seek to reinforce the importance of learning experiences focused on decomposition, since early grades, as a fundamental process for developing spatial structuring and fostering different ways of thinking as Duval (1998) purposes.

Identifying mathematics in the actions of very young preverbal children when playing with trains

Audrey Cooke

Curtin University, Australia; Audrey.Cooke@curtin.edu.au

This paper will report on the mathematics that may be visible when very young preverbal children play with trains. The paper analyses video obtained using a 360-degree camera in an early learning setting in Sweden. The video involves two preverbal children playing with train carriages and train track at a table. The work of Barad (2008), Franzén (2015), and Meaney (2016) underpin the use of the preverbal child's actions to identify the potential mathematics that may be evident from these actions. The iterative process used to analyse the video is described. The analysis of the children's actions is linked to the six mathematical activities identified by Bishop (1991). A discussion of the effectiveness of using the 360-degree video and the iterative process is followed by implications for practice. Limitations of the research are considered.

Keywords: Very young preverbal children, actions, mathematical activities, 360-degree video.

Introduction

Research into early childhood mathematics is now considering children of younger ages, even from birth (Alsina & Berciano, 2018). Very young children, even preverbal children, demonstrate mathematics in their behaviours and actions. Franzén (2015) states that there are many instances where very young children engage with mathematics during self-selected activities in early learning settings. Further, that very young children can express mathematics through their use of their body (Franzén). Meaney (2016) proposes that researchers working with very young children need to recognise how the child's uses their body to convey their understandings. She describes her investigation of how two very young children (referred to in the paper as toddlers) use their bodies to when solving problems, connecting the children's actions to their mathematical understandings, specifically Bishop's (as cited in Meaney, 2015, p. 11) mathematical activity of locating. Children's actions are communicative of their mathematical ideas, with Flottorp (2011) linking these to Bishop's mathematical activity of explaining. Although the children were verbal, Flottorp stated minimal language was used during the experiences.

Bishop's (1988, 1991) mathematical activities

Bishop (1988, 1991) presents six mathematical activities that he describes as universal, due to their presence in all cultural groups and the way they support how mathematical knowledge develops. Counting involves ordering or comparing discrete phenomena systematically. Locating is the exploration and conceptualization of the spatial environment. Measuring comprises the comparison or ordering through quantifying qualities (in contrast to counting, which involves discrete phenomena). Designing incorporates creating designs or representations of the spatial environment and objects. Playing recognises creating, using, or adhering to rules (both formal and informal), whether in games or general activities. Explaining is the accounting of phenomena, whether physical or non-physical.

Although Bishop (1991) states his mathematical activities were created by examining language, their descriptions can also be applied to actions. Cooke and Jay (2021) described how Bishop's mathematical activities could be reframed to focus on the actions of very young children. Counting was reframed to consider matching one-to-one (such as using one hand to grasp one item), changes in quantity, and recognizing patterns in actions, music, or items; the provided example was a child using one hand to select one object from a collection. Locating reframed focuses on children using their bodies within their environment and to engage with their environment, such as moving objects or positioning themselves; the example was a preverbal child moving objects in a purposeful way to make them useful. Measuring reframed involves preverbal children investigating attributes within their environment, identifying how much there is, and cataloging these features to enable them to compare other objects and environments; a provided example was trying to reach an object and, when not successful, moving their body closer to the object. Designing reframed occurs when the young child can identify the function of objects and consider this in terms of the attributes of the object; the example provided involved placing toys with wheels on the ground with the wheels touching the ground (and not upside down). Playing reframed focuses on the joy children display or the process of replicating everyday happenings; the provided example involved a child picking up a book and turning it so they can open it and look inside. Explaining reframed is evident when children's engagement shows they are using previous understandings in current environments or with objects and situations; the example given involved a child holding a bookcase to pull themselves up to standing.

Using video to collect data

Lynch and Stanley (2018) describe how video can be a valuable data collection tool in qualitative research as it enables a holistic way collect events as they occur – capturing the physical, temporal, and social contexts that exist beyond language. They state how this can be invaluable when working with children. In addition, the capacity of the researcher to revisit and review the captured video enables researchers to be consistent in their analysis of the video. Björklund (2008) also highlights the capacity of video to enable researchers to meticulously observe the actions that have been recorded, and de Freitas (2016) links this to the opportunities that video provides to make the understandings of mathematical concepts visible. The camera for collecting video captures 360-degree audio video. This enables all of the room to be seen and heard. The video format provides the capacity to focus in on a particular part of the video.

Theoretical Framework

Several elements that Barad (2007) proposes underpin the research. The first is the de-prioritising of language. Barad states that language has been elevated to a position of power, gifting it the role of most trustworthy in the representations of reality. She proposes that language not be preferenced and that attention also be given to matter – comprised of human and nonhuman – as it is not immutable and passive. This is connected to the second element – intra-action. Barad considers everything – all matter – to be intra-active in its becoming. Specifically, "intra-actions are nonarbitrary, nondeterministic causal enactments through which matter-in-the-process-of-becoming is iteratively enfolded onto its ongoing differential materialization" (p. 179). Reality is conceived as continuous and dynamic, where people are part of the world and their intra-action contributes as both cause and effect to the world's becoming.

In their research with very young children, Franzén (2015) and Meaney (2016) both use the work of Barad (2007) to depower language and focus on intra-actions, enabling the child's actions with their bodies to be interpreted as demonstrating mathematics. Franzén (2015) uses Barad's work to widen how young children's learning is perceived. Specifically, Franzén incorporates all ways that the child intra-acts with the matter within the world, such as through their body, and uses this to identify the mathematics that may be evident. She recounts the intra-action of a very young child (aged one year) with a large climb-on toy car and connects this to the mathematics that may support the child's engagement. In a similar way, Meaney (2016) also focuses on how young children learn through using their bodies to interact with their environment. Meaney's focus is on how the very young children use their bodies to demonstrate understandings of locating, which is viewed as the understanding of spatial relationships, in their world.

The aspects of Barad (2007), Franzén (2015), Meaney (2016) that are critical to this research are the emphasis placed on the child's actions, the recognition of the intra-active nature of the child's engagement with their world, the reduced focus on language to convey mathematical ideas, and the deconstruction of the child's actions to identify the mathematics that may support their intra-actions. These aspects enable the actions of the very young preverbal children, who are the focus of this research, to be analysed to identify the mathematics the children use when engaging with their world. In doing so, the child's agency is recognized. That is, they are able to act as they wish to act and to have the freedom to make choices (Lange, 2010).

Research question

As indicated by the work of Franzén (2015) and Meaney (2016), very young children, even preverbal children, can demonstrate mathematics through their actions. This paper considers what mathematics very young preverbal children might demonstrate through their actions when playing with train carriages on a train track without educator engagement. Specifically, the research question is – What might the actions of very young preverbal children show in terms of Bishop's (1988, 1991) six mathematical activities when they are engaging in self-selected play with toy train carriages and a train track?

Methodology

Before entering the learning centre, information about the project was provided to the manager, the educators, and the parents of the children and consent to participate was requested. A camera capable of capturing 360-degree video was attached to the ceiling of the room, making it unobtrusive to those in the room. The camera recorded whilst the children and educators were in the room. A section of video is analysed from a video that is 34 minutes and 19 seconds long.

Context and participants

Two educators and three children were in the room. All three children were female and one year in age. Two of the three children did not use verbal language and the third has minimal verbal language. The two educators interact with the children, but the children had choice in what they did – that is, the activity was self-selected by the children. The educators' interactions involve speaking with the children, asking the children questions (related to what the children were doing), and responding to the children when they approached the educator, for example, handing the educator toys.

The section of the video that is analysed is 31 seconds in length. The two preverbal children had chosen to play at the train table and, although the educator was present, the educator did not engage with or interact with the children during this section of the video. The educator is watching the children and her only involvements are placing a train carriage on the train track after it had fallen to the floor (Child 1 had picked up two train carriages joined together, holding only one of the carriages, with the second train carriage falling to the floor); helping one child walk between her and the train table (holding the child steady as she passes by placing her hands on the child's sides); and moving the table and keeping a hand on it to hold it in place when one of the children tries to pass between the other child (sitting on the floor) and the table. The section starts when the educator places two trains on the train track then sat back to watch the two preverbal children play. Initially, Child 1 plays with the two train carriages the educator has placed on the train track and Child 2 plays with three train carriages on the train track. The video section ends when Child 2 walks towards the educator and hands her two train carriages.

Analysis

An iterative process is used to identify the actions of the child and then to identify which of Bishop's (1988) mathematical activities may have been evident through the children's engagement with their environment. The section of video was initially viewed in its entirety and a broad description of what occurred in the video was created as a frame. Then, each child was the focus for the subsequent viewings. The second viewing enabled details of the child's actions to be gathered. During this second viewing, the video was stopped frequently and reviewed to enable the detailed notes to be written. After the detailed notes were written, the video was viewed a third time, again in a stop-start manner, to enable the detailed notes to be checked against the video. A fourth viewing also followed the stop-start manner, but longer sections of notes were compared. A final viewing occurred to compare the full notes with the video, this time without stopping during the viewing. Narratives were created from the notes for each child that could be synchronized. The process of placing the narratives side-by-side to be synchronized with each other involved identifying actions of each child that occurred at the same time. Spacing was then used to clearly indicate which of the actions described for each child occurred at the same time.

Once the iterative process to create the detailed notes was complete, the actions in the notes were compared to the detailed descriptions Bishop (1991) provides for each of the mathematical activities and the ideas provided in Bishop (1988) to identify when the actions reflect the mathematical activities. As Bishop (1991) notes, it is possible that there will be instances where more than one mathematical activity is evident. The author has used this process with videos of young children for seven years with preservice early childhood educators as part of their work in early childhood mathematics education units. Work with colleagues interpreting videos of preverbal children has occurred over four years.

Results

The synchronized narratives for the two children are presented side-by-side in Figure 1.

Child 1 picks up the train carriages (as they are joined together), with the white train carriage in her right hand then drops the red train carriage to the floor (potentially just a result of only holding on to the white train and swinging her arm as she walks) and walks around the table to place the white train carriage on the train track curve at the end. Child 1 doesn't release the train, and takes it with her as she moves away from the train track to walk around the table.	Child 2 has three connected train carriages in front of her, placed on the corner of the table and not the train track – she has her left hand on the left-most train carriage and her right hand on the middle train carriage and is turning the carriage in the middle trying to reposition it (as it is upside down). The right-most train carriage detaches as Child 2 twists the middle train carriage – she looks briefly at the carriage that has detached then back at the two train carriages that are still joined (with her left hand on the left-most one and her right hand on the right most one).
Child 1 walks around Child 2 to the other end of the table. She places her left hand on the table with her fingers splayed. The train carriage is still in her right hand. Child 1 places the white train on the track. It is positioned sideways (the front and back off the track) and starts pushing it around the train track, even though it is not placed correctly.	With her left hand on the first train and her right hand on the second train carriage, Child 2 drives the two train carriages on the table corner in front of her. Child 2 stops and manipulates the second train carriage with her right hand, then starts driving them on the table again, following the curve of the train track (but driving on the table, not the train track). When Child 2 gets to the end of the table, the two train carriages tumble to the floor (separating as they do so).
Child 1 squeezes between the educator and the table, taking the train carriage off the track, and then walks to the other curved end of the train track. Child 1 places the white train carriage on the table next to the train track but slides it partially on the track (at right angles again) and proceeds to drive it around the curve of the train track. Child 2 is in the way (sitting on the floor), so Child 1 partially steps over and partially sits on her to get past while keeping the train carriage on the train track and her left hand on the table (the educator also moves the table slightly to enable the child to fit through).	Child 2 looks down at the train carriages on the floor then reaches simultaneously with each hand to pick up the two train carriages (the right hand goes to the train slightly under the table and the left to the train further away), crouching and bending to reach them. Child 2 fumbles then drops the train carriage in her left hand when it gets closer to her body, so she uses both hands on the other train carriage (she is still crouching). Child 2 briefly looks at Child 1 who is driving a train carriage around the train track and getting closer to her, then passes the train carriage to her left hand and uses her right hand to pick up the train carriage from the floor. Child 1 slightly knocks her as she is picking up the train carriages. Child 2 ends up with one train carriage in each hand. Child 1 bumps her again and Child 2 falls forward and to her left.
Child 1 takes the train carriage off the train track, placing her left hand on the table as she goes around the corner and down the long side. When Child 1 gets to the hill in the train track (roughly the middle of the track/table), she puts the train carriage on the train track and holds the train track with her left hand. Child 1 swings both hands, so the train carriage is going forward and back on the train track in her right hand and her left hand is going forward and back, with the train carriage and her left hand hitting together several times. While Child 1 is doing this, she is leaning her stomach against the table, which makes it move slightly away from her. Child 1 places the train carriage on the table on the other side of the train track and removes her right hand and raises it, while her left hand is on the table. Child 1 reaches forward again with her right hand and drives the train carriage on the table, then closer to the grey tunnel.	Child 2 uses her hands to help push herself up to stand, with the train carriages still in her hands. Child 2 lets go of the train carriage in her left hand and it drops to the floor. She reaches for the train carriage, looking like she is trying to reposition her grip. She picks up the train carriage with her left hand and straightens to stand. Child 2 walks back towards the train table and moves past it to where the educator is at the other end of the train table. She still has one train carriage in each hand. As Child 2 gets closer to the educator, she stretches out her hands to give the train carriages to the educator (one in each of her hands).

Figure 1: The narratives for the two children side-by-side

Bishop's (1988, 1991) mathematical activities evident in the children's actions

Each of Bishop's (1988, 1991) mathematical activities were evident in the children's actions. There are actions where more than one mathematical activity is evident (Bishop, 1991, p. 108). Example actions for each mathematical activity are listed below:

- Counting

Child 1 demonstrates one-to-one correspondence by using one hand to hold one train carriage. Likewise, Child 2 demonstrates one-to-one correspondence when she holds one train carriage in her left hand and one train carriage in her right hand. Child 2 also shows ideas around quantity when the third train carriage is detached from the other two – she looks at the one that had detached then places one hand on each of the remaining train carriages.

- Locating
  Both children demonstrate their capacity to orient themselves in space. Child 1 walks around the table, places the white train carriage on the track, and drives the train carriage held in her right hand forwards and back to meet her left hand engaging in the mirror action. Child 2 positions her body lower to pick up the two train carriages that have fallen on the floor. She also uses her right hand to push herself up to standing.
- Measuring
  Child 2 demonstrates measuring when she reaches her hands out to pick up the two train carriages after having crouched down to do so. This indicates that she recognizes that her hands were too far away from the train carriages initially, and that she has to change position and reach to be close enough to them. Child 1 demonstrates measuring when she tries to lift her leg and foot high enough to step over Child 2 when she is walking around the table.
- Designing
  In rolling the train carriages on their wheels to perform a 'driving' action, both children are showing their understanding of the properties of the train carriage (that it can be 'driven' on the surface). Child 2 shows this when she is trying to manipulate the middle train carriage to turn it over onto its wheels as it is the wheels that 'roll'. Child 1 demonstrates designing through the templating of the table to ensure she can move around it while 'driving' the train carriage on the train track.
- Playing
  Both children follow the procedures for placing the train carriages on the train track by putting them wheels down. Although Child 1 places the train carriage incorrectly on the train track several times, she 'drives' it around the track, walking around the table as she does so (removing the train carriage from the train track when she cannot reach). Child 2 uses her past experience in how to hold the train carriages to change her grip to increase her chance of picking the train carriage up from the floor.
- Explaining
  The children show their understanding of the conventions of train carriages by placing them wheels-down when they are 'driving' them on the table or on the train track. Likewise, although there are other objects on the train table, the children only 'drive' the train carriages on the train track, showing they know which items are classified in the category of 'driving on the train track'. Child 2 uses gestures to explain that she would like the educator to take the two train carriages by holding them out towards the educator.

Discussion

The 360-degree video makes it possible to identify opportunities where the very young preverbal children were engaged in self-selected activities (Lynch & Stanley, 2018). The positioning of the camera on the ceiling enables the collection of video that shows the full room, making visible a range of activities and levels of children's agency – their choices (Lange, 2010) – to be viewed. The format of the video from the 360-camera also provided opportunities to focus in on specific activities. The captured video enabled the use of an iterative process through which to analyse the actions of the children (Björklund, 2008). Without this iterative process, it would have been more difficult to observe both children and to note down sufficient detail to compare to Bishop's (1988, 1991) mathematical activities and, in effect, make the mathematics visible (de Freitas, 2016).

As Meaney (2016) noted, even though very young children do not reflect on or share their learning using language, they are capable of showing what they know through their actions. The actions of the two very young preverbal children in self-selected play with train carriages and a train track can be used to identify mathematics in terms of Bishop's (1988, 1991) mathematical activities. This is made possible through the deprioritizing of language and the focus on intra-actions (Barad, 2007) to enable

Conclusion

Even though these very young children are preverbal, they both demonstrate each of Bishop's (1988, 1991) mathematical activities and do so without language. This underscores the importance of not preferencing language when looking for ways that very young children may engage with mathematics, much as Franzén (2015) demonstrates with her identification of the mathematics the young child's engagement with the climb-on toy car. Likewise, the children's spatial awareness, both in terms of the positioning of the physical objects and in their use of their bodies to engage with the environment, reflects the capacities Meaney (2016) shared.

This research has limitations. The interpretation of the children's actions and the identification of the mathematics behind their actions cannot be checked with the participants themselves. Franzén (2015) states that researchers need to use children's actions to try to identify children's intentions, but that this may be limited due to the differences in perspective between the researcher and the child. This can occur in all research but is very much present with preverbal children – those who are the focus of this paper. In some ways, it is similar to the issue Bishop (1988, p. 184) expresses regarding his work, that "there is no real prospect of my being able to test whether or not this 'universal' structure will be adequate for describing the mathematical ideas of other cultural groups" – however, he did not consider this a weakness. Bishop (1988) hopes that his analysis would encourage others to engage in similar analysis, an aim that this research would do well to emulate.

Franzén (2015) discusses how the researcher who interprets the actions of young children holds much power. As part of this power, the researcher needs to recognize they are interpreting what they are seeing from a perspective that includes both their own and the child's. Franzén suggests that the researcher needs to accept that there will be ambiguity in interpreting the preverbal child's actions, but in providing an interpretation of the preverbal child's actions, the researcher may be giving voice to these very young preverbal children. However, it is the researcher's interpretations of the actions and, even with vast experience, there is no opportunity to confirm the interpretations are correct. Further investigations with more children may assist in the veracity of these interpretations and the connections of the actions in terms of Bishop's (1988, 1991) mathematical activities.

An analysis of a kindergarten teacher's choices and justifications regarding teaching of a mathematical activity

Ingvald Erfjord[1], Per Sigurd Hundeland[1], and Martin Carlsen[1]

[1]University of Agder, Department of Mathematical Sciences, Kristiansand, Norway;

Ingvald.Erfjord@uia.no; Per.S.Hundeland@uia.no; Martin.Carlsen@uia.no

This paper aims to increase the insight into kindergarten teachers' justification of their teaching. The study was done in a context with mathematical activities developed by the researchers in collaboration with the teachers. This is a context we consider as rich to reveal their choices and justifications made in advance of and during the teaching of a mathematical activity. Data from a semi-structured, post-teaching stimulated recall interview based on an activity with 5-year-old children was analysed employing the Knowledge Quartet proposed by Rowland et al. (2005). We identify seven choices made by the kindergarten teacher that reveal aspects of the kindergarten teacher's knowledge-in-action and knowledge-in-interaction. She adapts the activity through questions, comments, particularities within the activities, and use of artefacts. Thus, she nurtures the children in their mathematical learning process.

Keywords: Knowledge Quartet, Mathematics teaching in kindergarten, Teacher's choices, Teacher's justifications.

Introduction

The aim of the current study is to reveal insights regarding the choices kindergarten teachers (KTs) make during the teaching of mathematical activities in kindergarten and the justifications they provide with respect to these choices. Research has shown that high quality early childhood programs carry the potential of improving children's early learning. Moreover, intervention programs have shown to positively effect children's learning of mathematics (Clements & Sarama, 2011; Stehler et al., 2013). The current study draws on data collected as part of the research conducted within the Agder Project[1] (AP). The AP is a research and development project, designed as a randomized control trial with an experimental group and a control group, with the intention to even out differences between children as they enter school. The AP thus bares characteristics of an early childhood intervention program. In the project focus was on nurturing 5-year-old children in their development within four competence areas (social skills, self-regulation, literacy, and mathematics) that research has shown to significantly contribute to children's school readiness. In the AP, researchers designed mathematical activities in close collaboration with participating kindergarten teachers (KTs); activities that the KTs taught with the group of 5-year-olds from their own kindergarten.

The mathematical activities were designed based on two main principles, playful learning (Hirsh-Pasek et al., 2009) and inquiry (Wells, 1999; see also Breive et al., 2018 for further details with

[1] The Agder project is funded by the Research Council of Norway (NFR no. 237973), The Sørlandet Knowledge Foundation, The Development and Competence Fund of Aust Agder, Vest Agder County, Aust Agder County, University of Agder and University of Stavanger.

respect to the design). The current study thus takes as point of departure these two principles when researching the teaching of mathematical activities in the kindergarten context. Research has documented that emphasis on playfulness in engaging with mathematics in the early years is particularly important with respect to long-lasting effects (Marcon, 2002; Singer et al., 2009). Research has also documented that adopting an inquiry approach to mathematics learning is promising regarding children's learning of mathematics (Breive, 2019; Wells, 1999)

A huge amount of research has been conducted with respect to mathematics teachers' knowledge regarding mathematics and mathematics teaching. These studies are drawing on well-known frameworks such as Mathematical Knowledge for Teaching (cf. Ball et al., 2008), the Teaching Triad (cf. Jaworski, 1994), and the Knowledge Quartet (cf. Rowland et al., 2003; 2005). However, the number of studies analysing kindergarten teachers' practice is more scarce. Mosvold et al. (2011), drawing on the framework of Ball et al. (2008), analysed mathematics teaching in Norwegian kindergartens. They found that they needed to adjust the theoretical framework slightly to make it fit with the kindergarten setting. Breive (2019) also analysed mathematics teaching in a Norwegian kindergarten setting, and she revealed insights into the subtleties of KTs' practice. However, these studies drew on observational data to reveal insights into the KTs' mathematics teaching. We, on the other hand, draw on interview data associated with a taught mathematical activity to reveal glimpses into one KT's choices and justifications for her choices in the activity. Through this approach, we seek a more personal view upon mathematics teaching in kindergarten. Our approach is to some extent in line with the study of Sæbbe (2019), as he, building on the work of Ball et al. (2008), also drew on interview data immediately following observations of mathematics teaching in kindergarten. Nevertheless, our foci on choices and justifications for choices deviate from Sæbbe's, as he discussed whether KTs' practice may be characterised as teaching, whether it is mathematical, and the challenges and demands for KTs' competence. Moreover, our study deviates from Sæbbe's as we adopt a complementary, theoretical framework in our study, the Knowledge Quartet (Rowland et al., 2003; 2005). As such, our study is theoretically in line with Hundeland et al. (2017), who also drew on this quartet in their analysis of a KT's practice. To our knowledge, the Knowledge Quartet has not been used as an analytical framework to analyse interviews before. Thus, our study represents a novel attempt to scrutinise a KT's choices and justifications for her choices in the activity.

Previous studies have shown that substantial insights into KTs' accounts of their teaching practice may be revealed through interview data (Erfjord et al., 2012; Hundeland et al., 2011). The current study draws on this experience as interview data from one volunteering KT from the AP has been analysed. This KT was selected based on the following procedure: The 42 participating KTs in the experimental group were, during the intervention year, invited to accept an invitation from the team of researchers who are the authors of this paper as well as teachers in the professional in-service program the KTs were part of. 12 of the KTs, randomly selected from the 42, accepted the invitation to be observed during their implementation of designed activities as well as a post-teaching interview. The particular KT in this paper was selected from one of these 12, at no other basis than an initial judgment that the activity was conducted as planned (that nothing unfortunate happened like sickness, external need for change in plans etc.). The interview of this selected KT has been analysed in order to address the following two research questions:

1. What choices does a kindergarten teacher make in her teaching of a mathematical activity?
2. What justifications does the kindergarten teacher provide regarding her choices in teaching the mathematical activity?

The KT taught an activity called 'The secret bag'. An analysis of the mathematical discourse emerging in this activity is communicated elsewhere (Hundeland et al., 2020). The activity encompasses reasoning with respect to two-dimensional and three-dimensional geometrical shapes, firstly displayed for all and secondly located in an in-transparent fabric bag. The KT and the children first discussed features of and connections between these shapes. Then, having the shapes into the bag, one child at a time tactilely felt and reasoned what shape the picked one was.

The Knowledge Quartet (KQ)

Rowland et al. (2005) describe mathematics and mathematics teaching and the mathematics teacher's subject matter knowledge regarding these areas through four dimensions. These dimensions are called Foundation, Transformation, Connection, and Contingency, hence the label 'The Knowledge Quartet'. This label not only signifies that there are four dimensions of mathematics teachers' knowing, but also that these dimensions are intertwined – as a quartet. These dimensions emphasize the situations during mathematics teaching in which one may observe the mathematics-related knowing of the teacher.

Foundation is the dimension directed towards the use of propositional knowledge. That is, in the current study in what ways the KT, in her interview responses, reveals relevant knowledge of mathematics and mathematics education as well as her view regarding the goals of mathematics education and ways children appropriate mathematics. The analytical contributory codes used were: "awareness of purpose; identifying errors; overt subject knowledge; theoretical underpinning of pedagogy; use of terminology; use of textbook; reliance on procedures" (Rowland et al., 2005, p. 265).

Within the KQ there are two dimensions addressing knowledge-in-action. *Transformation* refers in the current study to the KT's choices of representations, demonstrations, and use of examples, e.g. geometrical shapes, and how these are revealed in interview responses. Basically, this dimension concerns in what ways the KT shows evidence of appropriately transforming the mathematics for the children's learning. The analytical contributory codes used were: "choice of representation; teacher demonstration; choice of examples" (Rowland et al., 2005, p. 265). *Connection* refers in the current study to how the KT makes connections between the activity involved mathematical concepts and procedures, i.e. features of geometrical shapes and their relations, as well as ways to challenge the meaning of these concepts and ideas. The analytical contributory codes used were: "making connections between procedures; making connections between concepts; anticipation of complexity" (Rowland et al., 2005, p. 265).

The fourth dimension is called *Contingency* - a dimension of knowledge-in-interaction. This dimension encompasses the nature of adult-child interactions and responses, and in the current study as how the KT responds appropriately, take advantage of emerging opportunities for learning, make the activity her own, and to what degree she deviates from her set foci and goals. The analytical contributory codes used were: “responding to children’s ideas; use of opportunities; deviation from agenda” (Rowland et al., 2005, p. 266).

According to Rowland et al. (2003), “the quartet is comprehensive as a tool for thinking about the ways that subject knowledge comes into play in the classroom” (p. 97). Nevertheless, we will analyse the KT’s answers in a post-teaching stimulated recall interview and align her responses with the relevant dimension(s) and associated codes.

Semi-structured interviews

Semi-structured interviewing is a commonly used method of data collection (Bryman, 2016; Kvale, 1996). Characterising features of semi-structured interviews are (non-exhaustive): 1) A list of questions is prepared; 2) The respondent may elaborate the response; 3) There is no strict order of the questions; 4) New, non-prepared questions may be asked; and 5) All prepared questions are asked.

We are aware of the deficits of qualitative interviews when it comes to trustworthiness, as people tend to rationalise on their thinking rather than trying to tell what they are/were thinking in interview settings. However, one of the authors both observed the taught activity as well as conducted the interview immediately after the activity. Extensive collaboration between the researcher(s) and the KTs was also established in the AP. These aspects add to the trustworthiness of the KT’s answers with respect to choices made and the justifications for these choices.

In the current study we particularly analyse a post-teaching stimulated recall interview. Designing our interview in this way is in line with how Rowland et al. (2005) designed their interview when developing the framework of the Knowledge Quartet. Furthermore, we designed our interview paying close attention to the codes behind the four dimensions of the Knowledge Quartet. Thus, we were formulating our questions aiming to address the particular codes in order to implicitly address the four dimensions. For example, we asked the question “What was the intention behind the activity?”, to address the code ‘awareness of purpose’.

Context and participant

The current study analyses a semi-structured interview with the KT, immediately following her teaching of a mathematical activity, ‘The secret bag’. The activity was designed based on the principles of playful learning and inquiry. The written description of the activity encompassed an intention of the activity with respect to participating children’s possibilities for making mathematical experiences, suggestions for preparations, and suggestions for how to implement that activity including mathematical questions and prompts to use.

Results

Despite the collaborative design of the mathematical activities, including explicit intentions and suggestions for implementation of the activity, the KT was left with a lot of freedom regarding how to teach the activity in detail. Each interview was analysed based on the following procedure: Initially, as mentioned above, the interview guide was collaboratively developed by the three researchers adaptive to the codes behind the four dimensions of the KQ. The conducted interviews were transcribed, and individually we analysed the transcripts, marked the statements and selected illustrative statements for the choices made. After the individual analysis, we met, shared and discussed our outcomes and found that we strongly agreed on the outcomes and the respective statements. Finally, the statements were translated to English and added to our analysis section. From this analysis of the post-teaching stimulated recall interview, we identified seven novel choices that the KT made prior to and during her teaching. We have grouped them according to the dimensions of the KQ.

Choices and justifications associated with Foundation and Connection

With respect to these dimensions, we asked questions about the intentions behind her activity, whether the intentions were achieved, her emphases on making connections between involved mathematical concepts, decisions about sequencing. The KT communicated the following choices:

1. She wanted to promote a particular mathematical focus and mathematical learning purpose of the activity.
2. She was conscious of the design and order of elements engaged with in the activity.
3. She was conscious of what mathematical questions to ask each of the children.

Even though the written description of the mathematical activity encompassed an intention, the KT explained that she made explicit choices in line with her intention. With respect to 1): "I wanted to emphasize a mathematical discussion concerning the features of the geometrical shapes"; "I wanted to let the children come up with answers, to give them time to think, to let them philosophize"; "I have twisted the activity a bit, made it my own". With respect to 2): "I wanted the children first to engage with the geometrical shapes that I brought, and then for them to recognize geometrical shapes in their environment"; I wanted the children to experience the shapes in two different learning arenas". With respect to 3): "There are substantial differences amongst the children. Thus, I do not ask them questions with equal difficulty"; "If I am to include mathematics into the children's play, it is important to ask the good questions". These choices testify that 1) the KT consciously decides and is aware of the mathematical learning purposes of the activity; 2) the KT consciously decides on the organisation of the activity; 3) the KT consciously decides on the mathematical foci through her questioning; and 4) the KT anticipates the mathematical complexity involved in the activity. Thus, we argue that these choices exemplify an operationalisation of the dimensions of Foundation and Connection. The KT draws on her propositional knowledge both with respect to mathematics and mathematics education and establishes connections between the purpose of the activities and the children by adapting the inherent mathematical difficulty.

With respect to the first choice above, the KT argued that she wanted to nurture a discussion amongst her children concerning the characteristics of two-dimensional and three-dimensional shapes. Furthermore, she wanted her children to use visual, auditive and tactile senses to make mathematical experiences from the activity. Concerning the second choice, the KT argued that she followed the written activity quite closely, but also that she had prepared extra material for the children to engage with. She argued that her activity was flexible in its own right, offering her possibilities to both make it easier and to develop the activity further. Justifications for the third choice were as follows. The KT argued that the mathematics questions ought to be adapted to each child's level of competency and that it is important to know each child's competency in order to ask appropriate questions.

Appropriate questions are furthermore needed to make the activity successful in terms of participation and mathematical learning opportunities.

Choices and justifications associated with Transformation

With respect to this dimension, we asked questions about how she adapted the activity to suit the children's mathematical experience, her reasoning with respect to how successful she was in adapting the mathematics, explanations, and use of manipulatives. The KT communicated the following choices:

4. She was conscious of how to engage each of the children in the mathematical activity.
5. She was conscious of how to use manipulatives and other mediating artefacts.

Both these choices signal that the KT is consciously aware of how to best communicate with her children. The KT is careful in how she mathematically approaches each of the children, and she adapts her questions and prompts to each child based on her particular insights regarding each child. "I wanted all children to be able to participate in the mathematical activity"; "There are many ways to engage the children in the mathematics". Furthermore, the KT reveals that she made conscious choices with respect to the various manipulatives she used in the activities, both particularly mathematical manipulatives and other mediating artefacts such as what shapes and number of shapes to include. The KT was also attentive to how she used mathematical language, use of pointing gestures, and displaying artefacts. "I used the fabric bag to introduce some mystery, something exiting, and I used a balloon and some pictures". These choices demonstrate, we argue, that the KT's taught activity was revealing the dimension of Transformation.

Regarding the fourth and fifth choice, the KT argued that all children were actively engaged in the activity. She sought to make them curious about the shapes and used the shapes of artefacts in the room, a brought artefact, and the small plastic shapes to let the children "experience the shapes in two different learning arenas".

Choices and justifications associated with Contingency

With respect to this dimension, we asked questions about how the KT responded to and took advantage of the children's various contributions, whether and why she deviated from her plans for the activity. The KT communicated the following choices:

6. She made choices regarding how to communicate with each of the children.
7. She was attentive to children's comments and made deviations from plans and acted in the moment.

These two choices demonstrate that the KT is particularly aware of how she communicates with the children, especially to what extent and how she responds to the children's questions and initiatives during the activities. "My plans are rarely executed fully. It's about being spontaneous. The children steadily discover new things". "I wanted to let the children come up with answers, to give them time to think, to let them philosophize". The KT was also explicit about the various deviations she made due to the children's contributions, and she explained that she had to act in the moment according to the emerging issues. "I planned to use a game with shapes, made copies for each child. But then I experienced that the mathematical conversation was running smoothly. Introducing the game would then just disturb them"; "I had to make one the children sit on my lap"; "I saw that the children were engaged in the activity. But after 30 minutes I realized that it was time to finalize".

With respect to the sixth choice, the KT emphasized to let the children come up with the answers, to let the children philosophise. She also gave the children time to think for themselves for a while, for them to come up with answers. As regards the seventh choice, the KT argued that it was important to her to follow up on the children's philosophical-mathematical questions. She wanted to discuss what the children were mathematically occupied with, to be spontaneous and flexible and react to the mathematically unexpected. However, she also took actions on the spot with respect to her leadership of the activity.

Discussion

This paper aims to increase the insight into KTs' justification of their teaching. The study was done in a context with mathematical activities developed by the researchers in collaboration with the KTs, a context we consider as rich to reveal their choices and justifications. We set out to come up with answers to the following two research questions: What choices does a kindergarten teacher make in her teaching of a mathematical activity? and What justifications does the kindergarten teacher provide regarding her choices in teaching the mathematical activity? Findings suggest that the revealed justifications for the teaching choices made, give insights into this KT's knowledge-in-action and knowledge-in-interaction.

From the analyses of the post-teaching stimulated recall interviews, we argue that the KT made deliberate choices with respect to her teaching of the mathematical activity as well as justifications for these choices. She chose the particular mathematical learning goals for the taught activity, she chose to ask particular mathematical questions and raise mathematical issues for the children to wonder about. She chose various mathematical artefacts and talked attentively with each child in a deliberate way. All these choices were thoroughly justified.

Based on the KT's revealed justifications for the teaching choices made we argue that the KT made the activities her own, in a way featured by the four dimensions in the Knowledge Quartet (Rowland et al., 2003; 2005). She adapts the activity through questions, comments, particularities within the activities, and use of artefacts. Thus, she nurtures the children in their mathematical learning process.

These insights reveal that the Knowledge Quartet is applicable as an analytical framework for analysing post-teaching stimulated recall interviews of kindergarten teachers. Furthermore, through our elaborations of the KQ dimensions and associated codes in our analyses, significant insights are implicitly revealed regarding a kindergarten teacher's teaching of mathematics and the issues she has to handle in situ to make the participation in the activity a nurturing mathematical learning process for the involved children.

Opinions of prospective elementary school teachers on word problems in mathematics

Word problems are an important part of learning and teaching mathematics. However, they differ, among other things, in the extent to which they are related to reality. From this point of view, we distinguish intra-mathematical word problems, "dressed up" word problems, and modelling problems. Our research revealed that prospective teachers of lower elementary grades (N = 81) consider intra-mathematical problems and "dressed up" problems more suitable for use in mathematics instructions than mathematical modelling problems. In addition, prospective teachers would like to include the mentioned two types of word problems to a greater extent in their teaching of mathematics than modelling problems. Additionally, we will show what advantages and disadvantages they identify for each of the presented word problems.

Keywords: "Dressed up" problem, intra-mathematical problem, mathematical modelling, prospective elementary teacher, word problem.

Theoretical framework

Word problems help prospective teachers understand the role of mathematics in reality and prepare them to apply mathematical skills in everyday situations. We know that there is a wide range of mathematical tasks used to apply mathematical models and procedures to reality, ranging from simple word problems to complex modeling problems (Dröse, 2019). In addition, word problems can deepen and broaden prospective teachers' knowledge, improve their logical and critical thinking skills, and enhance their creativity. Moreover, they can provide prospective teachers with the opportunity to apply their mathematical knowledge to complex real-world problems, as they can work at their own pace and decide for themselves how to approach the problem (see, e.g. Van de Walle et al., 2016; Verschaffel et al., 2020).

One of the best-known characteristics of word problems is how they are connected to reality (Krawitz & Schukajlow, 2018; Rellensmann & Schukajlow, 2017). From this perspective, there are generally two types of problems: problems connected to reality, real-world problems, and problems without such a connection, also called intra-mathematical problems.

Real-word problems describe a reality-based problem situation involving objects from the reality, such as objects from nature and everyday life. Many authors distinguish two types of real-world problems: modelling problems and "dressed up" word problems (Rellensmann & Schukajlow, 2017; Krawitz & Schukajlow, 2018).

The basis of modelling problems is a demanding translation process between reality and mathematics (Blum et al., 2007; Krawitz & Schukajlow, 2018). Solving modelling problems is often described as a cycle of activities that begins and ends with a real-world situation (Galbraith & Stillman, 2006; Blum & Leiß, 2007). According to Blum and Leiß (2007), this process consists of the following seven steps: (1) understanding the problem and constructing an individual ”situation model”; (2) simplifying and structuring the situation model and thus constructing a ”real model”; (3) mathematising (translating the real model into a mathematical model); (4) applying mathematical procedures to derive a result; (5) interpreting mathematical result in terms of reality and attaining a real result; (6) validating the obtained result concerning the original situation (if the result is unsatisfactory, the process may start again with step 2); and (7) exposing the whole solution process. Note that prospective teachers' processes in mathematical modelling are usually not linear but jump back and forth between mathematics and reality several times (see, e.g. Borromeo Ferri, 2007).

“Dressed up” word problems are also connected to reality, but in these problems, the reality-related mental activities are much simpler than in modelling problems. This is because a real model, which is simplified, is already included in the description of the problem. Actually, “dressed up” word problems are just mathematical problems to which we add a figurative context related to reality. Consequently, prospective teachers do not have to structure and idealize the given information, and interpret and validate the mathematical results according to the real-life situation. In addition, “dressed up” word problems do not contain redundant or missing data. This means that prospective teachers do not have to make assumptions about missing data and separate important from unimportant information, which is a challenging property of modelling problems. Finally, from the teachers' point of view, validating the result of a “dressed-up” problem is much easier than in the case of modelling problems since it is mainly limited to checking the mathematical part (Krawitz et al., 2016; Schukajlow et al., 2012; Krawitz & Schukajlow, 2018).

Intra-mathematical problems are those which have no relation to reality. They are, therefore, pure mathematical word problems. Consequently, these problems do not require any reality-related mental activities (Krawitz & Schukajlow, 2018).

Note that the differences between these problems arise from the cognitive processes required to solve these problems (Blum & Leiß, 2007; Galbraith & Stillman, 2006; Schukajlow et al., 2012). All three types of problems have their own advantages and disadvantages, depending on their purpose. All types of problems require mathematical-technical skills, whereas modeling problems and “dressed up” word problems (but at a very low level) also require cognitively demanding translation processes (Krawitz & Schukajlow, 2018). Consequently, all three problem types have their characteristics and of course, they are all essential for learning mathematics.

Since word problems have many other characteristics, for example, linguistic characteristics, numerical characteristics, and the interaction between linguistic and numerical characteristics (Daroczy et al., 2015), it is not easy to determine whether or not each word problem is appropriate in a particular situation.

Particularly for teachers with little experience, it is often difficult to select or create a suitable word problem (Luo, 2009; Simon, 1993; Lee & Kim, 2005). For example, Luo (2009) found out (N=127) that a significant percentage of the prospective teachers from the United States could not construct appropriate word problems for the given symbolic expressions of fraction multiplication. Simon (1993) also found that 70% of the prospective elementary teachers in his study could not form an appropriate word problem for fraction division. In addition, Chapman (2012) has highlighted that studies of prospective elementary mathematics teachers have raised issues about their problem-solving knowledge, suggesting potentially matters related to their problem-posing knowledge.

Leading educators and researchers have proposed some guidelines to determine the level of appropriateness of a problem in a given situation (e.g. Cathcart et al., 2000; Hyde & Hyde, 1991; NCTM, 2000, as cited in Lee & Kim, 2005; Van de Walle, 2001) that can help teachers in selecting and creating word problems. Appropriate problems should be taken out of reality; should be recognised by the prospective teachers as meaningful and valuable; includes significant mathematics; integrates multiple topics and makes connections between different mathematical fields; requires justifications and explanations for answers and methods; is solvable in many ways; generates student interest in working on it; sometimes contains missing, redundant, or contradictory information; the problematic or exacting aspects of the problem must be related to the mathematics the prospective teachers are supposed to learn (e.g. Cathcart et al., 2000; Hyde & Hyde, 1991; NCTM, 2000, as cited in Lee & Kim, 2005; Van de Walle, 2001).

Purpose of a research

This study aims to investigate prospective elementary school teachers' views on different mathematical word problems. We were particularly interested in their opinions about the various word problems depending on their connection to reality. In addition, we want to examine what are, in their view, the advantages and disadvantages of a given word problem.

Methodology

The quantitative empirical pedagogical research methods we used are descriptive and causal non-experimental methods.

The study has been conducted based on a survey of 81 prospective elementary school teachers, more precisely 4th and 5th-year prospective teachers, since the study for an elementary school teacher lasts five years at the University of Zagreb, Croatia, after which they receive a master degree. Printed surveys were distributed to prospective teachers after the lecture, and all 4th and 5th year prospective teachers completed the surveys. The survey was conducted in June 2020. The data obtained from the surveys were analyzed using IBM SPSS Statistics 23. Here we list only a part of the results from the described study.

The anonymous survey included questions about the prospective teachers' year of study and attitude towards mathematics and some questions about word problems. The latter refers to word problems in general and to specific word problems proposed by us (intra-math problems, “dressed up” problems, and modelling problems). In the survey, we presented prospective teachers with six word problems, and in this paper, we will show the results for three of them. For each word problem, prospective teachers had to list some advantages and disadvantages and answer whether they thought the problem was suitable for lower grades of elementary school. In the last part of the survey, prospective teachers had to rank the given word problems according to the level of difficulty and according to what extent they would include a particular problem in their math classes. We also asked them if they felt competent enough to create word problems.

The word problems, which were given to the prospective teachers, were the following.

Word problem 1 (intra-mathematical word problem): *The addend is 14 400, and the augend is 16 500. What is the sum?*

Word problem 2 ("dressed up" word problem): *Carlo wants to buy a car that costs 18 600 euros. Can he buy that car if he only has 16 000 euros in his bank account?*

Word problem 3 (modelling problem): *Carlo and his mother were shopping for a car. Carlo wants a car that will be fun to drive, does not consume a lot of gasoline and is not too expensive. On the other hand, Carlo's mother, who will help pay for the car, wants the car to be reliable and safe. Your job is to make a list for Carlo and a list for his mother that shows which cars are best for them. Then they will have to decide which one to buy! Car information is given in the table below.*

Table 1: Car information

Car	Year	Price	Colour	Mileage	Fuel consumption per 100km	Additional equipment
Nissan Juke	2015	11 000	Red	112 000	9	navigation, automatic air conditioning, radio, front fog lights, cruise control
Ford Mondeo	2017	16 000	White	83 400	10	navigation, automatic air conditioning, radio, front fog lights, cruise control, parking sensors
Audi A4	2018	21 000	Black	91 600	11	navigation, automatic air conditioning, radio, front fog lights, cruise control, parking sensors, leather seats, rain sensors
Ford Fiesta	2016	8 500	Red	60 400	8	automatic air conditioning, radio
Hyundai Tuscon	2017	18 600	Blue	40 900	11	automatic air conditioning, radio, front fog lights, cruise control, parking sensors
BMW X2	2018	35 000	Silver	38 600	11	navigation, automatic air conditioning, radio, front fog lights, cruise control, parking sensors, leather seats, rain sensors, LED lights, sports seats

Reanult Captur	2018	11 600	Blue	111 400	9	automatic air conditioning, radio, front fog lights, cruise control
Opel Astra Karavan	2017	10 400	Silver	112 300	10	automatic air conditioning, radio, front fog lights
VW Golf	2016	12 000	White	70 000	9	automatic air conditioning, radio

Results and discussion

We asked prospective teachers if they thought the given word problems were appropriate for lower elementary grades. This was followed by two open-ended questions in which they were asked to state the advantages and disadvantages of the given problems. The last question related to the word problems was whether they would do such a problem in their mathematics classes. The results for all problems can be found in Table 2 and are described below.

Table 2: Questions about given word problems (WP)

	WP 1		WP 2		WP 3	
	f	f %	f	f %	f	f %
The word problem is suitable for lower grades of elementary school.						
Yes	77	95.1	75	92.6	25	30.9
No	4	4.9	6	7.4	56	69.1
I would do such word problems in my math classes.						
completely disagree	3	3.7	5	6.2	36	44.5
partially disagree	7	8.6	5	6.2	15	18.5
neither agree nor disagree	36	44.5	19	23.5	18	22.2
partially agree	20	24.7	24	29.6	8	9.9
completely agree	15	18.5	28	34.5	4	4.9
∑	81	100.0	81	100.0	81	100.0

Table 2 shows that prospective teachers consider intra-mathematical problems and “dressed up” problems to be more suitable for mathematics classes than mathematical modelling problems. Moreover, the mentioned two types of word problems would also be included to a greater extent in their teaching of mathematics. These responses were to be expected since students consider it less important to be able to solve modelling problems than “dressed” up word or intra-mathematical problems (Krawitz & Schukajlow, 2018).

We asked prospective teachers to write in an open-ended question what they considered to be advantages or disadvantages of a particular word problem. For the first word problem, 33 prospective teachers, i.e. 41% of them, mentioned the simplicity of the problem, and 23 of them, i.e. 28%, noted the repetition of terms in addition and the practice of adding numbers as an advantage. As for the disadvantages of the first word problem, 14% of the prospective teachers stated that the numbers are too large for lower elementary grades, and the vast majority, 48% of the prospective teachers, stated monotony and lack of context as the disadvantage of the word problem. In other words, prospective teachers indicated that word problem 1 seemed boring and uninteresting to them.

Among the advantages of the second presented word problem, more than half of the prospective teachers (57%) stated that this problem requires prospective teachers to think, and that the problem is good because it has a context from everyday life, and therefore could be more attractive to prospective teachers than the first presented problem. Other benefits prospective teachers mentioned were comparison and evaluation. Prospective teachers disagreed on what was a disadvantage of the second word problem. To some, it seemed too simple, while others thought the problem was too complicated. Some even noted that the problem focused too much on material things and that it would be better to have something closer to the prospective teachers’ experiences in the problem, i.e., their age and not cars.

For the third word problem from mathematical modelling, 17% of the prospective teachers mentioned a table presentation as an advantage. Another advantage was that the problem was realistic, excellent for inquiry, and engaging. For the third word problem, 40 prospective teachers (49%) did not state any advantage. Therefore, we can conclude that they do not see the advantages and benefits of this type of word problem at all in the lower grades of elementary school mathematics. As for the disadvantages of the third problem, prospective teachers were almost unanimous. Those who mentioned a disadvantage (84%) stated that the problem was complex/complicated and would take too much time. Additionally, they stated that such a word problem would be more suitable for prospective teachers who are better at math.

Looking at the results overall, we see that prospective teachers are much more inclined to standard word problems. By this, we mean intra-mathematical word problems and “dressed up” word problems, which they encountered much more frequently during their education than word problems involving mathematical modelling. More than 90% of prospective teachers responded that problem 1 and problem 2 are suitable for lower elementary grades, while nearly 70% of prospective teachers answered that problem 3 has no place in lower grades of elementary school. The vast majority of prospective teachers thought problem 3 was too complicated, with too much data and would take up too much of their mathematics class time. Other studies have come to similar conclusions. For example, Lee and Kim (2005) conducted a survey (N=22) that revealed that most teacher candidates found typical routine problems to be good and showed strong resistance to some non-routine problems with atypical features. In addition, Krawitz and Schukajlow (2018) found that there are significant differences in prospective teachers’ task values depending on the type of problem (intra-mathematical problems, “dressed up” problems, and modelling problems). Namely, in their study, prospective teachers reported the lowest task values for modelling problems compared to the other types of problems.

In this paper, we have only presented a part of the survey and the questions from the survey questionnaire. The challenge for all teachers, particularly prospective elementary school teachers, is to constantly upgrade their knowledge and experience in their professional development, including knowledge of word problems and their quality creation.

The construct of playful learning in primary mathematics: A literature overview

Linn Flaten

The University of Agder, Department of Mathematical Sciences, Kristiansand, Norway; linn.flaten@uia.no

This paper scrutinises the main scientific journals and books concerning early years mathematics education for the learning of playful mathematics in primary school. The search process resulted in 2633 studies which were then screened according to title and abstract before reading 61 studies in more detail. The resulting 13 studies were further examined to explore how the different mathematics education researchers characterised playful learning in mathematics. Based on these examinations, the paper provides a working definition of playful learning in primary mathematics education.

Keywords: Literature overview, mathematics teaching in primary school, play, playful learning.

Introduction

This literature overview aims to define playful learning (PL) in primary mathematics education (ME). When reading previous research literature, I discovered that early years ME researchers often do not define PL but view PL situations regarding teaching opportunities by stating what children learn, such as dealing with counting, operations on numbers, shape, and measuring (Ginsburg, 2006), geometrical thinking (Clements & Sarama, 2014), classification, seriation, conservation, one-to-one correspondence, estimating, quantitative concepts, number words, space-time orientations (van Oers, 1996) to name a few. Of course, what pupils may learn through play is highly important, as education has a learning perspective. However, I argue that PL does not depend on the specific mathematical content. In this literature overview, a total of 2633 studies were screened before reading 61 studies in more detail. When scrutinising the resulting 13 studies and identifying the ME researchers' common features of PL, my argumentation contrasts with the argument of Brooker et al. (2014), who concludes that a consensus on the definition of PL in early childhood never will be reached. Also, I argue that researchers studying the effectiveness of a PL approach and what mathematical content pupils learn when participating in PL situations could benefit from a definition of what constitutes PL in mathematics in the first place. Therefore, next, I draw on previous research providing insights into key concepts and a further rationale for conducting this literature overview, deliberately labelled an overview, rather than a review, because the interest is not in the studies' research findings. The aim is purely theoretical; to explore how ME researchers characterise PL to define PL in primary ME.

Background

As a pedagogical approach, PL is a broad construct capturing the interrelationship between play and learning (Hirsh-Pasek et al., 2009). It encompasses learning through free play, guided play and games (Fisher et al., 2012; Ginsburg, 2006). Free play is child-initiated and child-directed. Guided play is adult-initiated and child-directed. In both, the child is active and in the lead. The difference is the adult's passive role in free play, compared to an active role in initiating the activity in guided play (Fisher et al., 2012; Weisberg et al., 2013). Thus, the adult can create more learning opportunities by enhancing the children's engagement in the activities (for a review, see Fisher et al., 2010). The pupils are unlikely to get the full benefit from PL without teachers' engagement (Ginsburg, 2006). However, balancing adult and child participation can be challenging (Breive, 2019), with a risk of the activity becoming of the instructional type. Compared to free and guided play, direct instruction is adult-initiated and adult-directed (Fisher et al., 2012; Weisberg et al., 2013). Thus, guided play lies between free play and direct instruction, involving adult guidance while allowing children to direct the activity (Weisberg et al., 2015). However, there exist various perspectives and differences in opinions of play and learning. Some might even view the two as incompatible (Fisher et al., 2010). What defines PL is unclear (Samuelsson & Carlsson, 2008), as is the distinction between the three approaches (free play, guided play, and direct instruction) it overarches. Especially according to the degree of adult guidance where guided play falls on a continuum where the adults' involvement "varies according to the adults' curricular goals and the child's developmental level and needs" (Fisher et al., 2010, p. 343). In general, it is essential to differentiate between child-initiated (play-based) and adult-initiated activities (instruction or more school-like tasks). However, mathematics instruction can involve various instructional approaches (Sarama & Clements, 2009). It does not have to be direct instruction, and PL can also include different instructional approaches. The integration of play in the learning process is precisely why play in teaching has such great importance (Wood & Attfield, 2005), a potentially valuable educational tool also in primary school mathematics teaching and learning.

The relationship between mathematics and play can be seen as either "mathematics made playful" or "mathematising elements of play" (van Oers, 1996). Mathematics is made playful when it is the primary activity, e.g., games where counting or sorting activities are transformed into playful activities. Elements of play are mathematised when play is the primary activity, e.g., when the teacher tries to be responsive to the children's actions and introduce mathematical concepts to the activity. As such, in both conceptions of the relationship, the teacher may provide opportunities for further mathematics learning. Teachers' ability to respond to the opportunities during play is critical to enhance the children's mathematical thinking (van Oers, 1996), in line with Fisher et al. (2012) and Ginsburg (2006) regarding the adults' role in guided play. However, as play is challenging to define, it is also challenging to assess its quality (Samuelsson & Carlsson, 2008). Thus, it is difficult to draw clear lines between different types of play and between play and instruction. These demarcation difficulties may explain why existing research on play often has focused on mathematical content. Thus, a literature overview is needed to provide a working definition of PL in primary ME.

Methods

The literature overview, conducted in June 2021, was limited to searching six resources for studies of pupils aged 5-12, published in 2010-2021, with no limitations regarding research methods. The resources and the respective number of studies screened were: Educational Studies in Mathematics (ESM, 610), Journal for Research in Mathematics Education (JRME, 177), Journal of Mathematical Behaviour (JMB, 366), (The) Journal of Mathematics Teacher Education (JMTE, 248), The International Journal on Mathematics Education (ZDM, 784), European Early Childhood Education Research Journal (EECERJ, 127), Early Childhood Education Journal (ECEJ, 160), Nordic Studies in Mathematics Education (NOMAD, 87) and four conference proceedings from A Mathematics Education Perspective on Early Mathematics Learning between the Poles of Instruction and

Construction (POEM, 74). Reasons for choosing these journals and proceedings were: The first five journals are ranked A* and A in ME (Törner & Arzarello, 2012). EECERJ and ECEJ are dedicated to early childhood education in psychology and sociology. NOMAD captures the social pedagogical tradition in Scandinavia, relevant to my future research on PL in primary mathematics in Norway. PL has also been a reoccurring topic at the POEM conferences. The keywords were limited to *play* and *playful* but combined with *mathematics* for EECERJ and ECEJ. Both keywords proved influential as three papers only containing *play* were eventually included. The keyword play was expected to capture studies on games, which was investigated in four of the included papers. NOMAD was also searched for the Scandinavian countries' word for *play* ("*lek*"). Table 1 provides the collective screening based on *one* reason for each study's exclusion, with descriptions exemplifying the criteria. The search process resulted in 2633 studies that were screened by reading the title and abstract in phase one, with italicised numbers of excluded studies. In phase two, no papers were excluded based on criterion 3 as non-empirical studies were identified and excluded based on title and abstract. However, when in the slightest doubt of exclusion, the paper was read in more detail, e.g., when *play* appeared in the abstract, only to reveal in phase two that it was used without providing any features (criterion 2). Therefore, phase two included 61 studies, with bold numbers of excluded and included studies. For example, the search of JMB provided 366 studies (*157* + *181* + **9** + *16* + *2* + **1**), excluding *157*, *181*, *16* and *2* studies in phase one according to criterion 1 – 4, and reading ten studies in phase two of which **9** was excluded according to criterion 2 and **1** was included. The collective screening provided 13 studies ($n = 13$) scrutinised for features of PL. However, due to the mentioned limitations, there might be research that this overview does not capture.

Table 1: Results of the first (numbers in italic) and second (numbers in bold) screening phases

Reason for exclusion. Description exemplifying each criterion.	**EECERJ**	**ECEJ**	**ESM**	**JRME**	**JMB**	**JMTC**	**ZDM**	**NOMAD**	**POEM**
1) The school level. The pupils' age or school level was not stated or was not relevant.	*22* **3**	*22*	*113* **3**	*40*	*157*	*46*	*113* **3**	*27* **2**	*34*
2) The use of play or playful. E.g. used without providing features, in a different context (like the theatre) or words like dis*play* or inter*play*.	*25* **4**	*45* **6**	*412* **4**	*80*	*181* **9**	*178*	*632* **9**	*40* **1**	*24* **4**
3) The paper is not empirical. E.g., editorial, a review etc.	*17*	*6*	*71*	*53*	*16*	*24*	*25*	*17*	*7*
4) The subject. The study was not specific to mathematics.	*64*	*81*	*5*	3	*2*	*0*	*0*	*0*	*0*
Studies included ($n = 13$)	**2**	**0**	**2**	**1**	**1**	**0**	**2**	**0**	**5**

Results

The resulting 13 studies were all written in English and conducted in Norway (2), Sweden (2), England (1), Germany (1), Italy (1), Canada (2), the Netherlands (3), and Switzerland (1). I will now give an account of the 13 studies' perspectives when italicising the features of PL that they provide.

Gejard and Melander (2018) studied five-year-old children's geometrical learning and multimodal resources during block play. No clear definition of play was found to be provided in the article. However, they underline the importance of *balancing* the adult's and pupils' *control* in the activity. Further, they emphasised *active participation* in *collective* and *social* activities within a cultural setting where the pupils *negotiate* when displaying their understanding of the encountered geometry.

The role of teaching in a game setting was emphasised by De Simone and Sabena (2020) when investigating five-year-old children playing strategy games in a guided play setting where the teacher initiated the activity and supported the children in the reasoning processes. Thus, involving *interactive participation* where the "attention is on participating in the game (possibly on winning), and feeling pleasure and enjoyment are essential parts of the game" (De Simone & Sabena, 2020, p. 157). As such, it appears the researchers emphasised *interaction*, *communication* (of strategies) and *participation* and the children's perceptions like feeling *pleasure* and *enjoyment* in the PL situation.

McFeetors and Palfy (2017) investigated pupils' reasoning and strategies playing commercial games in a multi-aged grades five and six class. By implementing games dependent on logical reasoning, the authors aimed to "value reasoning as an integral part of thinking mathematically" (McFeetors & Palfy, 2017, p. 536). Overall, they emphasised providing an *engaging*, *authentic*, *collaborative*, and *social* context. Also, the teacher posed questions verbally and in writing to encourage pupils to express their reasoning and explore more sophisticated reasoning, which was recognised by the pupils as helpful and by the authors as vital for the advancement of pupils' reasoning in the play context.

In the following study, McFeetors and Palfy (2018) emphasised the participants' activity when 5th and 6th graders *interacted* while playing in pairs, prompted by adults' questions to emphasise *conversation* about strategic moves and strategies. The pupils were *encouraged to reflect* and build on their previous strategies. Games thought to foster *discussion* and which the pupils would find *appealing* was chosen. By being commercial games, they were perceived as *authentic*. Thus, *interaction*, *reflection* and *communication* in *authentic* game-playing contexts found *appealing* by the participants are features emphasised by McFeetors and Palfy (2017, 2018) in their two studies.

The participants' experiences were also emphasised by Vogt et al. (2018), indicating higher learning gains for pupils experiencing a PL approach. Activities that "are *fun*, *voluntary*, *flexible*, involve *active engagement*, have no extrinsic goals, involve active engagement of the child, and often have an *element of make-believe*" (Weisberg et al., 2013, in Vogt et al., 2018, p. 592, own italicisation).

Van den Heuvel-Panhuizen et al. (2013) investigated the role of a dynamic online game in 10–12-year-olds' early algebra problem-solving. They considered mathematical play in a game context as "that part of the process used to solve mathematical problems, which involves both *experimentation* and *creativity* to generate ideas, and using the formal *rules* of mathematics to follow any ideas to some sort of conclusion" (Holton et al., 2010, in van den Heuvel-Panhuizen et al., 2013, p. 285, own italicisation). Also, PL was aligned with mathematical processes by contributing to non-threatening environments making it safe for pupils to present incorrect solutions and confront misconceptions.

Helenius et al. (2016) identified features that linked mathematics to play, the interacting components being *creative*, *participatory*, and *rule negotiation*. The *creative* aspect involved the 6-year-olds' modelling of a situation, where they *incorporated some elements of reality and altered others* when posing and solving problems they encountered. Furthermore, playful mathematics activities were dependent on *participation* and contributions from others in a *collaborative, social* context "both at the local level of the immediate situation and also at the societal level which determines the rules and values that affect immersion in reality" (Helenius et al., 2016, p. 146). Thus, the participants engaged in the free play situation and a more comprehensive societal reality, excluding individual play as mathematical. In these situations, the participants abided by *rules* which could be changed and *negotiated*, thus "forming the boundaries of the play situation" (Helenius et al., 2016, p. 147). The criteria were independent of the mathematics content and identified as interactional.

Two studies by van Oers (2010, 2014) were included in the overview. Building on the study from 2010, van Oers (2014) considered mathematising as "the activity of producing structured objects that allow further elaborations in mathematical terms through problem solving and (collective) reasoning/argumentation" (p. 112). Productive mathematising was defined as a "playful activity that has its roots in young children's playful participation in cultural practices" (van Oers, 2014, p. 112). Thus, productive mathematising could be interpreted as PL activities when contrasting productive mathematising to re-productive activities or instruction. The characteristics of the play activity were that the activity was *rule-driven* with a high level of *involvement* and some *degree of freedom* given to the pupils. According to van Oers (2014) the activity could contain elements of instruction if it was meaningful, contributing to the children's participation, and balancing "creative construction and sensitive instruction" (p. 121). Thus, the degree of freedom might vary "as long as the activity as a whole remains a playful activity, i.e. is based on personally acknowledged rules, is engaging, and preserves some degree of freedom" (van Oers, 2014, p. 121). The level of involvement included the motivation to keep the activity going, to *engage*, *collaborate* and be *creative*.

Black et al. (2019) built on the characteristics by van Oers (2010) when they investigated a six-year-old boy's expression of his emotion-cognition experience, who described the playful activity as "fun" and the school mathematics experience making him "tired".

Also, Tubach and Nührenbörger (2016) adopted the characteristics of van Oers (2014). They investigated play as a promising approach to link the informal with the more formal mathematics learning in the transition from kindergarten to primary school.

Hundeland et al. (2020) studied the quality of a kindergarten teacher and five-year-olds' mathematical discourse, emphasising *active* children *in the lead* of the PL activity. They referred to Hirsh-Pasek et al. (2009), who stated that "playful learning, and not drill-and-practice, *engages* and *motivates* children in ways that enhance developmental outcomes and lifelong learning" (p. 4, own italicisation).

Incorporating inquiry and playfulness studying five-year-olds engaging in PL activities in kindergarten, Breive et al. (2018) stated that playfulness "has to be founded in *rules* acknowledged between the players, the activity has to be *engaging* and the activity has to emphasise the *player's* *possibilities to deliberately play in his/her own way*" (p. 185, own italicisation). Furthermore, adult guidance provided children with the needed will to ask questions and construct mathematical ideas.

Discussion

Even though not explicitly revealed, several of the excluded papers incorporated PL as an approach to mathematics learning without providing features of PL or clarifying what it constitutes, which is a finding in agreement with other research (e.g., Helenius et al., 2016; Samuelsson & Carlsson, 2008).

Researchers providing features of PL in mathematics do so frequently in terms of *interactional*, *participatory*, and *social* situations. These situations are characterised by *involvement* (van Oers, 2014) and *participation* (Helenius et al., 2016), allowing pupils to *engage*, be *creative*, and *collaborate* when *negotiating* and *discussing* the encountered mathematics. To keep the activity going by *engaging*, *collaborating* and being *creative* are included in the level of involvement by van Oers (2010, 2014), whereas *creativity* was singled out as a separate criterion by Helenius et al. (2016). Several of the researchers provided features of PL independent of the specific mathematical content and more related to mathematical processes in guided play (e.g., Breive et al., 2018; van Oers, 2010, 2014), free play (Helenius et al., 2016) and games activities (e.g., De Simone & Sabena, 2020; McFeetors & Palfy, 2017, 2018; van den Heuvel-Panhuizen et al., 2013).

Further, the PL situations are characterised by researchers as involving *authentic* (McFeetors & Palfy, 2017, 2018), *cultural* activities (van Oers, 2014) with an imaginative *element of make-believe* (Vogt et al., 2018) or *incorporating and altering elements of reality* (Helenius et al., 2016). Also, PL activities are rule-driven (van Oers, 2014), potentially involving negotiation of implicitly or explicitly expressed *rules* (Breive et al., 2018; Helenius et al., 2016; van den Heuvel-Panhuizen et al., 2013).

Several researchers also argue for a need for a mutual understanding and coordination of participants' perspectives of what is engaged in, talked about, experienced, and learned (e.g., Breive et al., 2018; Gejard & Melander, 2018; McFeetors & Palfy, 2017, 2018). It is especially crucial regarding the adults' role in PL situations, which should provide the pupils with the opportunity to be in the lead (Hundeland et al., 2020) and to play in their own way (Breive et al., 2018). Thus, PL situations are characterised by balancing the adult's and children's control (Gejard & Melander, 2018) in activities where creative construction and sensitive instruction provide a degree of freedom to the children (van Oers, 2014). This feature, mentioned by several researchers, could collectively be termed as participants *right of co-determination*, an element allowing pupils a degree of freedom to be *creative* and influence the activity, which may also contribute to the pupils' *feeling of enjoyment*.

Based on this literature overview, common features of PL among ME researchers are identified. Following the identified features, I thus define PL in primary school mathematics as *situations where participants with a right of co-determination actively participate in a rule-driven, imaginative, cultural mathematics activity while discussing the encountered mathematics*. Since the 13 studies included all three approaches, the definition applies to PL as an overarching construct of learning mathematics through free and guided play and games (Fisher et al., 2012). The features of *collaboration*, *interaction*, *creativity*, *emotions* and *authenticity* are not mentioned explicitly. However, following the previous argumentation, the definition encapsulates these features. There are aspects of *collaboration*, *interaction* and *creativity* encompassed when pupils are given a *right to co-*

determination when engaging in PL activities *discussing* the encountered mathematics. Also, *creativity* is encompassed by the *imaginative* feature, allowing participants to influence the activity, which may also lead to feelings of *enjoyment* and *pleasure*. Thus, the features align PL with mathematical processes rather than with mathematical content. The participants coordinate their perspectives when posing their suggestions and developing the activity while trying to solve the encountered mathematics tasks. However, emotions are highly subjective and can vary within the same activity. By intending to provide a working definition applicable for teachers and researchers assessing or investigating the quality of play (Samuelsson & Carlsson, 2008), emotions are not mentioned explicitly. Also, the *authentic* feature (of games) is encompassed by the *cultural* feature in the definition. Notably, there can also be a varying degree of fulfilment of the different features, as in the scrutinised studies. As such, the definition includes a familiar resemblance of features of PL, without necessarily each situation exercising all features to the same extent. Also, since the taken approach has its limitations, it will be interesting to test and, if needed, refine the definition when researching primary mathematics teaching claimed to be playful.

Didactic transposition of natural numbers in the first year of compulsory schooling: a case of comparative curricula analysis

Birgitte Henriksen

Aarhus University, Denmark; bhen@edu.au.dk

The first year of school has recently become mandatory in Denmark, and for the 5 to 7 age group, a national curriculum for mathematics has been designed. This study aims to present an analysis of the didactic transposition of natural numbers in the first year of school to foster reflection on the national curriculum design. The focus is on the didactic transposition from scholarly knowledge into knowledge to be taught occurring in the national curricula of three countries: Denmark, Sweden, and Australia. The methodological approach is curriculum mapping using a table. The results show that the main elements of scholarly mathematics related to natural numbers on a sector level are identified in all three curricula; still, analysis on a theme level shows significant differences.

Keywords: Didactic transposition, the first year of compulsory schooling, comparative curricula, natural numbers.

Introduction

Guidelines have existed for many years in early education, but curricula for preschool on a national level in OECD countries are a newer creation (Samuelsson et al., 2006). In Denmark, the first year of school, which forms a transition year, changed from voluntary to mandatory in 2009. In 2014, the Danish Ministry of Education presented a national curriculum for compulsory schooling (Retsinformation, 2014). One subject/competence area was mathematics. Play constitutes a critical element in teaching, and teaching should be based on several subjects/competence areas simultaneously, e.g., mathematics and commitment and community. Comparing this national curriculum with other international curricula may provide a broader insight into international perspectives on the knowledge to be taught designed for early years mathematics. This study aims to analyse the didactic transposition of natural numbers from scholarly knowledge into knowledge to be taught occurring in three national curricula covering the first year of compulsory schooling. On this background, the research question is: How can scholarly mathematics be used to analyse aims related to natural numbers for the first year of compulsory schooling in the national curricula from three different countries: Denmark, Sweden, and Australia?

Theoretical framework

The framework is built on the theory of didactic transposition and central theories of young children's development of different aspects of natural numbers.

Didactic transposition

The theory of didactic transposition is anthropological as it considers knowledge as "a changing reality embodied in human practices taking place in social institutions" (Chevallard & Bosch, 2014, p. 173). A systematic epistemological and institutional approach is employed to study these knowledge activities as they undergo a process from produced, designed to be taught, actually taught in school, and learned by students. When bodies of knowledge developed in one social institution are transposed to another social institution, they undergo a transformation, deconstruction, and reconstruction to adapt to their new social institution (Chevallard & Bosch, 2014). Chevallard and Bosch (2014) list four social institutions involved in the didactic transposition: Scholarly knowledge, knowledge to be taught, taught knowledge and learned knowledge. The scholarly knowledge, e.g., aspects of natural numbers, is the starting point of the process. Chevallard and Bosch describe scholarly knowledge as "…generally produced at universities and other scholarly institutions, also integrating elements taken from a variety of related social practices" (2014, p. 171). The transposed work from scholarly knowledge to knowledge to be taught is chosen and decided by actors who belong to the "noosphere," meaning "the sphere of those who "think" about teaching" (Chevallard & Bosch, 2014, p. 170). These actors can, for example, be researchers, employees in the ministry of education, and teachers/educators. A national or local curriculum and school textbooks governed the knowledge to be taught. The teacher's task is to transform the knowledge from national/local curriculum and textbooks into taught knowledge. Finally, the last part of the transposition is learned knowledge acquired by students. This study focuses only on the transposition of the scholarly knowledge into knowledge to be taught, also named the external didactic transposition (Bosch & Winsløw, 2020), and more specifically, the transposition of knowledge concerning natural numbers.

Natural numbers

Natural numbers constitute a broad research field in mathematics education; therefore, the total content elements on natural numbers of the three chosen curricula for this study have given a direction of a relevant theoretical framework. Scholarly knowledge on young children's development of natural numbers carried out by Fuson (1998) and Gelman and Gallistel (1978) is considered to be an essential part of the theoretical framework.

Historically, the Hindu-Arabic system of numerals, widely used today, has developed over many years from the tally system as a unary system to the positional numerical systems built around the base 10 (Sun et al., 2018). Conceptual development progress of the numeral systems can be grouped: "the tally system, additive system, multiplicative-additive system, and decimal place value system" (Sun et al., 2018, p. 96). This study concentrates primarily on the first group: the tally system connected with young children's learning of the system. A central origin in scholarly mathematic knowledge for young children, considering natural numbers, can be found in the notions of cardinality and ordinality.

> Early number consists of a network of inter-related skills and knowledge, broadly divided into cardinal and ordinal aspects, that is, those concerned with number as a representation of quantity, and those concerned with number as a representation of position in a sequence. (Bruce & Threlfall, 2004, p. 3)

Concerning ordinal aspects, Siegler (2009) states that the most basic ordinal concepts are more and less. The cardinal aspects of number include determining quantity by counting or by subitising. Subitising is the ability to instantly recognise the cardinal value of a small set of objects without counting them (Bruce & Threlfall, 2004; Fuson, 1988; Siegler, 2007). When children are 3-4 years old, they become proficient at establishing the cardinal value of a set by counting (Siegler, 2007). However, children saying a number sequence or string is not necessarily bound to cardinality or ordinality. Fuson (1988) states that children can repeat number sequences only as a verbal activity, independent of cardinality and ordinality. There must be a shift from counting to numerical meaning for children counting to be cardinal or ordinal. Five developmental stages in young children's ways of counting are outlined: The number sequence: 1) as a string 2) as an unbreakable list (one, two, three …) 3) as a chain that can be broken 4) as a numerable chain 5) as a bidirectional chain where the forward- and backwards- counting is related to each other.

Decomposition and composition or part-whole number knowledge are stressed to be fundamental to developing a deep understanding of arithmetic. Both cardinal and ordinal situations are related to numerical sequence, i.e., when a child knows that there are n-1 entities in the cardinal set, which precedes the n^{th} ordinal entity (Fuson, 1988)

Gelman and Gallistel (1978) identified a set of principles that preschool children at age 5 possess when counting. The first three principles, one-one, stable order, and cardinality, focus on how the process of counting is carried out. The last two principles, abstraction and order irrelevance, focus on what to count and define what can be counted.

To communicate effectively using numerals, children need to know three numerical representations, i.e., number words, numerals, and nonsymbolic quantities and understand each representation and how a representation maps to other representations (Hurst et al., 2017).

Method

Curriculum mapping

Curriculum mapping refers to the method for developing and employing a curriculum map "A curriculum map is a visualisation of relationships within and between a curriculum or curricula" (Greatorex et al., 2019, p. 3). This study follows the 6 key stages of the curriculum mapping method for comparability research: "1. Define study aims and use; 2. Decide which curricula will be considered; 3. Determine the curriculum features that will be the basis of comparison; 4. Collect relevant documentation and sources of data; 5. Extract data and input it into the standard instrument; 6. Consolidate findings through visual representation" (Greatorex et al., 2019, p. 5). However, changes concerning key stage 3 are made as the features that will be the basis for this study are not solely the curricula but scholarly mathematics/theoretical framework. As stated in the theoretical framework section considering natural numbers, the content of the table is not designed independently from the three curricula to be analysed. In this study, the 6 key stages are covered in the paper sections: key stage 1, introduction; key stages 2 and 3, selection and context; key stages 4, 5 and 6, results. Based on the theoretical framework, a table has been designed.

Selection and context

This study analyses aims related to natural numbers learning for young children in the national curricula from three different countries Denmark, Sweden, and Australia. The selection of those three countries' curricula is based on similarities and differences in their early childhood education. The school system in Denmark and Sweden is similar about a transition year from kindergarten to school and a strong cultural emphasis on play. Australia differs from Denmark and Sweden as the country follows a British school tradition focusing on formal learning and less on play (OECD, 2006). The data collection comprises what three curricula say on natural numbers for age 5-7 years, from Denmark, Sweden, and Australia. Natural numbers related to other content areas of a curriculum, e.g., algebra/pattern and measurement, are not included in the analysis of the study. Mathematical processes such as, e.g. proficiency strands of problem-solving are included if they involve natural numbers. The Danish national curriculum includes learning objectives and teaching instructions (Danish Ministry of Education, 2019). The Swedish national curriculum consists of core content and competencies (Skolverket, 2018). The Australian national curriculum includes content descriptions and proficiency strands related to natural numbers (Australian Curriculum, Assessment and Reporting Authority, 2016). Children must have begun compulsory schooling in all three countries by turning six years of age. In Denmark and Sweden, the children are five-and-a-half to six years of age when they start compulsory schooling. However, some children start compulsory schooling in Australia when they are four and a half years of age. In the three countries, the children attend the class for one year. The terminology used to show the first year of compulsory schooling in Australia is "foundation year," in Denmark "kindergarten class" and in Sweden "preschool class". In the three countries, the teachers or the educators below first grade are generalists with 3½-4 years of education at bachelor a level.

Terminology

Following Bosch and Winsløv (2020), terminology of levels has been applied to organise this table appropriately concerning the data collection (curricula). The levels are domain, sector, and theme. The mathematical domain is natural numbers; the sectors are cardinal aspects; ordinal aspects; numerals as names. The themes are subsectors, e.g. the theme one-one correspondence is a subsector of cardinal aspects. The table thus also forms a reference model with an explicit description of relevant scholarly knowledge of the domain natural numbers, which is used as a reference for analysing the presence or absence concerning the content of natural numbers on sector and theme levels. Explicit presence is marked in the table with a code, and an empty box shows absence. Based on the table and code extracts, the three curricula are shown. Finally, a comparison regarding similarities and differences is made.

Results

Table 1 shows the mapping of the analysis of the three curricula with a code: a letter and a number indicating the presence of scholarly knowledge/theory in the form of theme and the belonging sector in the current domain.

Table 1: Comparative curricula analyses – presence and absence of sectors and themes

Domain: Natural numbers				
Sector	Theme	Danish curriculum	Swedish curriculum	Australian curriculum
Cardinal aspects	The one-one correspondence	D1	S1	A1
	The stable order	D1	S1	A1
	The cardinality		S1	A1
	Order irrelevance			
	Abstraction			
	Subitising			A2
	Composing and decomposing (whole-part)		S1	
	Early arithmetic	D2		A3
Ordinal aspects	The ordinal property "more numerous" (more and less)	D3		A4
	The relative magnitudes of numbers	D4	S2	A4
Numerals as names	Saying the number names	D5	S1	A1
	Connect number names, numerals, and quantities	D6		A5

Below are content extracts from the three curricula, informing the coding decision shown and supplemented with an explanation, if necessary. The content extracts are listed in the native language and translated into English where necessary. The native content extracts are stated in italics.

D1) *Har viden om metoder til antalsbestemmelse*/knows methods for counting. Methods for quantification are not explicit in the curriculum, but the first two principles of counting, as one-one correspondence and stable order, are fundamental. Regarding Fuson (1988), children may count but do not make a cardinal integration; therefore, the third principle (cardinality) is not coded.

D2) *Regnehistorier, der rummer et problem, som eleven skal regne på*/problem solving with early arithmetic in a real-world context.

D3)*Bruge forklaringer med ord som større og mindre, når der arbejdes med antalsbestemmelser*/uses explanations, which include terms as more and less when working with number sets.

D4) *Har viden om talsymbolerne og deres ordning*/knows the number symbols and their order.

D5) *Kan læse etcifrede naturlige tal*/can read single-digit natural numbers.

D6) *Forstå sammenhængen mellem mængde, antal, talord og talsymbol*/understands the relationship between quantity, number, number word and number symbol.

S1) *Naturliga tal och deras egenskaper och hur de kan användas för att ange antal and ordning*/ Natural numbers and their characteristics and how they can be used for counting and order. Concerning natural numbers, the Swedish curriculum only contains 24 words. The sentence of cardinality is interpreted to include the three principles of how to count one-one correspondence; stable order; cardinality (Gelman & Gallistel, 1978).

S2) *Del av helhet och del av antal*/part of a whole and part of a quantity.

A1) *Establish understanding of the language and processes of counting by naming numbers in sequences, initially to and from 20, moving from any starting point. A point marks a position but has no size. Understanding that numbers are said in a particular order, and there are patterns in the way we say them.*

A2) *Subitise small collections of objects. Using subitising as the basis for ordering and comparing collections of numbers*.

A3) *Represent practical situations to model addition and sharing. Estimating and calculating with whole numbers.*

A4) *Compare, order and make correspondences between collections, initially to 20, and explain reasoning. Comparing and ordering items of like and unlike characteristics using the words "more," "less"… and giving reasons for these answers. Understanding and using terms such as "first" and "second" to indicate ordinal position in a sequence.*

A5) *Connect number names, numerals and quantities, including zero, initially up to 19 and then beyond. Estimating and calculating with whole numbers. Understand and use number in context.*

A comparison of the three curricula regarding central similarities and significant differences is outlined. Regarding similarities, all three sector levels (cardinal aspects, ordinal aspects, and numerals as names) were identified in the three curricula. This means that the main elements of natural numbers concerning scholarly mathematics are preserved in all three curricula or the knowledge to be taught. None of the curricula has explicitly included scholarly mathematics of order irrelevance and abstraction on the theme level. Only the Swedish curriculum has explicitly included the theme composing and decomposing. Only the Australian curriculum has explicitly included the theme subitising. The Australian curriculum has explicitly included more themes (9) than the Danish curriculum (7 themes) and the Swedish curriculum (6 themes). The themes indicate that the

Australian curriculum is more detailed and precise and goes closer to practice than the Danish and Swedish curricula. Concerning the levels of didactic transposition regarding the content, the Danish and Swedish national curricula tend to be organised at the sector level. In contrast, the Australian national curriculum tends to be organised at the theme level.

Discussion and conclusion

The present study sought to answer the research question on how scholarly mathematics can be used to analyse aims related to natural numbers for the age 5-7 years in the national curricula from three different countries. The study shows that the main elements of scholarly mathematics related to natural numbers on the sector level are identified in all three curricula. Analysing and identifying the aims of the curricula elements related to natural numbers on theme level call for some validity considerations because the designs of the three curricula differ. A significant difference is the detailed design of the Australian curriculum versus the compact design of the Swedish curriculum, while the design of the Danish curriculum is in between. According to Greatorex et al. (2019), the level of detail of curricula data varies, which can influence the usability of data. In the present study, the varying degree of detail makes the selection criteria in the analysis "explicit presence" challenging. The challenge is addressed by informing the coding decision, e.g., the Swedish curriculum where the sentence of cardinality is interpreted to include the three principles of how to count (S1). Furthermore, this study is constrained to the national curricula, while other documents of the knowledge to be taught, e.g., school textbooks, may elaborate on these content areas.

When the scholarly knowledge of natural numbers is transposed into three national curricula, the transformation, deconstruction, and reconstruction (Chevallard & Bosch, 2014) of each curriculum are linked to the educational culture and tradition of the current country (Greatorex et al., 2019). Australia has a longer curriculum tradition within early childhood education than Denmark and Sweden have. The contrasting can foster reflection on the two relatively compact Scandinavian curricula, especially considering the next step of the didactic transposition from knowledge to be taught into taught knowledge. It is the teacher's task to transform the knowledge from the national curriculum into taught knowledge, and it is an open question to what extent she needs scaffolding.

The present study has made some of the cultural differences of the didactic transposition of natural numbers on the national curricula level transparent. Thus, the curricula analyses have provided reflections on different ways to select and design knowledge of natural numbers to be taught in early childhood. The study could be supplied with an analysis of school textbooks considering natural numbers. Also, the study of the national curricula could be extended to include other content areas and mathematical processes. In a questionnaire for educators in the Danish kindergarten class, I will follow up on how often different mathematics skills, including natural numbers, are taught in the classes.

Content and organization of grade 0 mathematics education in the Faroe Islands

Ingi Heinesen Højsted[1] and Sissal Maria Rasmussen[2]

[1]University of the Faroe Islands, Faculty of Education, Tórshavn, Faroe Islands; ingih@setur.fo

[2]University of the Faroe Islands, Faculty of Education, Tórshavn, Faroe Islands; sissalmr@setur.fo

In this paper we study the content and organization of preschool mathematics for grade 0 in the Faroe Islands from a formal and praxis point of view. We elaborate on motives for the genesis of grade 0 and unveil formal documents. We present data from two cases in which we interview two grade 0 mathematics teachers. The data is analyzed in relation to Bishop's six fundamental activities for mathematical enculturation and we report on the educational resources that are used in these activities. Our results show that the content and organization from a formal point of view is limited, while data from our cases indicate that mainly two of Bishop's activities are employed, and that the content is heavily influenced by the chosen mathematics textbook system. We conclude that the lack of formal organization is problematic from an educational point of view and deliberate future perspectives.

Keywords: Preschool grade 0 mathematics, policy and curriculum, Bishop's activities for mathematical enculturation, educational resources.

Introduction

During the last three decades, national level preschool curricula have become more commonplace in early year mathematics education in OECD countries (Henriksen, 2021a; Samuelsson et al., 2006). Members of the CERME Early Years Mathematics thematic working group have previously noted that there are similarities and differences between countries in terms of the curriculum and organization of preschool and express that there is a "need to know more about the organization of preschool in each country" (Bartolini Bussi et al., 2015, p. 1887). For example, in Italy, the preschool curriculum was developed based on Bishop´s (1988) six universal activities for mathematical enculturation: counting, locating, measuring, designing, playing and explaining (Bartolini Bussi et al., 2015), whereas Levenson and Barkai (2013) report that Israeli curriculum documents describe quite extensively the competencies and concepts that children should grasp in preschool by listing "explicity and separately which of those concepts may be promoted and which skills should be enhanced for children ages 3-4, 4-5 and 5-6 years old." (Levenson & Barkai, 2013, p. 2158).

In Nordic countries such as Denmark, Sweden, Finland, a one-year participation at grade 0 for children at the age of 5-7 (usually called "preschool") is now prevalent with the purpose of supporting the transition from kindergarten (age 0-5) to compulsory primary school (grade 1). Since the introduction of the grade 0 in Denmark in 1912, attendance has been voluntary, meaning that some children rather remained at kindergarten one more year, before entering primary school grade 1. However, in 2009, attending grade 0 became mandatory, and new foci on playful learning and cognitive development were introduced (Henriksen, 2021b, Vejleskov, 2017). The shift was soon followed by the implementation of national curricula for grade 0 (Børne- og

Undervisningsministeriet, 2014), which came during a time when results from PISA showed that a higher percentage among weak readers did not attend preschool for one or more years compared to all students (Fredrikson, 2012).

In the Faroe Islands[1], the grade 0 tradition is less established historically. Beginning in 1963, a single primary school introduced grade 0 (students aged 5-7), which was physically located at the school, and it remained the only school with this structure until 2010 (Matras et al., 2014). Since then, several of the larger public primary schools of the Faroe Islands have introduced this system, and as of September 2020, a third of Faroese public school students attend grade 0, even though attendance is still voluntary.

In this paper, we attempt to address the call of Bartolini Bussi et al. (2015) of the need to investigate the organization of preschool mathematics in different countries, in our case focusing on the context of preschool in the Faroe Islands. In particular, we center our attention on grade 0 (students aged 5-7), in which attendance has grown extensively in recent years, and on which no previous research has been conducted.

Our study includes, perhaps obviously, the elaboration of formal curricular documents, however, since the unfolding of curriculum in praxis is not necessarily a one-to-one correspondence, we also seek to collect perspectives anchored in praxis. In this paper, we therefore put forward the following research question:

What is the content and organization of preschool mathematics for grade 0 in the Faroe Islands from a formal and praxis point of view, respectively?

To shed light on our question, we investigate the historical motives and intentions behind the genesis of grade 0 in the Faroe Islands and unveil formal documents that describe the organization and content in preschool mathematics. To gain qualitative insights from a praxis point of view, we interview two mathematics teachers working in grade 0 and investigate which resources they use.

In the next section, we present Bishop's (1986, 1988) six fundamental activities for mathematical enculturation, which is the conceptual background that is used in our analysis. Afterwards, we present the methodological choices underlying our study, which is followed by an elaboration of pertinent policy documents as well as an historical account of Faroese grade 0. We then present interview data and ensuing analysis. Finally, we conclude on our study by referring back to our research question and deliberating future perspectives.

Conceptual background

As mentioned previously, in Italy, the preschool curriculum was developed following Bishop's (1986, 1988) six fundamental activities for mathematical enculturation (Bartolini Bussi et al., 2015). The activities are:

[1] The Faroe Islands is a self-governing country within the Kingdom of Denmark with a population of approximately 53.000.

"*Counting*. The use of a systematic way to compare and order discrete phenomena. It may involve tallying, or using objects or string to record, or special number words or names. […]

Locating. Exploring one's spatial environment and conceptualising and symbolising that environment, with models, diagrams, drawings, words or other means. […]

Measuring. Quantifying qualities for the purposes of comparison and ordering, using objects or tokens as measuring devices with associated units or 'measure-words'. […]

Designing. Creating a shape or design for an object or for any part of one's spatial environment. It may involve making the object, as a 'mental template', or symbolising it in some conventionalized way. […]

Playing. Devising, and engaging in, games and pastimes, with more or less formalised rules that all players must abide by. […]

Explaining. Finding ways to account for the existence of phenomena, be they religious, animistic or scientific." (Bishop, 1988, pp. 182-183)

According to Bishop (1988), these fundamental activities are, on the one hand, universal, because "they appear to be carried out by every cultural group ever studied" (p. 182) and, on the other hand, they are "necessary and sufficient for the development of mathematical knowledge." (p. 182).

Method

To investigate our research question from a formal point of view, we searched for and studied regulative frameworks, executive orders, ministerial reports (including PISA reports), and curricular documents published by the Ministry of Education as well as the Faroese primary and lower secondary school council.

In addition to our studying of policy and curricular documents, we visited two teachers in order to interview them and to see their facilities. This could provide us with some qualitative insights of the content and organization of grade 0 from a praxis point of view, although only as reported by the teachers. Our method comprised a mixture of closed and open questions in a semi-structured interview approach, which is characterized by the interviewer preparing a guide that can serve as a starting point for a conversation, but where the interviewer can improvise if there is a need to ask for examples or elaborations (Arksey & Knight, 1999; Tanggaard & Brinkmann, 2015). The interview guide contained our research questions, followed by interview questions that were formulated in everyday language (Hansen & Andersen, 2009), which we used in the interview situation. Besides asking broadly about what the mathematics practice in grade 0 comprised of, we asked directly if the teaching practice involved each of Bishop's (1988) six fundamental activities, and also which types of resources were used.

The collected data was transcribed and analyzed in order to unveil the constituents of the grade 0 mathematics practice in our cases, investigating from a praxis point of view to what degree Bishop's (1988) six fundamental activities were part of this practice, and which resources are used.

Our findings are presented in the next two sections, beginning with an elaboration of pertinent policy documents followed by interview data analysis.

From PISA to grade 0 – policy and curricular documents analysis

When the Faroe Islands participated in the PISA survey for the first time in 2005/2006, the academic results sent shockwaves through the Faroese education system and society in general. The students' results in mathematics, reading and science were by far worse than every other Nordic country, in fact, also below Mexico, which was the worst performing country in the OECD at the time (Egelund, 2006). In the aftermath, comparative analysis highlighted differences between the Faroese education system and education systems in other Nordic countries, and one detail that gained traction was that almost all Faroese students at the end of 9th grade had received only 9 years of education since there was only one school that included grade 0 in the Faroe Islands, whereas >99% of Danish 9th grade students had spent 10 years at school (Egelund, 2006). In the subsequent years, politicians and other stakeholders voiced their opinions on the matter (Nielsen & Joensen, 2013) including the Faroese primary and lower secondary school council, which recommended that children enter grade 0 (Matras et al., 2011).

As an increasing number of schools began to offer grade 0, a regulative framework, “Executive order on organization and learning in prechool” (Uttanríkis- og mentamálaráðið, 2013) was developed by the Ministry of Education, which outlined the aim, content and organization of grade 0. The two-page document mentions mathematics once: “The content of the education should at least include the foundations of […] mathematics and nature” (Uttanríkis- og mentamálaráðið, 2013). In the already existing regulative framework for grades 1-10, a paragraph was added concerning grade 0, which also mentions mathematics once “The children should learn the foundations for reading, writing and mathematics…” (Uttanríkis- og mentamálaráðið, 2019). Curiously, no curriculum has yet been developed for grade 0 in the Faroe Islands.

Interview data and ensuing analysis

In table 1, below, we have collected some of the interview excerpts that pertain to each of Bishop’s fundamental activities.

Bishop’s activities	Classroom practice
Counting	Teacher 1: “We use many activities of counting […] count how many days they have been to school. We use straws […] when we get to 10, then we bundle the straws with an elastic and call it ‘one tens’ […] centicubes […] jars with different colors to put the straws in ones, tens and hundreds […] We have the abacus, which is old and actually brilliant, but actually it is not easy for them to understand…”
Locating	Teacher 1: “exactly that is in the book […] They see a tall building where there are different characters […] then I ask ‘what is to the side of the man?’ […]” Teacher 2: “the teacher guidance book is very good in that aspect (it says) ‘use the students to explain prepositions, e.g. can you, Linda, stand in front of Magnus’”

Measuring	Teacher 1: "it's one chapter [in the book]. how long is the table… how many pencils is the table… and if we have clips, then ask, how many clips long is the book. Or they throw a paper ball on the wall and measure how many clips the ball fell from the wall – then it becomes a tournament, then they cheat and the clips become shorter, but that is also fun, it is a process. Teacher 2: "and we measure heads, hands, noses etc. using strings with clamps" Teacher 1: "yes, there is a page about that"
Designing	Teacher 1: "yes that is a really good chapter. There is a lot concerning patterns. It is further ahead in the book. You see a picture from an Asian city, where there are towers with different beautiful shapes […] The shapes are typically triangles, quadrilaterals, both rectangles and squares, and then we have circles. Circles we call '0-edges' in grade 0 […] a student said it this year, and I like it so much I will use it going forward"
Playing	Teacher 1: "There is a lot playing, we have something called 'free play' where they can play what ever they want […] And they play many games such as dice games" Teacher 2: "Cards and dice games […] board games, memory and some of them can play beginners chess"
Explaining	Teacher 1: "explanations is mostly… so we try to explain extremely well when we are explaining, but to make them explain… we do try to ask them questions to make them explain, some of them explain in great details […] in each chapter there is a page that is about describing" Teacher 2 (with the book in his hands): "now I took a random page – they have to explain how many apples there are […] I am not sure if this is what you are asking"

Table 1 – Bishops' fundamental activities in the classroom practice

From the teachers' utterances, we can identify that each of the fundamental activities are present to some extent. However, the frequency of the activities, and the reasons that they are present, differ across the categories. On the one hand, **counting** and **playing** are frequent activities that the teachers consciously and in a goal-oriented manner activate in many different contexts. On the other hand, the activities of **locating**, **measuring**, and **designing** are present, yet to a lesser degree, and seemingly only because there are certain pages of the chosen mathematics textbook that encourage this type of activity. **Explaining** is the lone activity that the teachers are hesitant about, which indicates that it is not a particular focal point, however, they explain that it is partly included in the classroom discussions, in which the teachers ask the students questions that stem from the textbook, hence requiring explanations from the students.

When asked directly and indirectly about the type of resources that the teachers used in relation to each of the fundamental activities, the following resources were described: Counting (Straws, jars, centicubes and Abacus); Locating (Textbook, teacher guidance book, and chairs); Measuring (Textbook, pencils, clips, amd strings with clamps); Designing (Textbook, and the outdoors); Playing (Cards, dice games, board games, memory, and chess); Explaining (Textbook).

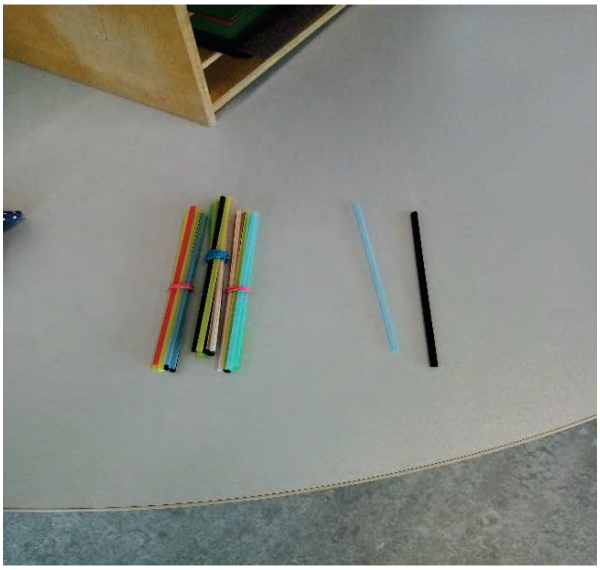

Figure 1 – Straws as ones and bundles of ten

Figure 2 – Cards, dices and other games

Most of the resources are oriented towards **counting** and **playing**, and a few that are used in relation to **measuring**, while the other fundamental activities are based on pages from the mathematics textbook.

In figure 1 we see some of the straws that are used in different teaching activities related to counting, while figure 2 shows a few of the educational resources that are used in playing activities.

Concluding discussion

Referring back to our research question, we can conclude from a formal point of view, firstly, that the content and organization of preschool mathematics for grade 0 in the Faroe Islands is scarcely developed, with only vague peripheral policy documents available. Secondly, from a praxis point of view, our cases indicates that Bishop's six fundamental activities are to a varying degree a part of the classroom practice, with **counting** and **playing** being the main activities that the teachers in our cases emphasize. That is supported by the fact that many of the educational resources that they employ are oriented towards counting and playing. Conversely, the mathematics textbook seems to be the main reason that **locating**, **measuring**, and **designing** are employed. We should stress that our insights into praxis are limited in this case study that consists of interviews with only two teachers. In addition, our data is teacher reported and not observed from the classroom. Therefore, the data may not depict the actual praxis for various reasons.

As mentioned previously, there are many possible approaches to organizing preschool, e.g., the Danish focus on playful learning; the Italian focus on Bishop´s (1988) six universal activities for mathematical enculturation; or the extensive Israeli description of learning goals in terms of competencies and concepts that children should grasp. Deciding which approach is suitable is not a trivial task from an educational point of view, however, we would argue that **some** organization is needed.

Hence, we find it problematic that there is no curriculum for grade 0 in the Faroe Islands. The consequence being that the content and organization is altogether in the hands of the individual teacher, and possibly quite different between schools. A conceivable consequence, which is somewhat evident in our cases, is that the content will be heavily based on the chosen mathematics textbook system.

Looking forward, we argue that the important goal of supporting Faroese students' mathematical development demands a coherent goal-oriented organization, which includes at least a curriculum that describes goals for these critical years in children's development.

Preschool children estimating lengths – the role of standard units as relevant prior knowledge

Jessica Hoth[1] and Sebastian Fricke[2]

[1]Goethe University Frankfurt, Germany; hoth@math.uni-frankfurt.de

[2]University of Rostock, Germany; Sebastian.fricke@uni-rostock.de

Length estimation is a relevant ability in our everyday life. Especially during the Corona Pandemic, estimating a distance of 1.50 m is crucial for our health and social life. Standard units play a central role in many length estimation processes that occur in our everyday surrounding. However, standard units as well as approaches to length estimation are generally discussed with children in elementary school while children already face situations already in their preschool age. This research addresses the question of how preschool children deal with length estimation. In a study with 189 preschool children who were about to start elementary school, we assessed their length estimates and analyzed the role of standard units in this context. It shows that standard units are used by the majority of kids to estimate lengths. However, their estimates are far from precise but the relation between the measures they name is mostly correct.

Keywords: Length estimation, estimation strategies, preschool education, prior knowledge.

Introduction

Estimating lengths as precise as possible is one main ability that becomes relevant in various situations of our everyday life. Especially in traffic there are many situations that require length estimation – the GPS system gives directions in standardized measures or there are zones with reduced speed for a given length. Children get in touch with length estimation in several situations as well. Reading books about dinosaurs holds several situations about length estimation as well as length comparison: the tooth of a Tyrannosaurus Rex was about 15 cm long which is about as long as a banana while the dinosaur itself could reach a length up to 12 m. In these books there are several pictures showing the relation of lengths between the dinosaurs and objects that are known from today. Another example situation where children are faced with length estimation is when they are baking cookies with their parents who have to place the cookie dough in a certain distance from one another or when they are travelling and they ask their parents how much longer they have to drive, they might get a response about the remaining kilometers. These examples are just a small selection of all the situations where children meet length estimation requirements. The majority of these situations also hold standardized units of lengths. Many of these situations already occur before the children start their school career meaning that they necessarily start school with prior knowledge about how to estimate lengths and a variation of intuitive approaches. As the examples already show, there are different estimation situations that require different approaches: Estimating a length in a standardized measure – such as: how many centimeters is this sheet of paper long? – requires knowledge about the standard unit centimeter, about scaling, conceptions about this specific measure as well as knowledge about the measuring process. In contrast, when asking children about what is as long as a Tyrannosaurus Rex, they might just provide a reference object (e. g. a truck) while they do not necessarily need prior knowledge about standard units but rely on direct comparisons instead. If precise concepts about standard units are still missing, this will affect the length estimation's approach as well as its success. It is an open question, to what extend preschool children use standard units for length estimation and how their estimation results are affected if their concepts of these units are still imprecise. With this research we want to contribute information about this point of children's early years' mathematics in this field.

Measurement estimation

Measurement estimation is defined by Bright (1976, p.89) as "the process of arriving at a measurement or a measure without the aid of measuring tools. It is a mental process though there are often visual or manipulative aspects to it". In the process of estimating measures such as lengths, there is specific knowledge and certain skills (such as strategies) that become relevant in order to reach a precise estimation (D'Aniello et al., 2015; Sowder, 1992; Joram et al., 1998). This is supposed to be knowledge about physical measurement (Joram et al., 1998), types of measures or basic conceptual knowledge that can be used as a reference to estimate (Sowder, 1992). Coming back to the dinosaur example from the beginning, children have to know the length of an adult man in order to estimate the height of a dinosaur that is pictured right next to him. In this case, the knowledge about a man's height functions as a reference in the estimation process. Alternatively, they might have a precise concept about a specific standard unit (such as meter) and use this knowledge to estimate the length of a man by counting how many units fit the length of the person. In these examples, we described the two main strategies that are differentiated in the literature for length estimation (1) benchmark comparison and (2) unit iteration (Joram et al., 1998)[1]. Empirical research shows that students from higher grades estimate lengths and areas more precisely than students from lower grades (Huang, 2014; Desli & Giakoumi, 2017).

This theoretical part about the process of length estimation shows the relevance of knowledge about standard units (e. g. the strategy unit iteration can only be used if standard units are known and concepts about their lengths available). In addition, if children encounter length estimation in their everyday life, the estimate will generally be given in a standard unit. Therefore, we put a focus on the role of prior knowledge about standard units for length estimation in this research.

(Prior) knowledge about standard units in the process of length estimation

Measurement generally bridges two mathematic fields: geometry / spatial relations and real numbers (Clements, 1999). Geometrical objects are assigned with a size indication. This consists of a number and a unit. Understanding the various concepts belonging to length measurement (including the meaning of size indication and unit) is a central part of mathematics education. Referring to the developmental theory of measurement by Piaget et al. (1960), it is generally taught in several steps, starting with direct comparisons followed by indirect comparison with a non-standardized unit and, finally, with a standardized unit. This approach is generally chosen in order to reveal children the need for standard units (Clements & Stephan, 2004). However, there is critique about this approach

---

[1] There is a third approach classified in the literature – the decomposition / recomposition approach – which is also based on either unit iteration or benchmark comparison (e. g. Joram et al., 1998).

(Clements, 1999) because children (already in preschool) prefer to use standard units comparing objects and they are even more successful using standard units to measure as compared to measuring with non-standard units (Boulton-Lewis et al., 1996, Kotsopoulos et al., 2015). Empirical studies show that preschool children are already able to use standard units. Boulton-Lewis et al. (ibid.) observed that they used it even if they do not understand it. In this regard, Barret et al. (2011, p. 638) summarize that “students’ unit concepts are rarely well formed. Although students may use unit labels to name a quantity, they often do so without being able to show the meaning of the relevant unit.” Therefore, we find some evidence that preschool children already have prior knowledge about standard units although – as Boulton-Lewis et al. (ibid.) point out – they do not understand them and may not develop conceptual understanding about their lengths and relations to one another yet. However, this understanding may become relevant in the process of length estimation. As Desli and Giakoumi (2017) analyze, third as well as fifth grade students estimated more successful if they used nonstandard units instead of standard units. Therefore, we aim to analyze how this (however incomplete) prior knowledge about standard units may affect their length estimation efforts.

Bringing the ideas about length estimation and unit concepts together with regard to preschool children and their previous experiences, it can be hypothesized that they are missing relevant knowledge in certain situations. Overall, neither length estimation nor standard units were systematically discussed at that point of their education, meaning that they might choose intuitive approaches that they either observed in their surrounding or developed during that situation. For example, due to the fact that they generally did not yet discuss the different standard units and their relations to one another, providing length estimations in a standard unit may not be possible. Therefore, this study focuses on the question of how preschool children deal with different situations of length estimation and what role standard units play in these approaches.

Research questions

As the literature review indicates, preschool children prefer to use standard units for measurement purposes. However, there is some evidence that their unit concepts as well as their conceptual knowledge about these standard units are still incomplete but may be relevant in order to estimate lengths in a standard unit. Therefore, we focus the following two research questions:

1. To what extend do preschool children use standardized units to estimate lengths?

In order to gain information about how the preschool children’s understanding of standard units affects their length estimates, we additionally focus on the estimations’ accuracy. If children only estimate a number and add a standardized unit that they know about, their estimates will be somewhat imprecise. Therefore, the second research question focuses this aspect.

2. How precise are the preschool children’s length estimates?

Methodological approach

In order to analyze the role of standard units in preschool children’s length estimates, we conducted short interviews with standardized questions in Kindergarten with those children who were about to start elementary school only a couple of months later (school enrollment in summer 2021).

Interview design and administration

Four trained student teachers who interviewed the children individually conducted the interviews. Children's responses were assessed on a documentary sheet. The student teachers worked with a standardized interview script that held text about what the students should say as well as specifications about what kind of gestures they should use and what kind of material is given. The interview contained a couple of objects whose lengths should be estimated by the children. The children were asked in each of the five cases to estimate how long the object might be. The questions were intentionally held as open as in order to not limit children's responses and / or strategies. Of course, all the to-be-estimated-objects were standardized in their lengths as well.

In total, the children were asked to estimate the lengths of five objects. For item construction, we followed the suggestions by Heinze et al. (2018) and varied the different characteristics regarding the To-Be-Estimated-Object (TBEO)[2], e. g. its physical presence, accessibility, size and need to construct a representation. Table1 shows one example item of the interview.

Table 1: Task example and excerpt from the interview guide

	Material	**Material treatment**	**Question / verbal instruction**
T2[3]	Green brick (see picture) 	Place the green brick in front of the child. Move your finger along the longest side of the brick.	What do you think: How long is this brick? *Wait for the response.*

The other four items were constructed similarly. In T1, children were asked to estimate the length of a rope, T3 asked the children to estimate the height of a carton of milk, children were asked to estimate the height of the door in their kindergarten classroom in T4 and, finally, were asked to draw a line as long as a piece of toilet paper in T5.

[2] Benchmarks were intentionally not given (dimensions 5 & 6 by Heinze et al., 2018) and it was not prescribed whether children should estimate in a standard or non-standard unit (dimension 7) in order to leave the preschool children the choice what kind of approach they want to choose (they might provide an estimate in a standard unit but might as well just name an object that is about as long as the TBEO). However, the dimensions regarding the TBEO were varied in the five questions.

[3] T2 means second task. In tables 2 and 3, all entries in the line called 'T2' refer to this task.

Sample size and characteristics

In total, 189 preschool children participated in the study. All of these children were about to start school only about two months after the interview. The children attended 14 different Kindergartens in the north of Germany – more precisely in the areas of Mecklenburg-Vorpommern and Schleswig-Holstein.78 of the children are girls (41.3 %) and 111 boys (58.7 %). The children were averagely 5.99 years old – there were 171 children in the age of 6 years, only nine kids were five years old and seven children were seven years old[4].

Data analysis

In order to evaluate the amount of children who use standardized unit in length estimation (research question 1), we determined the absolute and relative frequency of children in our sample that gave an answer holding a standardized unit. In order to analyze the role of standard units in children's length estimation processes (research question 2), and how precise children's' concepts about standard units are, respectively, we analyzed the accuracy of children's estimates. For this second analysis, we only used the sub-sample of those children who estimated in a standardized unit because we cannot evaluate whether estimates such as 'the brick is as long as my hamster at home' is true without measuring the length of the hamster. In order to analyze the estimates' accuracy, we used the deviation of the child's estimate and the actual length of the TBEO. We clustered the children's results in the intervals that are generally chosen in research to code the accuracy of length estimates: if the estimate deviates equal or less than 10 % from the actual length, we consider the estimate as very precise. A deviation of $10\ \% < x \leq 25\ \%$ is still somewhat precise while a deviation between $25\ \% < x \leq 50\ \%$ is acceptable. If the estimate deviates between $50\ \% < x \leq$. 100% from the object's actual length, it can be considered imprecise. Finally, if the estimate deviates more than 100 %, the estimate is very imprecise. In order to gain additional information about the children's approaches and estimation accuracy, we analyzed whether the numerical values fit the right relation to one another. In this regard, we converted all given estimates into meters and evaluated whether the children gave adequate order relations between the measures.

Results

Regarding the four questions that required the children to estimate a length[5], it shows that a majority of the preschool kids use standard units for their length estimates. Due to the fact that a systematic introduction to length units occurs generally in second grade in Germany (Franke & Ruwisch, 2010), these results give another indication that children start with a great variety of prior knowledge in this field. Table 2 shows the amount of children using standard units for their length estimates, and what kind of unit they chose, respectively.

---

[4] For two children, the age is missing.

[5] In T5, children were asked to draw a line that is about as long as a piece of toilet paper. Therefore, standard units were not named here.

Table 2: Amount of children using standardized units for their length estimates

	Amount of estimates given in mm	Amount of estimates given in cm	Amount of estimates given in m	Amount of estimates given in km	Total amount of estimates given in a standard unit
T1 (length of TBEO: 1.3 m)	1 (0.5 %)	18 (9.5 %)	119 (63 %)	6 (3.2 %)	144 (76.2 %)
T2 (length of TBEO: 6.2 cm)	4 (2.1 %)	43 (22.8 %)	90 (47.6 %)	5 (2.6 %)	142 (75.1 %)
T3 (length of TBEO: 20 cm)	4 (2.1 %)	41 (21.7 %)	87 (46 %)	6 (3.2 %)	138 (73 %)
T4 (length of TBEO: 2 m)	2 (1.1 %)	17 (9.0 %)	118 (62.4 %)	6 (3.2 %)	143 (75.7 %)

Table 3: Accuracy of preschool children's length estimates in T1 – T5

	Actual length of the TBEO	Range of the children's responses	Children with a difference < 10 %	Children with a difference 10-25 %	Children with a difference 25-50 %	Children with a difference 50-100 %	Children with difference > 100 %
T1	1.3 m	*Min*=10 cm *Max*=100 km	0	44 (30.6%)	0	32 (22.2 %)	68 (47.2%)
T2	6.2 cm	*Min*= 0.5 cm *Max*= 14 km	3 (2.1%)	6 (4.2%)	14 (9.9%)	18 (12.7 %)	99 (69.7%)
T3	20 cm	*Min*=0.8 mm *Max*=10000 km	6 (4.3%)	6 (4.3%)	6 (4.3%)	31 (22.5 %)	89 (64.5%)
T4	2 m	*Min*=10 cm *Max*=100 km	15 (10.5%)	3 (2.1%)	15 (10.5%)	25 (17.5 %)	85 (59.4%)
T5	12 cm	*Min*=2.5 cm *Max*=25 cm	7 (3.7%)	26 (13.8%)	29 (15.3%)	8 (4.2%)	70 (37%)

However, if we focus on the accuracy of the estimates (table 3), it shows that only a small amount of children reached an estimate that differs less than 50 % from the actual length of the object. It shows that the estimate of the majority of the children (generally about half of the sample) varies more than 100 % of the actual length while only some children estimated very precisely (discrepancy < 10%).

These results show that preschool children are aware of standard units and use them in length estimation situations to provide the lengths of different objects. However – as table 2 shows – they may not choose the different length units most appropriately and their length estimates are not very precise (table 3). This may indicate that they do not yet have precise conceptions about the standard units. The analysis about the order relation showed that 161 kids (79.3 %) gave all four estimates in the correct order (however we did not check for proportional differences). This indicates that preschool children are already able to assign objects with numbers that are given in the correct order relation. However, they may just add the name of a standard unit without really understanding their meaning.

Discussion

Since children get in touch with lengths as well as situations of length estimation in their everyday life, it can be assumed that children bring a lot of prior knowledge and skills in this field when they start elementary school. It is crucial for teachers to be aware of these preconditions in order to start efficient learning processes. The results of this study give hints about these starting points. It becomes apparent that the majority of preschool children provides an estimate using standard units, however, the estimates are often not very precise. This is in line with previous research about students' estimation accuracy and its connection to students' age (e. g. Huang, 2014; Desli & Giakoumi, 2017). However, if we focus on the relation between the estimated values, almost all children's estimates are in a correct order relation to one another. This may indicate that children know about standard units and use them in length estimation contexts but their understanding of the units is still incomplete (as indicated by the imprecise estimation). Therefore, the majority of children uses standard units to estimate lengths even though their understanding is not yet sufficient. These results closely connect to the findings of Boulton-Lewis et al. (1996). Supposedly, children merely estimate a real number and simply add a standard unit that they have heard of before.

Of course, there are limitations to this study. From our results we cannot reconstruct what exactly the children thought in their process of length estimation. We can only hypothesize their approaches from our results. In addition, the Kindergarten teachers may have talked with the kids about standard units before we arrived in their classes (even though we asked them not to do that) because the amount of kids using standard units is amazingly high.

Overall, we suggest that students' prior knowledge should be closely considered as a starting point of learning processes. Further research should provide evidence about how different starting points combined with different learning approaches lead to specific learning outcomes in the field of length estimation.

A framework for analysing drawings as tools for mathematical reasoning

Astrid Hågensen Kleven

Norwegian University of Science and Technology astrid.h.kleven@ntnu.no

The current paper presents a way of explaining and understanding children's drawings as tools for mathematical reasoning. The paper has two aims; to present a framework for analysing drawings as tools for problem-solving and describe how different drawings support children's mathematical reasoning in problem-solving. The study shows that drawings can offer different support for children's reasoning. Some drawings offer explicit tools to be manipulated for solving a problem. Some drawings are structuring tools, supporting systematic checking and re-checking of solutions, while others do not help solve a problem, but serve as tools for communicating with others.

Keywords: reasoning, collaboration, drawing, representation, early years mathematics

Introduction

Reasoning has acquired a more prominent role in several nations' curriculum, including Norway (Utdanningsdirektoratet, 2019). The Norwegian curriculum states that children should learn to 'follow, assess and understand mathematical chains of thought' and 'formulate their own reasoning to understand and to solve problems' (Utdanningsdirektoratet, 2019). Even though teachers are expected to facilitate reasoning on all school levels, some find it challenging to identify reasoning in young pupils' actions or words and, therefore, challenging to facilitate (Bragg et al., 2016). They also claim that the development of mathematical reasoning requires 'appropriate encouragement and feedback from [their] teacher who can only do this if they recognise mathematical reasoning in children's actions and words' (p. 523). According to Battista (2016), mathematical reasoning is about making conclusions based on evidence or assumptions after having manipulated and analysed objects, representations, and statements (p.1), and Bragg et al. (2016) claim mathematical reasoning consists of 'following a line of enquiry, conjecturing relationships and generalisations, and developing an argument, justification or proof using mathematical language'. In this study, reasoning is understood as children making conclusions or assumptions regarding problems after manipulating the task using drawing, and using drawing to follow lines of inquiry while solving tasks.

One way of developing reasoning skills is through paying attention to the different ways children create meaning and their representations. Mathematical representations capture the process behind mathematical concepts or relationships (Woleck, 2001) and play a critical role in children's conceptual and mathematical development (MacDonald, 2013). Mathematical representations can be symbols, physical objects, verbal language, or drawings used to understand mathematical concepts and relations and are a part of construction knowledge (Bobis & Way, 2018). Despite a large body of research on representations, little research focuses on one of the most important representations for the youngest mathematicians; drawings (Woleck, 2001). Drawings can serve as mediation or re-presentation of meaning that allows children's inner pictures and reasoning to become available to others. Thus, children's drawings play a role in meaning-making, problem-solving and early symbolism (Thom & McGarvey, 2015). Drawing is one of children's earliest (mathematical) representations (Papandreou, 2014; Woleck, 2001). Drawings and other written signs have a degree of permanence, allowing them to be re-examined, revised and argued for (Papandreou, 2019), which is why some claim that drawing play a central role in fostering mathematical reasoning for children (Saundry & Nicol, 2006).

By utilising children's representations of their understandings, like drawings or narratives, we are offered a window into their minds (MacDonald, 2013; Woleck, 2001). Children use drawings to bring their ideas or thoughts to the surface and to communicate them with others (Papandreou, 2014; Woleck, 2001). Learning to draw and drawing naturally occurs for most children, but the difference between drawing for fun and drawing with a purpose is big, and the transition from drawing out-of-school and drawing in-school contexts is a topic where several researchers claim teachers lack knowledge (Bakar, 2017; Woleck, 2001). Given the lack of research on drawings as representations (Woleck, 2001) and their central role in fostering children's mathematical reasoning (Saundry & Nicol, 2006), drawings should be offered more attention when researching reasoning and young children.

The project applies a sociocultural perspective on learning and development and considers knowledge to be developed and shared between people (Vygotsky, 1978). Although Vygotsky is mainly known for the relation between speech and reasoning, we can also relate his work to the drawing and reasoning. According to Vygotskian sociocultural theory, higher mental functions and human actions, like communication, are mediated by tools and signs (e.g. language and drawings) (Dahl et al., 2017). Tools are, within sociocultural theory, defined as the resources – both language-based and physical, available to us that we use to understand the world around us (Säljö, 2009, p. 21, my translation). Applying this perspective, viewing drawings as tools used to communicate and to understand the world around us, we can see the connection between drawing and reasoning.

This paper has two aims; the first is to present a theoretically anchored framework for analysing children's mathematical drawings as tools for mathematical reasoning. Which can be used for further research on drawing as a representation, both for researchers wanting to contribute or further develop the framework and teachers wanting to develop their pupils' competencies of using drawing as a meaningful representation and tool for reasoning. The second aim is to explain how different drawings support children's mathematical reasoning through some illustrative examples from two first-grade classrooms.

Framework for analysing drawings as tools in mathematical problem solving

The framework that is the starting point for what is presented below was initially developed by me for my master thesis (Kleven, 2019). It consideres two aspects of drawings in mathematics: the use of the drawing, and visual and multimodal aspects of drawings, and is a synthesis of other frameworks for examining drawings as a mathematical representation.

The first aspect concerns if and how drawings are used. It includes categories like used or did not use drawing, and different ways drawings that can be used for and of problem-solving (Saundry & Nicol, 2006). If used *for* problem-solving, the drawing is used for solving the problem, and drawing is both a process and a product (p. 57). In drawing for problem-solving, the drawing and problem-solving happen simultaneously. The drawing represents thoughts or internal pictures linked to children's mathematical reasoning. A drawing *of* problem-solving is produced after the task is solved, representing a solution (rather than a process). It functions as a tool for communicating with others (rather than solving the problem). Even though drawings of problem-solving are considered to be produced after solving the problem, Saundry and Nicol (2006) claim that pupils' artefacts when working on mathematical problems are a part of their reasoning and cannot be separated from it.

The second included approach to analysing drawings are the *visual and multimodal aspects* of drawings. The distinction between pictographic and iconic drawings is commonly used to describe visual aspects of drawings which could be useful for identifying and describing mathematical reasoning. Both pictographic and iconic drawings can support children's reasoning and problem-solving in mathematics, but at different times and in different ways. A pictographic (situational) drawing can, according to Rellensmann et al. (2017), help pupils better understand a problem by providing a way of organising the information provided in the task. However, simultaneously, a pictographic drawing can also include irrelevant details, getting in the way of an effective problem-solving process. In contrast, an iconic, mathematical drawing often only includes relevant elements, but given its abstraction, it often requires a higher level of mathematical skills to utilise. Further categories are based on Papandreou (2009), and concern whether the pupils include numbers, letters or words in their solution, and if the children use gestures or verbal language as a supplementary mode of communication. Although the table below (table 1) presents the whole framework, this short paper will only focus on a few categories and aspects. The colour-coding in the table is as follows: use of drawings in blue, and visual and multimodal aspects of drawings in purple.

Table 1 – A framework for analysing drawings as tools for mathematical problem solving

Category	Description and indicators of use
Used drawing	The pupil found one or several solutions using drawing.
Did not use drawing	The pupil only used numbers, letters or did not draw at all. Including the use of other concrete manipulatives (like counting on the fingers or using counters). Both correct and incorrect answers included.
Manipulative	Movement, like circles or lines, represent calculations or operations, similarly to physical manipulatives (Saundry & Nicol, 2006; Woleck, 2001). Drawings are used to organise and count the elements needed to solve the problem (Woleck, 2001) and serves as a placeholder for thoughts.
System support	A passive drawing without movement. Drawings are used in an elimination process by systematically sorting elements and creating a structure (Saundry & Nicol, 2006). The drawing is crucial for solving the task, and pupils often use it to count and re-count their solution.
Narrative	Pupils create a story with elements in the task or their surrounding life (Soundy & Drucker, 2009), then act out the story. Creativity, previous knowledge, and the ability to differentiate relevant and irrelevant information become explicit.
Dramatic representation	The pupil draws themselves as part of the problem (Woleck, 2001). E.g., a pupil draws himself pointing at a number line, showing the physical drama of solving the problem.

Imagery/ Visualisation	The problem is solved internally. The process is played out in their mind, and then they draw to *communicate* a solution (Saundry & Nicol, 2006). Information is still processed visually, even though it is not always visible on paper.
Pictographic	Is recognised by its realism compared to the elements in the task. E.g., If the task asks the pupils to put flowers into vases, the pupils will draw either flowers, vases, or both. Also called situational drawings (Rellensmann et al., 2017). Depict the surface of the problem have a low level of abstraction.
Iconic	Simple lines and shapes created to imitate the elements in the problem. It lacks the realism or affiliation to reality found in pictographic drawings. Also called mathematical drawings (Rellensmann et al., 2017). It depicts a mathematical structure and has a high level of abstraction.
Symbolic	Pupils include numbers or letters/words. Defined in this framework as the conventional numerals 0,1,2,3,4,5,6,7,8,9, all letters/words and non-conventional number symbols (Papandreou, 2009).
Gestures and verbal language	The pupils supplement their solution with gestures or use verbal language to support their communication.

The framework above shows different aspects concerning drawing, that one might consider when researching childrens mathematical drawings. Several other aspects were also considered in putting together the framework, and there is a possibility to build further on the framework, including categories and aspects relevant for the particular study one is conducting. The framework is meant to be a flexible framework, where one can make adaptions based on context and needs.

The examples below are from an Educational Design Research study investigating how teachers can facilitate productive conversations, where young pupils are provided with opportunities to develop their reasoning competencies. Video recordings of twenty-seven first-grade pupils (age 5-7) and three teachers have been collected to understand how pupils use drawings to reason and communicate in mathematics. Pupils worked in groups (of 2-4) collaboratively solving problem-solving tasks in mathematics. Participation was based on informed consent from pupils and parents, and the names included below are pseudonyms. For analysing how drawings were used, collected pupil work and video recordings were used. Video recordings were helpful in addition to the drawings because video recordings could help determine whether the children drew while solving the problem or afterwards. All video recordings were transcribed and analysed to supplement the analysis of the drawings. After categorising the ways of using drawings, I aimed to identify reasoning in the drawings, using the video recordings and transcriptions as supplementary information about the process. The examples below are from different sessions, where pupils work on the following problems: (1) 8 children share 12 cookies equally. How many cookies does each child get? And (2) A farmer has some animals that altogether have 14 feet. How many animals, and what animals does the farmer have?

Reasoning in drawings for problem-solving

The examples illustrate drawings used as manipulative and system support. In Figure 1a, drawing is used as manipulative to give one cookie to each child physically. We can see lines representing the process of sharing twelve cookies equally between eight children, resulting in each child getting one and a half cookies each. Based on the drawing, we can see that the pupils gave each child one cookie and then split the leftover cookies to give the same amount. Based on the drawing and the video recording of the two pupils collaborating, the drawing appears to be closely linked to their reasoning process of giving as many whole cookies as possible first and then splitting the rest equally as well.

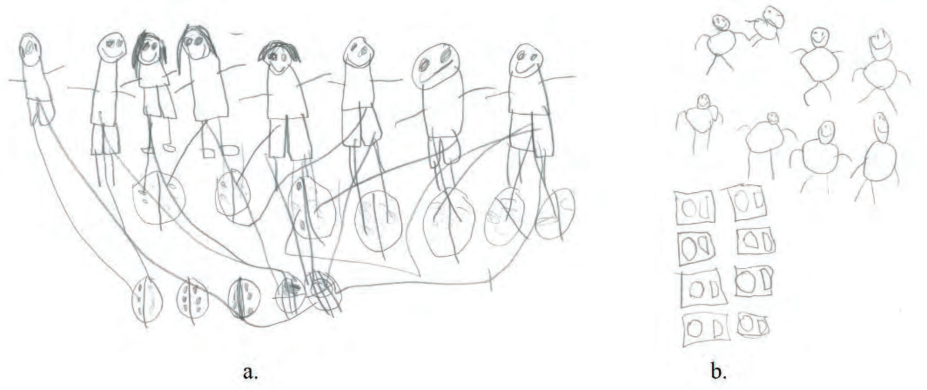

Figure 1a - Manipulative and 1b - System support

In comparison, Figure 1b shows a drawing used as system support for the same problem. The drawing provides an overview and organisation of the elements, but no operations or calculations are visible. In this drawing, we could need to turn to the video recording alone to identify whether the pupil put one and a half cookies in the lunch boxes at once, or if they put one cookie in each of the lunch boxes first, and then put half in each when it was not possible to give a whole cookie more to each child. Identifying the children's reasoning processes can be more difficult in drawings as system support, but the drawing still depicts some of the children's mental processes of sharing cookies equally.

Reasoning in drawings of problem-solving

For identifying imagery, one needs to be present during the process or have recordings (audio or video); this is because one requirement is that the problem is already *solved* when the drawing is produced. As an example of imagery, I would like to highlight Leo and Sam working on problem 2, the farmer problem (figure 2a below). Initially, Sam suggests five sheep, five cows and four hens while holding up five, five and then four fingers. This adds up to a total of 14 animals. After a while, Sam realised that his answer was wrong because it was 14 animals and not legs. Sam starts counting using his fingers and stops while holding up eight fingers. He says, "Two cows", and then Leo draws. Sam continues using his fingers to count and ends up at one sheep and one hen. The boys count all the feet and end up at 14 feet and are satisfied. Sam solved the problem before they made the drawing, and the drawing was used to communicate with others, not to solve the problem. The boys did, however, use the drawing to check their solution.

Figure 2a - Imagery and 2b – Visual aspects

Visual aspects and multimodality

As a short example of an analysis of visual aspects of a drawing, I would like to present a drawing made by a group of four pupils working on problem one, the cookie problem. Malin, Leo, Eric and Martin made an iconic drawing of cookies and children (figure 2b), in addition to a number line of the even numbers from 2-12. The video recordings show the four pupils discussing and trying to agree on which of the circles are children and which ones are cookies because they used the twelve circles to count both children and cookies. This sparks a discussion about if a circle is a cookie or a child, making the equal sharing of the cookies difficult. They are not able to solve the problem using drawing. In addition to using an iconic drawing, we can see that the group used both conventional number symbols and the words for children and cookies in Norwegian. The abstract nature of the drawing made it difficult for the children to reason both individually and in collaboration. A more pictographic drawing with a clear difference between children and cookies could have made this easier.

Discussion

This study aimed at presenting a theoretical framework for describing and analysing how children use drawings in mathematical problem-solving and show some examples of how different drawings can support mathematical reasoning. The framework was presented as a whole, although I only focused on small aspects of the framework in this study. However, the framework is a synthesis of different theoretical frameworks for describing different aspects of drawing in mathematics, enabling research on many different areas or aspects connected to mathematical drawings.

This study further shows that different drawings can support differently in reasoning processes. In drawings as manipulatives (Figure 1a), we can see that a manipulative-drawing allows children to use the drawing to solve the problem physically. A drawing as a manipulative can support the pupils reasoning process by giving the pupil something concrete (external) to solve the problem, thereby allowing the internal processes to become external. All problem-solving processes are visible on paper and are useful for teachers to identify how the pupils solved the problem without being present during the process. Looking back at Battista (2016), defining reasoning to concern manipulating a problem to make decisions or conclusions, a drawing used as a manipulative explicitly enables the use of a drawing to solve the problem, making the drawing a tool for the child's reasoning. As we can see in figure 1a, the lines enable the children to give one and one cookie, keeping tabs on the division happening in the problem. In drawings as system support, more extensive parts of the mathematical reasoning happen internally and therefore "beyond reach" of the drawing or those witnessing the process. Drawings as system support can support children's reasoning by providing them with a tool for organising elements systematically, making it easier to check multiple solutions, and keeping tabs of all elements of the problem without being overwhelmed by the problem itself (Woleck, 2001). As figure 1b shows, the lunch boxes with cookies allow the pupil to count and check his solution, both whilst solving the problem, and afterwards. Reasoning can also be identified in the process and products of pupils using drawings as *imagery*. A requirement for imagery is that the problem is already solved when drawing occurs. The drawing is then used to communicate or show the process or product to others. The drawing serves as mediation or re-presentation of meaning, allowing pupils inner pictures and reasoning to become available to others. Applying a sociocultural perspective allows us to think about the process (and product) of drawing as a direct re-presentation of mental pictures, and therefore as reasoning made available to others. To identify reasoning in drawings of problem-solving, we need to turn to children's verbal utterances and descriptions of their drawings, as illustrated above in the discussion in figure 2a.

Regardless of how the children use drawings, whether as manipulatives, system support, narratives or dramatic representations, all drawings have a degree of permanence to them, allowing them to be discussed, revised and argued for in collaboration with others or for oneself (Papandreou, 2019). By gaining knowledge on children's drawings as mathematical representations, we are offered a window into their minds and understanding of mathematical problems and concepts (MacDonald, 2013; Woleck, 2001). Though examining the children's drawings in the cookie-sharing context, one can gain insight into how young children treat the concept of dividing equally, which again can tell us something about their understanding of division more generally. Facilitating reasoning and sense-making should be the primary goal of mathematics instruction (Battista, 2016). It is, therefore, interesting to investigate how teachers can achieve this, particularly in the early years, where the amount of empirical research is limited.

A possible further analysis of data is needed, in order to see if there is possible to identify a connection between the different ways of using drawing (as a manipulative, system support and so on) and whether the students are able to present understandable chains of reasoning and arguments for their statements when communicating with others. Further studies into the use of more than one modality simultaneously and the quality of young children reasoning is another aspect which it will be both exiting and relevant to look at in the future.

The study had its limitations. What is presented above are empirical examples from one study, and should for that reason, not be generalised without considering all contributing factors. In addition, the framework could benefit from studies in other contexts with more participants with other prerequisites. Given the limitations in scope, several of the framework categories were not discussed, and more studies utilising and further developing the framework is both welcomed and needed to improve the quality of the proposed framework.

I didn’t notice that there was mathematics in kindergarten: Polish parents’ views about Norwegian kindergartens

Troels Lange[1], Dorota Lembrér[2] and Tamsin Meaney[1]

Immigrant parents’ views about mathematics education are rarely investigated, yet these are likely to affect their relationship to early childhood education and care (ECEC) and potentially their adopted country. In this study, Polish parents, who had immigrated to Norway, were surveyed about their views about mathematics education for young children, including what was made available in ECEC institutions in Poland and in Norway. We investigated whether the responses showed that parents’ views about what is mathematics in early childhood and how it should be taught or learnt could be related to parents’ considerations of the power and authority linked to their position as immigrants. The results have implications for multicultural ECEC and policy makers.

Keywords: Immigrant parents, counting, playing, power and authority

Introduction

Immigration in Europe is often described as a recent phenomenon and as such requires policies to support integration. Dustmann et al. (2012) described how different European countries implemented integration policies, including requirements for language fluency, as part of the immigration process, and how the contributions that immigrants bring to a society are frequently considered in relationship to the economic benefits for the receiving country. Education is considered important for ensuring that economic benefits are achieved from children of immigrants gaining the necessary skills to be employable (Sadownik, 2018). As stated by Bratsberg et al. (2012), “the convergence of educational attainment across generations [of immigrants] to that of natives is commonly seen as a key indicator of successful integration and several analysts emphasize education as the key pathway for integration of immigrants and their descendants” (p. 212). In integration policies, the knowledge about education that immigrant parents have is rarely acknowledged. Instead the focus is generally on how immigrant parents’ values about education could/should be brought in line with those of the adopted country (see for example, Sadownik, 2018). This can situate existing educational culture, such as in early childhood institutions, as being static and non-changing. In order to consider what immigrant parents’ views on mathematics education for young children could contribute to discussion about the role of education, we describe Polish parents’ views about mathematics education in Norwegian early childhood centres, known as *barnehage/r* (kindergarten/s). In Norway, there are more Polish immigrants each year than any other nationality (Østby, 2016). We particularly consider how Polish parents’ views about what mathematics is and how it should be learnt are related to considerations of power and authority to have those views heard by Norwegian barnehager.

On the whole, very little research has investigated parents’ views about ECEC. Nevertheless, Van Laere and Vandenbroeck (2017) show that in the Netherlands parents had a variety of views, such as a tension between the importance of developing children’s social competence so that children are not excluded and the importance of readying children for school. However, Sadownik (2021) highlighted that when parents considered their own children’s needs then they could move away from their value positions. In Sweden, Lembrér (2018) found that Polish parents' views about mathematics and how learning possibilities should be provided to children were aligned to those in the Swedish curriculum for early childhood, such as valuing learning mathematics through play. Similarly, Takeuchi (2018) found that immigrant Filipina mothers only taught their children multiplication strategies used in Japanese schools rather than the strategies they themselves had been taught and knew to work. Takeuchi (2018) described "how identity and power are strongly tied with appropriation of cultural tools" (p. 41). In a review of the literature about partnerships between early childhood professionals and immigrant parents, Norheim and Moser (2020) highlighted that asymmetrical power relationships often reduced the possibilities for parental engagement. The results from the studies of Lembrér (2018) and Takeuchi (2018) suggest that these power relationships may affect parents' views about what is valued as mathematics and how it should be learnt. This could have an impact on their engagement with educational institutions such as ECEC and on their integration.

To gain insights into this complexity, we investigate survey responses from 36 Polish parents on mathematics education in ECEC in Poland and in Norway. The research questions are: How are Polish immigrant parents' views of mathematics education for young children connected to authority and power relationships? How are their views likely to affect possibilities for integration in Norway?

Theoretical perspectives

For this study, we use three frameworks: Bishop's (1988) six mathematical activities to identify the mathematics that was in focus in the parents' comments; Walkerdine's (1988) distinction between pedagogic and instrumental interactions; and Wertsch's (1998) discussion of power and authority in mediated action. These frameworks we combine to be able to identify different aspects of the parents' responses. In doing so, we take licence from their perspective on networking strategies of Prediger et al. (2008), who state that "combining theoretical approaches does not necessitate the complementarity or even the complete coherence of the theoretical approaches in view" (p. 173), We then look at how these aspects, what is mathematics, how should it be learnt, and the ways that parents express their power and authority through their views about how barnehager work with mathematics, provide insights into the complexity of parents' views. We investigated whether the responses connected to the different aspects were related.

To determine the kind of mathematics that parents valued, we used Bishop's (1988) six mathematical activities. These are the basis for mathematics in the Norwegian barnehage curriculum (Reikerås, 2008) and have been used extensively in research on ECEC in Scandinavia (see for example, Fosse et al., 2020) . The six mathematical activities are: playing; explaining; designing; locating; measuring; and counting. Of these, counting is often emphasised by Norwegian parents (see Lembrér, 2020).

To identify parents' views on how mathematics should be learnt, we used Walkerdine's (1998) distinction between tasks where the focus was on the child learning specific number understandings (e.g., counting buttons in a cardigan), which she labelled pedagogic, and tasks where the child was engaged in solving an actual problem (e.g., finding the right amount of ingredients for a recipe), which she labelled instrumental. In earlier research (see for example, Helenius et al., 2016), this distinction has been used to determine how children are expected to learn mathematics in ECEC, either by being directly taught (pedagogic) or in the course of solving a problem that the child is invested in answering (instrumental). Sadownik (2018) highlighted that whereas in Poland early childhood education is focused on introduction to academic subjects, Norway's approach emphasised play and democratic participation. This can be considered a distinction between valuing a pedagogical and an instrumental approach, respectively, for engaging in mathematical learning situations.

To better understand how power relationships affected parents' views on the importance of different mathematical activities and the ways that mathematics should be learnt, we built on Takeuchi (2018) research by adopting Wertsch's (1998) ideas about the valuing of knowledge. In a discussion about mediated action, Wertsch (1998) described how "the acceptance of a particular utterance by an individual agent is not simply a matter of dispassionate, reflective choice" (Wertsch, 1998, p. 66), because the society provides input on what should/can be valued, and this can act as a source of authority within a situation. Agents can either reject, accept or be somewhere in the middle, the valued, societal views, depending on the power they see themselves as having within a situation, because "cultural tools are not always facilitators of mediated action, and agents do not invariably accept and use them; rather, an agent's stance toward a mediational means is characterized by resistance or even outright rejection" (Wertsch, 1998, p. 144). When parents with one set of values about engaging young children in mathematical activity from their home country, meet a different set of values in their country of residence, they can either appropriate (more or less), resist or reject the new set of values. Therefore, it is important to understand what immigrant parents value as mathematics and how it should be learnt or taught, and whether they consider this as being in conflict with the values of their home or adopted country.

Methodology

The data are responses to an online survey consisting of 14 questions answered between May and September 2017. The survey was provided in Polish and the link was made available on the website of the Polish organisation "Moja Norwegia" ("My Norway"). The survey asked about the parents' memories of mathematics in Polish ECEC, their children's experiences of mathematics learning in Polish and in Norwegian ECEC, and what would they tell barnehager about their children learning mathematics. These open-ended questions asked for examples of memories or experiences, which we considered were likely to provide insights into the complexity of parents' views. The second author, who is a native Polish speaker, translated the answers into English.

In this paper, we focus on responses from 36 parents who made an explicit or implicit reference to early childhood education in Norway and/or in Poland. All these parents had experiences of their children attending barnehager, some had themselves – or had children who had – attended ECEC in Poland. The responses do not describe what the situation is in either Norway or Poland but rather relate what the parents valued in these situations.

References to mathematics in the parents' responses were categorised according to Bishop's (1988) six mathematical activities. For example, when the parent described using number words to identify the total amount of things, the response was classified as being about counting. To classify what was valued as the ways that children should learn, we categorised the responses on whether the parents valued children learning through everyday situations and solving problems they were interested in (instrumental), or whether it was implied that an adult would teach the children (pedagogic) (Walkerdine, 1988). Finally, we looked for explicit (de-)valuing of what occurs in Norwegian or Polish ECEC to gain insights about whether there was an acceptance, resistance or rejection of a specific set of values (Wertsch, 1998). The combination of these results gave us insights into the role of power relations and authority that may have influenced parents' views.

Results and discussion

The results from the three analyses indicated that they were related and so in presenting them, we placed each parent's responses on a continuum, with specific aspects of the responses clustered at each end. The continuum was one way of showing the complexity of the relationship between the different aspects which enabled us to answer the research questions. At End 1 of the continuum, we placed the five parent responses, which identified several mathematical activities, including counting, described children as learning through everyday problem-solving situations, and depicted barnehager as providing good mathematical learning possibilities. At End 2, we situated the six parent responses in which counting was valued exclusively, children were expected to be taught mathematics, and approaches to mathematics in Polish ECEC were valued. The remaining 25 parents' responses were placed in between these two ends.

Parents' responses at End 1

The parents who valued the approach to mathematics education in barnehager tended to value a range of mathematical activities as being important for children and considered that learning should happen through everyday situations, play and problem solving. For example, Parent3 (P3), whose child(ren) had only attended barnehager, described their mathematical learning as involving, "sorting objects into collections, large/small/medium comparisons, measuring e.g., volume of liquids, playing with shapes, learning how to count". This indicated that more than just learning to count was valued. In responding to a question about why they thought these tasks could help children learning mathematics, P3 wrote:

> Mathematics is the science of abstract thinking. It's good that the beginnings were based on specific examples. Playing with water and in the sandbox is associated with measuring, that is, it familiarizes the child with the concept of volume. Puzzles and blocks are practical science of geometry. Counting and nursery rhymes are an introduction to algebra.

In this response, P3 makes connections to mathematics children will learn at school but indicates that learning happens through play as part of everyday interactions. This was reinforced in the response to the question about what parents would like to tell the barnehage:

> I am very happy with the way children are taught mathematics in our (Norwegian) kindergarten. Children learn it casually, on specific examples. The road to abstract thinking goes gradually, starting with things that children know, that they can touch. Thanks to this they get used to mathematics as a natural part of life. I am very happy about this approach.

Here, how barnehager support children to learn in everyday situations was considered valuable. This acceptance of the adopted country's values is very similar to what Lembrér (2018) found in Polish parents' views of Swedish ECEC.

Sometimes parents at this end of the continuum made explicit comparison with Polish ECEC, "At the Norwegian kindergarten, he focuses on learning logical thinking and associations. In the Polish ECEC, you go directly to memorising activities such as addition and subtraction" (P1). For P1, the barnehage approach was more valued than the Polish one, which they considered was based on memorisation. At this end of the continuum, the parents seemed to have appropriated cultural tools (Wertsch, 1998) from barnehager about mathematics and how it should be learnt so that they had adopted the views as their own, with no indication of resistance to these ideas.

Parents' responses at End 2

At the other end of the continuum, parents emphasised the importance of counting alongside children needing to be taught, and that Polish ECEC provided a better approach to mathematics education or that Norway lacked a good approach. For example, in the question about their own experiences of ECEC in Poland, P6, whose children had also attended ECEC in Poland, stated, "many mathematical play activities, counting fruit, objects, furniture etc, addition, subtraction, division, multiplication through play activities. Very well-prepared staff, nice atmosphere during play activities". When answering a question about why they thought situations would help develop children's mathematics learning, P6 reinforced the importance of children learning counting, "Because children are beginning to understand the connection between numbers and objects". Although P6 described situations in the Polish ECEC as play, the focus on counting things and the need for well-prepared teachers indicated that teachers were expected to be in control.

In response to the question that asked parents to describe a situation where children learn mathematics in barnehager, P6 stated, "instead of splashing around in the mud outside, they could be doing something useful". Other parents also commented on how children being outdoors so much, a valued activity in Norway (Sadownik, 2021), restricted the possibilities to learn mathematics in more appropriate ways, such as inside and being taught, "he learns outdoors when counting cones, stones, there are no activities" (P21). At this end of the continuum, the strong valuing of counting and the need for teachers to explicitly teach, often appeared in conjunction with a devaluing of barnehager:

> There is a tragic level of education in Norwegian kindergarten compared to any preschool in Poland. The Norwegian kindergarten is a children's storage room until parents take them home. I am very disappointed; I plan to return to Poland because I see that children do not learn anything here and only at school from the first Grade, do they start learning anything. (P6)

The language in these responses was often more emotive than the responses placed at End 1. Similar to P6, P10 responded to the question about what they would tell barnehager about their children learning mathematics by stating "a disaster". P19 highlighted the impact on future schooling, "it is a very important but neglected field of science, especially in kindergartens, which unfortunately later negatively affects school". These responses suggest that resistance and rejection of cultural values (Wertsch, 1998) of the adopted country may have led to these parents using stronger forms of language to highlight both that they have an alternative set of values and that these values would provide better possibilities for their children's future. Norheim and Moser (2020) found that immigrant parents faced difficulties in expressing disagreements with early childhood professionals, because of a lack of language and knowledge of how to approach professionals, exacerbated by an asymmetry in power relations. The survey may have provided a safe place for the parents to express their dissatisfaction with what they saw as restricted opportunities for their children to gain the academic preparation they felt their children needed for school.

For P6, whose dissatisfaction with mathematics education in barnehager had resulted in her considering taking her children back to Poland, integration as envisioned in the policy documents could be seen as failing, with the possibilities for economic gains for the adopted country from the parents and their children reduced. This was not because the parents did not value education but because they consider barnehage education as limiting their children's possibilities. As Wertsch (1998) stated, "a focus on resistance and rejection leads one to consider a host of issues that do not arise when one assumes that cultural tools are friendly helpers" (p.145). In the responses at End 2, these issues included a concern for their children's future school achievement.

Parents' responses along the continuum

The parents whose responses fell between the two ends of the continuum presented different views about how they viewed mathematics and how it should be taught/learnt. For example, P47 provided a range of learning situations, connected to different mathematical activities, but in reflecting on what should be said to barnehager, raised both positive and negative concerns.

> I am happy that mathematics is an integrated part of children's play, and that they meet with it on their own terms. Certainly, it is possible to nurture a child's interest in mathematics by supporting play. Another issue is whether this freedom of access to games that stimulate mathematics can increase the differences between children. So that children who are not interested in mathematics can avoid it [play activities which include mathematics] and not be noticed.

Although the barnehage approach to mathematics education seemed to be appreciated, P47 was concerned that teachers needed to notice who might be excluded or exclude themselves in engaging with mathematical activities. Several parents raised the need to improve the quality of barnehage staff. For example, when describing the benefits of learning through play, P12 wrote, "I think that teachers, especially those without education, should be involved in courses that make them more aware about it". The discussion of barnehage staff qualifications has regularly been in the news (see for example, Kunnskapsdepartementet, 2015). This may have provided parents with cultural tools (Wertsch, 1998) to support stating that staff needed to be better educated, which may have helped them to resist appropriation of the values connected to mathematics education in barnehager.

Other parents were less happy with what happened at barnehager, but, implicitly or explicitly, did not completely agree with the approach in Polish ECEC. P38 stated that children in Polish ECEC learnt mathematics through everyday activities, but in a class, suggesting set tasks. In barnehager, P38 stated that they did not learn mathematics, "only picture counting". However, when asked about what they would tell barnehager about their children learning mathematics, P38 wrote, "counting, for example, to 20 is OK, but not adding or subtracting as they teach in Polish preschools". This indicates that P38 considered that barnehager should do something, but they did should not adopt the approach of Polish ECEC. Similarly, P46 expressed disappointment that "unfortunately" mathematics was not taught/learnt in barnehager but offered the suggestion that this could be done in a way which echoed the valuing of play, "it is worth starting the adventure with mathematics through play". Hence, P46 criticised the lack of mathematics education in barnehager, while also suggesting that they should adopt an instrumental, rather than a pedagogical approach to mathematics.

The views that lay between the two ends suggest that the majority of parents evaluated what they knew about mathematics education in Polish ECEC and in barnehager and resisted appropriating some aspects of both. (Wertsch, 1998) described how actors can use alternative knowledge, such as in our case about mathematics education in Polish ECEC, to invoke an authority structure in order to be seen as knowledgeable. Given that immigrant parents struggled to have their views recognised and valued in barnehager (Norheim & Moser, 2020), their evaluating of cultural tools to do with mathematics and how it should be taught could be seen as a way to have their knowledge recognised as valuable and hence as having authority.

Conclusion

In this paper, we have analysed Polish parents' views about their children engaging in mathematical learning opportunities in barnehager. Barnehager are required to make available pedagogical plans and to provide mathematical learning experiences (Kunnskapsdepartementet, 2017). Yet, parents, such as P6, did not consider that there was any mathematics education in barnehager, similarly P8 wrote "I didn't notice that there was mathematics in kindergarten". As pointed out by Takeuchi (2018), cultural values can come into conflicts when there are no opportunities to discuss alternative approaches to mathematics education. The Polish parents came with expectations about how their children would engage in mathematical learning situations. Although some parents were able to adapt to the new cultural values in Norway, they did so by denouncing the approaches in Polish ECEC suggesting that integration is only achievable if they give up some of their Polish values. However, rejection of the barnehage approach to mathematics education of learning through play caused conflicts with Norwegian values.

Wertsch (1998) described appropriation, resistance and rejection of cultural tools. Present immigration policies with their emphasis on the role of education seem to assume the acceptance and thus the appropriation, of the adopted country's values about what should be learnt and how. However, the responses in the survey suggest that this is not necessarily the case. Many parents resisted or even rejected the acceptance of barnehage approaches to mathematics education, even if they had master knowledge of them. This is likely to have an impact of the integration of Polish immigrants into Norwegian society and the potential economic outcomes.

On the use of boardgames to develop young children's number sense

Andrea Maffia[1] and Liliana Silva[2]

[1]University of Pavia, Italy; andrea.maffia@unipv.it

[2]University of Messina, Italy; liliana.silva@unime.it

With the aim of nourishing the discussion that has taken place during CERMEs in TWG13, we present a review of results presented in previous CERMEs about the possible roles of boardgames in developing young children's number sense. Several contributions in CERMEs have shown that difficulties related to teacher education and curriculum design emerge when analyzing the boardgames that are proposed and their management in classrooms. However, the discussion about the contribution of boardgames to preverbal number sense is still underdeveloped when compared to literature from research journals. Also, the potential of boardgames in providing challenging mathematical tasks seems still unresearched. Hence, possible future paths of research for the use of boardgames in early years mathematics emerge.

Keywords: Boardgames, number sense, literature reviews.

Introduction

Play can be considered as the main learning experience for young children in general, and for early years mathematics in particular (Schuler, 2011). Among the many possible playful activities in which children may engage, we can roughly distinguish between free play and guided play, the latter consisting of adults structuring of the play environment but leaving control to the children within the environment (Weisberg et al., 2013). In this contribution we will focus on guided playful activities, to which we will refer as games. There is a large body of research about the use of games in learning (game-based learning), but not all kinds of games have been studied with the same attention. While literature about videogames is getting larger and larger (e.g. Yong et al., 2021), boardgames were rarely researched (Ramani & Siegler., 2008). We consider as boardgames all those games that are played on a printed surface by one or more people usually sitting around a table (Parlett, 2018); they might include the use of cards or dice. As testified by the available literature, boardgames can play an important role in the teaching and learning of mathematics (see next sections). Such relevance might be even higher at early grades, as stated in some contributions from previous CERMEs (e.g. Schuler & Wittmann, 2009; Schuler, 2011; Tubach, 2015).

The aim of this paper is to nourish the discussion that has taken place during CERMEs in TWG13 by summarizing results presented in past proceedings. Such review of the literature is intended to suggest further limits and opportunities in using boardgames in early mathematics education. Our discussion is limited to number sense; the next session is devoted to explaining what we mean by that.

Number sense

The construct of 'number sense' is present since many years in the discourse of researchers in mathematics education in general, and in the ERME community in particular (Rezat & Ejersbo, 2018). Several definitions have been proposed, mostly in the form of a list of abilities that a child should develop in order to show number sense. Such lists are often not equivalent. In this contribution we adopt the classification provided by Andrews and Sayers (e.g. Andrews & Sayers, 2015) who distinguish three categories of number sense.

Preverbal number sense includes the innate abilities necessary for quantitative understanding. Research literature (within and outside mathematics education) shows that very young children can discriminate small quantities (e.g. subitizing) and arrange them as a linear representation, called 'mental number line' (e.g. Deahene, 2001).

Applied number sense refers to competences that prepare the learners for the adult life. Applied number sense should enable a person to

> look at a problem holistically before confronting details, look for relationships among numbers and operations and […] consider the context in which a question is posed; choose or invent a method that takes advantage of his or her own understanding of the relationships between numbers or between numbers and operations and […] seek the most efficient representation for the given task; use benchmarks to judge number magnitude; and recognize unreasonable results for calculations in the normal process of reflecting on answers (Reys 1994, p. 115, as quoted in Andrews & Sayers, 2015).

Finally, there is a set of intermediate abilities that are developed thanks to instruction, usually between the end of preschool and the beginning of primary school; then they are particularly relevant for early years mathematics. This set of eight abilities, called *foundational number sense*, is listed in Table 1.

The distinction between preverbal, foundational, and applied number sense will serve as a framework for organizing our presentation of the reviewed literature. The next sections are devoted to describing if and how each of these three types of number sense was considered in past contributions to TWG13 about boardgames. Furthermore, we will list limits evidenced by researchers.

Selection of papers

The papers selected for the presented review are taken from proceedings of the last six editions of CERME. A mapping review of all the abstracts of the paper presented in the working group about 'Early Years Mathematics' (TWG14 in CERME6, when it was founded; TWG13 in the following edition) served for a first phase of selection. Among the 124 contributions, we selected those explicitly referring to numerical abilities and to a playful/game context. We then realized a second phase of selection by reading the full text; only papers specifically including boardgames were left. We ended up with the four papers listed in Table 2.

The fact that a low number of contributions were selected sustains the claim that research about boardgames is still underdeveloped. Surely, TWG13 is not the only TWG interested in boardgames and number sense (e.g. Sensevy et al., 2001), however as we will discuss later, we believe that this topic is particularly relevant for TWG13. We can notice that papers about these topics appeared in this working group during several editions of CERME; we may then affirm that a discussion has started, and there is still room to widen it. The four selected papers have been categorized referring to the framework introduced above. Results are presented in the following sections.

Boardgames and preverbal number sense

Research on preverbal number sense usually focuses on children aged 0–6 and then this stream of research should be considered as part of research in early years mathematics education. Indeed, TWG13 has collected contributions about subitizing (e.g., Schöner & Benz, 2017), but none of them included the use of boardgames. One of the selected papers refers to subitizing (Schuler, 2011), but it is not the main focus of research. Surely this fact does not depend on the impossibility of using boardgames to assess or develop preverbal numbers sense. For instance, we may notice that many traditional boardgames (like Shut the Box) include the use of dice. Traditionally, cubic dice show quantities through dots arranged in a canonic way. Research shows how subitizing gets easier when children recognize patterns in the arrangement of dots; furthermore, developmental dyscalculia can cause a deficit in the estimation of canonically arranged dots (Ashkenazi et al., 2013). This fact suggests that playing boardgames can help in recognizing specific difficulties that might depend on inexperience with canonical arrangement of dots or on learning disabilities.

Table 1: Components of foundational number sense (Andrews & Sayers, 2015)

(1) Number recognition	Recognition of number symbols; their vocabulary and meaning. Ability to identify a particular number symbol from a collection and name a number when shown.
(2) Systematic counting	Counting systematically to twenty and back or count upwards and backwards from arbitrary starting points; knowing each number's position in the sequence of all numbers.
(3) Awareness of the relationship between number and quantity	Not only understanding the one-to-one correspondence between a number's name and the quantity it represents, but also that the last number in a count represents the total number of objects.
(4) Quantity discrimination	Understanding magnitude and comparing of magnitudes. Use of language like bigger than or smaller than.
(5) Understanding of different representations of number	Understanding that numbers can be represented differently, including the number line, different partitions, various manipulatives and fingers.
(6) Estimation	Estimation, whether the size of a set or an object. Moving between representations of number; for example, placing a number on an empty number line.
(7) Simple arithmetic competence	Performing simple arithmetical operations, transformation of small sets through addition and subtraction.
(8) Awareness of number patterns	Extending simple number sequences and identification of a missing number in simple number sequences.

Another clear example is given by research conducted on the development of the mental number line using linear boardgames (boardgames with linearly arranged, consecutively numbered, equal-size spaces, e.g. Chutes and Ladders, Game of the Goose) – we are here referring to research that was not presented in CERME proceedings, but in research journals. According to Siegler and Booth (2004) and to Ramani and Siegler (2008):

> In such games, the greater the number in a square, the greater (a) the distance the child has moved the token, (b) the number of discrete moves the child makes, (c) the number of number names the child has spoken, (d) the number of number names the child has heard, and (e) the amount of time since the game began. The linear relations between numerical magnitudes and these visuospatial, kinesthetic, auditory, and temporal cues provide a broadly based, multimodal foundation for a linear representation of numerical magnitudes. (Ramani & Siegler, 2008, pp. 376–377)

Research shows that playing these boardgames strengthen preschoolers' number line estimation, magnitude comparison, numeral recognition, and counting skills (Siegler & Booth, 2004; Ramani & Siegler, 2008). Also, evidence shows that playing boardgames correlate positively with numerical knowledge, while this is not the case for videogames and card-games. Children from middle-income backgrounds reported playing more boardgames, and fewer videogames, than age peers from low-income backgrounds. This is considered as one of the possible explanations for differences in the development of preverbal number sense in relation to socio-economic status (Ramani & Siegler, 2008). Whyte and Bull (2008) have compared linear boardgames with card-games and found that card-games can improve some aspects of children's number sense, but not numerical estimation (evaluated as positioning on a number line). Playing with linear boardgames helps children to shift from a logarithmic to a linear representation of numerical magnitudes (Whyte & Bull, 2008).

Boardgames and foundational number sense

All the contribution selected for our review focused on foundational number sense. The quality of the game and the role of the educators (parents or teachers) appear to be central for all the authors.

Foundational number sense needs explicit teaching (per definition) and thus the choice of a boardgame should be guided by the aim of a teaching intervention. Following Brousseau's Theory of didactical situations, an appropriate game is selected when it allows "bringing together a 'milieu' and a 'player', with this game being such that a given piece of knowledge will appear as the means of producing winning strategies" (Brousseau, 1998, p.57). The equilibrium between the game and the mathematical content seems hard to achieve, as has been shown by contributions to previous CERMEs. On one side, the game should be mathematically productive, meaning that the game materials should be reinterpreted as representations of mathematical relationships (Tubach, 2015).

On the other side, it is important that the game is an actual game to children for exploiting the game's idea and affordance (Schuler & Wittmann, 2009). However, there is also the risk that a game remains just a game. As reported by Schuler (2011, p. 1920) while referring to a boardgame about counting and comparison of numbers:

> Mathematical potential develops through the educator's comments on the game's course, through questions that stimulate explanations, reflections on actions and thoughts, and reasoning. She has to communicate individually challenging rules through stimuli, comments, questions and requests what requires a sensitivity for possibilities and variations in the games course.

Dorier and Maréchal (2009) refers about teachers selecting games based on the pleasure they are supposed to give to students, while the mathematical content remains secondary. They analyze a game called 'Turn the Dice' proposed for first grade in the official curricular material of the French-speaking Switzerland. By their analysis, to play correctly, students should know how to make sums correctly. However, if they do not, they may play anyway, because nothing in the managing of the game is organized to provide any feedback. In their words "nothing is organized didactically for them to learn sums, they have to know, but they can make errors without being corrected, except if the other player knows better or the teacher is there to correct" (Dorier & Maréchal, 2009, p. 2580). They also observed a teacher conducting the game in one of her classes and found how she had probably underestimated the difficulty of the game.

While research elsewhere as shown how boardgames may provide a good opportunity for the development of foundational number sense (Peters, 1999; Stebler et al., 2013), the discussion going on in TWG13 has pointed out possible limits for the exploitation of such potential.

Boardgames and applied number sense

Potentialities of boardgames for developing applied number sense are as many as the different representations of numbers, calculation algorithms, and so on. In the context of TWG13, the interest could be in understanding how boardgames may help, in the context of early years mathematics, to foster the development from foundational to applied number sense. In one of the selected papers, Dorier and Maréchal (2009) note that even simple games can hide interesting opportunities for introducing more complex mathematics. For instance, they show how, by slightly changing the rules of the game, 'Turn the Dice' shows strong similarities with the famous game 'Race to 20' which offers interesting opportunities to introduce the Euclidean division (Sensevy et al., 2001).

This example helps us in introducing an opportunity provided by boardgames that has been studied scarcely. In their paper from the *Journal für Mathematik-Didaktik*, after analyzing children playing the game Shut the Box, Stebler and colleagues conclude that:

> This first exploratory analysis leads us to the hypothesis that boardgames like Shut the Box can provide a high-quality teaching and learning arrangement, offering cognitively activating and challenging learning tasks, adaptive for different levels of mathematical competencies and allowing for diverse strategies, embedded in a collaborative setting (2013, p. 172)

Such hypothesis needs confirmation, but the possibility of using boardgames as context for mathematical activity that is adaptive for different levels of competencies is proposed by other authors in research literature (e.g. Vogt et al., 2018). Some authors notice that the challenges that are posed by a boardgame are particularly effective for children with higher mathematical competences, while more traditional training program could lead to better results for low achievers (Vogt et al., 2018); other authors suggest using boardgames even in the case of disabled children since they prove to be successful with students of different ability levels (McConkey & McEvoy, 1986).

Conclusion

General education literature converges on attesting that game-based education can foster learning providing students with a high motivational context, and this is also confirmed in the case of mathematics (Yong et al., 2021). Research about motivation and games is widespread in journals and conferences, but we can recognize that the reviewed research focuses more on the cognitive and relational aspects that are specific to the development of number sense using boardgames. The focus on the different didactical variables, including the teacher's role, appears peculiar to TWG13.

Drawing on literature from research journals, we have noticed that linear boardgames and playing with dice can help in fostering preverbal number sense (specifically, the mental number line and the subitizing ability) and in assessing deficits, however research about boardgames and preverbal number sense is still missing in CERME. Contributions in CERMEs have shown that difficulties related to teacher education and curriculum design emerge when analyzing the boardgames that are proposed in mathematics classes. However, we believe that these difficulties do not constitute good enough reasons to avoid the use of boardgames in preschool or primary school, since there is evidence that these games can provide the context for challenging tasks. Downton and Sullivan (2017) have documented (in the context of word problems) how challenging tasks may prompt the use of more sophisticated calculation strategies and then flexibility. This could be particularly true in the case of strategic games. Further research is needed to prove this kind of conjectures. If any, positive results may serve as basis for a larger implementation of boardgames in mathematics classes.

Research literature testifies that teachers participating in experimental interventions involving boardgames are particularly enthusiast (Vogt et al., 2018), and such involvement is considered one of the possible causes of good results of these experiments (Ramani & Siegler, 2008). Enjoyment may lead teachers to propose tasks that are more challenging than those they are used to and then prompts an explorative approach that is often prevented by teachers' insecurities (Peters. 1999). However, as noted above, teachers may misjudge the mathematics involved in a boardgame (Dorier

& Maréchal, 2009). The design of teacher professional development programs appears as needed and may constitute an interesting context of research (Maffia & Silva, 2021).

Concluding, we can claim that boardgames show several potentialities in relation to the development of young children's number sense, however in TWG13's discussion there is still room for more research aimed at: (1) understanding the features of boardgames for developing and assess preverbal and foundational number sense; (2) developing teachers' education to help them in analyzing games and exploit their potential.

Toddlers’ ways of experiencing the meaning embedded in the question “How many years are you?”

Hanna Palmér[1] and Camilla Björklund[2]

[1]Linnaeus University, Sweden; hanna.palmer@lnu.se

[2]University of Gothenburg, Sweden; camilla.bjorklund@ped.gu.se

This paper focuses on toddlers’ (1- to 3-year-olds) ways of responding to the question “How many years are you?” and in what respect their responses may connect to a mathematical meaning. As a part of a longitudinal study on toddlers’ numerical development, the question was posed to 15 toddlers five times at approximately six-month intervals. At the beginning of the study, no toddler responded to the question with a mathematical representation. The results show how the toddlers started to discern the question as one to be answered with a mathematical representation, either number words or a finger pattern. The results also show how some of the toddlers started to connect these two modes of representations. In the paper, we also explore the different ways the toddlers used finger patterns to answer the question.

Keywords: early mathematics, finger pattern, numbers, representations, toddlers

Introduction

This paper focuses on toddlers’ (1- to 3-year-olds) ways of responding to the question “How many years are you?” (direct translation from the Swedish expression “Hur många år är du?”). The starting point for this interest was a Swedish combined research-development project on toddlers’ numerical development. Even though there is a growing consensus in research and practice that children’s numerical competencies start to develop at a very early age, few tools have been developed to make their progress in learning visible and researchable. Thus, one part of the project was to develop a research tool to make toddlers’ ways of experiencing numbers researchable (Björklund & Palmér, 2021). In this paper, we take a closer look at one of the questions used in that tool.

There are challenges in exploring young children’s numerical competencies, since verbal utterances cannot be taken as the primary source for analysis of their understanding. Furthermore, it is crucial to establish joint attention between child and researcher in a conversation or task to maintain the focus on a common objective (Siraj-Blatchford, 2010). When developing the research tool, we thus wanted to make it possible for the young children to relate to and reason about the content based on their previous experiences as well as enable them to express different ways of experiencing numbers. Based on methodological reviews on studies involving children, we knew that, especially in research with very young children, multiple-method activity approaches had proven successful (Aubrey & Dahl, 2005). Thus, the decision was made to design a task-based interview that included a variety of tasks and manipulatives making it possible for the toddlers to express themselves in different ways. This task-based interview was to be held in a naturalistic setting, placing the children at the centre of focus, recognizing their social and cultural experiences and understanding. The context of the interview became the birthday of Kitty the cat as even toddlers have experienced birthdays. Also, the use of a toy cat was intended to engage the children's interest and promote joint attention.

As an introduction to the interview, the children got to see and, if they wanted to, hold Kitty the cat. The children were told that it was the cat's birthday. Then the question "How many years are you?" was posed to the children. The question had a twofold purpose: partly to arouse curiosity and interest by inviting the children to a joint conversation and partly to see how the children responded to this question, which they had most likely heard before. At one point, when we presented the study at a national research conference, a researcher in mathematics education asked whether the question "How many years are you?" is a mathematical question. Inspired by that question, we here analyse how toddlers responded to the question. Our approach is that it is not up to us to decide whether the question is mathematical or not; it depends on the toddlers' ways of experiencing the meaning embedded in the question. Whether or not the question "How many years are you?" is mathematical is thus an empirical question, which this paper will focus on by answering : How do toddlers respond to the question "How many years are you?" and in what respect do their answers connect to a mathematical meaning?

Four fundamental aspects of numbers

We cannot empirically investigate whether children experience the question as a mathematical question; we can only investigate their responses to the question and whether their responses include mathematical representations. Together with ordinality, cardinality and part-whole relations, representations are fundamental aspects of the complex construct of numbers that are known to be necessary for children to learn about in order to develop their numerical competence (Björklund et al., 2021; Baroody & Purpura, 2017). The meaning of ordinality implies that every object or number word has an exclusive position in a sequence and relates to the others in the same sequence (Fuson, 1988). "How many" questions mostly refer to the meaning of cardinality in numbers, that is, number words are used to describe a coherent set. This is often observed in counting acts where the last uttered number word includes all the counted items (Gelman & Gallistel, 1978). Knowing that number words represent a set or composed unit of items is, further, a requisite for understanding numbers' part-whole relations, which allows children to compare sets, add, subtract and in different ways operate with numbers to solve numerical problems (Venkat et al., 2019). Thus, number words include several aspects that become significant for making use of them, and their meaning is also connected to the context in which the words are used (see Fuson, 1992). As numbers are abstract by nature they have to be *represented* in some way in all communicative situations, for example, by number words as exemplified above. Lesh (1981) emphasizes five modes of representation that are important in mathematics education, where the learning (for example, of numbers) is reflected in the ability to make connections *between* and *within* these modes of representation: Real-World Situation, Pictures, Verbal Symbols, Written Symbols and Manipulatives. But, even if toddlers respond to the "how many" questions, for example, with finger patterns or number words, it is not self-evident that the representation used mediates a mathematical meaning. The meaning of representations has to be learnt through communication with others whereby representations assigned to children's actions mediate mathematical meaning (Van Oers, 2010).

Theoretical framework

The theoretical framework in this study is the variation theory of learning (Marton, 2015) which brings to the fore the child's perspective, or more precisely, children's ways of experiencing a phenomenon (see also Sommer et al., 2010). In every situation, several aspects of a certain phenomenon can be discerned and the aspects that are discerned are decisive for how the phenomenon is experienced by the child. The theory directs attention towards children's learning and explains learning in terms of changes in the child's ways of experiencing a phenomenon. In the analysis, how children respond to the question "How many years are you?" and changes in these responses are interpreted as expressions of discerned and undiscerned aspects. As we in the study focus on the emergence of numerical awareness among toddlers, non-numerical meaning is just as important to observe.

Method

The project was conducted in close collaboration between researchers and three preschool teachers in Sweden over two years. The project, including development of tools and methods, has been approved by the Swedish ethical review authority (Dnr: 2019-01037). During the longitudinal study, the play-based interview was conducted five times at approximately six-month intervals. The interviews were all video-recorded, with the written consent of the toddlers' legal guardians. The interviews were conducted by the preschool teachers. This was important as it is not reasonable to expect that a researcher who does not know the toddlers would be able to provide the children with the best conditions to show their knowledge. As toddlers' expressions are very subtle, the interviewer needs to have extensive knowledge of the individual children's ways of expressing themselves.

Altogether, 110 video-recordings focusing on the question "How many years are you?" were transcribed. Also, how the children responded to the follow-up question, "Can you show with your fingers?", was noted. This follow-up question was asked to the children who did not use finger representation in relation to the first question. The results presented in this paper are based on analysis of 75 of these video-recordings from those children who were between 12 and 18 months when the project started and who took part in all five interviews. This was in total 15 children born between January and September 2018. The children's responses were first categorized based on correct or incorrect answers and then inductive based on the representations they used. Then, each inductive category of representation was analysed focusing on discerned and undiscerned aspects in line with variation theory principles (Marton, 2015). This way of analysing the data provides information on toddlers' ways of experiencing the phenomenon that in this study is the question "How many years are you?".

Results

First, the results from the inductive analysis on the representations used will be presented. Each category (C) of representation will be elaborated on separately, then followed by an elaboration of the categories related to the longitudinal perspective constituting the five interviews. Finally, the toddlers' use of finger patterns in all the interviews are focused on.

Table 1: The children's responses to Q1 "How many years are you?" and Q2 "Can you show with your fingers?" (asked to children who did not use finger representation in answer to the first question)

		Int. 1	Int. 2	Int. 3	Int. 4	Int. 5
C1	Q1 No mathematical response	15	13	8	2	3
C2a	Q1 incorrect number word		1		1	
C2b	Q1 correct number word			6	5	
C3a	Q1 incorrect fingers				2	1
C3b	Q1 correct fingers			1	1	1
C4a	Q1 number word and fingers, but one of them incorrect				1	1
C4b	Q1 number word and fingers, correct		1		3	9
C5a	Q2 incorrect fingers		3	2	4	2
C5b	Q2 correct fingers		3	4	2	
C5c	Q3 no response	15	8	8	2	1

Table 1 presents an overview of the 15 toddlers' responses to the questions "How many years are you?" (Q1) and "Can you show with your fingers?" (Q2) in the five interviews (Int. 1-5). In C1, the children gave no apparent mathematical response to Q1. However, many of them did interact with the interviewer, for example, by talking about Kitty the cat. Some children did use numbers and/or fingers as responses in other tasks but did not seem to discern any numerical aspects in this question. For example, one boy did not respond to this question, but afterwards when the interviewer showed him two fingers asking "Is this three?", he answered "No, it's two." Thus, this category includes both children who did not use mathematical representations at all in the interview and children who did not experience this specific question as one to be answered with a mathematical representation. The nature of the question here comes to the foreground since it is likely to be more challenging for the child to present a number word as an answer to a "how many" question (regardless of the items asked for) than to determine the quantity of a (re)presented number (for example shown finger pattern).

In C2a and C2b, the children responded by saying either an incorrect (2a) or a correct (2b) number word. Both responses indicate that these children experience this question as one to be answered with a number words. However, based on only this question it is not possible to determine whether the number words used by the children have a mathematical meaning, for example ordinal or cardinal meaning, or not.

In C3a and C3b, the children responded by showing either an incorrect (3a) or a correct (3b) finger pattern. Both responses indicate that these children experience this question as a question possible to be answered with a mathematical representation. What distinguishes this way of responding to the question from the verbal number words is that the question was posed in one mode of representation (verbal) but the children responded in another mode of representation. However, based on only this question it is not possible to determine whether the finger patterns used by the children have a mathematical meaning for them, it may be a learnt procedure.

In C4a and C4b, the children responded by saying a number word *and* showing a finger pattern at the same time. The number word and/or finger pattern may be incorrect (4a) or correct (4b). Both responses indicate that these children experience this question as a question possible to be answered with mathematical representations and that they have discerned a connection between modes of representation. However, as previously mentioned it is not possible to determine whether the number words and/or finger patterns used have a mathematical meaning for the children.

As mentioned, the second question (Q2) was only asked to the children who did not use fingers in response to the first question (thus C1 and C2ab). Some children gave no response (5c) while others responded by showing either an incorrect (5a) or a correct finger pattern (5b). Some children showed a finger pattern consistent with the number word used to answer the first question. Thus, they may have been connecting these two modes of representation. Some children who had not answered the first question now showed the correct finger pattern, which may be a representation with mathematical meaning but could also indicate that the question "Can you show with your fingers?" induced a procedure (showing a finger pattern) not grounded in any discerned mathematical meaning.

A longitudinal perspective

In the first interview, the age of youngest child was 12 months and the oldest was 18 months. As the intention in the project was to initiate the investigations before the toddlers had begun to use numbers, the toddlers' limited responses that may be connected to mathematics in interview 1 were expected. In the second interview (age span 18-24 months), 13 children gave *no mathematical response*. Two children responded to the first question, one with an incorrect and one with a correct number word, "one", in combination with showing one finger. To Q2 (asked to the 14 children that did not use fingers in Q1) six children responded with finger patterns, three of them correctly. As mentioned, this representation may or may not be connected to a mathematical meaning.

In the third interview (age span 21-28 months), eight children gave *no mathematical response*. Seven children responded correctly to Q1, six used number words and one used a finger pattern. The use of number words and finger patterns indicates that these children had an expectation to answer with a (to the observer) mathematical representation. The children aged one answered "one", and the children aged two answered "two". Thus, they may not have known "how many" one or two is, but they experienced that these representations can be used to answer a "how many" question. To Q2 (asked to the 14 children that did not use fingers in Q1) six children responded with finger patterns, four of them correctly. As mentioned, this representation may or may not be connected to a mathematical meaning.

In the fourth interview (age span 27-34 months), two children gave *no mathematical response.* Six children responded with a number word on Q1, five of them correctly. Three children responded with finger patterns, two correctly. Four children responded with number words in combination with finger patterns, thus coordinating two representations. Three of them did this correctly. Similar to the above, these children may not have known "how many" one or two is regardless of representation, but they seemed to know that this was a way to answer this question. On Q2 (asked to the eight children that did not use fingers in Q1), six children used finger patterns, two of them correctly.

In the fifth interview (age span 33-40 months), three children gave *no mathematical response.* Two children responded to Q1 with finger patterns, one correctly and one incorrectly. 10 children responded to Q1 with number words in combination with finger patterns, thus coordinating two representations. Nine of them did this correctly. Similar to the above, these children may not have known "how many" one or two is regardless of representation, but they seemed to know that this was an answer to this question. On Q2 (asked to the three children that did not use fingers in Q1), two children used finger patterns, incorrect.

How do toddlers use finger patterns?

In the five interviews, three different ways to use finger patterns as a response to Q1 and Q2 emerged:

1) Respond by showing all fingers (three examples in Figure 1). This way of using finger patterns indicates that the children have discerned a representational aspect, but this is not yet connected to any numerical aspect. Nevertheless, the questions can be answered by showing finger patterns as representation, although the finger patterns used are not yet *mathematical* representations.

Figure 1: Different ways of showing all fingers

2) Respond by showing a finger pattern with a selected number of fingers, but not the correct number. Some children instantly selected a number of fingers, others worked to fold down a number of fingers with the help of the other hand. This way of using fingers indicates that they have discerned that different finger patterns mean different things and it is therefore necessary to be precise when creating the finger patterns. It is possible that these finger patterns are experienced as representations of a "unit". But because of the lack of connection to the number asked for, it is likely that the finger patterns are still undifferentiated in an exact cardinal sense.

3) Respond by showing a correct finger pattern (three examples in Figure 2). Some children used fingers on one hand and others used fingers from two hands, the last when showing two by

using the index fingers close together. Similar to the above, this way of using fingers indicates their discerning that finger patterns have a specific meaning and may also be based on an experience of finger patterns as representing a "unit". Some sense of cardinality may here come through in that "two" is not merely an act of creating a pattern but an intended action of bringing one finger on each hand together to compose a set.

Figure 2: Showing two with one or two hands

Discussion

The questions elaborated on in this paper are how do the toddlers respond to the question "How many years are you?" and in what respect do their answers connect to a mathematical meaning? In accordance with the variation theory of learning (Marton, 2015), how children respond to the question is interpreted as expressions of discerned and undiscerned aspects. Someone might argue that the toddlers, over the course of the five interviews, learnt which number words or finger patterns to use. However, one delicate issue is that the correct answer to this specific question changed with each birthday. Thus, the children changed their answers between the interviews (correct or incorrect), which indicated that they had not learnt one specific way to answer this question by taking part in the interviews. The question is quite difficult form a mathematical perspective based on the lack of visible set to connect to the question "how many". The results show that the toddlers initially did not discern aspects of the question that brought them to respond with any mathematical representations. One explanation may be that the toddlers had not yet discerned mathematical representations and therefore these were not part of their possible responses to the question. However, this is not true for all the toddlers as there were toddlers who did not respond to this question with a mathematical representation but used mathematical representations when responding to other questions in the same interview. Throughout the study the children on group level discern that the question can be answered by using what we interpret to be mathematical representations (number words and/or finger patterns). However, based on the analysis in this paper, we cannot know if the children do experience mathematical meaning of the representations that they use (Van Oers, 2010). To know the explicit meaning the representations have for the children, more situations in which they use representations must be analysed. Nevertheless, recent findings have shown that young children who make use of several representations, whether used in correct correspondence with a number of objects or not, are more attentive to learn cardinal meaning of numbers (Gibson et al., 2019). Lesh (1981) emphasizes five modes of representation, three of which are at play in this task, real-life situation provides context for the task while the toddlers respond by using number words and/or finger patterns. The children most often used one representation, then they started to use two representations in combination to a larger extent. However, the toddlers may not experience them as two different representations but as a whole, and they may not have known that the representations were mathematical; that definition is in the eyes of the observer.

Spontaneous activities in kindergarten as inquiry-based mathematics

Finding the flowers – a spontaneous IBMT activity initiated by the teachers

This pilot study is a cooperation between the project SUM, organized by UiT The Arctic University of Norway, and the Norwegian Centre for Mathematics Education. The main focus in the SUM project is to investigate challenges in the transitions in the Norwegian educational system and how inquiry-based mathematical teaching (IBMT) can make these transitions more coherent. The participants in the SUM project, from both kindergarten and school, were introduced to a 3-phased didactical model for structuring IBMT (Haavold and Blomhøj, 2019). The model includes these elements: Phase 1: Setting the scene, phase 2: investigating and phase 3: shared reflections. This view on how to approach and learn mathematics resonates with how the Norwegian Framework Plan describes the mathematics subject area (Quantities, spaces and shapes) and how to work with it (Norwegian Directorate for Education and Training, 2017).

The participating kindergarten teachers (KTs) and school teachers problematized differences in, for instance, teachers' and kindergarten teachers' planning time and the distribution of spontaneous activities, free play and planned activities in the kindergarten context compared to the school context. In this pilot study we approach these differences with the following research questions:

How might the three phases in the didactical model for structuring IBMT appear in a spontaneous activity in a kindergarten context, and can spontaneous activities be regarded as inquiry-based mathematics?

The term "teaching" itself is not commonly used in the Norwegian kindergarten context although the work that kindergarten teachers do is considered as professional work. The Norwegian Framework plan is specific about what kindergarten teachers must do to achieve the content and tasks described in the plan. We therefore choose to use the term teaching to describe the professional work that both kindergarten and school teachers do. However, there are some differences in the work of teaching in Norwegian kindergarten contexts compared to the school context, which also is described and debated by the participants in SUM. Hence, we argue that a model suitable for teaching in a school context may need to be adapted to fit the kindergarten context.

We define spontaneous mathematical activities as activities that are not planned and can be initiated by either children or kindergarten staff. In the IBMT didactical model, mathematics is in focus. In daily life, however, children just want to solve the problem. Spontaneous activities therefore present some challenges along, due to the influence of the staff. Lossius and Lundhaug (2020) discuss the dilemma that arises when choosing between joining or observing an activity. Mason and Spence (1999) argue that this is knowledge about how to act in the moment.

This study is a pilot case study and a part of the SUM project. The data collection method is observation, field notes and interview. The researchers participated in the everyday life in one Norwegian kindergarten for one day. The researchers observed and interviewed two kindergarten teachers in daily situations and aimed to focus their observations on the mathematics involved in spontaneous situations. However, as Flottorp (2020) states, it is difficult to capture these situations by being present. Consequently, participating kindergarten teachers are co-researchers since they made additional observations and fieldnotes without the researchers present. We illustrate one of the spontaneous activities by the following vignette:

> The kindergarten teachers had planned to go looking for meadowsweet (mjødurt in Norwegian) which is used to make juice. The aim of first excursion was just to find the plants, not to pick them, so one of the kindergarten teachers asked the children how they would be able to find the plants again the next time, when they were going to pick them. After some discussion, they agreed upon making a map about the places.

In the vignette above, the KT made the activity more inquiry-based by posing a question. This question acted as a phase 1 element and set the scene for children to investigate the problem in phase 2. Making a map was not part of the original plan, but a spontaneous idea from one of the KTs. In the interview the KT told the researchers that the suggestion was based on her experiences from the SUM project. She decided in the moment that this idea had the potential to turn the "looking for plants" activity into an inquiry-based mathematics activity for the children.

Knowing how to act in the moment and to change your plan is an important part of kindergarten teacher's mathematical knowledge. We argue that the vignette is an example of an inquiry-based mathematics activity, that was not planned. It also illustrates our initial finding, that at least phases 1 and 2 can appear in spontaneous activities. Our next step is to further investigate how we can identify phase 3.

Intuitions of 5-6-year-old children related to measure sense and measurement

Marta Pytlak and Bozena Maj-Tatsis

Institute of Pedagogy, University of Rzeszow, Poland; mpytlak@ur.edu.pl; bmaj@ur.edu.pl

In this paper, we present the results of a study conducted among 5–6-year-old children, with a focus on their intuitions regarding aspects of measure sense and measurement. The results show that children at that age have different intuitions in terms of measure sense and measurement and they can use them while problem solving. Additionally, our results show that appropriate activities can assist children in developing their abilities of comparing different distances and applying measurement rules.

Keywords: Early years mathematics, measure sense, measurement, intuition.

Introduction and theoretical framework

One may claim that the two basic pillars of preschool education are arithmetic and geometry. In the field of arithmetic, counting and comparison are the competences which are mainly developed: children at such ages are quite good at counting and at providing the cardinality of a set. In the field of geometry, preschool education focuses primarily on recognising and measuring basic geometrical shapes (Clements & Sarama, 2000). According to Buys & de Moor (2008), there are three forms of measurement that are essential for young children:

- Measuring through comparing and ordering
- Measuring through pacing off, using a measurement unit (natural or standard measure)
- Measuring through the use of a measuring instrument. (p. 17)

The first experiences in measurement are related to comparisons. Children compare each other on an everyday basis: who is taller, who has a longer foot or who built a higher tower (Buys & de Moor, 2008). This is why van den Heuvel-Panhuizen & Buys (2008) claim that “Both measurement and geometry enable children to make connections with their daily environment” (p. 10), which in turn stresses the need for everyday contexts as the starting point for relevant activities (MacDonald & Lowrie, 2011). The use of informal units of measurement with young children is advocated in most studies (e.g., Haylock & Cockburn, 1989), while in other studies children are asked to use informal and standard units of measurements to solve some tasks (e.g., Boulton-Lewis, Wilss, & Mutch, 1996). In the process of developing measure sense and measurement, one cannot ignore the importance of intuition:

> Mathematizing involves reinventing, redescribing, reorganizing, quantifying, structuring, abstracting, and generalizing that which is first understood on an intuitive and informal level in the context of everyday activity. (Clements, 2004, p. 12)

The above considerations have led us to design a research project to investigate measure sense and measurement among young children, with a focus on children’s intuitions. Our research project was realised in two stages, which will be described in the next section, aiming to answer the following research questions:

1. What intuitions related to the concepts of measure sense and measurement do 5–6-year-old children have before their formal introduction to these concepts? (Stage 1)

2. How do children measure different objects, what units do they use if any? (Stages 1, 2)

3. Are children able to compare different objects by using their dimensions? Can they develop a universal unit and/or measurement rules? (Stages 1, 2)

Context of the study and methodology

The present study is part of a larger project related to the understanding of the concepts of measure sense and measurement by children at the preschool and early years levels. The research group consisted of twenty 5–6-year-old children; eighteen of them took part in the first stage and all of them in the second stage. They were attending a public kindergarten in Rzeszow, Poland.

According to the Polish curriculum for the preschool level, numbers and arithmetic are the most significant topics (Podstawa Programowa/ National Curriculum, 2017). Although many activities are related to counting and calculating, geometrical concepts appear less often, and are usually related to the recognition of figures and shapes; measurement contexts appear less frequently. Comparison skills usually refer to comparing the number of elements in sets, rather than in the context of measuring length and size.

The first stage of the study focused on children's intuitions regarding aspects of measure sense and measurement. Individual meetings took place with the children, which were designed to identify their intuitions on measuring. Our aim was to answer the question on what "to measure" means for them. We were also interested in how children compare the length of two objects (e.g., two trains made of blocks) and on what tools they use to measure the length (how they check which object is longer).

The second stage focused on analysing how children use their intuitions when solving measurement tasks. The children were divided into two groups of ten. Each group worked separately under the supervision of the researcher, performing the same tasks. During the group discussions, the researcher did not assess the answers of individual students. The two tasks were presented in the form of stories, depicted with physical props. They were as follows:

Task 1. In the world of toys, a doll, a ball, a cube and a teddy bear decided to visit each other (Figure 1). Who is the furthest away from the bear? And who is the closest to the ball? How can we check it?

In this task no way of solving was imposed, nor it was suggested that the distances between the toys should be measured. The idea was to provoke pupils to discuss the problem posed: how to compare the distances between objects? A string and paper feet were used as measurement means in this task.

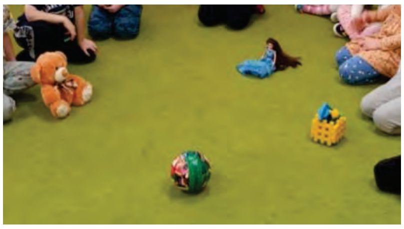

Figure 1: The initial situation of task 1

Task 2. a) The animals held a competition in throwing balls. The fox and the bunny were judging, and the deer, the owl and the beaver were the players and stood on the starting line (see Figure 2, from left to right we see the fox, the deer, the owl, the beaver and the bunny). Each of the players made one throw. Which of the animals won the competition? Why?

Figure 2: The initial situation of task 2

Figure 3: The measurement done by the fox (task 2b)

b) The fox was the first to judge. He used feet for the measurement (see Figure 3). The fox announced his verdict: the beaver won (the blue feet in the Figure 3). Do you agree with the verdict of the fox judge? Justify your opinion.

c) A bunny has joined the judging. With his feet, he marked each of the distances between the player and his ball. It looked like this (Figure 4):

Figure 4: The measurement done by the bunny (task 2c)

The bunny announced his verdict: there is a draw, everyone threw his ball on the same distance. Do you agree with the bunny judge's verdict? Justify your opinion.

At the beginning of this task, the children could propose their own solutions. This was to examine the children's intuitions about measuring, especially if they perceive distance as the shortest line (segment) between objects, which is perpendicular to the end line. Then, the solution proposed by the children was confronted with two other, erroneous solutions.

The research data consisted of video recordings of the individual interviews with the children as well as video recordings of the activities conducted with the two groups of children. Our analysis of the transcribed discussions mainly focused on the way the children were working, as well as their interactions with the researcher (the first author of the paper) and with other children. The collected data were analysed quantitatively (Stage 1) and qualitatively (Stages 1, 2). In this paper, we focus on presenting Stage 2 of the study, together with a discussion on the obtained results. Stage 1 of the study is presented in another paper (Pytlak & Maj-Tatsis, 2021), but we shortly describe its results in the next section, in order to assist the reader of the paper. The collected data of Stage 2 were analysed interpretatively, by categorising the children's utterances according to: measurement methods and rules, comparison methods, and measurement units.

Results

Results from stage 1

The analysis of our data showed that it is possible for children aged 5-6 to hold valid intuitions on measure sense and measurement. They were able to interpret the distance between objects as a straight segment connecting them. At the same time, their understanding of the shortest way was twofold. For some children, it was the 'straight' way (e.g., a straight line without loops and bends, which could be verified visually). Other children understood the shortest route as a segment perpendicular to the starting line, which is consistent with the mathematical understanding of the concept of distance.

During measuring, the children paid attention to both the units and the way the measurements were made. In order to compare two objects (trains made of blocks), they arranged them next to each other, from the same starting line. However, this way of comparison was important mostly in a situation where trains were made of blocks of different lengths. When both objects were made of the same blocks, the children did not feel the need for physical comparison. Then, it was enough for them to count the elements in both trains. Thus, in this situation, measuring was identified with the cardinality of a set (for details see Pytlak & Maj-Tatsis, 2021).

Results from stage 2

Task 1. In both groups, children agreed that individual distances should be somehow measured. Various proposals were made to make measurements, most often it was to determine the distance by using the spat of the arms. The teacher's proposal to use the string for distance measurements was accepted. They correctly marked the distances between individual toys with a string. They also proposed a way to investigate which distance is the longest. In order to do that they compared the strings with each other. The shortest of them was a 'scoop', according to which the length of the others was determined. One of the boys took the first of the strings and successively applied it to the second and the third. He commented on the results in the following way: "this one is longer", "this one is shorter".

Researcher (R):	To what toy does the bear have the furthest?
A:	To the doll.
F:	No, to the cube.
R:	A. says to the doll, and F. says to the cube. Who is right? How to check it?
F:	You need to measure the strings.
R:	So measure the strings.
F:	[takes the strings and lays them along each other, "centered"] This one is longer and this one is shorter.
A:	No. [corrects the strings so that they all start from a common point, from a teddy bear]
R:	Ooo, A. put all the strings together. Is that a good thing? Do you agree?

F: Here you can see that this one is longer, and these are shorter (Figure 5).

In the above excerpt, we can notice that when comparing objects (here: strings illustrating the distance between toys), children do not always pay attention to the appropriate position. The visual aspect is more important. If something is directly visible, certain properties can be visually evaluated, then additional aspects do not have to be taken into account.

Figure 5: Measuring and comparing the distances between the teddy bear and the other toys

In addition to measuring the distance with strings, the children also proposed the use of a ‘centimeter’, which could be a reference to experiences from everyday life. Furthermore, attempts were made to use hands (spreading arms over a measured distance), legs (distance measured with legs’ extension) or one’s own body for measurements. However, the children themselves noticed that in this way it is not always possible to measure something. The researcher suggested measuring the distance with her feet. Firstly, she asked one of the girls to measure the distance between the teddy bear and the ball with her feet, and then she measured the same distance herself. Two different results were obtained: 3 feet of a researcher and 6 feet of the girl. For the children, this situation did not cause any conflict, it was unanimously noted that the results differ due to different foot lengths. It seems that the children did not see the need to use the same measuring units in all measurements. All that mattered was the way it was measured.

R: L. measured and she got 6. I will also measure [measures with her feet the distance between the teddy bear and the ball, counting loudly] once, two, three. So, who is right? Is there a distance of 6 or 3?

F: Well, because L. has smaller feet.

R: Oh, so if there are smaller feet it will be differently, and if they are larger it will be differently, right? [children are nodding]

F: Because larger feet take up more space and smaller feet take up less.

R: If I wanted to measure the distance between all the toys, do I have to measure with the same feet or can I measure a bit and L. a bit?

Children: I don’t know [shaking their heads]

R: Well, listen, L. measured the distance from the teddy bear to the ball and it was 6 feet. I measured the distance from the teddy bear to the cube and it also was 6 feet. You said that the teddy bear is further to the cube than to the ball, right?

Children: [nodding]

R: But it was the same - 6. So, can you measure with different feet to compare distances?

Children: [silence]

The children unanimously approved the researcher's method of measuring distance with her own feet and began to use it by themselves. They noticed very quickly that the result of the measurement depends on the unit used. Therefore, obtaining different values for the same distance did not cause any cognitive conflict in the children. They were a bit surprised when the researcher pointed out two identical results obtained when measuring two different distances (from the teddy bear to the cube and from the teddy bear to the ball). They knew that these distances differed greatly, but they could not explain why the same numerical result came out in both cases.

Task 2. The children unanimously suggested that the middle player (the owl) won the competition (Figure 2). They justified it by the fact that the ball had the longest distance from the starting line. They indicated with their hands how the segments depicting individual distances were running. Here it was clear that the children appealed to the intuitive understanding of the distance between objects as the shortest distance between them.

When assessing the fox's judgement (Task 2b in Figure 3), the children referred to two aspects: the process of measuring the distance and the result obtained by individual players.

R: Who according to the fox threw the ball the farthest?

Children: The beaver.

R: And do you agree with such a measure by the fox?

Children: Yes... No…

R: Did the fox measure well?

D: Yes, because here is 8, and here is 9 and here it is so straight [in the air he outlines segments depicting the distance between the fox and individual balls] (...)

R: At the beginning you said that you thought the owl won. Why? How did you measure it?

W: From the owl [points his finger from the owl to the ball]

R: So, arrange it as you would count it.

W: [arranges – initially uses all the feet, creating an arc, but after a while he removes some of the feet, and arranges the rest in a straight line]

The way of measuring the distances by the fox did not arouse any protests in children. They treated it as a measure of three different segments that had a common beginning and different ends. This was consistent with the understanding of the distance between objects as the shortest segment connecting them. Only the researcher's reference to the original solution presented earlier caused them hesitation. Then they paid attention to which segments had to be compared with each other. They very quickly verified the solution and made changes in the arrangement of the paper feet (Figure 6). By measuring subsequent distances with the paper feet, the children tried to maintain the parallelism of the segments and start them from the same line. Counting the paper feet (treated as units of measurement) in the segments rather referred to the comparison of the sizes of three sets.

When the children gave the numerical value of the measured segments, the cardinal aspect came to the fore.

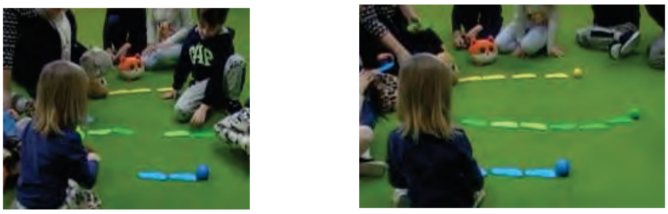

Figure 6: Rearranging the paper feet while measuring the distances between animals and balls

In the next part of the task (2c), it turned out that the judge (the bunny) measured distances in such a way that each of the competitors achieved the same result. The children immediately noticed the mistakes. First of all, they did not agree with the result itself, clearly indicating that the distances obtained in the ball throw are different. They primarily referred to the visual representation of the task. In addition, the children paid attention to the precise way of measuring: the feet were not laid in a straight line, but in an arc (Figure 4).

Discussion

Children enthusiastically and actively participated in solving the proposed tasks. They tried to justify their answers, strongly supporting themselves with gestures. The results obtained during the first stage of research allowed us to assume that that it is possible for children aged 5-6 to hold valid intuitions on measure sense and measurement. They were able to interpret the distance between objects as a segment perpendicular to both objects. Straightness was understood by them both as a straight line but also as a perpendicular line. This corresponds with the formal mathematical understanding of the concept of distance. The second stage of our research confirmed these assumptions. Moreover, the children have shown their intuitions about measuring. They understood the distance between two objects as the shortest segment connecting them, the end of which is perpendicular to the final object. This is consistent with the notion of distance that students encounter during mathematics education in primary school. The comparison of segments was made through visual verification: they arranged them parallel to each other and checked which one protrudes beyond the others.

The introduction of measuring with feet can be identified with the use of a measurement unit. Measuring with different feet (the researcher's and a child's) relates to the use of different units of measurement. Our results have shown that in making measurements of length, the unit of measurement was not so significant. The process of measurement by itself was more important: maintaining a straight line and accurately measuring units (putting foot by foot). The children were aware that by measuring the same segment with different feet (that is, different units) they would receive different results. However, they were not fully aware that in order to compare different segments, they had to use the same unit. We believe that this result goes in line with studies which suggest the use of informal units with young children (e.g., Haylock & Cockburn, 1989; Heuvel-Panhuizen & Buys, 2008).

The children in our study perceived measuring as an activity, a process, not as providing a numerical value. It was important for them how the measuring process takes place, whether the right direction and straightness of the line are maintained and whether the measuring unit is applied evenly. The numerical result of this process was of secondary importance. This was especially evident when working on the second task. When assessing the judgement of the fox and the bunny, the main consideration was whether the designated segment is straight and connects the starting point with the end point. Therefore, the arcs made by the bunny were immediately treated as an erroneous way of measuring. However, without hesitating much, the children agreed that the straight lines set by the fox are the correct way to measure the distance at which the players threw the balls. The results of our study show that length measurement should not be treated as a simple skill, but rather as a combination of concepts and skills that develop over time as part of a learning trajectory (Clements, 2004; Heuvel-Panhuizen & Buys, 2008). Moreover, informal activities based on everyday and playful contexts, which include object comparison can be useful in enhancing children's measurement and measure sense.

Building the meaning of measurement in kindergarten: the case of length

Elisabetta Robotti

University of Genova, Department of Mathematics, Genova, Italy;

robotti@dima.unige.it

This paper deals with a teaching experiment concerning length measurement in kindergarten for children aged 4-5. Through a classroom-based intervention, designed according to the Semiotic Mediation theoretical framework and developed on a multimodal approach, children produce a definition of measure as product of the action "measuring", working with a chosen measurement unit. The qualitative analysis of data collected highlights the specific role of the teacher and of artifacts in supporting the process of semiotic mediation through which children transform the signs linked to artifacts (used to develop the meaning of measure) into mathematical signs (which present the results of measuring in geometrical way).

Keywords: Measurement, kindergarten, length, multimodality, semiotic mediation.

Introduction.

In the Italian National Guidelines for kindergarten (3-6 years) children are asked to acquire skill in measuring. This doesn't occur necessarily through standard tools of measuring (such as ruler, meter, balance), rather through any tools aiming to develop the meaning of measure, measurement unit and measure as product of the action "measuring". Accordingly with this perspective, I focus on the concept of length measurement, placing the teaching-learning act in the context of kindergarten. Research has shown that the understanding of space and its representations in mathematics has an intuitive experiential basis before primary school (Bryant, 2008) and that development of children's spatial skills are crucial nodes in the conceptualization of space and geometric space (Sinclair & Moss, 2012; Robotti 2018). Furthermore, bodily experiences and experiences mediated by the use of tools act as a bridge between the physical modelling of space and the conceptualization of a geometric space (Casey, et al., 2008). For this, I consider the multimodal approach crucial to pursue the educational aim. As far as measurement is concerned, research has long underlined that, already in pre-school age, children experience the comparison of quantities and, explicitly or implicitly, measurement (Buys & Veltman, 2008). Despite this, the action of measuring and the conceptualization of measurement are not without difficulties for children. Peter Bryant (2008) identified some difficulties in the measurement procedure for preschool children. Let's consider, for example, the act of measuring a length. Generally, children are perfectly able to define the sequence of actions needed to measure, as well as understanding the importance of one-to-one correspondence, which is an essential part of relating measurement unit with the length to be measured. However, measuring hides pitfalls and difficulties related to the iteration that is, in fact, at the basis of the action of measuring with an instrument. If we consider, a ruler, the measurement of a linear length consists of repeated actions (measurements), just as the ruler is made up of a set of iterated measurement units such as centimeters. The iteration is necessary when the length to be measured is longer than the measurement unit. Another difficulty identified by Bryant concerns the "asymmetric" one-to-one correspondence involved in measuring a line with a ruler: the measurement units (centimeters, inches) are visible and clear on the ruler but must be imagined on the length to be measured. Thus, through body experiences according to the multimodal approach (Arzarello & Robutti 2009; Radford, Edwards & Arzarello, 2009; Nemirovsky 2003; Radford 2014), the activities described in the following paragraphs will show how children developed the definition of measure as physical quantity, and also how they related measure with a chosen measurement unit. Moreover, I'll show how the teachers faced the difficulties highlighted by Bryant with appropriate didactic choices, designing activities through Semiotic Mediation framework (Bartolini Bussi & Mariotti, 2008). With these premises in mind, I argue it makes sense that geometry could be explored much earlier and more robustly than it is at the moment (at least in Italy), already during the kindergarten years (Robotti, 2018).

Theoretical perspectives.

The theory of Semiotic Mediation (TSM), developed to design and analyze educational activities, is one of the theoretical frameworks of reference in this research. It provides a powerful way for teachers and researchers to study the process by which activity with artifacts (in this research with Montessori sticks) can be turned into mathematical activity (geometrical activity allowing children to develop the definition of measure). Summing up the main elements of the TSM (for more details, see Bartolini Bussi & Mariotti 2008), the teacher takes in charge two main processes: the design of activities and the functioning of activities. In the former the teacher makes appropriate choices about the artifacts to be used, the tasks to be proposed and the mathematics knowledge at stake. In the latter, the teacher monitors and manages the students’ observable processes (semiotic traces), to decide how to interact with the students in order to transform signs linked to the use of artifact into mathematical signs. The students are in charge of the resolution of the task through the use of the artifact. Making this, they produce signs (objects, drawings, words, gestures, bodily movements, and so on), which are linked to the artifact and therefore they aren’t yet explicitly math signs. The teacher collects all these signs, in order to organize a path for their evolution towards mathematical signs that can be put in relationship with the aimed mathematical knowledge. In this research I also refer to Gallese and Lakoff’s (2005) theoretical approach, according to which mathematics teaching-learning processes are multimodal activities. Nemirovsky (2003) states that, understanding and thinking, included mathematical thinking, are perceptuo-motor activities, which become more or less active depending of the context. This means that, exploiting perceptual-motor components, the body becomes essential in the learning processes. In this perspective, the term multimodality is used here to underline the importance and mutual coexistence of a variety of cognitive, material and perceptive modalities or resources in teaching-learning processes and, more generally, in constructing of mathematical meanings (Radford, Edwards & Arzarello, 2009). According to these premises, this research aiming to investigate whether and how, in kindergarten, it is possible to transform signs related to the use of unconventional measuring instruments into geometric signs supporting the definition of measure as the result of the measurement action.

Methodology and teaching experiment.

The teaching experiment took place with 15 children of kindergarten aged 4–5. Two teachers were involved during the classroom activities. Seven sessions were carried out for 4 weeks (more or less twice times a week, 1 hour each) either in the classroom or outdoor, with a careful alternation of whole-class (with adult's guidance) and pair activity. The teachers and a researcher (the author) designed the educational activities. Each session was carefully observed by one of the teacher involved, with the collection of photos, graphical productions, videos and transcripts. Iterative qualitative analysis for data subsets and overall were carried out. Due to space constraints it is not possible to report all the activities, so I'll focus on the sessions in which the production of signs was been particularly meaningful and rich.

The teaching experiment.

The teaching experiment is part of a more articulated path, where Digital Sticks (Montessori material, see Figure 1) are used. In previous activities, sticks were used to introduce different aspects of mathematics including memorizing arithmetic facts as sums of numbers up to ten (in this educational activities children named them the "friends of ten"). Children, through the use of Montessori Digital Sticks, memorized the "friends of ten". The "friends of ten" act in a way that the length of the stick 10 can be obtained summing two lengths-sticks (9+1, 8+2, 7+3,...). The experience that I'll describe in this article arose spontaneously from the children's need to identify a not colored stick having the same length as a given colored stick (stick "five", as shown in Figure 2) in order to complete "the wall of friends of ten" (in that case with 5+5, as shown in Figure 1).

	
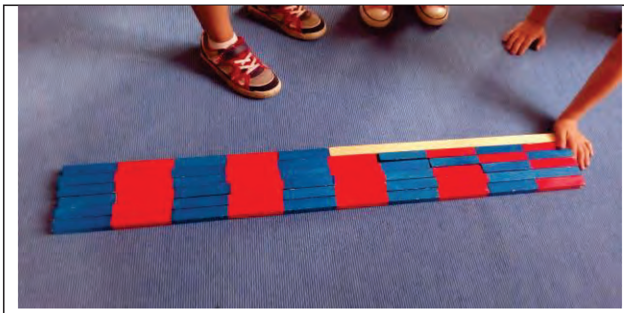

Fig. 1: The not colored stick is placed next to the stick "five" to complete "the wall of friends of ten"	**Fig. 2: Children superpose non-colored stick on the colored one in order to verify they have the same length**

Children referred to "a stick as long as the colored stick five" by comparing two objects directly in length. This is a necessary skill to develop the meaning of measure, but teacher knows that it is not a form of measuring. Moreover, since children referred also to "a stick that measures like the stick five", using the word "measure" in context, teacher decides to define a new didactic objective: introducing the concept of measurement of a length. Therefore, the teacher designs the educational activity in two phases having the following aims:

Phase 1: Building and sharing among all children a definition of measure and of measuring. This allows children to construct a meaning of measurement in geometrical terms. In this phase the educational activity is performed in classroom using Montessori sticks.

Phase 2: Applying the definition of measure in situations different from those they generated that definition and defining the relationship between "measurement unit" and "measure". In this phase the educational activity is performed in outdoor, still with the use of sticks.

Phase 1.

In order to complete "the wall of friends of ten", children need another stick "five" from another series of sticks (5+5=10). Teacher provides children the "non-colored sticks" series, so they decide to superpose the non-colored stick "five" on the colored one, verifying that it is as the colored stick (Figure 2). The superposition of sticks (signs linked to artifact) allows children to access to "comparison of length" meaning (math signs) expressed in verbal sign "the stick is as long as the colored stick five". Teacher's aim is now to approach definition of length measurement as much as possible. For this, relaunching an issue introduced by Nicolò, she opens the discussion with a question: is this [non-colored stick] a stick "five" as Nicolò said?

While children begin to think of a strategy to answer question, Matilde puts the non-colored stick next to the colored one (Figure 3) and she begins to count the colored segments of the colored stick through deictic gestures.

Fig. 3: Matilde counts the colored segments of the stick next to the non-colored one

This strategy implements several counting skills: the one-to-one correspondence, with the labeling process and the splitting process correctly implemented, is clearly detectable in pointing finger step by step on blue and red color; also the cardinal principle and the stable order of the numerical sequence are detectable, due to the verbal label “five” and the stated numerical sequence (Gelman & Gallistel, 1978). This strategy puts in acts the definition of measurement as the action of counting how many measurement units (stick “one”) are in the length to be measured. At the same time, this strategy puts in evidence the result of this action: the measurement of a length as physical quantity, that is as a number with the measurement unit. Matilde said: “yes, its length is five”. In this way, the signs linked to the use of artifact (deictic signs and numerals) are linked to math signs (measurement as physical quantity).

Unlike Matilde, Davide answers the question through an inference, exploiting arithmetic facts (Figure 4):

Davide: Five plus five equals ten. There are ten here [pointing the stick "ten", he refers to the measurement units]. Because here there are five [he points the colored stick "five"] then here necessarily there have to be five [he points the non-colored stick] and five plus five should make 10!

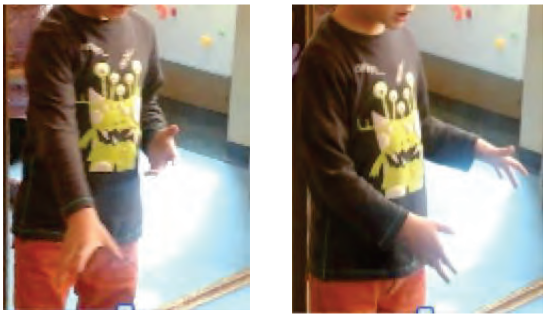

Fig. 4: Divide's gestures show the known part -the stick "five", that corresponds to 5 units- (Figure on the left) of a known whole -the stick "ten", that is 10 units- (Figure on the right)

Thus, if the stick "five" plus an non-colored stick are equal to 10 (stick "ten"), then the unknown measurement of non-colored stick has to be 5 (stick "five"): the equation $5 + x = 10$ is solved. Interestingly, here the measurement of the length is obtained without any action of measuring but through an arithmetical inference. The gestures evoke signs linked to artifact through which arithmetic fact 5+5=10 is recovered.

Afterwards, children are asked to measure non-colored sticks through colored sticks. This means teacher asks children to apply the definition of measurement shared by the class. Gabriele points the sticks "one" which compose two staircases, one of colored sticks and the other one of non-colored sticks, and says:

Gabriele: you see, the first two steps are the same
Alessandro: if they are the same, they start the same and they end the same [they have the same length]
Teacher: ok, but... do you also know their measurements?

In this excerpt the comparison of lengths is present yet as dominant concept. Therefore, teacher shifts the focus on the measurement. Alessandro and Ilaria take into account the non-colored stick "three" and they measure it (Figure 5) making explicit the meaning of "measurement of a length" and of "act of measuring" as follows:

Ilaria: I can put one after the other [the colored stick "one" as measurement unit] and I see that the non-colored one is like three of colored sticks [action of measuring].
Alessandro: so, we can see what the measurement [of the non-colored stick] is: it's 3 sticks "one" [measure].

Fig. 5: Alessandro measures the stick “three” with 3 sticks “one” as measurement unit

Note that Ilaria defines the action of measuring in terms of "seeing how many times the chosen measurement unit [stick “one”] is in the given length" and this corresponds to the shared definition by all children involved in the activity. Instead, Alessandro defines the measurement in terms of the result of this action, that is a physical quantity (3 measurement units, 3 stick “one”). Thus, the use of Montessori sticks promotes the measurement as repeated process in "posing measurement unit", giving sense to the measuring action and overcoming difficulties underlined by Bryant.

Phase 2.

In order the definition of measure becomes an "operational knowledge" and it falls within of the competences (that is a knowledge in act in other situations/contexts), the teacher asks children "measuring what they want" in the school garden, using Montessori sticks. This is why the children leave the classroom and chose to measure the side of an anti-shock mat about 3m long, placed under the swings in the school garden (Figure 6). Interestingly, children choose different measurement units.

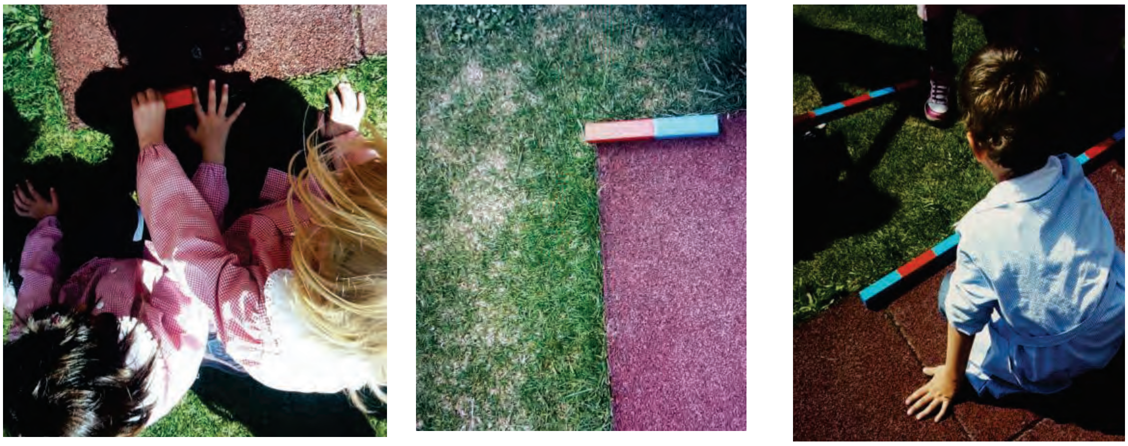

Fig. 6: Children measure the length of the side of the anti-shock mat through different measurement units (stick “one”, image on the left, stick “two”, central image, stick “ten” image on the right)

Children work in pairs: one child places one of the end of the unit-stick on the edge of the mat, the other child tracks, with his/her finger, the other end of the unit-stick, which will become the new starting point where placing the unit-stick. This repeated action allows children to cover the entire length of the side of the mat in *n* times the unit (iterated process). Note that, posing unit-stick one after another one is a repeated action that allows children to objectify the definition of measurement. In other words, this action, which is a sign linked to the use of the artifact, became mathematical sign in the verbalization of the obtained measurements. As matter of fact, the children find that the stick "one" is 29 times into the side of the mat (we consider a certain measurement error due to the approximation of measuring action), the stick "two" is 14 times into the side of the mat, while the stick "ten" is 3 times into the side of the mat. The following excerpt of discussion is representative of these results:

Teacher:	ok guys, how many did you had with the stick "one"?
Alessia:	29
Teacher:	ok, and with the stick "two"?
Alessandro:	14
Teacher:	and… with the big one, the stick "ten"?
Gabriele:	only 3, 3 times
Teacher:	but... why do the measures change so much?
Alessandro:	because the unit-stick change: one was bigger and the others smaller
[…]	
Gabriele:	[…] [the measure] it's larger if the stick unit [the measurement unit] is small, [the measure] it's smaller if the stick [the measurement unit] is large

It should be noted that teacher starts a discussion to highlight the relationship between the measurement unit and the measurement obtained in order to link the signs linked to the artifact (how many sticks) to math signs (measurements of the length). In fact, she asks why the measurements of the mat changes. Alessandro recognized a link between the measurement unit chosen and the measurement obtained, and Gabriele makes this relationship explicit in terms of inverse proportionality. The comparison among different measurements of same length reinforces the idea that measurement is a physical quantity (with a measurement unit of length).

Discussion and conclusion.

Different signs related to the use of Montessori sticks and the transformation of them into geometrical signs through the teacher's mediation, allowed children to develop the meaning of measure and the measure definition in relation with the chosen measurement unit. In order to reach this aim, and to overcome difficulties underlined by Bryant, perception and bodily experiences seem to play a key role in this teaching experiment. In particular, the use of Montessori sticks seems promoting the measurement as repeated process in "posing measurement unit", giving sense to the measuring action. As matter of fact, the physical, repetitive movement of positioning the measurement unit associated to the enumeration support the construction of the meaning of measurement as a physical quantity (i.e. *n* times the chosen measurement unit). This could reasonably facilitate the reading of the measurement on the ruler in the future (helping students to give meaning to the reiterated process that allows reading the length measurement on the ruler itself). At the same time, the one-to-one correspondence involved in measurement of a length with the Montessori sticks, overcomes the difficulty linked to the asymmetry of the ruler instrument: the measurement unit (the chosen unit-stick) must be physically superposed *n* times on the length to be measured. No ambiguity, therefore, linked to the need to imagine each measurement unit on the ruler (centimeters) on the length to be measured.

Criteria of future early childhood teachers to design problem-solving activities

Gemma Sala Sebastià[1] Adriana Breda[2] and Danyal Farsani[3]

[1]Universitat de Barcelona, Faculty of Education, Barcelona, Spain; gsala@ub.edu

[2]Universitat de Barcelona, Faculty of Education, Barcelona, Spain; adriana.breda@ub.edu

This work aims to identify the criteria contemplated by early childhood education preservice teachers when they reflect on the design of problem-solving tasks. The Didactic Suitability Criteria (DSC) and their indicators were used to analyze one of the tasks performed by future teachers. As a result, it was identified when they design their classes in a consensual way, they are implicitly based on the DSC. Still, not all their indicators emerge since their reflection is not guided by an explicit guideline that serves them to show their didactic analysis in detail.

Keywords: Early childhood education, Didactic Suitability Criteria, Ontosemiotic approach, problem-solving, task design, teacher training,

Introduction

In the field of Mathematics Education, problem-solving is considered one of the optimal scenarios for teaching and learning skills in this discipline. Current trends in this area consider that problem solving encourages the development of mathematical processes, such as reasoning, the establishment of connections and representation, and communication, among others (NCTM, 2003).

Starting from a competence approach from an early age is crucial since it is a stage where the curriculum presents content and processes in an integrated way, which favors new views that emphasize the content, the process, and the relationships established between them (Alsina, 2016). In this sense, the tasks posed by the teachers to the students are the starting point of their activity, which, in turn, produces their learning as a result (Pochulu, et al., 2016). Teachers' teaching practice determines the students' learning, and, in that sense, designing, implementing, and evaluating tasks is a crucial aspect and competence that the future teacher must develop in their training.

This professional competence, characterized by knowing how to design, apply and assess learning sequences through didactic analysis techniques and suitability criteria to establish planning cycles, implementation, assessment, and propose improvement proposals, is called, within the framework of the Ontosemiotic Approach (OSA) (Godino et al., 2007) as competence in analysis and didactic intervention (Godino et al., 2017). It is a competence long studied by the OSA with mathematics teachers where the results showed the Didactic Suitability Criteria (DSC) were a valuable tool to organize their reflections and evaluations and improve their task designs (Breda et al., 2017). Although there is research with DSC in early childhood education (3-6 years old), in particular, the design of a proposal for evaluation teaching and learning methods (De Castro, 2007) and the analysis of a sequence of tasks for the development of spatial perception (Moreira et al., 2018), until now, no research has been carried out that focuses on the design and analysis of tasks, in particular, problem tasks, from the perspective of DSC in the training of future early childhood education teachers. In this work, we focus on the DSCs agreed by future early childhood education teachers when asked to reflect together to justify the design of their tasks.

The objectives of the paper are: to study what aspects future early childhood education teachers consider essential when planning and designing a sequence of arithmetic problems for the teaching and learning of numbering; which of these aspects can be identified as DSC and; to identify which elements of the DSC are not considered by the students.

Theoretical framework

Design of problem-solving tasks for the first ages

Concerning problem-solving-type tasks, according to NCTM (2003), four aspects should be worked on in the classroom: a) build new mathematical knowledge through problem-solving; b) solve problems that arise from mathematics and in other contexts; c) apply and adapt a variety of appropriate problem-solving strategies; and d) control and reflect on the process of solving mathematical problems. Along the same lines, there are some key aspects regarding the use and meaning of problems in the classroom and that, therefore, should be taken into consideration when designing the tasks. There is an agreement among researchers that a problem situation must be a new situation for which the resolution method is not known in advance. There is also agreement on how one learns to solve problems by manipulating, simulating, discussing, sharing, imagining, observing, visualizing, etc. Moreover, in this sense, in the resolution process, each child should be allowed to use the strategy that best suits his or her possibilities: a drawing, a diagram, mental calculation, the manipulation of a particular material, etc. (Alsina, 2016).

Focusing on the mathematical activity that students develop when solving tasks, there are different teaching approaches but, in the case of early childhood education, citing Baroody and Coslick (1998), the following can be distinguished: 1) the skills approach; 2) the conceptual approach; 3) the problem-solving approach; and 4) the investigative approach, which is a combination of conceptual and problem-solving approaches, the primary purpose of which is for students, with the mediation of teachers, to reach their conclusions through reflection, reasoning, representation, problem solving and research. In this study, students were asked to work assuming the latter approach.

Didactic Suitability Criteria in the design and management of tasks

The use and application of the DSC, proposed in the OSA, allow a teacher to guide the teaching and learning processes of mathematics, design tasks and assess their implementations. The OSA considers the following DSC: Epistemic suitability; Cognitive suitability; Interactional suitability; Mediational suitability; Affective suitability; Ecological suitability. To operationalize the DSC requires defining a set of observable indicators, which allow assessing the degree of suitability of each of these criteria (Breda et al., 2017). For example, from the epistemic aspect, there is consensus that it is necessary to implement "good" mathematics. DSC construct considered good mathematics those that are rich in mathematical processes (connection, argumentation, problem-solving, etc.) and contemplate certain representativeness of the complexity of the mathematical object to be taught (different meanings of the mathematical object, different representations and languages or a variety of problem typologies), etc. Based on the DSC, Gusmão and Font (2020) defined a set of observable indicators (included in

Table 1) to be able to assess, in an operational way, the degree of suitability of each of these criteria in the design and analysis of mathematical tasks.

Table 1: Task design indicators according to the Didactic Suitability Criteria (Gusmão & Font, 2020)

Epistemic suitability
1. Is the task's description in a clear, correct, and appropriate language for the level of education?
2. Are different languages and forms of mathematical expression used (verbal, graphic, symbolic, etc.)?
3. Is the selection of tasks representative and varied, and whether it includes tasks of a closed and open nature?
4. Are the tasks of different types?
5. Does the generation of hypotheses promote open thinking (reversible, flexible, decentralized thinking) and encourage the use of argumentation and justification processes?
Cognitive suitability
1. Is it based on the prior knowledge of the students?
2. Is knowledge expanded, reinforced, and systematized?
3. Is the level of cognitive development of the students respected?
4. Is the use of different, creative, and original resolution strategies encouraged?
5. Are different learning objectives met, and are students developing different cognitive and metacognitive skills?
Interactional suitability
1. Are there moments of dialogue and discussion between students or between teacher and students?
2. Is the resolution of tasks individually, in pairs, or in groups encouraged?
3. Does it allow the generation of cognitive conflict and the negotiation of meanings?
4. Do they promote responsibility for the study (exploration, formulation, and validation)?
Affective suitability
1. Does it promote interactivity, attraction, fun, raising self-esteem, the feeling of inclusion and a taste for mathematics?
2. Are the different types of reasoning and responses valued?
3. Is participation encouraged and interest generated?
4. Do they favor the perception of the usefulness of mathematics in life and at work?
5. Is student involvement promoted in solving tasks (return of learning in Brousseau's sense)?
6. Are there possible challenges to be achieved, triggering levels of thought, each one more complex?
7. Do they present the application and beauty of mathematics?
Mediational suitability
1. Are manipulative and/or technological materials provided, or is their use recommended?
2. Is sufficient time allowed for its completion and the maintenance of concentration and interest?
3. Are the times appropriate for each of the different types of tasks?
4. Are adequate spaces provided for its realization?
5. Are moments of hands-on experimentation provided to aid understanding of concepts and their applicability?
Ecological suitability
1. Are official curricular documents (national and local) considered?
2. Is the articulation between different contents of Mathematics and between different areas of knowledge sought?
3. Are the tasks contextualized with the social and cultural environment?
4. Are the contents of the tasks useful for social and work life?

Among other authors, Canals (2009) and Chamorro (2005) highlight some aspects to consider in the design of problems for early childhood education. These aspects coincide with some of the DSC indicators in Table 1. For example, starting from the children’s interest and curiosity and promoting playful situations (indicator 1 of Affective suitability); contemplating the children's different languages and forms of expression, such as oral, gestural, pictorial, musical, plastic, dramatic, corporal, etc. and promote communicative processes that favour the exchange and exploration of ideas, allowing children to advance in language and modes of representation (indicators 2 and 5 of Epistemic suitability and indicator 1 of Interactional suitability); favour situations that offer challenging experiences (indicators 5 and 6 of Cognitive suitability), that encourage children to explore, observe, compare, pose and test hypotheses, make decisions, propose and solve problems, and that consider the different fields of mathematics, articulating them whenever it is possible and necessary (indicators 3, 4 and 5 of Epistemic suitability).

Methodology

The participants were 76 students from two groups of the Mathematics Didactics subject that were carried out in the next-to-last (3rd) of the Early Childhood Degree of a Catalan public university (Spain), during the first semester of the 2020-2021 academic year. This degree is organized in four years with only two mathematics subjects: “Mathematics, Science and education” (in 2nd year) and “Mathematics Didactics” (in 3rd year). The course began with mixed teaching and, given the evolution of the health situation due to Covid-19, it became virtual and the BlackBoard Collaborate application was used in the course schedule which has made it possible to configure rooms for work in small groups when it was necessary. However, when students worked independently outside of class sessions, they could choose the platform that best suited their preferences. The teacher of these groups along with the first author had to redesign the programming of the Numerical Thinking content block to adapt it to the new teaching modality. For this, he prepared various tasks that are part of the context of a broader study than the one presented in this work (some parts of which we are still analyzing), with the general objective of studying how future early childhood education teachers build their didactic mathematic knowledge about arithmetic problems solving.

One of the tasks before the one analyzed in this work carried out by the participants (we will call it Task A) had the purpose that the students knew a didactic-mathematical source, as a practical example, on which to base the development of their next task we will call it Task B. This work only focuses on Task B because it is the part of the data currently being analyzed and responds to the specific objectives indicated in the introduction section.

To carry out Task A, the students organized into workgroups of 3-5 people (in total, 19 workgroups), carried out an analysis task outside class hours from De Castro and Escorial (2007) reading, "Solving verbal arithmetic problems in early childhood education: an experience with an investigative approach." This article explains, among other aspects, how a teacher raises a series of seven problems for her 5-year-old pupils and the development of the sessions where they solve them. The problems and the resolution strategies used by the children were classified based on a table prepared by the authors of the reading article and based on the typology of Carpenter et al. (1993).

First, each person in the group, individually, had to read the article and, later, share doubts and reflections on it with the rest of the members of their workgroup. Second, they had to choose by consensus at least three of the seven problems in the article and analyze them based on the following demands: identify the problem statement; identify and justify the type of problem involved (according to the table in the article) and what strategies the children use in solving, as explained in the narration of the article; explain if the strategies identified are the ones that would correspond according to those set out in the table of the article; identify the material resources used by children and how they use them for the resolutions presented; they also had to solve the chosen problems with material resources other than those in the article and reflect on whether, when changing resources, the resolution strategy also varies (comparing the resolution strategy itself with that used by the children in the article).

Description of Task B analyzed

This task, which was presented to the students in a virtual joint session, consisted of designing a minimum of three problem-solving sessions for a classroom of twenty 5-year-old children. This task had to be developed with the same groups as those in Task A, outside the hours of the virtual joint sessions. For this, the teacher recommended consulting the early childhood education curriculum, the article by De Castro and Escorial (2007) analyzed in Task A and the rest of the documents of the content block. It was also part of the task to present the recording of a video conference where the group members discussed the aspects of the design and the implementation methodology that they considered essential to incorporate and reach a consensus and/or seek solutions. Before the final delivery of the works, a 2-hour class session was dedicated to presenting their designs and obtaining feedback from their classmates and the teacher. Thus, they had time to incorporate improvements in the design of their sessions. Finally, they presented a file in PDF format with the design of the sessions and a file in MP4 format with the recording of their decision-making session (video conference). We analyzed the recordings of the video conferences and the document of the design of the sessions of the 19 working groups.

Analysis methods

This is a study of qualitative characteristics on the aspects that the participants consider essential to consider in their designs of a sequence of problems for the teaching and learning of numbering for 5-year-old pupils and analyze which of these aspects can be identified with DSC and which elements of the DSC are not considered. The phases of the thematic analysis proposed by Braun and Clarke (2012) have been adopted in this study. In the first phase, to familiarize ourselves with the data, the group's videoconference recordings were viewed concerning the planning of the work to be carried out, and aspects of the design and management of the problem-solving sessions addressed by the participants were identified. Then, it was compared with the written works sent as a final document to verify that these aspects were reflected in their final works and/or considering other aspects that emerged. After this, the presentations before the final submission have been reviewed to observe the improvements made in the final work because of the influence of the sharing session, but it is a part of the research that we will not deal with here due to the limitation of the space.

In the second phase, the first author systematically applied the a priori categories based on the indicators in Table 1 to the evidence (identified basically in their written works) of the aspects that the students considered necessary for the design and management of their resolution sessions of problems to analyze in a descriptive and interpretive way which criteria could be identified with the DSC and which aspects of these were not contemplated. For example, when students said their problem is contextualized with “a story that calls them [the pupils] the attention”, we considered it is evidence of Affective suitability, specifically of indicator 3 (see Table 1). The third phase was focused on the categorization revision by three authors. Also, in this phase, the identification, analysis, and interpretation of the pieces of evidence were triangulated with an expert in using the DSC. In the last phase, the three authors discussed the results.

Results

Although the participants were not given any training on DSC, all groups implicitly used DSC to justify decisions about the design of their tasks, although no group evidence is observed for all indicators. All designs have high *Affective suitability*. For example, in videoconferences, the 19 participating groups express the intention that the activities motivate children to participate in them and find them fun. To do this, seeking to activate empathy, characters such as the class mascot or the school cook are incorporated, who supposedly live in problematic situations and ask for help, games are created, stories, in their own words, “a story that calls them the attention,” etc.

Regarding *Mediational suitability*, all groups plan to offer material resources to children to solve their problems. However, all adhere to the resources seen in the training classes and add non-specific materials (pencils, pasta, stones, chickpeas, etc.) and others related to the context of the problem (reproductions of fish, drawings of trees, and apples, sports medals, etc.). Only one of the guideline designs offers five specific material resources and a program that rotates through the small groups of children formed for each session. However, it is not contemplated that each child can choose and experiment with the material that he or she sees fit, and it is not considered that some of the resources are better than others depending on the problem to be solved. In addition, in all the designs except one, the activities are planned to be carried out entirely in the classroom environment. Only one designer schedules sessions on the playground and in the psychomotor room.

Regarding *Epistemic suitability*, 14 of the 19 designs are concerned that the children’s organization and time includes a space for the explanation and argumentation of the process through which the answer has been found. However, only 2 designs specifically explain how to manage it, and the only one provides possible dialogues with good questions to promote the generation of hypotheses, argumentation, and justification. Although future teachers have studied problem-solving from an investigative approach and have analyzed an example (in Task A), none of the designs considers it. All the groups work from verbal statements, with clear and straightforward questions, and freedom is left for different proposals for resolutions to arise that will be put together (only 5 of the 19 designs do not foresee a pooling to explain the possible diverse resolutions of the children).

There is less evidence that students took the criteria of *Cognitive suitability* of their tasks into consideration, but all designs consider introducing problems with a gradual increase in their difficulty. In their dialogues, they start from what theoretically 5-year-old pupils should know according to the curriculum (for example, in their words: “they have to know how to count to 20”, “we have to consider the 5-year level”), but only one of the designs incorporates prior knowledge exploration activities. In their dialogues, future teachers do not debate about which concepts the teacher is going to reinforce or systematize; they only say that “she will have a guiding role,” “she will interact with the children”, “she will go around the groups to review the processes and results,” “at the end the children will stand in a circle so that the teacher can clarify doubts.” On the other hand, we have observed aspects related to the evaluation of pupils that, although implicit in cognitive (and ecological) suitability, are not explicitly contemplated with indicators in the DSC. The 19 works analyzed are concerned with evaluating pupils learning, with various proposals such as rubrics, lists of actions to observe, or lists of questions for children to answer.

Regarding the *Interactional suitability*, all the students' designs organize the activity to solve the problem in small groups, arguing: "so that they help each other." When they want to increase the difficulty, they propose that they be individually resolved. However, no design reflects how to get 5-year-old children to collaborate and, therefore, no working group considered that the activity implies that they must negotiate meanings and promote it. None of the groups designed activities self-validating: the process and the validation of the results always go through the teacher's approval.

Evidence of *Ecological suitability* is obtained since curricular objectives and competencies are incorporated for the second cycle of early childhood education, specifying them for each activity. However, none of the groups attempts to articulate different mathematical contents since, apart from the typology of problems studied, no other concepts are incorporated (such as logic, which is a block of knowledge dealt with in the course in the months before this work), or other knowledge areas. The statements of the problems contain elements that future teachers think are every day for children but are based on imaginary stories with children's characters, more in the sense of activating empathy and obtaining a high emotional fitness. Only 3 of the 19 designs are based on real experiences: athletics games at school, activities in the school garden, and a trip to a lake. However, they are only a motivating contextual excuse to put elements in the statements of the problems, and in no case are the activities proposed in an interdisciplinary way.

Discussion and Conclusions

It can be affirmed that, in the training of early childhood education teachers, it is essential to promote dialogue to make consensual decisions in the design of tasks for the teaching and learning of suitable mathematics, since group reflection enables the generation of proposals, opinions, and decisions taken as a group. Regarding the aspects that future preschool teachers consider essential when planning and designing a sequence of arithmetic problems and which of these are identified with the DSC, future teachers are implicitly based on criteria identified with the DSC. However, not all its indicators emerge since their reflection is not guided by specific DSC and they do not have an explicit guideline to guide their didactic analysis. This result agrees with the conclusion reached in recent works such as Breda et al. (2017) and Sánchez et al. (2019). In this sense, it is observed that DSC appears as a regularity when teachers or future teachers want to justify the criteria on which their decisions are based without being taught the use of this construct. The reason could be related to the fact that DSCs reflect consensus on what good mathematics teaching should be, widely assumed by the educational community. From a didactic point of view, this study offers indications that it would be convenient to offer early childhood education preservice teachers a tool such as DSC so that they have explicit criteria to guide the designs of their mathematical tasks. In this sense, a future line of research opens, much needed, to adapt the DSC to the singularities of this educational stage.

Patterning in Early Years,

A Synthesis of Research

Marianna Tzekaki

Aristotle University of Thessaloniki, Greece; tzekaki@auth.gr

This paper attempts to summarize the research related to patterning in early childhood (4-8 years). In doing so, the basic concepts, rationales, methods, and findings are systematized to provide a foundation for forthcoming design. The purpose of this presentation and the suggested discussion is not to present new data but to systematize existing as a guide for future research.

Keywords: patterning, definitions of pattern, pattern activities, pattern abilities, pattern strategies

Introduction

Systematic exploration of early patterning begins in nineties as an important element of early mathematics education. Researchers accept that children's familiarization with patterns and structures influences their future mathematical development (Clements & Sarama, 2009) and provides a foundation for understanding complex mathematical situations and making generalizations (Rivera, 2013).

To date, a large number of different studies have been conducted on early patterning in mathematics education. These studies approach the idea of pattern differently, use a variety of pattern forms, propose similar but also dissimilar pattern activities and understand the connection of pattern to mathematics in various ways. Therefore, we believe it is important and mature to attempt a synthetic presentation of this research in the following axes, covering aspects such as: (a) the *conceptual definitions* and types of patterns, (b) the *rationales* for linking patterns to mathematical development in different contexts, (c) the research related to patterning *skills and strategies*. These elements are considered important for planning future research. A synthesis of the research of this content would also require an outline of the main findings, but as we will see, due to the diversity of research, this synthesis could only be done on certain axes, therefore it is limit to presenting only findings on patterning skills and strategies.

Clarifications

Pattern definitions

Not all researchers define the meaning of pattern in the same way, since pattern is not a distinct mathematical concept. A first approach describes pattern as *a sequence of elements* of different nature (numbers, shapes, sounds, symbols) organized according to a rule. This definition implies regularity and therefore predictability (Papic, Mulligan & Mitchelmore, 2011; Radford, 2008).

However, according to Liljedahl (2004), the *nature of the elements* of a pattern is crucial. He argues that the concept of a pattern is a primary notion defined within the set of specific forms of regularities to which it belongs (e.g., sound, space, arithmetic, etc.) and has features within that set. Thus, he supports that, for example, a sound or a spatial pattern, even if they have the same e.g.

ABB structure as an arithmetic pattern, they are of different natures and can be approached differently.

Extending the above view, Papic et al. (2011) identify patterns in the context of mathematics as, a) a *regularity in an object* in which some of its elements are related in a systematic way, b) an *ordered set of objects* in which each element is connected to the next by a specific relation, and c) *two ordered sets of objects* whose elements correspond to each other. So, the above researchers extend the corresponding concept by including elements organized on the basis of a structure (such as a clock), endogenous or constructed or introduced by a mathematical system (Mulligan, Mitchelmore, English & Crevensten, 2013).

Summarizing the above, it is understood that different research approaches in pattern definition are recorded, but the *basic component of a pattern* - common to all views - is the relationship between the elements that constitute it, which either enforce its organization into a structure or allow the prediction of the subsequent terms of its sequence (Radford, 2008; Rivera & Becker, 2009; Warren & Cooper, 2008).

Pattern categories

There are also a variety of categories and terms regarding patterns that appear in relevant research. In general, researchers have identified and widely reported *three specific forms*: repetitive, evolving, or relational patterns (Lünken, 2018; Mulligan, Mitchelmore, & Prescott, 2006; Threlfall, 1999).

For repetitive patterns, a further distinction is made based on the type of *iteration unit* (e.g. ABAB, ABABA, Liljedahl, 2004; Papic et al., 2011; Threlfall, 1999), but also on the changing parameters (e.g. shape only, or shape and size, etc., Fyfe, Evans, Eisenband Matz, Hunt, & Alibali, 2017; Skoumpourdi, 2013). As for the developing patterns, Rivera and Becker (2009) group them into *additives* or *multiplicatives*. Rivera (2013) also distinguishes patterns in terms of their elements in arithmetic and geometric forms, while Warren (2005) includes regularities with elements in the form of shapes, colors, movements, sensations and sounds (especially for young children). The relevant findings are related to these categories.

To these forms Mulligan et al. (2006) add *algebraic* (triangular formations with numbers), *metric* (with repetition of unit elements) and *diagrams*, but also *two or three-dimensional* formations (Mulligan et al., 2013). Similarly, Ma (2009) refers to *iconographic patterns* (mainly geometric) that lead to the formulation of verbal rules.

In this category, Chua and Hoyles (2013), who study schematic or figurative forms that lead to arithmetic relations and refer to rules (function type), distinguish their categories on the basis of the formations, but also of *the type of the function type* to which each form refers (e.g. some lead to types of linear functions, e.g. $5 + 3ν$, while others lead to types of secondary functions, $ν^2 + 2ν$, etc.).

Composing the above, a variety of categories emerges in the relevant research, which can be organized in the *following axes*, with mainly mathematical content (i.e. without sound or kinetic patterns) and corresponding combinations: *content or type of elements* of the pattern (iconographic, schematic, geometric, metric, arithmetic, algebraic, etc.), *type of development* (repetitive, evolving, retrospectively evolving, etc.), *spatial dimensions of development* (e.g. one-dimensional, two-dimensional, three-dimensional), *structure of the pattern* (for repetitive: AB, ABB, ABBA, etc. – developing: additive, multiplicative, etc.), *material* (tangible, virtual and/or symbolic). The research has been conducted only in some of these categories.

Pattern activities

In this section, it is important to add the activities suggested by the researchers from the youngest to the older students.

At young ages, activities with patterns include *replication* with or without copying, *continuation* or extension of regularities, and *recognition* of structurally similar regularities. To these activities there is also research with *pattern creation* (Papic, Mulligan & Mitchelmore, 2011), *search of a missing element* (Warren, 2005), and *alteration of material* (Clements & Sarama, 2009).

Finding and describing the *iteration unit* or smallest unit of a pattern is recognized by many researchers to be a particularly important activity (Mulligan, Mitchelmore, English, & Crevensten, 2013; Clements & Sarama, 2009). Similarly, *predicting later terms* for generalization (near or far) (Ma, 2009). These two activities, distinguishing units and predicting terms, as well as linking them to a next position (e.g. what is the 10th term?) are considered very important as they lead to generalizations and symbolism (Michael, Elia, Gagatsis, Theoklitou, & Savva, 2006; Lannin, 2005). It is argued that pattern generalization but also verbal explanations (Lüken, Peter-Koop, & Kollhoff, 2014), drawings, or other forms of symbolism (Mulligan, et al., 2013) are an important introduction to both later numerical or developing patterns leading to formulas at this age.

In composing, research suggests the following activities, different in their treatment and difficulty: *copying*, *reproducing*, *extending*, *transferring to another material*, *recognizing the repetition unit*, *identifying the same units of repetition*, *finding the missing element* (interpolation), *finding the error* (Wijns, Torbeyns, De Smedt, & Verschaffel, 2019), *generalization* (finding a *formula*, *finding a term in a specific position*, Lannin, 2005).

Students' skills in pattern's development

The finding that young students (ages 4-8, kindergarten and elementary school) have an ability to develop patterns is a common thread throughout the literature. The results of research on children's performance on activities that involve patterns reveal the basic types of regularities and the types of activities that young children successfully master without a specific didactic approach. Thus, in general, even preschoolers are able to explore repetitive patterns, language patterns, and some linear patterns and perceive regularities during their leisure activities (Lüken, 2018; Fox, 2006; Waters, 2004).

Most research in early childhood focuses on examining performance on repetitive patterns, with the majority of children able to reproduce, continue, and create a repetitive pattern AB or ABC (see, e.g., Skoumpourdi, 2013; Papadopoulou, 2010; Warren & Cooper, 2008). More complex forms, including those of the ABB type, seem to cause greater difficulty, while the pattern material does not seem to have a significant impact.

However, analyzing the pattern in its structural elements and finding the iteration unit is becoming more demanding issue, which has led researchers to consider iteration unit location, complementing (finding the missing element) and identifying (which patterns are the same? is this a pattern?) at a higher developmental level of the respective ability (Wijns et al., 2019).

Developing patterns that is an early introduction to functional reasoning, appears to be more challenging, leading to less emphasis at younger ages. Although the performance of young children has not been systematically studied, the relevant research mainly concerns children in the last grades of elementary school and the first grades of high school, it seems that in this area the material and the structure play a crucial role (one-dimensional or two-dimensional growth). Several researchers point out that children reach high percentages in repetitive patterns by the 2nd grade, but less in increasing geometric or arithmetic patterns (Papadopoulou, 2010; Warren, 2005; etc.).

In relation to the building patterns of objects of different types (Mulligan et al., 2013), the developmental trajectory of young children has been studied in depth through a systematic program of activities from the prestructural to the structural level (intermediate levels: emerging and partially structural). This view brings the importance of curriculum and instruction to the first level, as a number of studies - (not examined in detail in this paper) - highlight the positive impact of appropriate educational interventions and programs.

In summary, children up to first grades succeed, even without educational help, to recognize patterns with simple structures or materials and identify a simple rule, but have difficulty with more complex forms as well as numerical, developing patterns. There is a lack of meaningful research on systematic and verbal finding of the unit of repetition and near or far generalization (e.g., what is the form at the next or next but one place - near generalization, or what is the form at the 10th or 20th place - far generalization).

Patterning strategies

By studying the activities of students with patterns, some researchers have also studied the strategies they use at an early age. A common assumption is that children make one-to-one correspondences to the proposed pattern activities that mainly involve copying, reproducing, extending, or transferring to other material, or that they take a rhythmic approach based on a sequence (which, however, according to Threlfall, 1999, cannot lead to generalization), such as finding the unit of repetition or 'breaking into pieces' (Mulligan et al, 2013).

Papic et al. (2011) categorize children's strategies into *direct matching*, *alternation*, *repetition* of basic units, and *integrated repetition* of units. Accordingly, Lüken (2018) summarizes relevant results and records five strategies of students in solving activities with patterns: in the 1st, there is *no reference* to the design, except for the holistic reproduction of the pattern; in the 2nd, the focus is *on some features*; in the 3rd, *on comparison* and classification; in the 4th, *on the sequence*; and finally, in the 5th, there is *a focus on the unit of repetition*.

In summary, young children successfully develop strategies to find the next element in a pattern or its rule, but according to some researchers (see Lüken (2018)), copying, imitating or reproducing without generalization and symbolism cannot be recognized as a mathematical activity, that is the finding of the iteration unit, its generalization and its possible symbolism. The next section gives some answers about the importance of developing patterning skills and strategies.

Relationship between pattern development and mathematics

Researchers engaged in studies with patterns argue that patterns are important because "... *Mathematics is the science and language of regularities*" (Steen, 1990, p. 5, in Fox, 2006) and familiarity with them also promotes mathematical thinking, exercises the ability to find rules and structures, both in everyday situations and in symbolic objects or symbols, such as the elements of algebra (Vogel, 2005).

In general, connections to Mathematics relate patterns to numbers (e.g. repetitive structure of the decimal system, cumulative and multiplicative structures), to geometry (e.g. regular shapes), to measurement (e.g. creating and repeating a unit of measurement), and to data processing (e.g. finding rules and relationships) (Lüken, 2018; Mulligan, Mitchelmore & Prescott, 2006).

The connection with algebraic reasoning (Fox, 2006) as well as with functions (Warren, 2005) is another axis that many researchers have worked on (see Ma, 2009; Papic et al., 2011). More generally, it is agreed that the formation of generalizations, subtractions and symbolizations enhanced by pattern activities as an indispensable element of Mathematics (Lüken et al., 2014).

Several studies examining the relationship between performance in patterns and performance in other mathematical domains (e.g. arithmetic) or other cognitive skills (e.g. reading, memory, etc., Fyfe et al., 2017) show important connections. Some others, also investigating whether high performance in patterning is a predictor of later mathematical achievement (Rittle-Johnson, Zippert, & Boice, 2016), reach different conclusions.

Combining the above, it becomes clear that different pattern forms and activities support different aspects of mathematical concepts. Thus, *repetitive patterns* (with the characteristic feature of circular character and repetition unit) and activities requiring *continuity, completion, finding a missing element, finding an error, finding a unit of repetition*, etc., can help students approach mathematical objects or processes that are systematically repeated phenomena, such as number systems, regularities in shapes, repetition of units of measurement, etc. (Liljedahl, 2004); *generalization, and symbolism* are important in mathematical domains such as problem solving (Rivera & Becker, 2009; Radford, 2008) or equations (McNeil & Alibali, 2005). Accordingly, *arithmetic regularities* and activities requiring *finding not only some next elements* or the type/function that generates them (e.g., a number sequence 1, 5, 8, ...), but also some elements of the pattern that are in a particular position (far generalisation), support functional thinking from an early age.

Discussion for future research

From the above review, we need to highlight the following points for future research: First, the number of studies that have been conducted on early patterning is large, but there is a variety of contents, aims, questions and approaches, thus the concepts and terms used in them are not always clearly or similarly defined. For this reason, systematic concern regarding terms, categories and activities are needed in any future research.

Then, the review presented show that regularities or patterns, as well as related activities, can be categorized in many dimensions. Therefore, it would be important to conduct synthetic comparisons and compare performances surveys but only in common approaches. Also it is also important to systematically investigate the extent to which certain pattern forms and activities are related to mathematical content and the mathematical skills they promote, as not all regularities lead to mathematical activity and thus to Mathematics.

Finally, we know that children in general can develop important patterning skills at a younger age, but not all of them are related to mathematics. Therefore, in research or classroom practice, the researcher/teacher needs to know which developmental pathway serves which content, material, structure, and/or action.

Keywords: early mathematics, picture books, teachers' awareness

Research topic and theoretical framework

There is growing research which provides evidence that the use of picture books in the early years of schooling can contribute to the learning of mathematics (e.g., Van den Heuvel-Panhuizen et al., 2016; Van den Heuvel-Panhuizen & Elia, 2013). However, it is also known that different books can generate different amounts and different kinds of mathematical talk (Anderson et al., 2000). Therefore, it is essential to know what picture books can offer to elicit mathematical thinking of children. In particular, this knowledge is important for early childhood (EC) teachers when they use picture books to create opportunities for children to gain informal mathematical experiences. The study presented in this poster is a part of a research project which is carried out to acquire cognizance of how to enhance teachers' competence in using picture books in early childhood mathematics education.

The study builds on our previous research in which we developed and researched a framework of learning-supportive characteristics of picture books for learning of mathematics (Van den Heuvel-Panhuizen & Elia, 2012). This framework consists of two parts. Part A incorporates the mathematical content that is offered in a picture book. Besides the usual content domains this also refers to mathematical processes and attitudes, and mathematics-related themes. Part B describes how the mathematics is presented. It includes both the way of presentation and the quality of it.

The goal of the present study is to investigate whether the teachers are aware of the learning-supportive characteristics of picture books, specifically whether they are aware what mathematics can be found in picture books and the way the mathematics is presented, and whether the framework is of use for recognizing opportunities of picture books to support children's mathematical development. The latter is the focus of the poster.

Method

To investigate whether the framework helps to improve teachers' awareness of the opportunities picture books offer for early childhood mathematics education, a qualitative study was conducted in Cyprus and Norway with respectively 6 and 4 in-service EC teachers, who had to evaluate two picture books with and without the framework by filling in for each book two times an open questionnaire specially developed for each book. The picture books are regular trade books of high literary quality, not purposely written for teaching mathematics, but they tell appealing stories which form a meaningful context for engaging children in mathematical thinking. In both countries we used the same wordless picture books. In this way teachers have also more freedom to recognize learning-supportive characteristics and can develop their own ideas of using them. In the data analysis the focus was on finding noteworthy changes in teachers' answers between the two rounds.

Results and discussion

Overall, we found that in both rounds teachers' answers involved to a greater extent learning-supportive characteristics included in the supply of mathematical content (Part A) than characteristics referring to the presentation of mathematical content (Part B). Moreover, the answers often were short and without explaining their thinking. They rarely referred to mathematical processes or dispositions. Possibly they are not accustomed to using picture books or the framework did not appeal to them. Regarding the mathematics that was found, the framework helped the teachers to see different or more mathematics and further specify the identified mathematics from the first round. The framework also had a positive contribution to teachers' evaluation of how the mathematics is presented. However, in some cases the framework did not have added value. In the second round a few teachers just used the wording of the framework, while their answers earlier were more detailed and relevant.

Our study has shown that the framework has potential to make teachers aware of the learning-supportive characteristics of picture books for supporting children's learning of mathematics. Our next step will be to use our findings to set up a professional development for EC teachers.

This paper presents the design and construction of a professional task aimed at analysing experiences that foster reasoning in children aged 0 to 3 years old. The process served to organise and validate a task that mobilises future teachers' knowledge of how to foster reasoning in early childhood education. The task allows the recognition of metacognitive actions that show how, in the cases studied, relationships of cause and effect are produced as a prelude to strengthening mathematical reasoning. This permits a reflection on the way in which children at this stage intuitively construct their knowledge.

Keywords: Initial teacher training, professional task, reasoning, early childhood education

Introduction

Some research reflects on the capacity of young children to establish causal relations and their capacity to draw conclusions based on certain experiences and representations (Sobel & Legare, 2014). It is explained that educators can improve thinking skills in children aged 0 to 3 (Sturman et al., 2005). Recent research findings attest to the importance of early mathematical learning. They show that the understanding of complex mathematics and abstract reasoning develops much earlier than was once thought (Vukatana, 2013; Clements et al., 2019, among others). Although these authors presented their work some time ago, the amount of literature on early childhood mathematics education remains rather limited as regards logical reasoning in the early years. On the other hand, Ivars and Fernández (2018) and Moreno et al. (2021) point out that during their initial training it is important to encourage prospective teachers to gain experience from different contexts where they can observe teaching situations in a structured way. One of the possible contexts is the analysis of in-school experiences. Such experiences, when described as a narrative, can be a powerful instrument for the construction of professional tasks. Our interest in the initial training of early childhood education teachers has prompted us to consider, among other aspects, the different approaches and professional tasks faced by future teachers.

The purpose of this paper is to describe the process of designing and structuring a professional task focused on the analysis of experiences that promote reasoning in children aged 0 to 3 years old. This kind of task seeks to involve pre-service teachers in processes of interpretation and decision-making (in teaching situations) so that they begin to "notice" the mathematical activity in the classroom (Mason, 2021). This type of study is considered to play a key role in reformulating training programmes and responding, on the one hand, to the challenge of involving future teachers in reflective processes and, on the other hand, identifying experiences that make it possible to promote mathematical logical reasoning in young children. In our context, early childhood preservice teachers are trained to teach children aged from 4 months to 6 years old. In this study we will focus on the mathematical education of the youngest group, specifically children aged up to three years old.

Theoretical background

The logical mathematical reasoning of children aged 0 to 6 years old can be organised according to its complexity (from least to most) in three parts: a) identifying, defining and/or recognising qualities, b) relating qualities, and c) operating qualities (Canals, 2009). This organisation can not only help teachers to design activities but also to analyse children's level of understanding and the problems children face when they have to tackle a task that requires logical-mathematical reasoning. Some studies describe the emergence of category-based inductive reasoning during infancy, focusing on adherence to a fundamental induction principle, premise-conclusion similarity. It is shown that infants aged 13-22 months use both category information and perceptual similarity to guide their inductive inferences about non-obvious properties under various conditions (Graham et al., 2020).

One of the difficulties encountered by future early childhood education teachers consists of recognising the knowledge that underlies children's actions, especially when it is not verbalized, as in the case of children under 3. It is important that pre-service teachers are familiar with activities that foster reasoning at this stage. And that they are able to design and manage tasks that address processes such as attribution, designation and characterisation, which lead to the idea of classification (Peres, 1984). Prospective teachers must be provided with enough tools to be able to develop the specific skills needed for educational practice (Llinares, 2013). One of these competences is the so-called noticing, which involves the development of the prospective teachers' cognitive skills in order to identify and interpret the students' mathematical thinking and enable informed decision-making with regard to their teaching proposals (Jacobs et al., 2010). In recent years understanding how this teaching competence can be developed has become a research goal in the mathematics education (Dindyal et al., 2021).

Criswell and Krall (2017) argue that the noticing competence enables teachers to go beyond the more easily observed issues, such as students' behaviours and actions. It enables them to address issues that need to be meaningfully inferred, such as students' thinking about a given mathematical notion. Ginsburg (2016) states that teachers cannot teach well if they do not understand children, mathematics and the associated pedagogy. Therefore, it is crucial that teachers and future teachers learn to recognise and understand children's mathematical thinking.

Research on task design focuses on a number of aspects (Swan, 2007; Charalambous, 2010). One of them is the use of narratives in pre-service teacher training, which provide relevant starting points for the discussion of problems faced by teachers when making decisions about the various teaching and learning situations, such as how to apply certain curriculum requirements to school activities, classroom management techniques, and/or how to assess and track students' learning (Chapman, 2018). We use narratives to reflect on the thinking and actions of prospective mathematics teachers in the context of mathematics content and mathematics teaching and learning itself.

As pre-service teacher educators, we have to select, plan and design professional tasks that enable them to identify children's behaviour, thereby supporting the development of their thinking and consequently their ability to make justified professional decisions. In early childhood education, prospective teachers are not usually specialists in mathematics teaching and this means that the selection and design of professional tasks must be more carefully carried out if a satisfactory understanding of mathematical notions and processes and the associated didactics is to be achieved.

Methodology

This research features a qualitative approach of a descriptive nature (Cohen et al., 2018). It is based on intervention research that focuses on action, seeking to understand and explain its effects. This intervention study was carried out with students pursuing a degree in early childhood education at a Catalan university during the 2019-2020 academic year. The participants had worked on the content dealing with logical-mathematical reasoning and the mathematical problem-solving process. The professional task was designed to enable future teachers to observe, analyse and reflect on real experiences that promote logical-mathematical reasoning in the 0-3-year-old period. The professional task had five stages: 1) a review of studies on the teaching and learning of logical-mathematical reasoning in 0-3-year-olds; 2) a review of studies, materials and activities used to work on logical-mathematical reasoning in early childhood education; 3) a choice of narratives for future teachers to observe and analyse; 4) the implementation of the aforesaid professional task in a pilot group; and, 5) the definition of levels to characterise teaching competency in advance. The written work produced by each group of students provided the data for this study.

The design of the professional task (PT) presented in this study is based on a previous professional task (PPT). This task (PPT) focused on the design and implementation of activities for children (0-3-year-olds) based on the use of non-specific materials. The PPT was developed in the 2018-19 academic year by 80 students pursuing an early childhood education degree, organised into working groups of four to five and from two Catalan universities. Each working group designed and implemented an activity using non-specific materials, with the purpose of developing logical-mathematical reasoning in 0-3-year-old children. The goal was to provide opportunities for the children to discover and establish common (or distinct) characteristics by manipulating and experimenting with different objects. This is the perceptual basis of processes such as attribution, designation and classification. The PPT also included a reflection on the materials used, on its potential and relevance when promoting reasoning in this children's age group. As a final product the future teachers submitted a written report and a visual record of the task implementation.

In the following course (2019-2020), some of the proposals made by the pre-service teachers who developed the PPT were used as the basis for the design of the PT for a new group of prospective teachers. This new task focused on the study of narratives, with proposals specifically derived from the PPT. The aim of the new task was to strengthen other aspects of teaching competency in the new group of prospective teachers, particularly as regards the analysis of real classroom experiences.

The professional task (PT) was organised into three parts. Firstly, the prospective teachers were asked to examine the main characteristics of two activities (a sensory wall and heuristic play respectively). Identifying the type of objects used in each activity, indicating the attributes of each object or groups of objects, and describing the actions that could be done with each object. Secondly, the future teachers were invited to associate each of the children's actions with the logical thinking skills of identifying, relating, and operating, and also to evaluate the design and management of each of the activities. Finally, the prospective teachers were asked to give their reasons for whether or not they would again use the same or similar objects to those employed in the two activities.

The PT was initially carried out with 37 students pursuing an early childhood education degree, who were studying the course's introduction to mathematics didactics. These future teachers had studied content related to logical-mathematical reasoning and the problem-solving process. We proposed that they develop the task in small working groups (3-4 people) for purposes of a joint reflection that could promote the competence of didactic analysis of learning situations. As a result of their analysis, each group submitted a written report that provided the data for this study. In total there were 10 groups and 10 papers.

Results

Having completed the task, the answers provided by the different groups of future teachers were organised in order to refine the task for future use and also characterise the teaching competence of noticing. Different levels associated with the different teaching competences – identifying, interpreting, and making decisions – were established (Jacobs et al., 2010).

By way of an example, we present the levels associated with interpreting skills. In this research we found that prospective teachers recognised measurable attributes, spatial relationships associated with movements, and attributes associated with comparisons and order (e.g. large-small; thick-thin; high-low). They also identified different relationships, for example, when children showed unequivocal signs of being able to identify similar elements. Given the type of action performed, they distinguished causal relationships.

Regarding the interpreting competence, three levels were established previously:

L1 – Identification of actions of comparison and some relationships of cause and effect by indicating them descriptively

L2 – Metaphorical allusion to types of reasoning, indicating terms such as 'visual' and 'deductive', but without specifying what they mean. Describing actions associated with the different logical thinking skills (identifying, relating, operating), but without a theoretical justification.

L3 – Evaluation of children individually, appropriately associating types of abilities and possible types of mathematical reasoning. Discrimination of key aspects of the adequacy of the activities according to age.

Table 1: shows extracts from the answers provided by the different groups and the allocation to the different levels

Table 1: Examples of answers and the levels associated with the interpreting competence

G	Level	Answer Extract	Analysis
10	L1	"…They realise that when they take a *metal tube* and *hit* it, it makes a *noise*, and that the *harder they hit it*, the *louder the noise*"	The group of prospective teachers described actions that allude to relationships of cause and effect, but without any justification. They only refer to them.

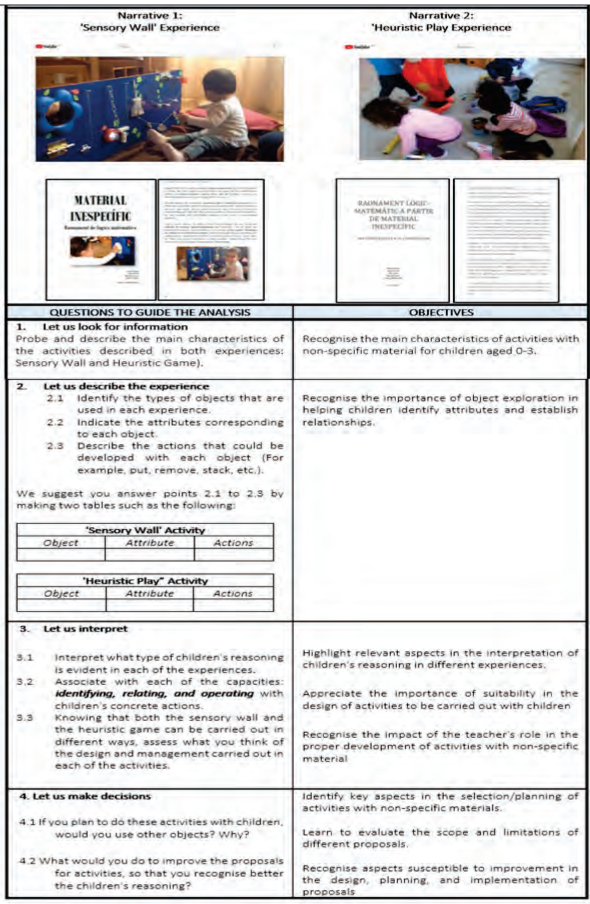
2	L2	“On the sensory wall, we saw that the girl can *identify different elements* through touch. It is a process of identification by touch.” “...They observe that when *they move some objects* in a *specific way* or when these *collide with each other*, they make a *noise*. They establish a *relationship* between the *action (hitting) and the noise.’*	This group interpreted different actions and associated them with different competences (identifying and relating).
4	L3	“…In other words, with this experience, children begin to *discover and get to know the different objects* in the classroom. *Then* they begin to *do actions* with them, for example, making a noise, and finally they *play the symbolic game*, where those objects stop being what they are to become other things such as necklaces, snails, telescope, etc.” “Perhaps if we used a treasure basket instead for this activity, *it would be more appropriate*. Given that Eva *cannot crawl yet*, the educator had *to help her to reach* the objects’	This group recognised key moments in the development of experiences where children move from observation to discovery. They also interpreted the value of heuristic play for the introduction of the symbolic game. They appreciated the relevance of the activities according to the age and characteristics of the children (for example, their degree of independent mobility and how this conditioned exploration).

Thus, in the case of the interpreting competence, we observe that the prospective teachers alluded to types of reasoning (inductive, abductive, etc.) metaphorically, erroneously referring to the visual and deductive without specifying how to verify it. They cited descriptive traits of actions associated with logical thinking capacities without offering any theoretical discussion.

After the first implementation and an initial analysis of the reports submitted by the sample of prospective teachers involved in this research, we decided to make some adjustments to the final structure of the professional task. One of the products generated by this study was a professional task that aims to mobilise the professional knowledge of prospective early childhood teachers with regard to experiences and activities that help promote logical-mathematical reasoning at the 0-3-year-old stage.

The final version of this task considered the skills that characterise professional noticing: identifying, interpreting and making decisions (Jacobs et al., 2010; Ivars & Fernández, 2018); the notion of narrative and its potential to encourage reflection on mathematics teaching and learning situations; two types of activities with non-specific material, which we consider suitable for encouragement of reasoning in children at this stage (Goldschmied & Jackson, 1994); and, lastly, specific aspects of reasoning in early childhood education such as the logical thinking skills of identifying, relating and operating (Canals, 2009). The final version of the professional task was structured in four parts (see Figure 1).

1. The future teachers were asked to explore the main characteristics of the two activities (sensory wall and heuristic play).
2. The future teachers were asked to identify the type of objects used in each activity, indicate the attributes corresponding to each object or groups of objects, and describe the actions that could be carried out with each object.
3. The future teachers were asked to associate each of the children's actions with the logical thinking skills (identifying, relating and operating) and assess the design and management of each activity studied.
4. The future teachers were asked to decide (and justify) whether or not they would again use objects similar to or the same as those employed in the two activities and invited to reflect on how they could improve the two activities in order to better understand the children's reasoning.



QUESTIONS TO GUIDE THE ANALYSIS	OBJECTIVES
1. Let us look for information Probe and describe the main characteristics of the activities described in both experiences: Sensory Wall and Heuristic Game).	Recognise the main characteristics of activities with non-specific material for children aged 0-3.
2. Let us describe the experience 2.1 Identify the types of objects that are used in each experience. 2.2 Indicate the attributes corresponding to each object. 2.3 Describe the actions that could be developed with each object (For example, put, remove, stack, etc.). We suggest you answer points 2.1 to 2.3 by making two tables such as the following: 'Sensory Wall' Activity: *Object* / *Attribute* / *Actions* 'Heuristic Play" Activity: *Object* / *Attribute* / *Actions*	Recognise the importance of object exploration in helping children identify attributes and establish relationships.
3. Let us interpret 3.1 Interpret what type of children's reasoning is evident in each of the experiences. 3.2 Associate with each of the capacities: ***identifying, relating, and operating*** with children's concrete actions. 3.3 Knowing that both the sensory wall and the heuristic game can be carried out in different ways, assess what you think of the design and management carried out in each of the activities.	Highlight relevant aspects in the interpretation of children's reasoning in different experiences. Appreciate the importance of suitability in the design of activities to be carried out with children Recognise the impact of the teacher's role in the proper development of activities with non-specific material
4. Let us make decisions 4.1 If you plan to do these activities with children, would you use other objects? Why? 4.2 What would you do to improve the proposals for activities, so that you recognise better the children's reasoning?	Identify key aspects in the selection/planning of activities with non-specific materials. Learn to evaluate the scope and limitations of different proposals. Recognise aspects susceptible to improvement in the design, planning, and implementation of proposals

Figure 1: Professional task of analysis of experiences that promote reasoning in 0-3 cycle

Final considerations

It is in the process of designing and redesigning tasks that the possibility of increasing teachers' knowledge arises. In this case, the professional tasks designed involved future teachers in what Serrazina (2010) calls the process of planning - action - reflection, which plays a fundamental role in the construction of prospective teachers' mathematical and didactic knowledge. Learning to evaluate the adequacy of activity planning and design though the analysis of other people's proposals is also a key competence that should be developed by prospective teachers. Being able to observe and study the implementation of these proposals and observe how an activity with children functions in different contexts allows the integration of both the knowledge developed during training and the observation of how certain processes actually develop in early childhood education.

Thanks to the study of the two activities (sensory wall and heuristic play), the future teachers were able to recognise different types of attributes (sensory and measurable characteristics) and interpret the link between children's actions and different types of relationships (equivalence, order, causal, spatial, etc.), as well as observing actions that indicate changes (shape, position and measurement, among others). These factors play a key role in the promotion of intuitive, informal mathematics in children under three years of age.

The professional tasks described made the prospective teachers more aware of what happens during different activities carried out with children under three. One of the tasks focused on the process of design, planning and implementation of activities to promote reasoning in the 0-3-year-old stage, while the other professional task invited the prospective teachers to evaluate the said activities in order to make decisions for their improvement. All this implies an analysis of the mathematical content, reflecting on how to organise this content in order to teach it, analysing and interpreting children's productions, and considering how this type of activity can be managed. In short, as proposed by Moreno et al. (2021), the goal is to help prospective teachers learn to notice and provide them with a wider range of resources to make effective teaching decisions.

We intend to continue developing this approach, designing and redesigning proposals to improve prospective teachers' professional knowledge and contributing material to the discussion around the type of education in mathematics and didactics of mathematics needed by prospective early childhood teachers.

The multifaceted argumentative structuring of peer interactions in block play situations: Opportunities for early mathematical learning

Anna-Marietha Vogler[1], Esther Henschen[2] and Martina Teschner[2]

Since the 2000s, early co-constructive mathematical learning in kindergarten has been the focus of political discussion and mathematics didactic research. This is based on the fact that kindergarten is the first place for subject-specific mathematical learning, alongside socialization in the family. The focus of research on this first institutional learning in kindergarten is often on the interactions between children and preschool teachers, which are depicted as a key variable for learning. Beyond this, it is the interactions between peers that take up a large part of the time in everyday kindergarten life. In these interactions, children negotiate a variety of topics that are relevant to them. In the following article, these peer interactions in block play situations and especially collective argumentation processes in these interactions are the focus of the research interest.

Keywords: Preschool children, kindergarten, collective argumentation, interaction process analysis, peer groups.

Introduction

Early learning in different contexts is of especially high importance for children's learning biographies. This also applies to mathematics. Already in their first months and years, children experience mathematical contexts and develop a variety of skills in different mathematical areas (Sarama & Clements, 2009) by interacting with others and thus participating in different early mathematical discourses. A large number of studies deal with early mathematical learning in terms of enculturation (van Oers, 2019) in interactions with adults, family caregivers and professionals in daycare centers and kindergartens (cf. Vogler, 2019). In contrast to these studies, there are only a few studies, that investigate children's mathematical exploration while playing with peers for example Flottorp (2011) and Zippert and collegues (2019). Thereby, peer interactions account for a large part of the interaction time (in kindergarten). Following Vygotsky (1978), it can also be assumed that interactions between peers, in particular, can be especially beneficial for the learning process, as these are characterised by a high degree of interactional proximity and adaptivity. The following article, therefore, focuses on such peer interactions in block play situations in a German kindergarten, which Henschen (2020) has analyzed. A special focus is placed on collective argumentation processes between peers, which, according to Miller (1987), assume a special role in learning, since they are constitutive for the construction of new (mathematical) knowledge. In this context, the question to be empirically answered is how peer interactions lead to collective argumentations that creates conditions for the opportunity of mathematical learning.

Theoretical framework

Early mathematical learning in interactions

Mathematical learning already takes place in children´s everyday life before they enter school. This initial learning occurs primarily in a co-constructive manner, and children develop mathematical content actively and through discovery in interaction. Learning, from this co-constructivist perspective, is to be seen as a process of becoming increasingly autonomous in interactions of discourse (cf. Krummheuer, 2013; Vogler, 2019). In line with this, conditions for an opportunity of learning (Miller, 1987) of "new things" are created by enabling children to actively and productively participate in the negotiation processes of discourse, thus opening up different so-called "leeways of participation" (Krummheuer, 2013 p. 253). Bauersfeld (1988) describes that such increasing autonomy is possible when children "rebuild" or "expand" their so-called "Domains of Subjective Experiences" (hereafter: DSE). These DSEs are knowledge resources that are connected to interactively meaningful action in an individual context of experience. They are activated in interaction to cope with the demands of the process of negotiation of (mathematical) meaning - to recognise what is being negotiated and how contributions can be realised.

Collective argumentations in early mathematical interactions

According to Miller (1987), collective argumentation in interactive processes of negotiation is particularly conducive to the development of such new, mathematically rich meanings, or DSEs. This is mainly because, during productive or receptive participation in collective argumentation processes, the possibilities of one's constructions or individual contextualization (based on the DSEs) are systematically exceeded (Miller, 1987). The more comprehensible and convincing the argumentation is to the individual, the more effective the collective argumentation is concerning the individual construction of new knowledge. For mathematical learning, it is of significant importance that collective argumentation is not only generally conducive to the growth of 'new knowledge' (Miller, 1987), but also determines the "thematic shaping" of the (new) individual constructions or contextualization (Krummheuer, 2013). In this context, Krummheuer (2013) speaks of the convergence function of collective argumentations. The collective and argumentatively structured negotiation process consequently conditions and influences learning. Such processes of argumentation are therefore the focus of research interest in this paper.

The role of peers in interactions of early mathematical learning

Miller (1987) considers also the adults to have a special role in the co-constructive and argumentatively structured negotiation processes described above. In early (mathematical) learning, it is referred to primarily as guardians, parents and elementary teachers (cf. Vogler, 2020). They are considered to be the persons who, through their head start in knowledge and scope of (formally) mathematically oriented DSEs, "introduce" children to the culture of doing mathematics and, in negotiation, support children in building new mathematical DSEs. In addition to adults, however, peers can also play an important role as interaction partners in processes of negotiation or argumentation and learning (Youniss, 1980). While language acquisition research focuses on these peers as important instances of language socialization in interactions in the kindergarten context (Arendt, 2019), there has been limited work in mathematics education to address the important role of peer interactions in early mathematical learning in the kindergarten context, although Henschen (2020), among others, can show that diverse mathematical content emerges in peer interactions. This research lack is particularly surprising because it can be assumed that learning in childhood occurs to a large extent through interactions in groups of children.

Research questions

Given the importance of peer interactions as a catalyst for early mathematical learning, it seems essential to closely examine the argumentative negotiation processes of peers and their contribution to the formation and restructuring of mathematical DSEs. Consequently, the questions emerge: (1) How do peer interactions lead to collective argumentations that creates conditions for the opportunity of mathematical learning? (2) What kinds of new or existing DSEs of children, resulting from these argumentative negotiations, can be reconstructed in these argumentations?

Data and method

Data corpus – Block play situations with peers in daily life at the kindergarten

The video recordings of autonomous play situations with building materials, already examined by Henschen (2020) about their mathematical content, serve as a data basis. These so-called block play situations are particularly suitable for the ethnographic observations presented here, as they represent an interaction situation that frequently occurs in the kindergarten context. Especially at preschool age, actions that enable mathematical experiences also result from the play event and from the stimulus of the play itself, as well as from the emotional proximity to the playmates.

Method of analysis

Henschen (2020) identifies in her work on block play with the help of Qualitative Text Analysis sequences that are particularly characterised by the density of mathematics-related negotiation. Starting from Henschen´s (2020) results, an appropriate example of interaction sequences between the peers from this data corpus is applied here. These interaction sequences are examined micro-analytically in terms of their thematic development and argumentative structures. The micro-analytical reconstruction of the interactions and the process of negotiation of mathematical meaning are carried out with the help of interaction analysis (Krummheuer, 2013). The argumentative structures are realised with the help of the functional argumentation analysis according to Toulmin, which has been successfully adapted for mathematics didactic research by Krummheuer (2013) and others. Thereby, argumentations are analysed with regard to their functional components and it is worked out how a conclusion (C) is drawn from existing data (D) through argumentation and how this conclusion is substantiated using warrants (W) and backings (B) (see figure 3).

Empirical example of a block play situation with peers

The situation presented and analysed in the following takes place in the block area of a kindergarten in Germany. Two boys, Ron and Max, aged 5, are building with the building material Sonos. The analysed scenes follow a building play phase in which the two boys have placed a self-made “forklift truck” on top of a “building” (Figure 1). They then decide to build a ladder so that the forklift can be reached. The design of the ladder in terms of its stability, attachment (Figure 2) and flexibility in use is the central theme of the negotiation in the following scenes. These topics show that the children are confronted with certain "construction problems". Therefore, it could be stated that the children's examination of these problems does not have a mathematical but rather an engineering focus. However, it should be noted that the solution of such problems involves, stimulates, or even requires mathematical thinking as Helenius and colleagues (2016) or Henschen (2020) shows. The children's argumentations, therefore, seem relevant from a mathematics didactics perspective.

Figure 1: Joint building action on the ladder

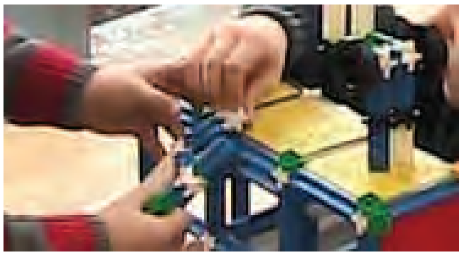

Figure 2: Fixing the ladder

Analysis of scene 1 – "And then how do they get up there?"

001	Max:	I have to fix there (incomprehensible).
002		*Actions on the building* (...)
004	Ron:	And then how do they get up there?

From the utterance in line 1, it can be interpreted that fixing the ladder is the focus for Max. The previous interaction, in which the children are looking for a solution to the problem of reaching the "forklift truck" on the building, "forces" the ladder to be fixed, from the boy's point of view. What is remarkable in the sequence is the obvious everyday world reference of Ron's utterance <4>. Ron raises the question of how anybody (for example humans) can get on the top of the building <4>. From a mathematical perspective, this construction problem focuses on the connection between two points or even two planes. Ron's question on this reveals mathematical experiences with the aspects of topography and spatial orientation (Henschen, 2020). The children seem to be in an "expert discussion" here about the design of the ladder. In this context, the question can be understood as a problem outline that requires argumentative discussion. In the sense of the Toulmin analysis, the fact that the forklift is on the roof of their construction is, therefore, the datum of the argumentation (D I), while building a ladder to get onto the roof can be interpreted as a conclusion (CI) (all argumentation elements are shown in Figure 3). It is possible that at this point Ron does not agree with Max's proposal for fastening or with the ladder and therefore asks for clarification, but this does not directly follow. In various subsequent scenes, however, it can be seen that the topic continues to be the subject of negotiation between the children: in the following turns, for example, different variants for dealing with the ladder are first considered, but without a taken as shared meaning being reached.

Analysis of scene 2 – "But they build the ladder together, you fool."

The main issue in the negotiation between the two children is whether the ladder is long enough for anybody to get onto the building and whether it is sufficient to place smaller pieces of the ladder between the 'floors' of the building. While Ron sees the solution as a construction task (to build a large ladder), Max shifts the solution to the narrative play action and pleads from line <53> that ladders can also be assembled by somebody if necessary.

052	Ron:	But otherwise they can’t get up there at all.
053	Max:	But they build the ladder together, you fool–

Here, Max’s statement can be interpreted as a narrative warrant (W I – Flexibility) for the conclusion (C I) that someone comes to the building through the ladder(s) because they assemble ladders in the course of the ‘story’. Together with the construction idea, which also becomes emergent in the following scenes (3 and 4), a non-hierarchical solution diversity is revealed here in the children’s contributions, since several warrants are identified for the implied argumentative conclusion that somebody gets onto the building with one or more ladders (C I). After some time, the two boys turn together to the construction of a large ladder from already existing sections and steadily lengthen it. In the following scene 3, the focus is on the further handling of the large ladder that has now been created in this way.

Analysis of scene 3 – “There must be a white button on it.”

080	Max:	We still have to be fixed up there.
081	Ron:	No.
082		*pulls the ladder a little in his direction*
083	Max:	So that it does not slip down. (...)
089	Ron:	No, we have to- I know. You have to put it away. Because otherwise you can’t curve it, you have to (incomprehensible).
(...)		*Construction work on the ladder* [Figure 1]
092	<Max:	No. Look at it!
093		*Runs his hand along a bar of the upper edge of the building*
094	<Ron:	There must be a white button on it. Otherwise you can’t put it here.
095		*Construction work on the ladder* [Figure 2] (...)
097	Max:	But look. Then it stretches the buttocks out backward. That’s stupid too, isn’t it?

In scene 3, the fixing of the ladder is negotiated. The need to use certain components <80>, to omit them <89> and <94>, or to pay attention to the design of the structure <97> is discussed. The different contributions can be understood as backings (B I and B II) of the warrant (W II) of the argumentative conclusion that someone can scale the building with a ladder, because this ladder is sufficiently fixed (C II) and reaches the bottom or can be fastened diagonally so that it is possible to climb up from the base of the building (W II - Anchorage). The negotiation subsequently intensifies and reaches its argumentative climax in the following scene 4.

Analysis of scene 4 – “And besides, I had the idea!”

117	Ron:	I HAVE TO FIX IT!
118	Max:	*constructs on the building*
119		No, you don't have to fix it at all.
120		*continues to construct the building*
121		Only this one has to be, simple.
122	Ron:	*stretches his hand with components towards Max and looks at Max*
123		But otherwise it can't hold.
124	Max:	It holds all-
125	Ron:	*kneels next to Max*
126		Please! (.) And besides, I had the idea!
127	Max	Look at this. Still holds.

Max statement in line <119> could be interpreted on the one hand as a support of the warrant ‘flexibility’ (W I) from line <53>; on the other hand, it could be interpreted as a further warrant of the conclusion that a ladder on which somebody can reach the upper floor must be stable (C II). This conclusion emerges in line <83> and can be interpreted as shared from line <123> onwards. With this, the children's statements in lines <119>, <124> and <127> can be interpreted, on the one hand, as a generally valid rule that even leaning ladders have this stability and can still be flexibly accommodated onto the building and, on the other hand, as justification for the above-mentioned conclusion (W III). Line <126> can also be interpreted as backing (B III) of the warrant 'anchoring' (W II). Social persuasion can be attributed to this statement by Ron. In the request, the rule can be recognized that in the building game, actions also receive their validity if they are demanded by a playmate. In a sense, it is a social warrant.

Empirical findings

Overall, the argumentation that emerges across scenes 1 to 4 can be summarised in the form of the following Toulmin scheme (figure 3).

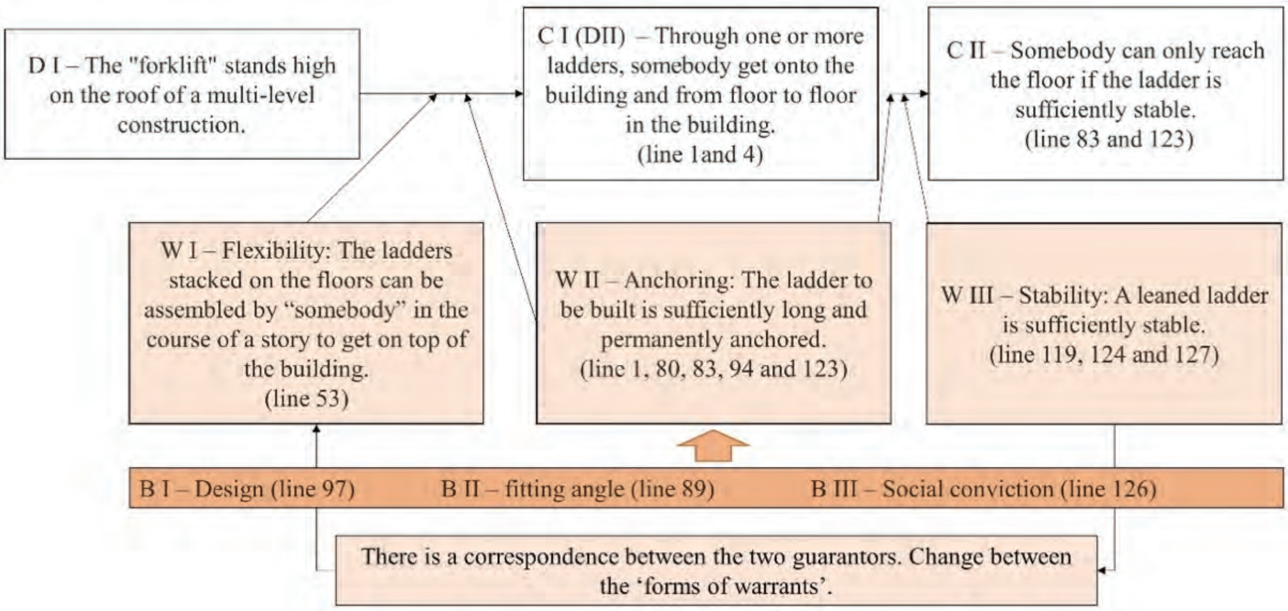

Figure 3: Toulminian argumentation scheme of scenes 1-4

In the reconstructive analyses, it becomes clear that the processes of negotiation in the block play situation with the children Ron and Max described here are structured argumentatively concerning mathematics-related content. A variety of warrants and backings which are collectively realized by the peers or negotiated over a longer time in the situation can be reconstructed. In connection with this, it becomes apparent, not least through the Toulmin schema presented, that the collective argumentation that emerges in the presented play situation has a special 'depth', as it is characterised not only by diverse warrants but also by the manifestation of supports or rules that support the validity of the securing warrants. According to Krummheuer (2013), it is precisely this 'depth' that constitutes a social persuasiveness of argumentation. The warrants and backings refer to multifaceted mathematics-oriented topics such as the stability and geometry of the structure 'ladder', with its various connections and angles of attachment, its length or its orientation in space, but also to informal, everyday considerations or domains of experience embedded in narratively structured play actions, such as the possibility that somebody can also assemble ladders to reach an elevated point.

Thus, what emerges here is not only a collective argumentation that leads to new interpretative perspectives for both boys, but there seems to be a networking of contextualised knowledge that is fostered by the varied argumentative structure. The children's reasoning processes, which are evident in the context of solving their construction problems, require and enable mathematics-related knowledge or DSEs about fixing angles, lengths, and the statics or geometry of buildings, even if the children do not (yet) negotiate this with formal or explicit mathematical expressions.

Concluding remarks

The paper aimed to work out how collective processes of argumentation emerge in peer interactions in block play situations, which create conditions for the possibility of learning "new" mathematical knowledge. Based on the theoretical approaches, analyses and empirical findings presented here, it can be assumed that it is precisely through the play situation, in which peers interact together, that many discursive degrees of freedom emerge that enable the children to construct different possible solutions and to pursue them over a long chain. Probably especially in such peer settings it is possible, for children to realise argumentative connections that are characterised by their "depth" and thus enable the development of sustainably networked knowledge. One reason why this is realised could be that the peers are interactively very coordinated because there is a symmetry in terms of power relations and a proximity in terms of their knowledge resources; both children can situationally slip into the role of the more competent other. In contrast, for example, analyses in Vogler (2020) show, in interactions in asymmetrical teaching-learning situations (e.g., with an authority figure, e.g. elementary education professionals) there is often a lack of argumentative depth. Children's participation is usually exhausted in one-word answers that appear in funnel pattern (Bauersfeld, 1988) and offer less opportunity for the sustained interconnection of knowledge. Following these remarks by Vogler (2020), it can be assumed that the adults (in contrast to the children) pursue a specific learning goal and therefore, in the case of hierarchically organised interaction roles, only anticipated responses are accepted by them in the interactional interplay. Consequently, the peer interactions seem to be less characterised by their "stringency" compared to the adult-child interactions, but they are particularly conducive to learning due to their argumentative multifacetedness, and the associated opportunity for participation and linking of informal and formal knowledge. From a pedagogical point of view, it would be advisable to systematically observe these peer interactions, to support them interactionally and to take up the negotiated attributions of meaning and argumentative structures with children afterward and develop them (professionally) further.

An educational design research on equity in early mathematics education

Maria Walla

Dalarna University, Falun, Sweden; wmr@du.se

Keywords: early assessment, design research, equity

This poster presents an educational design research study focused on equity in the Swedish preschool class. In Sweden, six-year-old students attend preschool class for one year of schooling with the aim to create continuity in early education, by relating to surrounding institutions – preschool and compulsory school. In comparison with the compulsory school, students' free choice and play is more focused on in the preschool class. According to Espinoza (2007), equity can be described as educational justice, meaning that both individual circumstances and differences related to individual needs and requirements are to be taken into consideration. In the Nordic countries, equity is emphasized as important in the creation of a "fair and equal society supporting democracy, participation, welfare, and life-long learning" (Klette, 2018, p. 59). However, since the turn of the millennium, Sweden of all the Nordic countries has departed the most from the Nordic model with a "control regime overshadowing the learning, equity and democracy agenda that is still in the curriculum" (Blossing & Söderström, 2013, p. 32). The differences between low- and high-performing students and between schools have increased, as has the significance of students' socio-economic backgrounds in terms of their educational outcomes (National Agency for Education, 2010).

According to Gutierrez (2002), equity issues can be addressed from four different dimensions: access, achievement, identity, and power. Foregrounded in this study are the equity dimensions of access and identity. In the field of mathematics education, equity can be described as "the inability to predict mathematics achievement and participation based solely on student characteristics such as race, class, ethnicity, sex, beliefs, and proficiency in the dominant language" (Gutierrez, 2002, p. 153).

The aim of this study is to explore how to design an equal education in early mathematics in the sense of an education that affords young students access to as well as prosperous attitudes towards mathematics. The basis for this study is a previous study on assessment in the Swedish preschool class. In that study the teachers talked about an increased awareness of the different needs that students have when it comes to mathematics. They described a dilemma in providing all students an equal possibility to learn mathematics, this as the students are at different levels. In addition, the teachers described the challenge with teaching students in such a way that they all find mathematics to be interesting. In this new study, the following research questions will be addressed: What does an equal mathematics education where all students have access to mathematics imply? What does an equal mathematics education where all students can develop prosperous attitudes towards mathematics imply? How can a mathematics education, that affords young students access to as well as prosperous attitudes towards mathematics, be designed?

Method

This study is developed within the frame of educational design research (McKenney & Reeves, 2012). The research approach is a case study, located within two classrooms. Educational design research can be described by five common characteristics: "theoretically oriented, interventionist, collaborative, responsively grounded and iterative" (McKenney & Reeves, 2012, pp. 12-16). In 2019, mandatory assessment material was developed and put into use in Sweden as a way to improve equity within the Swedish preschool class. Through the assessment, students' knowledge is assessed with the aim to identify what adaptions are needed for each student to meet the knowledge requirements, and for them to "reach as far as possible" (National Agency for Education, 2019, p. 1). In this study, this assessment of all students serves as a starting point of the design.

The process of generating data is defined by a number of cycles of invention and revision. Each cycle will consist of the following elements: classroom observations, student interviews, and dialogs between the teachers and the researcher. In line with educational design research, in each cycle adjustments will be made based on the two research questions. This iterative process intends to produce practical solutions based on a theoretical understanding, where the results of the research are relevant for education practice (McKenney & Reeves, 2012). The research results will be formulated as design principles, thus not only statements like what to do and how to promote equity in early mathematics education, but also theoretical and empirical explanations to support these knowledge claims (Van den Akker, 2013).

An educational design research on equity in early mathematics education

Maria Walla

Dalarna University, Falun, Sweden; wmr@du.se

Keywords: early assessment, design research, equity

This poster presents an educational design research study focused on equity in the Swedish preschool class. In Sweden, six-year-old students attend preschool class for one year of schooling with the aim to create continuity in early education, by relating to surrounding institutions – preschool and compulsory school. In comparison with the compulsory school, students' free choice and play is more focused on in the preschool class. According to Espinoza (2007), equity can be described as educational justice, meaning that both individual circumstances and differences related to individual needs and requirements are to be taken into consideration. In the Nordic countries, equity is emphasized as important in the creation of a "fair and equal society supporting democracy, participation, welfare, and life-long learning" (Klette, 2018, p. 59). However, since the turn of the millennium, Sweden of all the Nordic countries has departed the most from the Nordic model with a "control regime overshadowing the learning, equity and democracy agenda that is still in the curriculum" (Blossing & Söderström, 2013, p. 32). The differences between low- and high-performing students and between schools have increased, as has the significance of students' socio-economic backgrounds in terms of their educational outcomes (National Agency for Education, 2010).

According to Gutierrez (2002), equity issues can be addressed from four different dimensions: access, achievement, identity, and power. Foregrounded in this study are the equity dimensions of access and identity. In the field of mathematics education, equity can be described as "the inability to predict mathematics achievement and participation based solely on student characteristics such as race, class, ethnicity, sex, beliefs, and proficiency in the dominant language" (Gutierrez, 2002, p. 153).

The aim of this study is to explore how to design an equal education in early mathematics in the sense of an education that affords young students access to as well as prosperous attitudes towards mathematics. The basis for this study is a previous study on assessment in the Swedish preschool class. In that study the teachers talked about an increased awareness of the different needs that students have when it comes to mathematics. They described a dilemma in providing all students an equal possibility to learn mathematics, this as the students are at different levels. In addition, the teachers described the challenge with teaching students in such a way that they all find mathematics to be interesting. In this new study, the following research questions will be addressed: What does an equal mathematics education where all students have access to mathematics imply? What does an equal mathematics education where all students can develop prosperous attitudes towards mathematics imply? How can a mathematics education, that affords young students access to as well as prosperous attitudes towards mathematics, be designed?

Method

This study is developed within the frame of educational design research (McKenney & Reeves, 2012). The research approach is a case study, located within two classrooms. Educational design research can be described by five common characteristics: “theoretically oriented, interventionist, collaborative, responsively grounded and iterative” (McKenney & Reeves, 2012, pp. 12-16). In 2019, mandatory assessment material was developed and put into use in Sweden as a way to improve equity within the Swedish preschool class. Through the assessment, students’ knowledge is assessed with the aim to identify what adaptions are needed for each student to meet the knowledge requirements, and for them to “reach as far as possible” (National Agency for Education, 2019, p. 1). In this study, this assessment of all students serves as a starting point of the design.

The process of generating data is defined by a number of cycles of invention and revision. Each cycle will consist of the following elements: classroom observations, student interviews, and dialogs between the teachers and the researcher. In line with educational design research, in each cycle adjustments will be made based on the two research questions. This iterative process intends to produce practical solutions based on a theoretical understanding, where the results of the research are relevant for education practice (McKenney & Reeves, 2012). The research results will be formulated as design principles, thus not only statements like what to do and how to promote equity in early mathematics education, but also theoretical and empirical explanations to support these knowledge claims (Van den Akker, 2013).

Theoretical frameworks and the danger of relying on the one!

Anna Wernberg[1] and Maria Johansson[2]

[1]Malmö University, Sweden; anna.wernberg@mau.se

[2]Luleå University of technology, Sweden; maria.l.johansson@ltu.se

Inspired by Sfard we investigate the stories of teaching and learning situations using two different theories. We look at how the stories that the two theories tell are the same or different in order to answer the question about what can be gained and what will be lost when using two different theories in this case variation theory and pedagogical strategies. This is done using a video from a mathematics lesson in preschool class setting, 6-year-old children as a base and then comparing the stories that the two different theories tell about this situation.

Keywords: Theory of variation, sociological theory, domains of action, stories

Background

In this paper we use the definition of research as presented by Sfard (2018), where she states that research "is the activity of telling stories about some aspects of reality" (p.220). Using the terminology of Sfard (2018) we use two different theories and thus two different routine actions (analysis). This approach can be either using a multi-theoretical approach (Johnson et al) or coordinating different theories (de Freitas, et al., 2019). The use of theory and its necessity is an ongoing discussion (Bikner-Ahsbahs et al., 2019). In their paper, Bikner-Ahsbahs et al. (2019) give different approaches to the use of theories depending on if the theory is in the foreground or background or even if they are seen as a tool or an object in order to use as a lens. We will continue to use the vocabulary presented by Sfard (2018), when we talk about the different theories and the stories that they tell. If a theory consists of a small set of stories or narratives, which story do variation theory and pedagogic strategies (a sociological perspective) tell. The rational for choosing these theories lies in our interest and deep knowledge about them and a curiosity on what story each of them will tell when using the same set of reality. Lerman (2010) used sociological theories to claim that the use of several theories is a necessity. On this note, we use the same reality. We tell two, in some sense, different stories but they are both grounded in a common interest in teaching and learning mathematics. In this case we use a teaching and learning situation in mathematics in a preschool class setting (6-year-old children). For us it is important to spell out the primary stories, where the base for our different stories is. The base for the stories is the part of the theories that helps us perform routine actions, or in other words analyze the data. We do that by presenting the subset of stories valuable for our analysis across both theories. In the sense of asking a question about differences, we need to also address the following question: Do the two different theories add any new stories or do they just use different words to describe reality or are they even mutually exclusive? We tell the stories, that is, we craft the narratives based on the data set at hand. In this case, the data is a video of a teaching and learning moment in a preschool class mathematics lesson.

Let us discuss the word different in this case, since different is the core of the paper. Can these stories be seen as different, or do they add aspects to one another? None the less, one has to remember that from our different perspectives we have to choose which aspects to focus on. Sfard (1998) argues that there are two metaphors for learning and there is a problem of relying on just one of them. Inspired by this idea we argue that to tell the stories of a learning situation we would benefit from using different theories to tell different stories about the situation at hand. Still, we know different theories make us ask different questions and hence tell different stories.

Theoretical frameworks

In order to answer our research question, what can be discerned in the narrative using two different analytical tools, we use Variation theory (Marton, 2015) and Pedagogic strategies (Dowling, 1998) (a sociological perspective) in our routines (method of analysis) of a videoclip from a preschool class.

Variation theory

Although variation theory was developed in school-settings about 20 years ago it has also been used as a theoretical tool in preschool-settings (e.g., Björklund et al, 2021; Wernberg, 2017). Marton (2015) describes how learning means a qualitative change and a more developed understanding of knowledge. The understanding is developed by distinguishing more and more aspects of phenomena in the outside world (e.g., mathematical and mathematical didactic concepts) and giving meaning to the one who distinguishes them. The distinction presupposes an experienced variation of these aspects. Here we have mainly adopted the notion of critical aspects and critical features, while also adhering to the assumptions of the overall theory. One theoretical assumption is that learning is always the learning of something, and the ability to learn presupposes an experience of variation. Critical aspects can be defined as necessary features to be discerned for learning the object of learning. To understand what it is that enables learning in one situation, one can illuminate what varies and what is invariant using contrast. This pattern of variation is created by patterns of variation of the same aspect (Wernberg, 2009). The difference between a critical feature and a critical aspect is that the latter refers to a dimension of variation and the former is a special value in this dimension of variation. To discern something, it is necessary to experience a variation. In Figure 1 we use one pattern of variation, contrast, making it possible to distinguish the difference between a triangle and a rectangle/quadrilateral. It opens up a dimension of variation, geometric shapes, where triangle is a value in this dimension of variation.

Figure 1: Critical aspects and features

“Values correspond to features, and dimension of variation corresponds to aspects… A critical aspect is thus a critical dimension of variation and critical features is critical value" (Marton, 2015, p.47).

Pedagogic strategies (a sociological perspective)

The following theoretical perspective is based on Dowlings (1998), analysis of high school textbook series and redefined by Johansson (2012) for use in a mathematics classroom and in the interaction between students and teacher. The redefined method of analysis by Johansson (2012) has also been used in preschool and preschool class settings by Helenius et al (2018). Dowling (1998) describes four domains of action and a set of strategies within those domains. The four domains where esoteric, descriptive, expressive and public. These four domains were distinguished in two different ways based on content (signifieds) and expression (signifiers) and whether they were strongly classified or weakly classified. The domains of practice are shown in Figure 2.

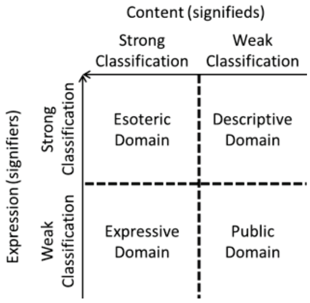

Figure 2. Domains of practices (Dowling, 1998, p. 135)

A mathematical activity in a teaching and learning setting uses all these four domains. However, the boundaries between these domains are not sharp and hence it is not always easy to separate them from one another. In order to clarify the impact of practices in these domains Dowling (1998) elaborated on a series of pedagogic strategies. These redefined pedagogic strategies are then used as a methodological tool for interpreting interactions (Johansson, 2012).

In a preschool class setting where the mathematical activities contain tasks that are not strongly classified regarding content or expression, the different strategies that come to use contribute to the development of more or less generalised mathematical knowledge or more or less localised knowledge.

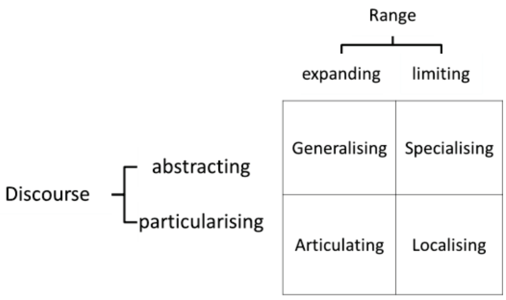

Figure 3: Distributive strategies (Dowling, 1998, p. 147)

As seen in figure 3, the four strategies are categorized in terms of range and discourse. When it comes to range of possible solutions, the strategies are categorized regarding whether they limit or expand the range and, in the same manner, regarding if they support an abstracting or particularizing discourse. The pedagogic strategies are used by both teacher and children and in one utterance the children and the teacher vary in their use of these strategies hence it is used in a microlevel analysis where each part of the dialog is categorized. The following description is based the redefined pedagogical strategies by Johansson (2012) and the examples is from the age group that is present in the situation at hand.

The *Specialising* strategy separates different cases or methods or concepts. In this strategy the children or teacher use specific ways when discussing the task or solution; this also means using specialised terminology. For example, using addition or subtraction. Since this strategy separates the methods or concepts, it reduces the range of possible solutions. However, it can contribute to the children's understanding of a concept or method. The *Generalising* strategy, on the other hand draws on different cases in relation to a common principle and so this strategy is expanding the range of solutions. Hence, it provides an understanding of how a common principle can be used in different settings and cases. These two strategies provide the children with opportunities for discussing and understanding the mathematical practice and the underlying principles. Specialising does this by providing opportunities to discuss differences in examples or cases and generalising does this by providing opportunities to discuss the commonality in examples or cases. Some examples of specialising are solving a word problem and modelling. Examples of generalising could be finding an appropriate drawing to illustrate an argument or applying a solution method to a range of different examples.

The *localising* strategy constructs one particular example but does not give the children any opportunities to engage in a mathematical discourse. The *articulating* strategy on the other hand highlights different examples, but these examples are not connected to any mathematical principle and so it is not possible to generalise from this in a mathematical discourse. These two strategies occur in preschool and preschool class settings and, by not making the connection to the mathematical discourse, the children must themselves determine what knowledge to be used in solving the tasks. If the children cannot determine that they should use generalising or specialising strategies, the mathematical discourse will not be visible.

Perceptual mediator - Data

The research was undertaken in a Swedish preschool class where most of the children were six-year-olds. Preschool class is the first place children have contact with formal school knowledge and ways of working. In the first half of 2013, video recordings were made on four separate occasions in one preschool class in Sweden. The preschool class had two different teachers and the video recordings captured a range of different interactions, set up by one or other of the teachers. We had asked to film problem solving tasks and later a free play situation. In this paper a part of one problem solving lesson is analysed. The teacher initially reminded the children about the activity previously done; They had asked different people if they preferred chips or candy and put the result in a bar chart (cubes on top of each other).

Figure 4a: The teacher coloring the cubes **Figure 4b: The teacher showing the newspaper bar chart**

The teacher colored the cubes to get the children's attention on the importance of making the cubes evenly high (figure 4a). Thereafter she showed a bar chart from a newspaper where you only could discern the height when comparing the different bar charts (figure 4b). Then again, she reminded the children about an earlier episode when she had asked the children to vote on a book to read in whole class. She took two books and put eight equally small blocks in front of one book and four bigger blocks in two different sizes in front of the other book (figure 5).

1 Teacher: Which pile became the largest, who received the most votes?

2 Children: That one. [Most of the children point at the pile with four cubes]

3 Teacher: Yes, is that the book that then won?

4 Children: No.

5 Teacher: Well, that pile is the biggest?

6 Theo: Well, it's not, check it's one, two, three, four blocks. One, two, three, four, eight, nine, no. Yes, but it's that one, that one has at least smaller blocks.

7 Klara: Eight

8 Teacher: Eight in that, and that one has only four. Well then, I say that is the biggest [the teacher points at the pile with four blocks] then I choose that book.

9 Children: No.

10 Teacher: But, why not?

11 Theo: Because it has four blocks, and four blocks are less than eight blocks.

Figure 5: Placing the blocks in front of the books

12 Teacher: Yes, that’s right, but if this were stacks then as it will be there later, then you do not see these boundaries [once again, the teacher pulls out the diagram from the newspaper, with no visible blocks, and compares it with the one they made for candy and chips, with visible blocks].

13 Teacher: That is why it is very important that we draw all the way up to the number. And here, all the way up to second. Do you remember that someone wanted to do a little less here so we had to sort of pull it up to the line? It is very important that it is right in both directions. It was chips and so it was up to the number. So, if we were to draw this, four, it would be there, right? And here is? How many were there now?

14 Children: Eight.

15 Teacher: Then it was eight here.

Routines – methods of analysis

In this part, we present the separate analysis for the teaching and learning situation in mathematics in the preschool class setting using variation theory and sociological theory. The analyses were made in parallel and were undertaken by one or the other of the authors (Wernberg VT, Johansson SP) and then discussed. The rationale for both the research question and the analysis is the authors different theoretical backgrounds which has been present in other common work where questions/curiosity have been raised due to this difference in their background.

Story - Variation theory perspective

In the introduction to the assignment, the teachers open up for a dimension of variation by contrasting the two diagrams: The one made in the classroom with the pupils and the one from the newspaper (figure 1a and 1b). Thereby, the teacher opens the ability for the children to discern one critical aspect, the importance of the "cube" being of the same size. The same size is, thus, a value in the aspect size with the values big, small and equal.

In the utterance (line 1) the teacher draws the children's attention to the two piles of blocks in front of her to, again, make them aware of the importance of the blocks being the same size. One pile with eight small books with the same size and the other pile with four bigger blocks with two different sizes. In line 8 she challenges the children's understanding by claiming that the children mostly voted on the book with four cubes in front of the book since that pile is the highest. Here, the teacher opens up for a dimension of variation by using blocks of different sizes in the highest pile and blocks of the same size in the lowest pile. Again, she opens up for the children to discern the critical aspect, same size, but in a different way. Here, she contrasts the height of the piles with the total number of the blocks in each pile.

In the end of this assignment (line 12), the teacher invites the children to look at the different diagrams, the one they made and that from the newspaper, to make them aware of the different appearances. Again, she opens up for the children to discern the critical aspect, same size, but in a third way. Here, she contrasts the bar chart from the newspaper with the data the children collected and put in a bar chart. It is when the two diagrams are being discussed at the same time through contrast it is made available for the children to discern.

Story - Sociological perspective

In the beginning of this utterance (line 1) we can see that the teacher is using a specialised language but is ending the sentence with a localising question. She is using the task at hand, namely asking: "Which pile became the largest, who received the most votes?". The children are specialising when most of them are replaying on the first part of the question: "which pile became the largest?". The teacher is then continuing with localising the discussion by asking: "Yes, is that the book that then won?" (line 3). The children then reply to the question with a "no" and the discussion continues by generalising and arguing why a large pile with few blocks is not the pile that has the most blocks (line 6-11). In this part the teacher is localising and specialising, and the children are specialising by focusing on the number of blocks at hand.

In line 8 the teacher is first responding to the students talk about the numbers of block: "Eight in that, and that one has only four". Then, she is localising by again taking the question back to the task of which book is most popular; she says: "Well then, I say that is the biggest then I choose that book". The children reply by generalising. By using two of the strategies, shifting between the discourses abstracting and particularizing, the teacher gets the students to generalise. Even though she does it on the limiting range, she still manages to get the children to generalise and see the point that she is trying to make. The interaction continues in this pattern. We can see that the teacher is shifting between localising and specialising and finally gets to the point where she can give the children an esoteric point with a specialised language (line 14). She is presenting how to make a bar chart.

Results

In this section we will highlight the findings from the analyses when exploiting the same data but two different theories. To be more precise, since research in mathematics education narrates the process of teaching and learning mathematics, the analyses of the same data (perceptual mediator) can be seen as two methods of analysis (routines) with its own keywords.

The most obvious differences between the stories are the depth of the mathematical discourses. The pedagogical strategy (sociological perspective) offers an insight to how the mathematical content is understood in a broader story in relationship to the discourse, while the theory of variation offers a more detailed description of the mathematical content. In the pedagogical strategy the routine reveals the vocabulary pattern, localising and specialising, the teacher is using to get the children to grasp the mathematical content being taught (how to make a bar chart) and she is given the opportunity to give the children an esoteric point with a specialised language (see figure 2 and line 14). If we look at the other analysis done with variation theory, the story comes closer to the mathematics being taught in the routine (method of analysis).

Maybe one could have predicted the findings because of the different possibilities the various routines offer, but as stated in the beginning of the paper we are not interested in discussing the possibilities of combining them but rather look at how the stories are the same or different to answer the question about what can be gained and what will be lost when using two different theories? In their paper Bikner-Ahsbahs et al., (2019) argue for the danger of becoming blind to aspects that a theory does not capture. We find that the pedagogical strategy revealing the discourse of language and how the teacher using questions make the children aware of how to construe a bar chart, while the theory of variation afforded opportunities to follow the mathematics being taught. So, the stories are different and give us different perspectives. However, by using both of them on the same situation it might be so that other questions can be asked and yet another story told.

Conclusion

We are aware that in general different theories ask different research questions to the same perceptual mediator (data) and thus get different stories. In this paper, we do not ask explicit research questions to the perceptual mediator, even if each analysis contains an implicit question. This means that we tell the story from two different perspectives, regardless of the research question. Hence our conclusion forms new research questions. More data needs to be analysed and the analysis compared in order to get answers and not only new questions. Johnson et al (2019) linked theory and method in their research design for an expansion of design possibilities. In this paper we used “an old” episode and analysed it, but could we like Johnson et al integrate theories, and thus their different epistemological roots?

Introduction

TWG14, *University Mathematics Education* (UME), was launched in CERME7 (Nardi et al., 2011) acknowledging the fast growth of research in UME, as well as some specificities proper to UME. Some of these specificities are: the abstract, formal nature of a significant portion of the mathematical content; the absence of national curriculum guidelines, leading to great variations in organization and practices across institutions; the general lack of systematic preparation for teaching; and, the volume of content to learn in a short period of time and the degree of autonomy expected from students. The consolidation of this research area, both outside and inside CERME, is visible through the number of UME-related activities in the last years: the publication in 2014 of a special issue about theoretical frameworks being used in UME research; the creation in 2015 of the *International Journal of Research in Undergraduate Mathematics Education*; the creation in 2015 of the *International Network for Didactic Research in University Mathematics* (INDRUM), which since 2016 has launched the biannual INDRUM conferences (an ERME Topic Conference) with associated special issues in journals (IJRUME and IJMEST) and the book *Research and Development in University Mathematics Education* (Durand-Guerrier et al. 2021); and, the organization in 2019 of the first *Calculus in upper secondary and beginning university mathematics* conference, to cite just a few.

In 2021 and 2022 we celebrated important anniversaries for the UME field: in 2021, the 10th anniversary of the creation of TWG14, the 30th anniversary of the publication of *Advanced Mathematical Thinking* (Tall, 1991), and the 20th anniversary of the publication of the ICMI study *The Teaching and Learning of Mathematics at University Level* (Holton, 2001); in 2022, the 15th anniversary of the emblematic handbook chapter *Mathematics Thinking and Learning at Post-secondary Level* (Artigue et al., 2007) with the follow-up chapter 10 years later, *Post-Calculus*

Research in Undergraduate Mathematics Education (Rasmussen & Wawro, 2017). For all these reasons, CERME12 provided an opportunity to celebrate UME research and to discuss its future.

This year, we received 41 paper and 9 poster submissions, with 27 papers and 14 posters presented at the conference and published in the proceedings. This number of presentations led to the decision to have parallel session in two groups (TWG14A and TWG14B) addressing six themes (see below). We also held some common sessions to discuss transversal issues and recent achievements and challenges in UME research. This introductory paper summarizes the works presented in both groups organized according to the six themes, as well as the common discussions.

As in previous CERMEs, a significant number of papers focused on *students' learning of mathematical topics and practices* (9 papers), such as Calculus, reasoning, and proof. Compared to CERME11, we received less papers in total (27 vs. 35) with some variation in the distribution in each theme: the number of papers addressing *teaching and teachers* decreased from four to three; the number of papers addressing *students' identity and experience* went from three to five; the number of papers addressing the *use of mathematics by non-specialists* remained the same (two); and, the number of papers in *interventions* decreased from seven to two. The CERME11 theme about resources and curriculum (five papers) became the new theme on *teaching and learning with digital resources* (six papers). Finally, studies on transition (a theme in CERME11) were discussed within the six themes above. In the next section, we briefly present the six themes with examples from paper contributions. While many papers could fit in more than one theme, this classification helped structure our work at the conference and the presentation below.

Themes and contributions

Students' learning of mathematical topics and practices

Ten papers (Baldino & Cabral; Borji et al.; Karavi & Mali; Körtling & Eichler; Noah-Sella et al.; Rogovchenko & Rogovchenko; Spratte; Utsch; Wallach et al.) and six posters (Beran; Fuchs; Hanke; Oldenburg et al.; Piroi; Vincenzi) were classified under this theme.

These studies investigated different mathematical areas, with Calculus being the dominant (Baldino & Cabral; Fuchs; Körtling & Eichler; Noah-Sella et al.; Oldenburg et al.), including advanced Calculus topics such as multivariable functions (Borji et al.), convergence of sequences (Utsch) and differential equations (Rogovchenko & Rogovchenko). There were also studies focusing on Linear Algebra (Beran; Piroi; Wallach et al.), Complex Analysis (Hanke; Karavi & Mali), and Abstract Algebra (Beran). Finally, one paper was on students' proof reading (Spratte) and one poster on incommensurability in regular polygons (Vincenzi).

Some of the papers discussed students' learning (Körtling & Eichler; Spratte; Utsch) focusing on students' definitions (Körtling & Eichler), their intentions when reading proofs (Spratte), and students' connections between their concept images and definitions (Utsch). There were also studies that discussed teaching innovations (Baldino & Cabral; Beran; Borji et al.; Fuchs; Piroi) focusing on visualization in Linear Algebra (Piroi); the connection between Calculus and modeling techniques in Physics (Fuchs); the introduction of the Fundamental Theorem of Calculus using discrete graphs (COVID-19 graphs) and then moving to continuous graphs (Baldino & Cabral); the use of mathematical structures (Beran); and, the introduction of activities designed using APOS theory (Borji et al.). Other studies investigated experienced and less experienced learners (Noah-Sella et al.). Finally, there were studies focusing explicitly on teaching resources and lecturers' practices (Hanke; Karavi & Mali; Rogovchenko & Rogovchenko; Wallach et al.). These dealt with definitions in textbooks (Hanke), the potential of Linear Algebra tasks to assist in transitions between multiple discourses (Wallach et al.), an investigation on differential equations tasks in terms of assessing students' conceptual understanding (Rogovchenko & Rogovchenko), and the proving routines used by a lecturer in Complex Analysis (Karavi & Mali).

Teaching and learning with digital resources

Six papers (Albano; Broley et al.; Davies et al.; Donevska-Todorova & Turgut; Gueudet et al.; Przybilla et al.) and one poster (Thoma & Iannone) were discussed in this theme.

Some authors considered the use of *traditional* technologies: Broley et al. explored the issue of learning programming for mathematical investigations with the Anthropological Theory of the Didactic (ATD – Bosch et al., 2020). They established an epistemological reference model and investigated a student's praxeological equipment. Gueudet et al. studied a similar issue with the instrumental approach (Gueudet, 2017), focusing on the social aspects in the schemes developed by students and associated to the programming artefact.

Other authors considered relatively *unexplored* technologies: digital assessment and its use by university teachers (Davies et al.) or an automated theorem prover and its impact on students' reasoning (Thoma & Iannone). Digital maps also seem to be a promising new tool, with different intended uses, such as fostering students' collaborative work and their conceptualization processes in Linear Algebra by connecting different representations (Donevska-Todorova & Turgut). Experts can design digital mathematical maps to evidence connections between secondary school and university mathematics (more precisely Geometry, in the study by Przybilla et al.).

As we mentioned above, the theme of digital resources was new in TWG14. One of the reasons for the emergence of this new theme was the COVID-19 pandemic, which was evoked in several papers and played a central role in the study by Albano around the new orchestrations required in the context of hybrid teaching. The generalized use of digital platforms in university courses and its consequences were discussed in TWG14 and identified as directions requiring further research.

Students' identity and experience

Five papers (Gandell; Göller; Kontorovich & Greenwood; Mullen & Cronin; Rasmussen et al.) and one poster (Nardi) were presented and discussed in this theme.

Three of the contributions to this theme focused on students' in-class experiences. Gandell investigated students' spontaneous mathematical thinking in movement, illustrating how this approach offers new insights into students' mathematical knowing. Kontorovich and Greenwood investigated student experiences with proof in a Topology course, where students were provided with opportunities to prove the same mathematical statement in different social situations. Rasmussen et al. analyzed the individual and collective mathematical progress of one small group of four students in an inquiry-oriented differential equations classroom as they reinvented Euler's method.

The other three contributions focused on students' out of class experiences and identity. Göller investigated first-year mathematics students' everyday coping strategies while dealing with the challenges they face transitioning from secondary to university mathematics. Mullen and Cronin described a suite of online and in-person mathematics supports designed for in-coming first-year university students. Finally, Nardi took up the question of how well undergraduates understand the actual work that mathematicians do and argued that more needs to be done to make this work more visible and salient for undergraduate mathematics students.

Teaching and teachers

Three papers (Nseanpa & González-Martín; Tabchi & Sabra; Viirman) were in this theme.

The first two papers paid particular attention to the use of resources in teaching, building on the documentational approach (Gueudet, 2017). Tabchi and Sabra investigated the connection between the teaching practices of a lecturer at a Lebanese university and her activity as a researcher in Graph Theory. The lecturer herself perceived little connection between the teaching and researching aspects of her work, but analysis of her teaching practice and use of resources revealed such connections, for instance, regarding the use of generic examples. Meanwhile, Nseanpa and González-Martín, in a study of the teaching of derivatives at the pre-university level in Cameroon, focused on how strong institutional constraints shaped teachers' practices and use of resources. These constraints included a prescribed textbook, official teaching guidelines and a high-stake national examination. Findings indicate that national examinations strongly influenced the didactical choices of teachers concerning the teaching of the derivative, shaping, for instance, the way derivatives are introduced. Calculus was also the topic of the paper by Viirman, which otherwise has quite a different focus from the first two papers in this theme. Viirman analyzed a set of 14 national accounts, written by experts in the field, of the teaching of Calculus in secondary education, at university and in teacher education. Differences and similarities between the accounts were highlighted, and findings were used to discuss how Klein's second discontinuity plays out in different countries around the world.

Interventions

Two papers (Albano et al.; Markulin et al.) and three posters (Akrouti; Dreyfus et al.; Vourenpää et al.) were presented under this theme.

The research work presented by Albano et al. addressed the development of the problem-solving competence at the university level. In particular, they presented the design, implementation, and analysis of an activity in Topology. Markulin et al. discussed the use of Study and Research Paths (SRP) in statistics courses. We return to this paper in the next section.

Regarding the posters in this theme, they discussed activities designed for the teaching of integrals (Akrouti), the use of flipped classroom formats (Vourenpää et al.), and the development of a methodological approach for characterizing the interplay of mathematical progress across individuals, small groups, and the whole class (Dreyfus et al.).

The use of mathematics by non-specialists

Two papers (Florensa et al.; Hitier & González-Martín) and two posters (Feil & Strauer; Schmitz et al.) were presented under this theme.

The two papers of this theme and one in the previous theme (Markulin et al.) used ATD as theoretical framework to address issues related to mathematics for students who did not chose mathematics as their main subject. Markulin et al. presented an analysis of the conditions and constraints affecting the implementation of SRPs in statistics courses at university level. Florensa et al. drew on ATD to analyse the discontinuities of the mathematical education of engineers. Finally, Hitier and González-Martín conducted a praxeological analysis of the use of the derivative by students in post-secondary institutions concurrently following Calculus and Mechanics courses. The use of gaps in worked-out examples (Feil & Strauer) and of application examples (Schmitz et al.) were also discussed.

Transversal issues addressed in plenary discussions

Resources (including digital) and interventions

The focus of this discussion was on interventions and digital resources and was organized around four thematic areas: design and sustainability of interventions; nature and impact of interventions; design of digital resources and use by teachers; and, digital resources and students' learning.

In relation to the design and sustainability of interventions, collaboration of mathematics education researchers with teachers with mathematics or non-mathematics specialty (e.g., physicists, biologists, etc.) is pertinent and necessary. However, practice highlights tensions in such collaborations, which calls for systematic studies of what makes those collaborations work effectively. Additionally, more evidence is needed on the sustainability of interventions. In this sense, it seems that having a community already working together helps the initiation and stability of changes. Our discussions also suggested that institutional and socio-cultural perspectives have the potential to capture the development of such changes. Moreover, there is an overall agreement that the pandemic has triggered significant changes to UM teaching and learning practice. Digital resources obviously played a significant role in those changes; however, doubts were expressed about whether and which of those changes will remain. Other questions we discussed are: Have online practices changed practices and interaction with mathematical content? If writing mathematics by hand is important, how can online platforms support mathematical communication effectively?

In relation to the nature and the impact of interventions, it seems that there is a variation of models regarding design and expectations. Several interventions aim towards inquiry-based learning and more student-centred approaches. However, the nature of those interventions is influenced by institutional characteristics. Consideration of such institutional characteristics should be critical in future investigations. Furthermore, clarity on the aims of proposed interventions is essential. Such clarity can assist the evaluation of the impact of interventions. Such impact is discussed in recent studies also in relation to specific student demographic profiles (gender, socio-economic status, etc.), a discussion that opens new opportunities for research on equity and access issues at UM.

Regarding the design and use of digital resources by teachers, some papers addressed new types of technology, such as theorem provers or digital assessment by indicating the pertinence of research into innovative technologies, in particular artificial intelligence, for future works. Other studies that are necessary concern teachers' use of digital resources (and how we could support productive uses and orchestrations), theoretical approaches and methods that can be appropriate to analyse the design and use of technology at UM (and the possible differences with other educative levels), and the short- and long-term impact of the COVID-19 pandemic on practices related to the use of technology (e.g., teachers' use of flipped classroom approaches during the pandemic may continue).

Finally, regarding the use of digital resources and students' learning, we discussed the importance of identifying some consequences of technology use on learning, as well as on the epistemological level of the mathematics taught and learned. We also discussed the importance of theoretical and methodological approaches to address these issues, and of assessing the short- and long-term impact of the use of technology during the COVID-19 pandemic.

Students' identity, experience and learning (including non-specialists)

Regarding these issues, we saw some innovative contributions at the tertiary level: the analysis of data about movement and its role in mathematical activity, the analysis of the individual-collective dynamic, models to study different transitions for non-specialists (pre-university to university; university to workplace; between mathematics courses and non-mathematics courses), studies about advanced topics (such as Topology and Complex Analysis), and studies about students' appreciation of mathematics (for instance, in support centers, or with non-specialists). We also discussed the methodological challenges for some of these studies and how to upscale them.

Among the main challenges for the future, we discussed those related to remote teaching (for instance, how to assess, how to consider communication) and its impact on students' learning and experience of mathematics. Another issue of interest is that, to better understand the experience of students in programs for non-specialists, we need to better understand how mathematics is used (or not) in other disciplines. These studies can also open new perspectives about students' appreciation of mathematics, their identity and experiences. Such studies have the potential to move beyond a decontextualized investigation of students' learning of specific topics.

We also discussed some potential challenges on research findings dissemination, such as the communication of research data related to innovative topics (e.g., students' movement, or how to share the large amounts of data that can be collected during remote teaching). Another challenge concerns the replication of studies conducted in other education levels with consideration of the cultural and institutional characteristics of UME. Also, some of the issues discussed in our group are not UME specific. These observations call for more interaction with other CERME groups.

Supporting university mathematics teachers and teaching

Research on UM teachers and their teaching has been gaining attention in recent years. However, research related to UM teacher education and professional development is rather scarce (Winsløw et al., 2021). Overall, there is a variation of practices and approaches on the preparation of UM teachers and the support they need for their profession. With this in mind, we opened the discussion around two questions: "What support for teaching do mathematics teachers have access to at your institution?" and "What would you like to see in research on UM teachers' support in the next years?"

Regarding the availability of support, practices shared by participants in the group confirm the variability mentioned above. Very often teacher education and support is non-mathematics-specific, with attention to general skills such as use of digital resources, organising lessons, engaging with educational literature and developing pedagogical practices. Mathematics-specific support often relies on ‘local’ projects supported by individuals or small teams. The proximity between mathematics and mathematics education departments seems to influence the interaction between mathematics teaching and research on mathematics teaching. Sustainable models of mathematics-specific teaching support seem to be those that are institutionally embedded and maintain mutual participation of mathematicians and mathematics educators. Institutionalized acknowledgment of and support for teachers and teaching-developmental activities (e.g., release of time, accreditation, funding) is also mentioned as a factor facilitating interventions and other teaching-related projects.

Education and support for UM teachers is an emerging area of research with need for further studies. Suggestions for future research proposed in our group include the study of the role of institutional structures on the support for mathematics teaching; the preparation of new or graduate teachers; the investigation around support for non-mathematics specialists who teach mathematics; and, the identification of the characteristics of productive collaborations between mathematics education and mathematics communities (see a recent publication by Goméz-Chacón et al., 2021). Furthermore, developmental research projects in this area should be more attentive to designing, implementing and evaluating pedagogical interventions towards institutional change, including the development of appropriate resources (design principles and implementation) for UM teaching.

Reflections and ways forward

We can see that many notable contributions of this year, as well as challenges for the future, are in line with the overview on CERME research in UME identified by Winsløw et al. (2018): (a) *what is it?*, namely research into current practices of UME (with no direct intervention), such as: mathematical content; methods and resources; transition phenomena; student experiences; and, teaching non-mathematics specialists; and (b) *what could it be?*, namely developmental or experimental research, that includes an intervention design as part of the research project (e.g., research on, and for innovation in UME; i.e., interventions in specific courses or programs) and professionalization of UME practice (preparation of mathematics teachers).

In our discussions, the different impacts of the pandemic on many aspects – such as teaching and learning, conducting research or collecting data – appeared as an important point for the research agenda. This impact may lead to more studies considering technological issues in UME research in the coming years. Other important topics are in line with those identified in CERME11 (González-Martín et al., 2019): 1) the establishment of different types of collaborations and the development of theoretical tools to study them; 2) the study of complex phenomena, and the networking of theories (or the use of theories from other fields); 3) the need for large-scale studies and replications to consolidate results; 4) the development and testing of innovative research methods and data collection procedures; 5) the identification of the cultural, institutional, and local characteristics in some studies, and how changes in these factors may influence studies and results in other contexts; and, 6) studies on new or understudied topics, such as equity, access, and inclusion in UME.

We believe the first ten years of existence of TWG14 have brought many advances in our field, and we predict more important contributions in the years to come. We are confident that the coming CERME conferences will allow us to pursue research on the areas and questions discussed this year, to address and propose implementations for practice, and to open new areas for investigation.

Students' process of learning integration in an adidactical situation at the first year of University

Inen Akrouti

Virtual University of Tunis & University of Carthage, LaRINa, Tunisia; akroutiinen@yahoo.fr.

Keywords: Integral, adidactical situation, approximation process

The integral is one of the most important topics in Calculus and is difficult to understand for many students. When solving definite integral application problems, previous research has emphasized that students found the antiderivative procedure more useful and easier than the approximation process or area (Akrouti, 2020). Kouropatov and Dreyfus (2014) argue that "students rarely acquire comprehension regarding the integral concept; rather, even in the best cases, students acquire no more than formal techniques for the solution of specific exercises and problems" (p. 533). Students have a great overreliance on algebraic representation. Some authors explain the difficulties by a lack of understanding of the multiplicative structure of integral (Orton, 1983; Sealy, 2014), a poor understanding of the rate of change (Thompson, 1994), and resistance toward accepting accumulation as a function (Kouropatov & Dreyfus, 2014).

To improve students' understanding of integration and deepen their knowledge, I propose an approach based in a physical phenomenon. My idea consists in that the formal definition should emerge from informal ideas that are intuitively clear. Students should use a form of intuitive knowledge through their interaction with the real world. In addition, these types of knowledge lead them to work with their personal experiences (Moreno-Armella, 2014). This approach consists of presenting a situation to introduce the definite integral where students are invited to implement an approximation process through which its underlying structure could progressively emerge (Fig. 1). My goal is to investigate how students understand the underlying structure of integral when working with an adidactical situation. The framework guiding the analysis of student understanding is based on Bloch and Gibel's (2019) Calculus Knowledge framework.

Data from this study is from a larger data set, which included audio recordings of two instructors teaching the Riemann integral. Students participating (18 students were present in these lessons) in this study were attending a first-semester course in calculus. In February 2020, I suggested the situation to a group of students (19/20 years old) enrolled in the first preparatory year of Mathematics-physics (MP) at IPEIT (Institut Préparatoire aux Ecoles d'Ingénieurs de Tunis). In preparatory classes, the courses are organized into lectures and tutorials that each lasts two hours. I developed a detailed analysis of the lectures on the Riemann integral. Observation of these lessons allowed me to see the interaction between the teacher and the students.

The analysis of the data collected emphasizes two obstacles encountered by students. The main one was how to consider the bar as a set of points. In fact, a few students viewed the bar as a continuously distributed line and then considered it as a collection of point masses. Therefore, they used the total mass divided by the total length of the bar. Then, they considered the length of the bar as a proxy for the number of points in order to implement an acceptable expression for dr.

The second obstacle for students was how to evaluate an infinite sum of products. In fact, it is a question of confusion between the limit of a sequence that converges to zero and the sum of an infinite number of terms of this sequence.

Through this research, I hope to be able to design activities for students about integration that develop their understanding of underlying integral structure and improve how integral can be used in physics phenomenon.

The proposed situation

Evaluate the force of gravitational attraction between a punctual mass m of 2 kg and a continuously distributed bar of 6 m long and mass of 18 kg in the position below:

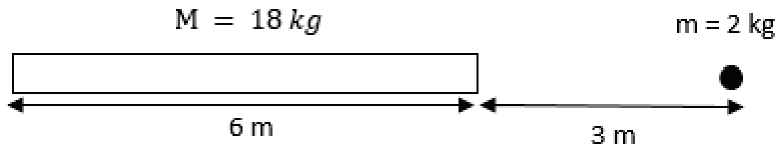

Figure 1: The bar situation

Orchestrating affective, cognitive and metacognitive dimensions of undergraduate mathematics learning in digital environments

Giovannina Albano

University of Salerno, DIEM, Italy; galbano@unisa.it

This paper focuses on the notion of orchestration and explores its possible meaning in digital environment in the new distance/blended setting caused by pandemic. I review the literature about the concept of orchestration. Starting from the description of a learning scenario, the emergence of a new possible meaning of orchestration arises and some insights for further research are given.

Keywords: university, orchestration, digital environment, blended learning

Introduction and context of the study

This paper wants to contribute to the debate on the theoretical construct of orchestration. The metaphor of orchestration has been largely exploited in education, both in mathematics education research and in research about technology-enhanced learning environments. However, the recent new context of digital education created by the pandemic, involving distance or mixed forms of participation in lessons (all the students at home or some students in the classroom and others at home), seems to highlight a needed evolution of the concept of orchestration.

The study is embedded in the such a context of distance learning caused by the pandemic. University courses moved to digital platforms for synchronous lectures (in our case Microsoft Teams), supported by Learning Management Systems (in our case Moodle) for providing students with materials and individual or group learning activities. According to previous studies, our experience in teaching mathematics courses (especially Linear Algebra) for freshmen engineering students confirms that the didactic contract rules of the teacher and of the students are not aligned:

> At the mathematics (subject) level, both in the UK and in France, the lecturer expected that the text of the lecture would be used by the students, not only to learn and understand the concepts, but also as a model for certain mathematical practices, in particular mathematical proof. In France, we observed that the novice students did not adhere to this rule, and searched for worked examples (as models for such practices) in different kinds of resources such as their tutorial notes, textbooks and websites. […] students were searching for worked examples trying to reproduce techniques (Gueudet & Pepin, 2018, p. 69, 71)

This is even more true in degree courses (such as Engineering degree) where mathematics is considered as a service subject, which often leads students to make the equivalence between learning mathematics and learning (by rote) mathematical procedures. In order to fostering change in students' attitude towards mathematics learning, I started to be interested in designing and exploiting digital activities, which students can be engaged in. Before the pandemic, the Information Engineering students attended all together (almost 150 students) face-to-face Linear Algebra lectures, addressing the topic from both theoretical and procedural point of view. Then they were offered a 2-hours session per week in smaller group, consisting of 50 students, in order to work on and deepen the content of the week lectures, supported by a tutor. Due to my interest, I designed and provided students with digital activities (e.g. Albano & Pierri, 2014; Albano, 2017), already implemented before the pandemic, with the didactic purpose of helping them in constructing relational mathematics/conceptual understanding of mathematics, as opposite to instrumental mathematics/procedural understanding (Skemp, 1976; Hiebert, 1986). Such activities have been designed according to an asynchronous setting and thus engaged students in their personal study time/space outside the classroom, so that they could participate at their own pace working at their home or wherever. In the weekly tutoring sessions, the students could discuss the activities with the tutor, as well as the tutor, having access to the digital platform where the students worked on the designed activities, could focus her interventions on the points of greatest difficulty detected. The new distance setting forced us to rethink the structure of synchronous lectures, with particular reference to the interactions and the involvement of the students that no longer could be the same than in a traditional face-to-face lecture. So I was concerned with two interrelated issues: finding out which Moodle tools offered support for interactivity and designing their use in order to enable students to develop relational mathematics knowledge. On one hand, questioning and answering is recognized as one of the most effective practice for promoting interactivity. On the other hand, conceptual understanding is not just a cognitive issue, but it is affected by affective (beliefs, perceptions, attitudes) and metacognitive (learners' awareness and control of their own learning processes) factors. This means that any successful teaching/learning intervention should take into account all these three learning dimensions (cognitive, metacognitive and affective). I was interested in exploiting tools allowing to implement closed-ended questions/answers sessions and to collect and display right away the class-wide distribution of responses. Two tools offered by Moodle are Quiz and Feedback. The former allows to create (self-)assessment tasks. The latter allows to construct and submit a survey. Feedback falls into the category of so-called classroom response system (CRS). One of the early works on the use of such systems (Siau et al., 2006) points out some relevant pedagogical and curriculum issues, that can be valid also for the Quiz, including 'when to introduce the questions, what questions to ask, and how much class time to allocate' (ibid, p. 402). In this paper we state that the design issue should be focused on a learning scenario where each tool serves a particular purpose within a more general didactical objective. The metaphor of orchestration immediately comes to mind and it will be the underlying concept through the rest of the paper.

Theoretical framework

In this section we make a review of the concept of orchestration in technology-based educational research and mathematics education.

Dillenbourg (2013) refers to orchestration as a form a management (regulation process) of integrated pedagogical and technical scenarios, including on one hand activities, that can be face-to-face or online, and on the other hand tools enabling the implementation of the activities. In his view, orchestration is not concerned only with learning, but also with various extrinsic constraints (time, space, discipline, curriculum,…). This is one of the features that distinguishes orchestration from instructional design, in addition to the fact that it relates to a group of students rather than an individual and that the teacher's control prevails over that of the system. Dillenbourg states that 'orchestration' strengthens the teachers' potential in steering classroom activities and enables teachers to view things otherwise invisible. In response to Dillenbourg position, Kollar & Fischer

(2013) argue that the metaphor of music orchestra can be effective if it refers not only to the arrangement aspects (that is real-time management of activities and events) but also to whole process underlying the creation of music, which includes composing and conducting aspects too. They consider orchestration as “the process of creating, adapting and enacting a technology-enhanced learning scenario under complex classroom conditions” (ibid, p. 508). In their view, what Dillenbourg refers to as orchestrating actually means conducting. Composing consists of describing a scenario, constituted by resources and tools, specifying how they are combined and used by the teacher. Arranging is what the teacher does adapting the defined scenario to her classroom’s constraints. All the three processes are essential for technology-enhanced learning (TEL) being effective in classroom. Finally, they emphasise that the main objective of TEL is to facilitate student learning, which should always be taken into account. A further conceptualization of orchestration concerns the way in which the students are involved in the activities: individual, small groups, large groups. The design can foresee more than one mode of involvement or the real constraints can ask for changing the designed ones. Weinberger & Papadopoulos (2016) introduce the idea of orchestration of different social modes of learning. Students can learn individually or collaboratively, in small and large groups. Orchestrating social modes of learning means organizing learning choosing one of them or merging some of them. They argue that the transition from one social mode to another one should be carefully planned by the teacher taking into account how each of them help the students to reach the global learning objectives of the course. The teacher is recognized as the centre of a complex technology-enhanced environment, where technology both requires to be orchestrated and can facilitate orchestration.

In mathematics education, Trouche (2004) proposes the term ‘instrumental orchestration’ in a computerized learning environment (CLE). An instrument encompasses an artifact (i.e. a given object) together with utilizations schemes socially constructed by the subject. The process which gives rise to an instrument is called instrumental genesis. Trouche highlights that the complex artifacts present in CLE produce a set of instruments. The process of instrumental genesis as well as the articulation of instruments in CLE cannot be left to the students themselves but demands the guidance of the teacher, which can be done by means of instrumental orchestration. In this strand, Drijvers and colleagues (2009) propose a three layer model: *didactical configuration*, meaning the setting of the teaching environment equipped with artifacts (technological tools and tasks); *exploitation mode*, that is the way the teacher uses the didactical configuration in order to reach her didactical objectives; *didactical performance*, referring to ad hoc and run-time decisions taken by the teacher while teaching. Within the Theory of Semiotic Mediation (Bartolini Bussi & Mariotti, 2008), two different meanings of orchestration come into play: one referred to Trouche in relation to the use of artifacts, and one related to mathematical discussion, intended as the coordination of various voices emerged by the students with the voice of the mathematicians.

In this paper we want to investigate the potential of the concept of orchestration as lens to analyse a learning scenario, implemented in a distance setting and based on the exploitation of technological tools offered by digital learning platforms. What is being orchestrated? The tools? The purposes for which the various tools are used? Something different?

A learning scenario

In this section we present an actual learning scenario, implemented in a Linear Algebra distance course for freshmen Information Engineering students, equipped with Teams and Moodle. The course provides the students with synchronous online lectures (7 hours per week), tutoring sessions (2 hours per week), didactical material (videos, books, notes from digital board, worked-out exercises, slides) and resources (weekly tasks, quizzes, FAQ forum, periodic workshops for reviewing macro-sections of course contents). Various questions arose: concerning the precise didactical purpose of promoting conceptual understanding, how can Quiz be used? and Feedback? And how to handle the use of both so that one can takes advantages of the other one?

The scenario and its implementation in class can be analysed in terms of orchestration. I choose to refer to Drijvers et al. (2009) orchestration model. I designed a didactical configuration, arranging an environment composed of three artifacts: a Moodle Feedback activity, investigating students' perception of their mastery on a given topic; a Moodle Quiz activity, investigating students' learning on the same topic; a Teams talk session for discussing the outcomes of the previous activities. The exploitation mode concerned the way I designed each artifact, described below, and the delivery timeline, which envisaged first the delivery of an affective activity, then a cognitive activity and finally a discussion that possibly moved to the metacognitive level. The design and the outcomes of the activities have been analysed both content-based and using the "in class" observation of the teacher-student interaction. The data have been collected by using Moodle reports related to Feedback and Quiz activities and recording the Teams talk session. I carried out a survey, by means of the Moodle Feedback tool, to collect students' opinions on their level of knowledge for the topic of linear systems. Thus I submitted the closed-ended question in Figure 1.

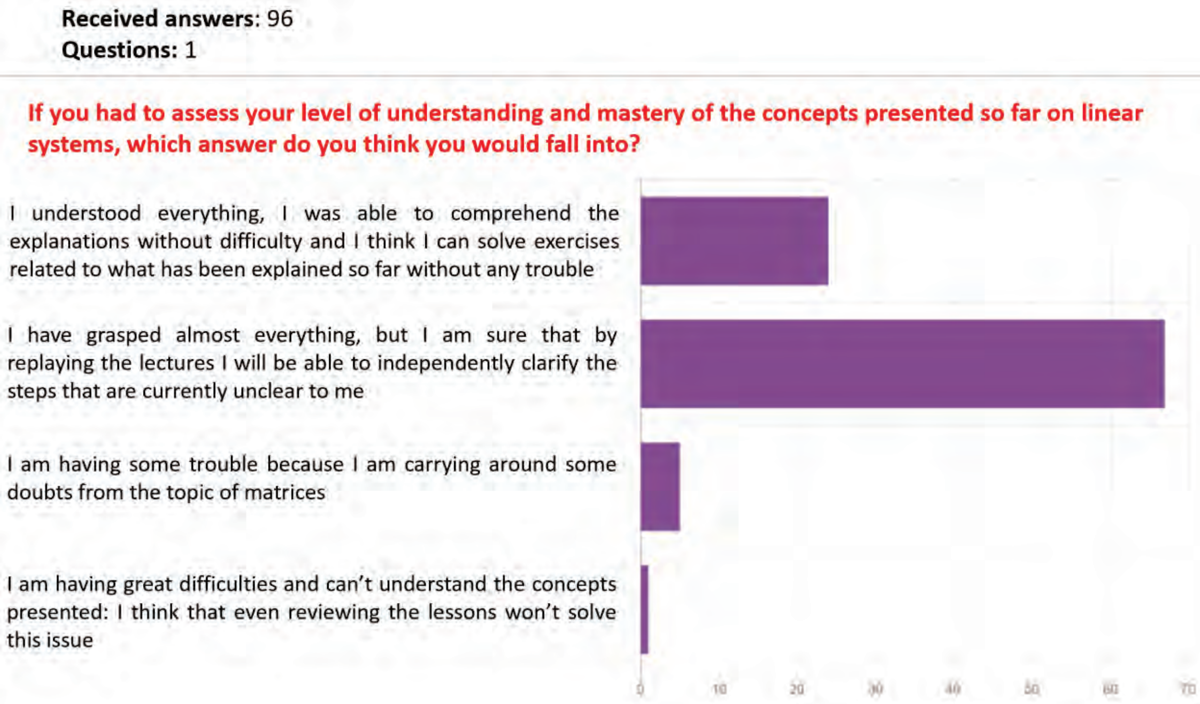

Figure 1: Results of the Feedback

I collected 96 answers, pointing that most of the students were satisfied with their comprehension of the topic (Figure 1). Indeed 25% of all the participants were completely convinced of their mastery, about 70% of the students admitted to having some doubts which they felt they could clarify by studying in more depth with the support of the recorded lectures, very few students reported having gaps from the preliminary topic or being unable to recover the gap. After showing the students and commenting on the graph in Figure 2, the mood in the class was very positive as it reflected the fact that the students felt very confident with the subject matter.

In the next lesson, I submitted a short quiz to the students: the first question shown in Figure 2 dealt with the notion of solution of a linear system, while the second question shown in Figure 3 dealt with the discussion of systems with echelon matrices. The former can be classified as an exercise, since establishing whether an item is correct or not requires direct application of previous knowledge, that is a definition. The latter can be classified as a problem, since it requires a certain reorganisation of the information given in the text and pieces of knowledge about linear systems and matrices in order to draw conclusions about the correctness or otherwise of the items at hand.

Let us consider the following linear system:

$$\begin{cases} x + 2y + z + t = 2, \\ 3x + 4y + z + 2t = 5, \\ 2x + 2y + t = 3. \end{cases}$$

Indicate which one(s) of the following statements is true.

- ☐ (2,1,1,-2) is a solution of the linear system
- ☐ $\forall y, z \in \mathbb{R}$ (z+1,y,z,-2y-2z+1) is a solution of the linear system
- ☐ none of the other items is true
- ☐ the system is incompatible
- ☐ the solutions of the linear system are (x,y,x-1,-2x-2y+3) $\forall x, y \in \mathbb{R}$

Figure 2: Question 1 of the Quiz

Let Ax=b a linear system of 4 equations in 4 variables, and let A be an echelon matrix.

Indicate which one(s) of the following item is true.

- ☐ If A has a zero row, the linear system is incompatible
- ☐ None of the other items is true
- ☐ If b=0, the linear system has only the zero solution
- ☐ If each non-zero row of A corresponds to a non-zero row of b, the linear system is compatible
- ☐ If A has two non zero rows, the system has ∞^2 solutions

Figure 3: Question 2 of the Quiz

Figure 4 shows the graph (produced by Moodle) of the marks (between 0 and 1,5 per question) received by the participants in the Quiz, with the total number of students distributed by grade range.

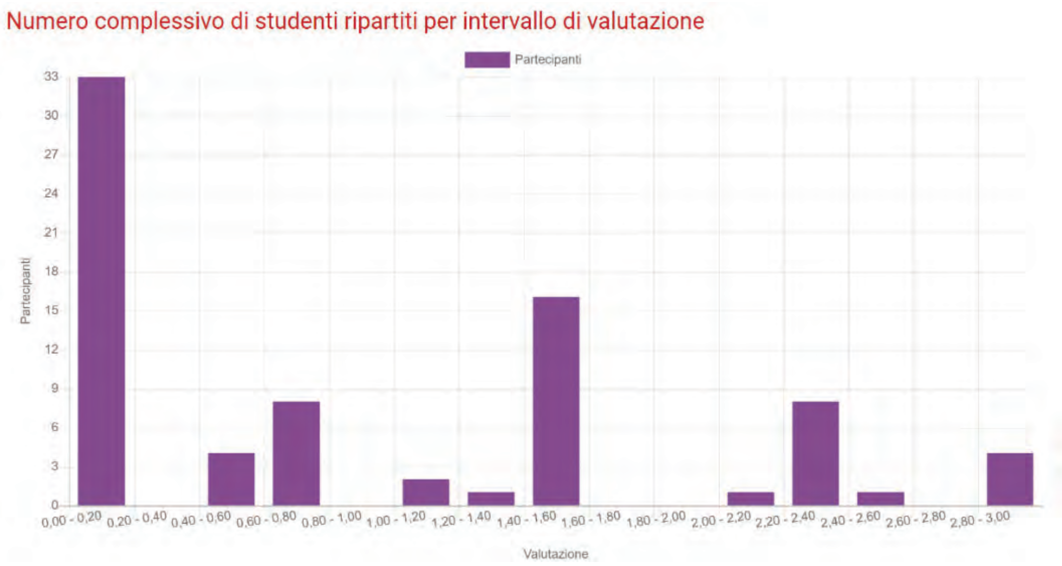

Figure 4: Results of the Quiz

After showing the results of the Quiz, everyone was astonished: they made evident a great gap between the students' perception of their mastery of the topic showed by Feedback and their actual mastery in solving the questions on the topic posed by Quiz. Thus the teacher started a collective discussion aimed at making sense of the gap. In terms of orchestration, the way in which the teacher led the discussion, the questions she chose to ask to guide the students' reflection, the mirroring of some of the students' interventions and the recapitulation of what emerged from the discussion concerns didactical performance. The discussion started with a question concerning the first question of the Quiz (Figure 2):

Teacher: How do you determine which of the items presented is correct? Tell me which strategy you used.

Student 1: Prof, I solved by using Gauss and got different solutions.

Various students agreed with Student 1, so the teacher asked for someone who acted differently.

Student 2: Yes, me, Prof. When he asked me if that 4-uple was a solution of the system I substituted it in and saw if it was equivalent.

Using this intervention, the teacher focused the students' attention on the definition of solution of a linear system and launched a collective discussion about its potential to investigate the items: it could be directly applied to items 1, 2 and 5, and depending on their value of truth some inferences could be done concerning the correctness of the remaining items. Then the students proceeded to apply the strategy come out from the discussion to answer to Question 1.

Once completed, the teacher opened a further strand of discussion concerning the difference between the approach used by most of the students and the one used by few, as Student 2, which turned out successful. The teacher highlighted that the request of the question was to establish the value of truth of the items, whilst many of them seemed to have acted as if the request had been 'solve the linear system'. Some students recognized that, taking this approach, they missed some correct items, since they were not able to recognize the equivalence between what they got solving the system and further description of the same solution set. From the discussion the need of a relational approach in contrast to a instrumental approach emerged. This let the teacher shift the focus to Feedback results and gave her interpretation of the results, based on the assumption of students' procedural learning, confirmed by Quiz outcomes and discussion:

Teacher: the perception of your mastery emerged from Feedback is not false because I am sure you know how to carry out exercises but you have to move a bit further ... a few days ago someone asked me if in the exam quiz there will be theory questions ... of course, this is a theory question.

The lecture proceeded discussing question 2 (see Figure 3). It was particularly suitable for activating relational knowledge, both because the question dealt with a generic linear system (therefore no solving procedures could be applied as in the previous case) and several items were "if... then..." propositions, which brought into play reasoning and argumentation competencies.

Insight for new research

The previous learning scenario does not remain confined to distance learning, but it is inherited by the face-to-face lectures. Indeed, most of the students attend lectures equipped with their personal mobile device (smartphones, iPads and notebooks), thus lectures can be redesigned according to BYOD approach. In my view, this scenario poses the issue of a further development of research. In mathematics education the concept of orchestration has been developed mainly with the perspective of guiding students' instrumental genesis. This is not the focus of the paper due to the general-purpose nature of the digital artefacts used by the students. But the instrumental genesis of the teacher using the digital tools could be a very interesting focus to be developed. For example, as we teach remotely, we develop many new schemes and sets of artefacts for teaching, and it can even influence how we teach in-person (providing evidence of the development of a scheme).Taking up Dillenbourg's idea of technology as something that makes visible what was invisible, we can look at what has been made visible by the orchestration performed in the above learning scenario. The use of feedback and quiz together, even in a specific order, made the students experience a discrepancy between their idea of mastery and that of the teacher that is realised in the exam paper (affective dimension), the subsequent (mathematical) discussion allowed the students to become aware of and reflect on their own learning processes (metacognitive dimension) through a cognitive analysis of the questions and answer items proposed (cognitive dimension). An hypothesis following this exploratory study could be that I started developing a scheme emerged by the presented scenario which allowed a successful integration of the three dimensions of learning that took place in the orchestration of the three activities feedback, quiz, discussion. This seminal study suggests new research to investigate the emerged hypothesis addressing the development of a renewed orchestration framework, taking into account the pedagogical aim of the teacher in using the digital tools, and a renewed teachers' instrumental genesis for reaching this pedagogical aim. Such a new framework should exploit elements from various theories, in mathematics education and in technology-based education, according to networking of theories (Prediger et al., 2008).

This paper addresses the didactic issue of promoting the construction of the problem-solving competency for undergraduate students. We report the design of a learning activity, engaging students in collaborative problem solving in topology, each of them playing as a cognitive function coming into play when a mathematician faces a problem. To shed light on the impact of the roles played by the students with respect to the solving-problem process, we analyze some student's protocols from which we carry out for each role some actions as well as some benefits recognized by the students.

Keywords: mathematics education, university, problem solving, cognitive functions, role-playing.

Introduction and conceptual background

Problem solving has a fundamental role in mathematics learning and its educational importance is stated at each school level and in every field of mathematics, as it provides experience of those key processes in mathematics education that are involved in exploring, conjecturing, proving, constructing examples and counterexamples, representing, monitoring etc. (Polya, 1945; Schoenfeld, 1992; Carlson & Bloom, 2005). An important problem-solving activity, particularly efficient for the construction of new concepts (Dahlberg & Housman, 1997) is the students' generation of examples satisfying particular constraints. In fact, the students' production of examples can be a very complex activity, also for university students, that promotes the activation of fundamental cognitive processes (Antonini, 2011). At university level, a rich and deep field of mathematics is topology, a basic working tool of mathematicians in a variety of fields that can offer the undergraduate mathematics students the experience of engagement in a real problem-solving process. In this paper we are interested in promoting the construction of problem solving competency for undergraduate students, attending a topology course within Bachelor of Mathematics. The study of introductory general topology topics requires activating the significant cognitive functions, that are the mental processes (Kiely, 2014) that come into play during the problem-solving process. Polya (1945) highlighted that often the teacher poses questions and suggestions useful to the problem solver and recognizes them as indicators of mental operations typically useful for the solution of problems. In this strand, Albano, Coppola and Dello Iacono (2021), looking at how mathematicians behave when solving a problem, individuated some mental processes they usually activate (e.g. looking for paths, questioning herself, organizing herself, systematizing the findings, …), identifying them as roles/cognitive functions that a problem-solver should activate. These roles are: 1) Boss: she manages the work from every point of view (organizes actions, calls to the task, requires participation); 2) Promoter: she gives insights to promote a path that, starting from and manipulating prior mathematical knowledge (concepts and propositions), leads to the construction of examples, conjectures and outlines a solving strategy. In case of trouble, she asks for the teacher's help; 3) Critical mind: she questions the truth of the arguments and the validity of the answers proposed by the group, with the aim of corroborating their findings; 4) Blogger: she collects and rearranges everything that emerges from the discussion, to draw up a document containing all the arguments, notes, doubts, questions, answers.

We face the issue of promoting the development of students' ability to solve problems by offering them structured opportunities which allow the students to imitate and practice (Polya, 1945) and to become aware of their cognitive processes, so being able to monitor and coordinate them (Schoenfeld, 1992). The assignment of roles expands the potential of students as it gives them the opportunity to improve their problem solving skills at various levels: cognitive, metacognitive, affective. Exploiting and extending the results of a national project[1], we used the metaphor of storytelling to characterize the problem solving process at two levels: the process itself is seen as a mathematical story and the cognitive functions coming into play during the process become characters of such a story. Students are engaged in collaborative problem solving, where each student is required to play the role of a character of the story, that is she personifies one of the envisaged cognitive functions (Albano, Coppola & Dello Iacono, 2021). During the problem solving process, the students are expected to develop a mathematical narrative, consisting of their co-constructed notes on a digital board and a final collective report on the problems' solution. In this paper we report the design of a learning activity (Podolskiy, 2012), engaging undergraduate students in collaborative problem solving tasks. We discuss the first outcomes of the analysis concerning the metacognitive aspects, that is the students' declarative knowledge and awareness of the cognitive functions they experienced by playing the corresponding roles during the activity.

Experimental design

The design of the learning activity foresees that the students face a problem-solving task, consisting of three problems. According to the engagement model of Albano, Coppola and Dello Iacono (2021), the students work in groups of four or five people, each of them playing the role of one cognitive function. The groups are engaged in problem solving at different levels. One group, called Solver group, is devoted to collectively solve the three problems, and each of the students in the group acts according to one of the cognitive roles described in the previous section. The remaining groups, called Onlooker groups, are required to observe how the Solver group is working. Each student is guided to reflect both on how a specific one Solver member acts with respect to her role and on how the mathematical process is carried out by the entire Solver group. Therefore, personifying an Onlooker role stimulates a critical reflection not only at the cognitive level, as it allows a student's engagement in the mathematical problem, but also at a metacognitive level, as it fosters student's monitoring skills related to a role to play in a subsequent activity. A further level of reflection is added with respect to the previously cited engagement model of Albano et al. Indeed, we assume an incremental goals' structure of the problem-solving task: each of the three problems aims at a specific sub-goal, going from routinary employing mathematical concepts, facts, procedures and reasoning to creating new

[1] PRIN "Digital Interactive Storytelling in Mathematics: a competence-based social approach", PRIN 2015, Prot. 20155NPRA5, national project funded by the Italian Ministry of Education, University and Research.

mathematical knowledge. We envisage as many Onlooker groups as there are problems, so that each of them is focused on one specific problem. Each student is required to draw up a personal Logbook, containing some guidelines to reflect on the role she assumed, both as Solver and as Onlooker. Furthermore, at the end of each activity, every group is required to draw up a collective Logbook, reporting the solution of the problem and the process made to reach it (detailing the experience, how the construction of the answers took place, paying particular attention to the arguments they adduced in solving the three sub-problems). In order to foster the awareness of all the cognitive functions, students change roles with each new activity, also changing Solver with an Onlooker group and permuting the Onlooker groups (so changing the problem to be focused on).

Methodology

The experience involved about fifty students attending the course of *Geometry III* at the second year of a degree course in mathematics. The course Geometry III aims to introduce students to the fundamental concepts of general topology and to stimulate them to be able to use ‘topological eyes’, often far from the Euclidean ones. Besides acquiring content knowledge, the main educational goal is to construct students’ mathematical reasoning capability, by means of analyzing and exploring problems, with an efficient use of topology concepts and results.

According to the design, each activity has an assignment on which students work in groups of 16-20, divided into 4 subgroups corresponding to the Solver group and the three Onlooker groups. In our experiment, all the participants have been split into three groups, named WG1, WG2, WG3, each of them consisting of four subgroups WSGi.1, WSGi.2, WSGi.3, WSGi.4 (i=1,2,3). Each student has been associated with a role-pair (subgroup role, individual role). Each subgroup acted as Solver or as Onlooker, so the corresponding value of the variable ‘subgroup role’ could be S or Oi, where Oi means that the subgroup acted as onlooker on the i-th sub-problem. The values assumed by ‘individual role’ corresponds to the cognitive functions played.

Along the course, students have been involved in three activities CWi (i=1,2,3). Both individual and collective roles changed as the activity CWi changed. More precisely, the assignment of roles in the passage from one activity to another can be described by a double permutation, one corresponding to the subgroup role and the other to the individual role. As an example, a student who has been assigned the role-pair (O1, Promoter) could take on the role-pair (S, Critical mind) in the next activity. This means that, while in the first activity the student belonged to the Onlooker group focused on the first problem and she was required to observe the work of the Promoter in the Solver group, with whom she confronted, during the second activity, she belonged to the Solver subgroup and acted a Critical Mind. In every activity CWi, the problem-solving task consisted of three problems: the first two concerned basic concepts introduced during the lectures and required the construction of examples of topological spaces or subspaces under given constraints; the third one was less routine (for instance, students may be asked to provide some characterization related to the property that is being investigated). Figure 1 gives a flavor of the kind of problems the students were asked to face.

PROBLEM n.1

1.a Construct a topological space (S, τ), where S is a non-empty set and τ a topology on S, different from those studied in class (invent it !!), in such that S contains two proper non-empty subsets X_1 e X_2 such that $Fr(X_1) = \emptyset$ e $Fr(X_2) \neq \emptyset$ in (S, τ), where $Fr(X_1)$ e $Fr(X_2)$ are the boundaries of X_1 and X_2 in (S, τ).

1.b Consider the set S introduced in point $1.a$. Denoted by τ_1 the topology τ and by τ_2, τ_3, τ_4, respectively, the trivial topology, the discrete topology, a topology of your choice distinct from the previous ones on S, determine

1.b.1 the frontier of X_1 in (S, τ_i), $Fr(X_1)^{\tau_i}$, for $i = 2, 3, 4$.

1.b.2 the frontier of X_2 in (S, τ_i), $Fr(X_2)^{\tau_i}$, for $i = 2, 3, 4$.

The boundary of a set can vary as the topology varies. Explain why.

PROBLEM n.2 Consider the topological space you defined in the previous problem (point 1.a). Construct, if they exist, three proper non-empty subsets of S, X_3, X_4, X_5, each distinct from X_1 and X_2, so that

2.a X_3 has an empty boundary with respect to all topologies.

2.b X_4 has a non-empty boundary with respect to all topologies.

2.c X_5 has empty boundary only with respect to some topology.

PROBLEM n.3

3.a Choose one of the topological spaces (S, τ_i) with $i \neq 2$ among those considered in problems 1 and 2 and investigate how a subset with an empty boundary can be constructed. In other words, characterize, if possible, the subsets with empty boundaries.

3.b Do the considerations made in the previous point or the statements you have reached also apply to the other topologies? Consider at least one of the two topologies τ_j on S with $j \notin \{i, 2\}$ and determine if the results found in (S, τ_i) continue to hold in (S, τ_j).

Figure 1: The task for the students

Each working group WGi had at their disposal a digital environment, consisting of various tools:
a) a collaborative board Miro, enabling to collectively brainstorm in order to solve the problems, by adding post-it, importing images, drawing and connecting ideas, exchanges comments by chat; b) a collaborative document (shared Google-doc), used to report the solution product and process; c) a personal document (private Google-doc), used to report the reflections concerning the roles played during the experience.

All the data concerning the learning activity have been digitally stored, by means of the used tools (Miro and Google-doc). At the end, a questionnaire was submitted for investigating the students' perceptions. Here, we focus the qualitative analysis of the roles, looking at the students' answers in:
- the personal Logbook: *Describe how you played your role (as Solver and Onlooker) and what your contribution was. Do you think that the interventions related to your role were useful to achieve the objective? Why? Would you have done something differently? Why?*
- the questionnaire: *In the activities you played a role as Solver or Onlooker. For each role, tell us from your point of view how it contributes to solving the problem. If you think about when you are solving a problem on your own, do you recognize any of these roles in what you do during the solving process? If so, which ones more frequently? Are there any other roles you identify? Tell us.*
In particular, we are looking for excerpts describing the characteristics of the roles and the benefits of playing such roles, as perceived by the students.

Preliminary findings and discussion

We analyzed the Logbook and the questionnaires of 24 students. The answers to the above questions shed light on the impact of the roles played by the students with respect to the problem-solving process and to their usual own experience of problem solving.

Concerning the role of the Boss, the student St1 says:

St1: I immediately noticed her attention to details. Thinking of doing something useful for those of us who might have some deficiency on the tools required to face the task, she wrote in a frame [on Miro] all the useful definitions, such as boundary, interior, closure [of a set]. This has created a sort of "safe-spot", a point where you can have everything you need ready for use. She acted as a leader.

This excerpt seems to highlight the Boss' characteristics of a leader, implemented as someone who makes the group "safe" with respect to the problem-solving process. This means that she takes charge of supplying the group with mathematical recall notes connected to the given problem. The student St6 reports a similar work of the Boss (recall definitions), highlighting that such work let all the students be more comfortable with the needed background mathematical knowledge.

The role of the Boss is a disputed one. On the one hand, it is considered as a key role:

St1: The only real distinction was therefore that of boss / rest of the solver group, but without this negatively affecting the results.

St4: The boss of the solver group is the main role because he coordinates the entire group and manages to make the onlookers understand the work done.

On the other hand, sometimes, it can be perceived/played as a rote-role, without any added value, as shown by the following excerpts.

St15: I think it is the least useful role, since its role is only to check if all the work is progressing correctly, but does not interact in any way with the other students.

Actually, it seems that the experience of student St15, playing as 'boss' or onlooking 'boss', leads her to perceive the role differently from the designers of the activity. In fact, the cognitive function corresponding to 'boss' envisages someone who coordinates and takes care that everyone participates in the solving process. It is not her business to check the correctness of the work.

The role of Critical Mind seems to have promoted the action of questioning, and it has been recognized how much such action fosters a broader view of the problem solving:

St7: This work allowed her to ask more questions about the topics useful for solving the problem, and to have a broader vision of how a given exercise could be solved with different methods and observations. The role of Critical mind and, at the same time, that of the onlooker of the critical mind, proved useful in stimulating new proposals and new points of view, questioning the choices that are made each time and rattling off the strategies adopted as much as possible.

It is worthwhile to note that the role of Critical Mind has stimulated the student to pose questions to herself and to promote a critical attitude:

St17: It helps me to understand the mistakes I make, saying to myself: "stop, think: why did you carry out this calculation like this? Would it be simpler in another way? Is there any theorem or statement that can help me solve this exercise more quickly? And I find all of this very useful for the smooth running of a problem".

The student S12 highlight the importance of this role at individual and group level:

St12: In addition to an individual utility, I believe that the role of critical mind was very important for the whole group because often in the resolution of an exercise it can happen to make mistakes or inaccuracies without realizing it and the critical mind, insinuating doubts, manages to bring to attention the steps on which we need to work better.

The student St5 points out the role of the Promoter as someone who sketches a working outline, to engage the whole group in developing a solution and activating a thinking process:

St5: My idea as a promoter is precisely this, to propose your ideas despite some small inaccuracies in order to encourage the intervention of others and reach the final solution.

St13: I think about how to develop a certain problem.

It is interesting to note that the Promoters' suggestions are constructed on previous knowledge:

St14: She manipulated known propositions and concepts to build examples and strategies that led to the resolution of the problems

However, the role of Promoter does not always find the same appreciation and this is probably due to different values and personal beliefs about the roles:

St22: I also appreciated the promoter but to a lesser extent than Boss and Critical mind only because I personally think that finding an idea is less interesting than stressing it.

Concerning the role of the Blogger, it seems to impact on the cognitive level (e.g. reasoning) as well as on the affective one (e.g. engagement of the group), as shown in the following:

St11: The student I observed, that is the one who played the role of Blogger, played his role well, collecting and tidying up the board, highlighting some definitions and observations useful for carrying out the exercises, through the use of arrows and schemes that made the key concepts clear. He exploited and used the comments made in the chats by the other members of the group as well.

St13: His interventions were therefore also useful for taking stock of the situation from time to time, reorganizing ideas and, asking to repeat some of the concepts, also giving the possibility to those who may have remained behind to pick up the thread of the discussion.

As for the Boss, also the Blogger is a disputed role. On the one hand, it is considered pivotal:

St12: I believe that the role of blogger was fundamental for managing space and order on the board. Working in an orderly environment, in my opinion, favors concentration, allows you to easily identify the elements necessary to conduct a certain reasoning.

On the other hand, it can be played at surface level, just looking at aesthetic aspects:

St15: It is a secondary role in my opinion, since in most cases he was only concerned with the stylistic point of view of the board, caring little or nothing about the content.

St22: …the blogger did not impress me as I found it marginal with respect to solving the problem.

Table 1 shows a synoptic picture of the performed analysis. The first column shows some excerpts from the personal Logbooks that the students filled along with the activity on the basis of the roles they played (steered by the questions reported in the 'methodology' section). The second column shows excerpts from the questionnaires, submitted at the end of all the activities.

It seems that the logbooks show descriptions of the roles according to the actions that are recognized as belonging to a certain role, while the questionnaires show the roles in terms of the characteristics that define them in a problem-solving process. Furthermore, the table shows that sometimes the roles are experienced by the students in a way that corresponds to the designers' model, while in other cases some students find them difficult or uninteresting or give them an interpretation different from that of the designers, as in the following examples.

Table 1: Students' excerpts

	Excerpts from the personal logbooks	Excerpts from questionnaires
Boss	– plans, arranges and coordinates the work – pays attention to certain details that can benefit all the group – briefly recalls the key starting concepts that could be useful for solving the problem – enforces the assigned roles – involves all members of his group in solving	– is a predominant role taking care of the group – puts all members of the group in the same starting conditions trying to eliminate all possible differences or prejudices about individual abilities – makes you break down shyness – keeps his group cohesive – is the least useful role
Critical mind	– raises questions, also concerning the validity of the arguments – allows questions to be asked – analyze the various procedures critically – stimulate new proposals and new points of view	– allows you to gain awareness and to understand your own mistakes – allows you to develop a broader view of how a problem can be solved – fosters reasoning and searching for alternative simpler ways of moving in the problem space
Promoter	– sketches ideas to be completed – manipulates known propositions and concepts to build examples and strategies – retrieves useful material (sources from books, lecture notes, ...) – communicates with the teacher for help	– allows you to start reasoning – allows you to repeat useful notions – allows you to think how to develop a problem – opens to change the way to solve the problem – promotes the engagement of peers – is less interesting than critical mind
Blogger	– rearranges the various information emerged from the discussion – clarifies the many ideas presented by peers – uses arrows and diagrams to make the key concepts clear – tidies up the board	– makes the solving process clear – promotes concentration – helps to keep the logical thread – helps to take stock of the situation from time to time – has a secondary role – it is marginal to the resolution of the problem

Sometimes roles didn't work out because students got 'too busy' with solving the problem. Here the roles functioned as a 'group', not fragmented:

St16: Personally, I didn't fully respect my role when I was in the solver group, as working all together, and taken up by problem solving, we didn't pay much attention to the roles we had to fill. .… I think this was the most difficult aspect to respect, everyone was aware of the roles, which were respected as a group but not by the individual.

What emerged and synthesized in the above table seems to confirm that the students actually grasped the characteristics of each cognitive function, recognizing their functional goal with respect to successful problem solving. Assigning a role serves to activate a specific cognitive function, to stimulate the activation of some cognitive processes, and the roles would seem to be tight especially to those students who usually activate all of them. Sometimes these kinds of students tried to cross over and join the group of solvers even if she was not part of it. We could compare the action of assigning a role with giving the student a piece of chalk, associating chalks of different colors to the different roles by which to write on the board Miro and to contribute to the construction of the story and the fabula. Thus, each group is engaged as in a *thinking classroom*, as "a space that is inhabited by thinking individuals as well as individuals thinking collectively, learning together and constructing knowledge and understanding through activity and discussion" (Liljedahl, 2016, p. 364). We could speak of “thinking groups” (Thinking Solver group and Thinking Onlooker group), where each member performs an active function to solve a problem, by means of an action that stimulates a cognitive thought process that could remain dormant and blocked.

We conclude by noting the educational importance of engaging students’ in experiencing all the roles, in order to recognize all of them as pivotal to be successful in problem solving, similarly to how a mathematician usually uses them all when facing a problem. However, it is not taken for granted that a student activates them all, and this can cause difficulties. There are problems in front of which some roles do not come out, maybe because students are not used to or are more comfortable only with some of them. The experiment allowed the students to share the profile of a mathematician and in some cases to recognize themselves as mathematicians. Generally speaking, the learning activity proposed aimed at promoting and developing processes involved in problem-solving competency and an attitude of a mathematician towards problems mathematics, not aimed at ‘re-producing’ theorems and proof learned in class, but to autonomously ‘produce’ something of their own, new and original. Further research will be needed to investigate the processes involved in playing specific roles in problem solving and in the personal development of such important competency.

Dialectics of language and Plato's cave of mathematics

Roberto R. Baldino[1] and Tânia C. B. Cabral[2]

[2]Universidade Estadual do Rio Grande do Sul, Brazil; cabral.taniacb@gmail.com

This is a theoretical article hailing at classroom practice. It was originally intended to be a report on an ongoing study introducing the fundamental theorem of calculus in a STEM freshman course, but the necessary explanation of our epistemological position has taken up most of the available space. Based on Hegel and Lacan, we argue for the reality of language against the implicit realistic positions that dominate mathematics education research. We describe how Cauchy's "one says that" (on dit que) *created a bubble of semantic conventions. From inside this bubble, mathematicians only recognize the students by their shadows on the wall, like in Plato's cave. We argue that learning occurs outside the bubble. Instead of dragging the students in, to teach them ready-made notations and methods, our study exercises the dialectics of language in interaction with the students. We stick faithful to our lemma: one teaches by listening and learns by talking.*

Keywords: Hegel and Lacan, dialectics of language, Cauchy, fundamental theorem of calculus, infinitesimals.

Introduction

Initially, we intended to report on our experience with constrained remote teaching during two semesters as teacher-researchers (Tabach, 2006). We introduced the fundamental theorem of calculus (FTC) by working out the graphs of Covid-19 as displayed in the media. Once the students could meaningfully state the FTC about the discrete bar graphs, we moved on to the continuous case by a sudden change of scale (Ellis et al., 2020), thereby changing the referent of discourse. Ideas of limits and infinitesimals emerged from the students. This didactic strategy is justified in the ensuing theoretical development. Some of the worksheets used are available in https://cabraldinos.mat.br/

In the present analysis, in order to bring the dialectics of language and the subject of speaking to the foreground, we engage in a critical dialogue with a certain mathematicians' perspective about teaching (Tall, 2009; Tall & Katz, 2014; Thompson, 1994, 2019; Ely, 2017). We focus on three signifiers used by Cauchy (1821): "one says that" (*on dit que*), "becomes an infinitesimal" (*devient un infiniment petit),* and "the neighborhood" (*le voisinage*). Referring to Hegel (Hippolyte, 1977) and Lacan (1973), we show how these signifiers have created a bubble of semantic conventions that can be called *mathematics of the twentieth century* (M20); this bubble is the epistemological habitat of mathematicians. We argue that, due to the inherent semantic limitation, mathematicians are unable to leave the bubble to meet the students on their path to the bubble. They can only drag the students in and produce models of students' ways of thinking by looking at their shadows on the wall. Important concepts like *mathematics*, *numbe*r, and *infinity*, remain outside the semantic reach from the bubble. Mathematicians tend to mix up teaching, understanding and learning.

Language and the subject come first

To ground our study, we sought to discern events that could be placed upstream of the epistemological flux that led to the FTC. Marx's maxim advised us: the anatomy of man is the key to the anatomy of the ape. We asked ourselves: do we know what we are looking for? Yes, in our classes we expect the students to express in current language: *the integral of the derivative is the variation of the function,* and *the derivative of the integral is the function itself.* Guided by these current language statements, we were able to locate one of the origins of the FTC in Barrow's theorem (Barrow, 1976, p. 78, Figure 109). It is well-known that this theorem became the cornerstone of a discussion that lasted two hundred years. We will take this theorem as an example of a *signifier*, a core concept for us.

Barrow did not write the theorem for us; he was addressing his contemporaries that shared a certain common epistemological spirit. We say that Barrow *took that theorem as a signifier to represent himself as a subject to another signifier* (Lacan, 1973, p. 188). More than three centuries later, it happens that this second signifier is available to us, so that not only can we understand the theorem and its proof, but we can *represent ourselves as subjects* by this second signifier to a third signifier, belonging to the reader, etc. This movement of language and subject from one signifier to the next we call the *dialectics of language*.

> Language is not only a system of signs alien to the signified, it is also the existing universe of sense, and this universe is the interiorization of the world as well as the exteriorization of the "I". Language is a double movement that must be understood in its unity. (Hippolyte, 1977, p. 24)

Due to this subtle but ubiquitous double movement, words acquire their meaning and we become their speakers. We were able to locate Barrow's theorem because what we were looking for was already specified in language. *Insofar as we 'make sense of the world' it is the world that posits its sense across us*. A double movement constitutes both, *human subjects* and *language*. The movement is prior to the opposing poles that it generates. Accordingly, there is neither a universal "I", owner of an inner meaning to be expressed, nor a world out there of which one can speak and make sense by "using" language. There is no "dialectics between", no "dialectic relation" (Pais, 2016).

We apologize for demanding of the reader the effort to understand ideas so strange to commonsense. They are necessary to elicit the realistic[1] positions prevailing in mathematics education research. For instance, the belief in "underlying mechanisms that shape human thought, building from the fundamental level of human perception (…)" (Tall & Katz, 2014, p. 100) leads to the postulate that "the underlying brain activity is more fundamental" (p. 102). The next step in this line of reasoning is to state that "our brains make sense of the world by assembling neuronal information" (Tall, 2009, p. 482). The apex of this chain of psychological materialism is the search for the "number neuron" (Dehaene, 1997, p. 57). A criticism of this chain of thought may be found in Pais (2019) and Webel & Stigliano (2004), as well as in Baldino (2019), a parody about the number neuron.

Dialectics vs understanding

By the time of Barrow, mathematics and philosophy had formed a single body of knowledge whose esthetic was modeled on Euclid. Newton followed this model, while Leibniz broke apart from it, and the two vied for being credited with the "discovery" of calculus. Berkely criticized them both. The story of this imbroglio is well known.

In the beginning of the nineteenth century, Hegel criticized the mathematicians for not been able to provide rational foundation for their science (1985, p. 236-309). By the end of the eighteenth century, Kant's philosophy had become prevalent. Hegel called it *understanding* (*Menschenverstand*) and referred to his own system as *speculative philosophy*. Hegel's went beyond Kant's philosophy. Understanding establishes clear cut distinctions between thought and being, subject and object, form and matter, discourse and referent, us and the world, etc. Due to these distinctions, understanding was prone to being well received in the imbroglio of philosophy and mathematics. Understanding was a reference for the movement for rigor that ran throughout the nineteenth century and is becoming stronger in STEM today. For instance, Kant's philosophy has been explicitly evoked to support the hegemony of mathematics over mathematics education; an "apprenticeship model" attributed to Dawkins and Weber (2017) is proposed by Rittberg et al. (2020) and criticized in Baldino and Cabral (2021).

Understanding postulates the existence of a beyond that cannot be reached by knowledge nor, consequently, by *language*: the so-called *thing in itself* is not cognoscible. This philosophical position favors the polysemy of the signifier "mathematics" discussed in Cabral and Baldino (2021): it favors inconsequent research in mathematics education, while the classroom resists. We argue that language must be brough to the fore. This endeavor naturally points to Lacan wo goes beyond Hegel and states plainly: "there is no being outside language" [2]. We cannot survey the meaning of the word "dialectics" from Plato to the present. We will retain the meaning it has in a formula that may condense the whole of Lacan's work: "dialectics of the subject and the Other" (Lacan, 1973, p. 205, 239). Accordingly, by "dialectics" we will refer to both, the dialectics of language, as in Lacan, and to Hegel's speculative philosophy which Žižek has elicited as the background of Lacan's work.

However, *dialectics is not a substitute for understanding*; this would be an assumption proper to understanding. *Dialectics exerts itself on understanding*, leading it to recognize the contradictions that unavoidably stem from its black-and-white divisions. Dialectics does not fight for victory; it is guided by the political necessity of the moment; it fights to continue fighting. If understanding dies, speculative philosophy dies too "and in this night of mere reflection and of the calculating intellect, in this night which is the noonday of life, commonsense and speculation can meet one another" (Hegel, 1977, p. 103).

The disentanglement of mathematics and philosophy is taking place today, under the arrogance of science over humanities. In his paper on quantum mechanics, Gauthier (2010, p, 2) aims to "make explicit the concept of probability in order to extract the mathematical content from its mystical

[2] " Il n'y a d'être que dans le langage." https://www.youtube.com/watch?v=njA-1a4N_iw

(philosophical) gangue [sic]". What is it that is being separated from its "philosophical gangue"? Strangely enough, this is left to philosophers to explain, since mathematicians do not say what mathematics is. Scott (2012) shows what happens when a physicist (Stephen Hawking) draws on his professional status to gather audience to speak about what he does not know. We must be aware of such antagonisms because understanding and dialectics face off when they meet the student in the common ground of the classroom, in the "noonday of life".

Cauchy and the bubble: *on dit que*

Concerned with the polysemy of the signifier, Cabral and Baldino (2021) characterize "mathematics" as special form of discourse that was born in Ancient Greece. This discourse, which they call *quilted speech*, aims to stop the slide of the signified under the signifier: each signifier would have a single precise meaning:

> The understanding would like "a fixity and an exactitude that is not found in existing language; the idea of creating a pure language, a system of symbols which remain absolutely invariant over the course of the diverse combinations they undergo comes from this. (Hippolyte, 1977, p. 46)

The whole imbroglio following Newton and Leibniz may be looked at as an attempt to quilt speeches; people refer to it as "rigor", "formalization", "definition of the concept" etc. In 1821, Cauchy introduced a precision into quilted speeches that eventually completed the separation of mathematics and philosophy. In his Cours d'analyse de l'École Royale Polytechnique, he wrote: "*One says that* a variable quantity *becomes* infinitely small when its numerical value decreases indefinitely so as to converge towards its limit zero" (Cauchy, 1821, p. 26, added emphasis).[3]

On the one hand, he cut the gordian knot of misunderstanding with a *semantic convention*: "one says that" (*on dit que*). However, on the other hand he conserved the movement of dialectics of language by saying "becomes" (*devient*).[4] Something ceases to be what it is and becomes something else. Hegel would appreciate this proposition as a perfectly dialectical one: its very utterance imposes a movement of language that preserves what it denies; this is expressed by the German verb "to transcend" (*aufheben*). Hegel (1985, p. 69) calls this movement of language "becoming" (*das Werden*).

Cauchy's semantic convention was followed by Weierstrass, Hilbert and many others. They created a language bubble that we call M20. This bubble became the habitat of a *community of speech* whose members are the mathematicians (Cabral & Baldino, 2021). This community decides what counts as a valid inference; for instance, it informally accepts the use of the axiom of choice and the continuous hypothesis.

The membrane that delimits the bubble is opaque for those inside it. Like in Plato's cave, mathematicians only see shadows of the external world. The infinite movement of the dialectics of

---

[3] On dit qu'une quantité variable devient *infiniment petite*, lors que sa valeur numérique décroit indéfiniment de manière à converger vers la limite zéro.

[4] In Portuguese, *devenir*, to become, is a reflexive verb: *tornar-se*: to change oneself is a perfect expression for learning, a movement that occurs in language through which a subject changes herself. It is up to the native speakers to compare the relative weight of these verbs in their respective languages.

language is left outside, including important concepts, like “mathematics”, “number” and “infinity”, that find no “definition” inside the bubble. The “repetition of a process with an underlying pattern of successive states” (Tall, 2009, p. 483) is what Hegel calls the bad (*schlechten*) infinity. The passage from one member to the next in a sequence is an indefinite repetition of sameness, with no risk of producing changes either in the subject or in the object in the dialectics of language. Only this finitized infinity is admitted into the bubble; the apex of finitization of M20 is Weierstrass epsilontics.

When mathematicians face the necessity of teaching, they have an inkling that something is wrong. They do not realize that the student is outside the bubble, plunged into the infinite movement of language. They try to pull her in to teach her the concept by “defining” it. Looking at her shadow on the wall of the cave, they offer us this precious confirmation of our criticism: “Students’ mathematics is the mathematical reality they experience, which is wholly theirs and is unknowable to us in the same way dark matter is unknowable to us” (Thompson, 2019, p. 39).

It is transparent that Kant’s philosophy supports this ideology: the thing in itself is not cognoscible. Mathematicians are aware of the failure of their teaching methods. For instance, even after four semesters of calculus, students are not only unable to use the FTC, but they do not recognize its use when it is presented to them (Tompson, 1994, p. 256, ex. 7.10). Limited by the opacity of the membrane, mathematicians tend to explain this failure by the tautology of lacking: the difficulties with the FTC “stem from impoverished concepts of rate of change and from poorly developed and poorly coordinated images of functional covariation and multiplicatively-constructed quantities” (Thompson, 1994, p. 229). That is, the difficulty lies precisely in what was taught to these students.

Tall (2009, p. 484) refers to the “notion of a generic limit” to account for the difficulties of students with the limit of sequences and the concept of infinitesimal. However, as justification of this concept we only find the expedients: “a *natural human belief* that the limiting object is endowed with the same properties as the individual terms” and “infinitesimal concepts are *natural products* of human imagination” (p. 483, both emphases added). We finally collect the mathematicians’ recognition of the impossibility: “Like with dark matter, the best we can do is make models that fit observations and are consistent with other models” (Tompson, 2019, p. 39).

Cauchy and infinitesimals: *devient…le voisinage*

A full account of the polemics around Cauchy can be found in Katz and Katz, (2011) and Tall and Katz (2014); these articles include an impressive list of references only available in universities of the so-called First World. By requiring “mastery of the field” as an academic prerequisite for anyone who has something to say on the subject, one risks blocking out the new and foment cultural imperialism.

We read the second part of Cauchy’s “becomes”, together with this other excerpt: “Besides, one also says that the function $f(x)$ is, in *the neighborhood* of a *particular value* assigned to the variable *x*, a continuous function of this variable (…)” (Cauchy, 1821, p. 35, added emphasis).[5] The French

[5] On dit encore que la fonction *f*(*x*) est, dans le voisinage d’une valeur particulière attribué à la variable *x*, fonction continue de cette variable (…).

singular "*le*" stresses that a numerical "value", has only one "neighborhood". Consequently, when this value is zero, we may assume that this neighborhood consists of the "infinitely small variables" (*variables infiniment petites*, p. 65). These signifiers do not belong to the quilted speech of the bubble. We agree with Katz and Katz (2011, p. 426) that we should "jettison the automatic translation-to-limits" in reading Cauchy. Instead, we propose a reading-to-infinitesimals as in Sad et al. (2001). Cauchy is saying that a variable that converges to zero becomes an element of the *monad of zero*, o, a whole universe of infinitesimals that is incommensurable with ours.

From the dialectical perspective, Robinson is not a "consequence" of Cauchy. Marx's aphorism about the man and the primate must be evoked once more. Cauchy's discourse on infinitesimals has actually been quilted and finitized by Robinson. Only from this perspective can we look back and ask where this quilting came from and what its trajectory to the present has been. To the myriad things that have been said about Cauchy, we dare to add: the mature Cauchy of 1853 was *waiting for rigor to catch up to him* when he restated his 1821 theorem (Sad et al., 2001). This was the trajectory of the dialectics of language that led from Leibniz to Robinson.

The completion of $\mathbb{Q}$ with the monads stemming from his sequences was already an embryo in Cauchy's "intuition", with no need to invent classes of equivalence of such sequences to fill in the gaps of $\mathbb{Q}$. Indeed, consider sequences (a_k) of rational numbers that satisfy Cauchy's condition:

$$(\forall \varepsilon \in \mathbb{R}^+)(\exists N \in \mathbb{N})(\forall m, n \in \mathbb{N})(m, n > N \rightarrow |a_n - a_m| < \varepsilon)$$

We can take adequate equivalence classes of such sequences and form what we now call the field of finite hyperrational numbers O. If we introduce the operations of addition and multiplication as well as the order relation elementwise among the monads, we get a complete ordered field (isomorphic to $\mathbb{R}$), namely, the quotient ring O/o (Stroyan & Luxemburg, 1976, p. 9, Katz & Katz, 2011, p. 448). We say that a single movement of the dialectics of language that is still taking place posits these signifiers under the form of an identity quilted speech inside the bubble and also *posits ourselves as subjects who utter these speeches.*

Consequences for mathematics education

The teaching experience that we initially intended to report consists in working on the COVID-19 graphs until the students are able to formally express and meaningfully utter that 1) the variation of the running total is the area under the daily deaths, 2) the moving average of the daily deaths is the variation rate of the running total and 3) the one-day-based moving average is the number of deaths of the day before. These, of course, are the statements of FTC. Next, we replaced the discrete graphs of a few days in the pandemic with continuous graphs of an endemic disease that lasted for many years (Ellis et al., 2020). We insisted upon the expression and formula for the one-day-based moving average. The whole discussion occurred in the realm of the *dialectics of language*; we only tried to collimate the students' discourses towards the signifiers in the bubble. For instance, only when they were trying to express one day in sixty years did we suggest *dt*, "a little bit of", according to Tompson (1914). For the areas under the graph, the students suggested $A(a, b)$; neither Leibniz notation for the integral nor Riemann sums were necessary.

We did not drag the students into the bubble to teach them how to interpret the M20 readymade symbols (Ely, 2017). We believe that the more one tries to do so, the greater the difficulty for the students. Asunder from the dialectics of language and modeling shadows of students with finitary processes, mathematicians can do no more than teach finite processes. Learning depends on the infinity of variables in the dialectics of language, insofar as the students start representing themselves as subjects in *current language* by new signifiers. In this respect, the possibility of open-camera, eye-to-eye communication and video recording was a blessing to our long-standing methodology (Cabral, Pais, & Baldino, 2019) based on the aphorism *one teaches by listening and learns by talking.*

Exploring symmetries with first-year students: a gateway into mathematical structures

Filip Beran

Charles University, Faculty of Education, Prague, Czech Republic; filip.beran@centrum.cz

Keywords: Mathematics education, mathematical structures, structural thinking, symmetry, university mathematics.

In the poster, I describe one part of my project of “structural thinking and its teaching” that focuses on the design and implementation of a seminar for first-year students at the Faculty of Mathematics and Physics. The aim of the seminar is to bridge the gap between secondary and university mathematics. This seminar is based on exploring symmetries of regular polygons and polyhedra, building on students’ previous knowledge and being a starting point to more abstract disciplines.

Mathematical structures constitute the core and simultaneously the image of modern mathematics (Corry, 2004). On the other hand, the attempt for the *modernisation of school mathematics*, promoted by the Bourbakist movement and culminating in the 1960s, ended rather unsuccessfully. This attempt focused on incorporating mathematical structures into secondary school mathematics via highly abstract university-style “definition-theorem-proof” led to formalism. Hence the gap (and so Klein’s *double discontinuity*) between “modern” university mathematics and “classical” school mathematics has remained wide open and still forms a barrier, especially for first-year university students of mathematics, including future teachers.

For this reason, the seminar at the Faculty of Mathematics and Physics was created aimed at trying to help students to accommodate different styles and also to inspire them for further studies. I have a repeated opportunity to make a few sessions with students where we are exploring the structure of symmetries of geometrical objects. My goal is to familiarize them with tools and concepts which they will meet in the following obligatory courses of linear algebra (in their first year) and abstract algebra with the basics of group theory (in their second year). I use a more constructivist and visual approach and relate new concepts to their current knowledge from secondary school.

Content

In this seminar, together with students, we first explore one particular, well understandable example: symmetries of a square. From secondary school, students are well acquainted with geometric transformations (from a synthetic viewpoint) and they can easily enumerate that square rests invariant under three rotations and four reflections. However, we realize that these transformations do not form only a set, but, as we can compose them – follow one by another –, they form some algebraic structure. Therefore, students are asked: How could we describe this structure, group of symmetries of a square?

Students’ first idea is usually to record it by a table of composition (*Cayley table*), as it is analogous to a well-known multiplication table. However, to deduce all combinations geometrically is exhausting. Moreover, students realize that some of the transformations do not commute. We would like to represent the symmetries in a way we can really *compute* with them – to represent them analytically. Here, I follow students' secondary school knowledge of analytical geometry and introduce linear transformations of a plane, represented by matrices. With a general form of a matrix of rotation and reflection, completion of the table is much easier. Another suitable representation is by permutation of vertices.

Then I raise a question: Are there any effective tools that enable us to understand such structure? In a similar manner, together with students we explore possible substructures and organize them as sets by inclusion – another already known concept for students – into partially ordered set (poset), more precisely *lattice of subgroups*. By this, students also recognise various properties of different subgroups: some are commutative, some are even cyclic, and we discuss how we could represent them by *additive and multiplicative groups of integers modulo n*. The next topic is the *presentation of a group* by generators and their relations; we visualize this with the *Cayley graph*.

The example of square symmetries is particularly suitable because we can illustrate enough interesting properties and also this group is small enough to make computations inspiring rather than tedious. In this elaborate example, I provide students with principal tools and concepts enabling them to grasp the structure of a given group. Subsequently, we can extend the scope and leave students to get familiarized with tools. Students have to describe the group of symmetries of an equilateral triangle and then generalize it on a dihedral group. After this, we move one dimension higher for symmetries of tetrahedron and cube and the most interested students can also explore the icosahedral group. Physical models of those regular polyhedra, a familiar topic from secondary school, are used to make the transformations more tangible. Later we can add more concepts (e.g., quotient groups) and also explore infinite groups: symmetries of friezes and wallpapers. Further connections to Galois theory can be added from Gray's textbook (2018).

Conclusion

The content rises from current students' secondary school knowledge: geometric transformations, analytical geometry, sets and their ordering by inclusion, regular polygons and polyhedra etc. It can be a starting point for more sophisticated concepts (matrix eigenvalues and eigenvectors, normality, group automorphisms) and abstract disciplines (not only linear algebra and group theory but also universal algebra, Lie groups etc.). This content is also used in a seminar for talented students at secondary school. I hope that these ideas may be inspiring for teachers both at the university and secondary school levels. Mathematical structures do not have to be taught as an axiomatically presented subject for itself but can be incorporated into secondary and university mathematics more implicitly, mainly as an effective tool for dealing with mathematical problems. In this way, they can also promote the development of students' general structural thinking.

A replication study of university students' understanding of functions of two variables

Vahid Borji[1], Rafael Martínez-Planell[2] and María Trigueros[3]

We used Action-Process-Object-Schema (APOS) theory to analyze the possibility of replication of results obtained in our previous research on student understanding of two-variable functions when using a similar teaching approach in a different institutional context. The experience was conducted at a university in a different country from those in previous studies. The experience consisted in comparing two groups of the same course, one taught through lectures and the other using collaborative work and activities designed with APOS theory. In this study, we show a summary of results obtained through a comparison of students' performance in both groups. Findings show the generalizability of results obtained in previous studies and the possible replication of didactic aspects across institutions. In particular, it was found that using APOS theory's didactical approach favors a deeper understanding of functions of two variables.

Keywords: Functions of two variables, APOS, reproducibility, understanding.

Introduction

Multivariable functions play an important role in many professional fields in modeling numerous phenomena which naturally depend on several variables. In this research, we discuss results obtained in a research study where the didactical approach developed by Martínez-Planell and Trigueros (2012, 2013, 2019) and Trigueros and Martínez-Planell (2010) through three cycles of research on the learning of two variable functions was used by a different teacher (the first author of this article) and in a different country. Our interest was to compare results obtained in a new context in terms of similarities with those obtained previously and critically analyze the possible similarities and differences obtained. Results of the first research cycle (Martínez-Planell & Trigueros, 2012; Trigueros & Martínez-Planell, 2010) stressed the importance of helping students construct an R^3 Schema including different subsets such as points and their movement in space, and fundamental planes and their intersection curves with surfaces (for a detailed description of an R^3 Schema see Martínez-Planell & Trigueros, 2019). The authors stressed the importance of conversions between different representations. They also underscored that generalization from the one-variable to the two-variable context is not easily done by students; the reconstruction of many basic ideas is needed. In their second research cycle, Martínez-Planell and Trigueros (2013) stressed the need to explicitly consider situations where the notion of free variable is needed to graph two-variable functions, cylinders, and make sense of other subsets of three-dimensional space. In the third research cycle, Martínez-Planell and Trigueros (2019) found that students in a section that had used their research-based activity sets and using the ACE cycle (activities, class discussion, and exercises) as didactical strategy outperformed students in a regular section (without the use of specially designed activities), and were more likely than students in the regular section to construct a conceptual understanding of function of two variables.

This study can be considered a replication study (Melhuish & Thanheiser, 2018) as it aims to confirm or refute previous results in the literature. “Replication study” has various possible meanings, none of which is generally accepted (Sanchez, 2020). In this article by “replication” we mean a test of a result of earlier research work that replicates most of the methodological features of the original study. Our study also satisfies conditions proposed by Star (2021), for a study to be a replication rather than a follow-up study, in that our study starts from results (rather than from a new idea) and it has a basic structure isomorphic to that of the original study, with methodological differences that do not alter that structure. Our replication study cannot be said to be either internal or external, in the sense that two of the researchers participated in the original study (internal) and one did not (external). The advantage of an internal replication is the knowledge of instruments, methods, and contributions of the original study, thus allowing a more faithful reproduction; the disadvantage is that it may be subject to some unconscious confirmation bias and that it might allow the incidence of “inside” knowledge that would make it difficult for others to conduct equivalent studies (Schoenfeld, 2018). Our study pairs internal and external elements and so has the experience advantage of internal replication, while the external member affords the needed independence to safeguard against confirmation bias and the incidence of “inside” knowledge. The merit of this type of study has been suggested by Melhuish and Thanheiser (2018), We consider that the inclusion of the external researcher helped in overcoming both the incidence of internal knowledge, with his independent teaching, and the subjective bias that the original authors may introduce in their results. Generalizability and confirmation bias (Schoenfeld, 2018) is further addressed by the negotiation of results in the independently obtained analyses. Mathematics education, as a field of study, strives to understand and describe findings but also to change and improve the way mathematics is taught. It is important to aim to go beyond basic research and propose and test research findings under the same conditions and also under new ones to describe the conditions, affordances, and constraints of the experience (Maass et al., 2019). Replication, as described above may validate research results, and help understand their possibilities and constrains under different conditions. Given the importance of multivariable calculus and the observed difficulties that students have learning this topic, it is important to study if pertinent research findings are applicable in different classrooms and to verify if this is the case in different institutional contexts. That is, it is important to question, could other researchers, in other types of institutions, with a different sample population, obtain comparable results?

Theoretical framework

In APOS (Arnon et al., 2014), an Action is a transformation of a mathematical Object that the individual perceives as external. An Action may be the rigid application of an explicitly available or memorized procedure. When an Action is repeated, and the individual reflects on the Action or on a chain of Actions, it might be interiorized into a Process. A Process is perceived as internal. The individual is able to justify the Process, to omit steps and anticipate results without explicitly performing the Process, and thus to generate dynamical imagery of the Process. When the individual is able to perceive a Process as an entity in itself, and is able to do or imagine doing Actions on it, the Process is encapsulated into an Object and new Actions can be performed on it to determine, for example, its properties. An Object can be de-encapsulated into the Process it came from when necessary. A Schema is a coherent collection of Actions, Processes, Objects, and other previously constructed Schemas having to do with a particular mathematical notion or topic. In APOS, mathematical knowledge with respect to a specific mathematical notion or topic, is defined as the general tendency of the students to perform Actions, Processes, Objects or Schemas in different problem situations related to the notion. Research in APOS typically starts by proposing a model, in terms of the structures and mechanisms of APOS, of how a student may construct a specific mathematical notion. This model is called a genetic decomposition (GD). It is used to design research instruments and didactic activities. After implementation of the GD-based activities, research is undertaken to find out what conjectured constructions students can do, which cause them difficulty, and what unconjectured constructions are done by students. Research results may suggest revising the GD and, consequently, the designed activities. The revised GD may then be tested through another research cycle. One may continue doing research cycles until the GD no longer needs revisions. At that moment the GD will model how students, in practice, do construct the mathematical notion of interest. The research questions in this study are: How do students' constructions when using research-based activity sets and the ACE cycle compare to those of students in a lecture-based section not using the activities? How do students' constructions compare with those obtained in the previous study?

Methodology

Two groups of an Iranian university participated in this study, one which will be called the APOS group, and the other the regular group. The APOS group worked collaboratively with GD-based activities designed for the third cycle of the Martínez-Planell and Trigueros (2019) study. Students in the regular section were taught mainly through lectures. Both groups used the same standard textbook (Stewart, 2012) and followed a very similar course syllabus (chapters 12 to 16 of Stewart), including the same assigned homework exercises. The main difference was the use of the additional GD-based activities (Martínez-Planell & Trigueros, 2017) for the APOS group and the teaching methodology. Eleven students from each group were chosen to be interviewed so that in each group they represented the spectrum from above average to below average students as determined by their one-variable calculus course grade. The participating students were chosen so that those course grades were as similar as possible. Both groups (APOS and regular) had the same professor in their previous one-variable calculus course; the professor that taught the multivariable calculus course to the regular group of the present study. The professor of multivariable calculus for the APOS group was one of the authors of this article. All of the interviews were conducted by the instructor of the APOS group. Each interview lasted about 1 h. Interviews were conducted in person (not online), recorded, transcribed, and translated. The transcripts were individually analyzed by the researchers and differences in opinion were negotiated. Students' response to the interview questions were graded for their mathematical correctness; this was used to identify general patterns. The instrument involved questions related to constructions of: 1) fundamental planes (planes of the form $x = c$, $y = c$, $z = c$, for c constant) and their intersections with surfaces, 2) free variables (i.e., variables that can take any value without affecting the values of the other variables, like y in $f(x,y) = x^2$, $z = x^2$, or in the intersection of the plane $x = 0$ with the surface $z = xsin(y)$), 3) graphing two-variable functions, and 4) domain and range.

Results

We compared the performance of students in the APOS and regular sections. Our comparison showed that the total percentage of correct answers in the graded interview questions obtained in the APOS section (65%) was more than twice that of the regular section (25%). Table 1 compares the average scores of students in the APOS and regular sections in problems dealing with the intersection of a surface with a fundamental plane, the notion of free variable, domain and range, and graphing. It also compares the results of this study with those of students of the original article (Martínez-Planell & Trigueros, 2019). The table suggests that the GD proposed by Martínez-Planell and Trigueros (2019) and the activity sets, designed to foster students' constructions described in the GD, seem to help students construct a deeper knowledge of basic and geometric notions of functions of two variables.

Table 1: Comparison of APOS and regular sections in the original and reproducibility studies, by problem categories (total points obtained/total possible points)

Problems dealing with:	% APOS section reproducibility study	% Regular section reproducibility study	% APOS section original study	% Regular section original study
Fundamental planes	70	15	85	25
Free variable	67	18	58	17
Domain & Range	64	45	72	21
Graphing	60	20	84	23
% entire instrument	65	25	77	34

Fundamental planes and their intersections

Eight of the eleven students in the APOS section showed to have constructed fundamental plane as a Process or were in transition to doing so. Student A6 demonstrated the construction of fundamental plane as a Process. When drawing in 3D space the collection of points in that satisfy the equation $y = 2$ and that are also in the graph of the function $g(x,y) = x^2 + x^3(y-2) + y^2$:

Student A6: I only need to know the graph of $g(x,y)$ when $y = 2$, umm the $y = 2$ is a plane. I consider $g(x,y)$ as z. I have to substitute $y = 2$ into $g(x,y)$ and x can be everything. So z will be umm $x^2 + 4$, its graph is something like a parabola which is placed on the plane $y = 2$. When x is 0 then z will be 4 so the minimum height of the parabola is 4 umm at the point $(0,2,4)$ [Figure 1].

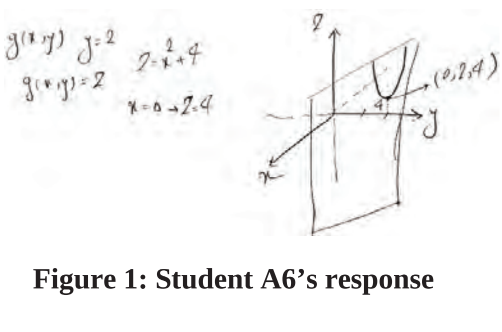

Figure 1: Student A6's response

Student A6's overall behavior gave evidence of construction of the Process of fundamental plane. He gave evidence of relating algebraic and graphical representations of fundamental plane, including its placement in space. Moreover, A6 also demonstrated to have encapsulated this Process into an Object by performing Actions upon it, in order to obtain the resulting curve and to place it in its appropriate place in space. In comparison to the APOS section's students, only three of the eleven students in the regular section showed the construction of fundamental plane as a Process or showed to be in transition to doing such a construction. To exemplify the understanding of fundamental plane constructed by most students in the regular section, we consider R4's response to the same problem:

Student R4: I know $y = 2$ is a line in 2D and it's a plane in 3D.

Interviewer: Okay, find what the question asks for.

Student R4: I can't draw $g(x, y) = x^2 + x^3(y - 2) + y^2$ in 3D.

Interviewer: Is it necessary to draw it?

Student R4: For solving this question yes, I need, so I can't solve this question.

Student R4's response showed that although he was aware that $y = 2$ is a plane, he believed that he needed to draw the surface in order to represent its intersection. He seemed not to be aware of the geometrical meaning of substituting a number for a variable in an equation; he showed a rigid understanding of its being a plane with algebraic representation as a variable equal to a constant but he was not able to use this information to do the needed Actions to find the intersection with the surface. R4's responses throughout the interview showed that R4's understanding of fundamental plane can be considered as consistent with an Action conception.

Free variables

We found that six students in the APOS section could construct a Process of free variable, meaning that they coordinated the Processes involved in relating the algebraic context of an equation (some with unnamed variables) and its solution set, with the verbally or symbolically given geometric context in which the equation and its solution set were to be interpreted. Two more students in the APOS section evidenced to be in transition to constructing such coordination. In contrast, two students in the regular section showed they had constructed or were in transition to constructing that coordination. We consider A5's response to one of the questions related to free variables. In the question, students were asked to draw the intersection of $S = \{(x, y, z): x^2 + 2x + y^2 = 3\}$ with the *x* axis:

Student A5: On the x-axis, we have $y = 0$ and $z = 0$, so I have to put 0 for y, I should solve the equation $x^2 + 2x = 3$, the values of x are 1 and -3, therefore the answer will be two points, (1,0,0) and $(-3,0,0)$.

A5 was able to interrelate the given equations, the unmentioned variable *z*, and the context of the *x* axis he was asked to presume. By contrast, only two students in the regular section (compared to eight in the APOS section) gave evidence of relating the given equation, unnamed variable, and presumed context for solving problems related to free variable, or were in transition to constructing such relations. There were seven students in this section who were not able to correctly or even partially solve any of these problems. R3 is an example of such a student. In the same problem as above:

Student R3: For $z = 0$ we have a circle umm it's $(x-1)^2 + y^2 = 2$, [sic] umm a circle with radius 2... Since we are in 3D, I think we have a sphere with center $x = 1, y = 0$, and $z = 0$. So, the intersection with the x axis will be a segment of the x axis.

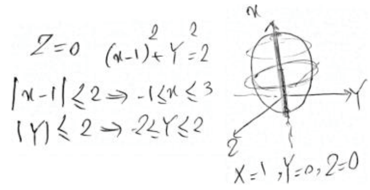

Figure 2: Student R3's work

Note, not taking into account her algebraic mistakes, that R3 attempted to graph the surface S rather than interpret algebraically the required context of the x axis, and she set the missing variable equal to zero ("for $z = 0$"), without making reference to the x axis, rather than treat it as a free variable.

Graphing

In general, the graphical representation of functions of two variables posed difficulties for students in all the sections. However, students in the APOS section were more likely to exhibit behavior consistent with a Process conception of function graphing than students in the regular sections, who seemed to rely more frequently on memorization or who showed not to have yet constructed a relation between fundamental planes and graphs. We consider A4 as an example of a student in the APOS section who evidenced construction of a graphing Process. When graphing $f(x, y) = x^2$:

Student A4: If my parabola $z = x^2$ that I drew it in the previous part moves in the y direction then I can imagine the graph $z = x^2$ in 3D, a surface umm it's like this [See Figure 3, left].

In her response, A4 showed to relate fundamental planes to graphing ("if my parabola $z = x^2$ that I drew it in the previous part") and gave evidence of dynamical imagery ("… moves in the y direction"). Showing connections between different representations and generating dynamical imagery is consistent with a Process conception. Eight of the eleven students in the regular section could do none or only one of the five problems dealing with the graphical representation of a function. We considered R3 as an example of these students. When graphing $f(x, y) = x^2$, R3 interpreted it as $y = x^2$ and directly generalized from the 2D to the 3D context to obtain a paraboloid (Figure 3, right). Moreover, she was not be able to justify, which is consistent with performing Actions.

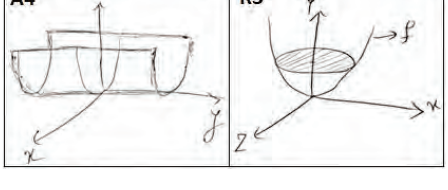

Figure 3: A4's work (left) and R3's work (right) in drawing $f(x, y) = x^2$

Domain and range

We will focus on two of the interview problems dealing with domain, where students had to represent the domain of $f(x, y) = x^2 + y^2$ restricted to the pairs that satisfy $-1 \leq x \leq 1$ and $-1 \leq y \leq 1$ as a subset of 3D space, and also had to find the domain of $g(x, y) = x^2$.

Student A4: It explicitly tells us that the domain of $f(x, y) = x^2 + y^2$ umm is all the pairs (x, y) such that $-1 \leq x \leq 1$ and $-1 \leq y \leq 1$. Its figure I mean the domain in 3D is like this square in the xy plane [Figure 4, left].

Student A4: [in the next problem] The domain of function $g(x, y) = x^2$ is R^2 because I can put all the points (x, y) of the xy plane into $g(x, y) = x^2$.

The above response shows that A4 reconstructed her notion of function domain to deal with the new situation of functions of two variables. Domain elements are now ordered pairs of real numbers rather than real numbers. Further, she relates her verbal set-theoretic description to the graphical representation of domain in 3D. Now consider the case of student R4.

Student R4: The domain of f is umm set of points $(x, y, 0)$ such that $-1 \leq x \leq 1, -1 \leq y \leq 1$, and x, y belong to R^3. The domain is this part on the x axis and this part on the y axis [Figure 4, right].

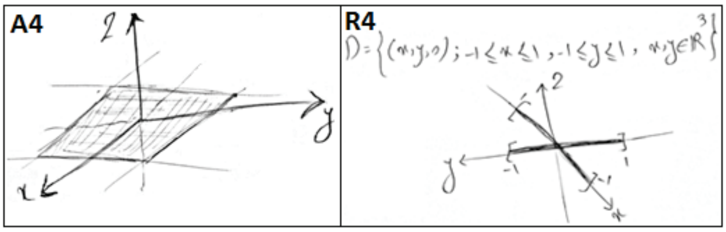

Figure 4. A4's work (left) and R4's work (right) in representing the domain

Student R4's drawing shows that he attempted to directly generalize his notion of one-variable function domain as an interval of real numbers to deal with the new two-variable function context. He did not show the reconstruction of domain as a set of ordered pairs.

Discussion and conclusions

In this study, as in the original, considerable differences in the constructions made by students in the APOS and regular sections were found. Observation shows that in both, the original and new studies, students who were taught using APOS theory's didactical approach and using the activities designed with a validated genetic decomposition showed the constructions of the expected Actions and some of them showed the construction of Processes demonstrating a deeper learning of topics related to functions of two variables. Discussing replicability of studies in the context of mathematics education research is difficult. Mathematics education is a social phenomenon and, as such, is also complex. We limit our attention to study if the use of a specific didactical approach based on a cognitive theoretical approach to teach a specific mathematics topic, functions of two variables in this case, results in similar learning in two different institutions. It is very interesting to observe that the mental constructions observed in students in the APOS and regular sections in both institutions seem, for the most part, to be independent of the country and the institution where they were studied. So, our results show that there may be cognitive factors that are somehow independent of social, cultural and institutional differences. Results show that the use of activities designed in terms of the constructions described in a validated GD, in this case for the teaching of two-variable functions, are useful in promoting a deeper learning of this topic in two different contexts when the teaching approach follows the ACE cycle. This may ratify the strength of the GD as a design model and also how research-based activities using this prediction model and collaborative work can result in students' learning with some independence of the teacher, the institution and the country where they are used.

University students learning programming-based practices for mathematical inquiry: Contributions of an institutional approach

Laura Broley[1], Chantal Buteau[1] and Joyce Mgombelo[1]

[1]Brock University, Canada; lbroley@brocku.ca

In mathematics education research, the use of different theoretical lenses can lead to a deeper understanding of phenomena such as the teaching and learning of programming for mathematical inquiry at university. In light of our past work leveraging the instrumental approach, this paper seeks to explore the potential contributions of a different lens: the Anthropological Theory of the Didactic (ATD). Through a comparative analysis of "practices to be learned" in a mathematical inquiry project and "practices actually learned" by one student, we demonstrate the usefulness of the ATD's notion of praxeology. The complementarity of the analysis with our past work calls for further reflection on the networking of institutional and instrumental approaches.

Keywords: Institutional approach, praxeology, mathematical inquiry, computer programming.

Introduction

Researchers working on the networking of theories in mathematics education claim that using different theoretical lenses can lead to a deeper and more complex understanding of a phenomenon of interest (Bikner-Ahsbahs & Prediger, 2014). In our work, we are interested in the teaching and learning of programming for conducting mathematical inquiry at the university level. So far, our research team has utilized the instrumental approach and demonstrated the usefulness of several of its tools: e.g., the notion of scheme for understanding individual students' learning over time (e.g., Buteau et al., 2019) and the notion of instrumental orchestration for exploring how instructors create a learning environment to support students' learning (e.g., Buteau et al., 2020). In this paper, our aim is to see what additional understandings could be gained about our phenomenon of interest when using a different theoretical lens: namely, the Anthropological Theory of the Didactic (ATD). More specifically, the research question guiding our work is: How can the theoretical tools offered by the ATD contribute to our understanding of students learning to use programming for mathematical inquiry at university?

The selection of the ATD was inspired in part by the fact that it has been used by the first author in several past works (e.g., Broley et al., 2018, which reports on mathematicians' use of programming in research and teaching). The ATD is also becoming increasingly used by researchers of university mathematics education; however, as far as we know, it has not yet been used in research about students learning to use programming for mathematical inquiry. Moreover, overviews of the use of different theoretical lenses to investigate university mathematics education have highlighted the potential complementarity of the ATD and the instrumental approach (e.g., Gueudet et al., 2014; Winsløw et al., 2014). As such, we see our work as providing both an empirical and a theoretical contribution. In particular, this paper is a natural first step towards a deeper reflection on the networking of the ATD and the instrumental approach, for the purposes of better understanding how university students learn to use programming for mathematical inquiry.

Theoretical framework

The ATD was initiated by Yves Chevallard in the 1980s and has since grown to include a significant collection of theoretical tools for investigating mathematical and didactic activities. In this paper – the beginning of our work on the question posed above – we will consider only a subset of these tools.

Central to the collection of tools offered by the ATD is the notion of *praxeology* (Chevallard, 1999), which provides a way of describing the practices (i.e., regularized and purposeful human actions) that are involved in any human activity. According to the notion, every practice is composed of four interrelated, essential components: a type of task (generating the need for the practice), techniques (ways of doing the types of task), technologies (discourses producing, justifying and explaining the techniques) and theories (the rational discourses underlying the technologies). Hence, practices necessarily comprise both a practical part (the types of tasks and techniques, called the *praxis*) and a theoretical part (the technologies and theories, called the *logos*).

Another critical tool in the ATD is the notion of *institution* (Chevallard, 1991): a relatively stable structural element of a society that frames and promotes certain kinds of human actions (towards the achievement of certain aims). Indeed, a fundamental idea behind the ATD is that the praxeologies of an individual (e.g., a student) do not exist in a vacuum, but are shaped by the social institutions (e.g., universities) where they are developed. Artigue (2016) explains that with the ATD:

> The lens is no longer directed towards the student and her cognitive functioning or development, but towards the institutional practices that condition and constrain, both explicitly and implicitly, what she has the possibility to learn or not. (p. 17)

Bosch and Gascón (2014) add: “an ATD analysis therefore starts by approaching *institutional praxeologies* and then referring individual behavior to them, talking in terms of the ‘praxeological equipment’ of a given person” (p. 69).

A third critical tool in the ATD is the notion of *didactic transposition* (Chevallard, 1991), which highlights the institutional relativity of praxeologies with respect to three institutions that are pertinent to thinking about university mathematics education: professional communities (which produce and use “professional practices”), an education system (which, through programs, curricula, course outlines, textbooks, etc., determines “practices to be taught”) and a classroom (where interactions between teachers and students determine “practices to be learned” – e.g., through the assessments given in the course, and “practices actually taught and learned”).

In this paper, we propose to use the notion of praxeology to describe and analyze practices that are involved in the activity of “using programming for conducing mathematical inquiry”. Since we are interested in “students learning” to engage in this activity, we start by working at the level of a classroom institution, embedded in a particular education system (described in the next section). Following an institutional approach, we start by examining institutional praxeologies (in particular, practices to be learned, inferred from assignment guidelines and anticipated solution approaches), which may shape the practices that students have the possibility to learn. We then use this as a base to investigate the potential praxeological equipment of (or practices actually learned by) students.

Context and methods

The study we present is part of a larger 5-year (2017-21) iterative design, non-interventional research that uses as a context three programming-based math courses at Brock University: Mathematics Integrated with Computers and Applications (MICA) I, II and III. In these courses, students design, program and use computer environments to investigate mathematical concepts, conjectures and real-world applications (Buteau & Muller, 2010) – i.e., to engage in mathematical inquiry.

We focus on MICA II, the second course in the sequence. Certain features of the education system (Brock's MICA concentration) ensure that the structure and operation of MICA II is relatively stable. With MICA I as a prerequisite, MICA II students are expected to have developed some practices for using a programming language to solve some foundational types of tasks (e.g., produce the graph of a given function); in MICA II, the aim is for students to use and build on these practices to engage in mathematics inquiry projects. Course outlines specify the evaluations: 4 mini-projects (worth 12% each), 1 final project (worth 22%) and 2 midterms (worth 15% each). Each week during a semester, students participate in 2-hour lectures (where the professor mainly introduces math content related to the projects) and 2-hour labs (where the students can work on their projects among their peers and with access to teaching assistants and/or the professor). In a certain semester, the professor giving the MICA II course determines the topics of the projects and hence the particular practices to be learned.

The current study used data collected from one MICA II classroom, when the course was given in 2019. The data is of two types: (1) guidelines for the 4 mini-projects and the final project (i.e., 5 assignments), which can be found in Ralph (2020); and (2) semi-structured interviews that were conducted with volunteer MICA II students shortly after they completed each of their assignments, which aimed to guide the students in reliving and describing their actions. In alignment with these two data types, our study proceeded in two stages. First, we constructed a reference epistemological model (Bosch & Gascón, 2014) of practices to be learned in the first MICA II assignment: i.e., practices that students may (be expected to) learn when engaging in the assignment. We modelled types of tasks and techniques by looking at the formulation of the assignment questions, considering the kinds of objects involved, and thinking about anticipated solution approaches of students, based on our understanding of the MICA courses (as researchers, instructors, and/or past students) and the mathematics involved in the assignment. We modelled technologies and theories by thinking about mathematical justifications for the modelled techniques. Note that our model does not necessarily reflect the exact material presented in lectures (we did not have access to that data for the current study) or the intentions of the professor (they were not interviewed for our study). Moreover, we do not claim that our model is absolute or comprehensive: It contains elements that helped us as researchers begin to explore what students may learn when engaging in the assignment. Second, we explored the praxeological equipment exhibited by one MICA II student, Mark, during the interview that followed assignment 1. To accomplish this, Mark's interview was coded to find evidence of his perceptions in relation to the different components of our reference model. These perceptions were recorded in "praxeology tables", with evidence sorted in rows according to whether it corresponded to types of tasks, techniques or technologies (as is typical of analyses of students' praxeologies, we did not find evidence specific to the level of theory). It is important to note that the interviews were not designed for the purpose of probing into Mark's perceptions in relation to the praxeologies in our reference model; and yet, Mark spontaneously provided evidence of his perceptions. This is part of the reason he was selected for the current study, to allow us to explore potential new directions for our work in terms of theoretical lenses and data analysis. It is also important to note that Mark may not be representative of all MICA students. He is a computer science and mathematics co-major who, unlike many of his peers, had significant programming experience prior to the MICA I course.

Results

A reference epistemological model of the practices to be learned in assignment 1

In this section, we present our reference model of the practices to be learned in assignment 1, using the notion of praxeology. Assignment 1 contains 5 questions (Q1, Q2, Q3, Q4, Q5), which invite students to work on and explore the scope of a statistical computational technique ("Monte Carlo") for "estimating numerical values" (we note that this is a *genre* of task, which is more general than a type of task; Chevallard, 1999). All students are required to do Q1-3 and then can choose either Q4 or Q5. For the complete assignment, including complete question statements, see Ralph (2020). In this paper, we focus on Q1, Q3 and Q5, due to space constraints, and since these were the ones for which Mark presented explicit evidence of his related praxeological equipment in his interview.

In lectures prior to assignment 1, students are introduced to the Buffon needle problem, including an analytical solution (a derivation of a formula) and a computational solution (the writing of a code) for the task: find/estimate the probability that a needle touches a line if it has length $l = 1$ and it is dropped onto a plane of parallel lines that are $d = 1$ unit apart. Crucial to these solutions is an initial modelling of the situation, which transforms the original task into a new one: find/estimate the area in $[0,\pi]$ x $[0,0.5]$ such that $y \leq (1/2)\sin(x)$. In Q1, students modify the code (and model) given in class to create a program (Figure 1) to "find" the probability if the length of the needle is changed to 0.5. Generally speaking, the task solved in Q1 (like the task solved in class) belongs to the type of task T_1: Estimate the probability of an event in a random experiment. However, the modelling of the random experiment leads to a task of another type: T_2, Estimate the volume of a bounded k-dimensional subset A. In Q3, students create a program to solve another task of this type: i.e., estimate the hypervolume of the unit hypersphere in R^4 ($k = 4$, $A = \{(x,y,z,w)|\ x^2+y^2+z^2+w^2 \leq 1\}$).

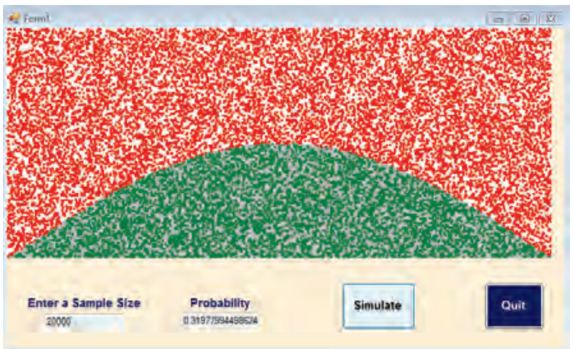

Figure 1: A student's program for solving Q1

We could model the Monte Carlo technique that can be used to solve T_2 as: τ_2, put A in a set B whose volume is known (e.g., B is the hypercube in Q3), choose n points at random in B (with n sufficiently large), keep track of the number of points m that are in A and calculate m/n*Area(B) (the estimate). One main technology underlying τ_2 is: θ_2, as the number of points increases, the estimation becomes more accurate. This is a particular instance of the "law of large numbers", which is supported by the theory: Θ, Probability and Statistics.

For MICA II students, a computational version of τ_2 is implemented in the vb.net programming language typically through modifying the original code given in class: studying the code and making relevant modifications may support students in abstracting the technique. In the tasks faced by students, B is provided (e.g., Q3 specifies to carry out the estimation by "choosing n points at random inside $[-1,1]^4$"). Moreover, the program students create enables them to vary n until it is judged to be sufficiently large to produce an accurate estimate; and in Q1 and Q3, this judgement can be made by comparing the output (an estimation) with a *known* actual value. Such a comparison may support students in developing θ_2 (though it would not be possible when trying to estimate an *unknown* value).

An additional part of Q3 introduces another way to judge the accuracy of an estimate. Students are invited to estimate the hypervolume accurate to one decimal place, which leads to a modification of $[T_2, \tau_2, \theta_2]$. To estimate the volume to a certain accuracy (T_3), students build on τ_2 to implement a new technique, τ_3: they create a program that carries out the estimation process described by τ_2 a specified number of times (w) and calculates the mean and standard deviation of the estimates (the mean is the new potential estimate), and then they vary n and w (increasing them) until a sufficiently small standard deviation is obtained (e.g., taking into consideration that 99.7% of all means would lie within three steps of the standard deviation from the mean). In this case, one main technology underlying the technique is: θ_3, a specified version of the "central limit theorem", which ensures an approximate normal distribution for a large number of independent, identically distributed variables.

Finally, Q5 introduces students to another praxeology based on a widened theory, including Calculus and Analysis. In particular, Q5 asks students to: suppose that two numbers a and b are chosen at random from $\{1, 2, \ldots, n\}$; let P_n be the probability that a and b are relatively prime; and answer: As n goes to infinity, does the limit of P_n exist? Can you guess the exact limit? The type of task explored here could be modelled as: T_4, find the limit of a sequence $(P_n)_n$, where the sequence values are the probability of an event of a random experiment. The technique τ_4 has two parts: students go back to engaging in a task of type T_1 to estimate a sequence value P_n for a given n using Monte Carlo techniques; then they vary the value of n, for larger and larger values, to see if P_n appears to approach a certain value. Underlying this technique are technologies, θ_4, related to the estimation of limits: e.g., if the values seem to get closer to a specific value as n increases, this may be the limit of the sequence.

Mark's praxeological equipment related to assignment 1

In this section, we use perceptions shared by Mark when describing his actions in completing assignment 1 to think about his praxeological equipment with respect to the reference model outlined above. Tables 1, 2 and 3 provide some selected quotes from Mark's interviews, which serve to exemplify his perceptions in relation to the three main praxeologies in our model.

Although there are some imprecisions in Mark's descriptions, they suggest a praxeological equipment that reflects well the techniques and technologies in our reference model. Consider, for example, the way Mark describes the technique for estimating the volume of the hypersphere (Table 1): he explains the existence of two embedded spaces, the dropping of random points and the required check for points that hit (or miss) the smaller space. He also justifies the technique by referring to the "large amount of points" he dropped, suggesting an awareness that the accuracy improves as the number of points increases. In a similar vein, Mark's perceptions of the practice for estimating the volume to a certain accuracy (Table 2) includes some key elements of the technique (the replication of the process of dropping points and the aim of "a really small" standard deviation) and the technology (the idea that the desired accuracy should be maintained several standard deviations from the mean since “over 99%” of means lie in that range). Finally, Mark’s perceptions of finding the limit in Q5 (Table 3) reflect a technique using “trial and error of inputs” with bigger and bigger numbers, supported by a technology of the sort: if the outputs get “closer” to a value, the limit exists (and that’s the limit).

Table 1: Mark’s perceptions in relation to [T_2, τ_2, θ_2]

<table>
<tr><td>T_2</td><td rowspan="2">“the code was similar to question one in the fact that you have um, a space, uh contained within a, a larger space, and you're dropping uh, random points and you're … simply checking uh if you're hitting or missing this smaller space, uh to estimate the volume of it”</td></tr>
<tr><td>τ_2</td></tr>
<tr><td>θ_2</td><td>“because I was able to … run a simulation where a large amount of points … are dropped, uh that gets a fairly high accuracy obviously because there's so many data points”
“because it's on computers you're able to do it so many times”</td></tr>
</table>

Table 2: Mark’s perceptions in relation to [T_3, τ_3, θ_3]

<table>
<tr><td>T_3</td><td>“once the program was done I had to switch over into math mode to … prove that the 4.9 was accurate”</td></tr>
<tr><td>τ_3</td><td rowspan="2">“I was able to run a simulation where a large amount of points … are dropped … and then that's also replicated … I was able to do I believe almost 100,000 or so points, um, nearly 200 times. Uh so because of this you're able to get a, um, fairly accurate mean value of uh 4.9 um, … the main thing was that you're able to get a really small standard deviation of 0.002 or whatever, um, so even three or four standard deviation points off you're still accurate to that 4.9 decimal place which um, obviously means that over 99% of your trials show up that it's going to be that 4.9 accuracy”</td></tr>
<tr><td>θ_3</td></tr>
</table>

Table 3: Mark’s perceptions in relation to [T_4, τ_4, θ_4]

<table>
<tr><td>T_4</td><td>“you're looking for basically a probability as Pn approaches infinity”</td></tr>
<tr><td>τ_4</td><td rowspan="2">“what I ended up … doing was … there's just a small table that kind of shows … the outcomes that um I did so that way I could show um as the numbers got bigger it did get closer to that probability.”
“it was more so … trial and error of inputs to uh, try and prove that uh, that the limit did exist, so um, it was uh trying to find a match between incredibly large numbers that you know, can quote ‘prove infinity’, uh versus finding numbers that would make you sit there through the entire lab waiting for an output”</td></tr>
<tr><td>θ_4</td></tr>
</table>

Interestingly, Mark does not refer to specific mathematical theoretical elements such as the “law of large numbers” or “central limit theorem”; in fact, he indicates that some technologies are “obvious” (Tables 1 and 2), which could be indicative of a “non-mathematical” theory (i.e., an explanation of a technology that is not based on relevant mathematical properties). Also, Mark’s perceptions highlight other kinds of technologies – specific to computational techniques – that were not included in our reference model and that relate to both the affordances of computers (e.g., they allow you to repeat mathematical processes many times; Table 1) and the constraints (e.g., even computers have a limit as to how many times they can repeat certain mathematical processes; Table 3).

Towards the end of his interview, Mark gives his view of the key idea behind assignment 1:

Mark: I would say this one the key kind of concept was finding exact, um, exact values through estimation … it was definitely a cool thing so, when you're building your program, and you're like "Alright I'm just going to throw in some really big numbers and we're going to get really close to this number that's mathematically correct".

Mark seems to perceive a genre of task that differs slightly from the one in our reference model, emphasizing the estimation of *known exact* numerical values (or numbers that are "mathematically correct"). In each of Q1, Q3 and Q5, Mark found an exact answer (e.g., using Google) to compare with the estimate produced by his computer program. It would be interesting to see how his praxeological equipment might differ when the numerical value being estimated is unknown.

Conclusions

In this paper, we sought to explore how the theoretical tools offered by the ATD can contribute to our understanding of university students learning to use programming for mathematical inquiry. We claim that our analysis demonstrates the potential usefulness of the notion of praxeology: e.g., it allows us to describe and reflect on specific mathematical practices students may have the possibility to learn while (and for) engaging in programming-based mathematical inquiry projects, and to investigate the degree to which certain students learn those practices or not.

We note that the praxeologies presented in this paper are not specific to a particular programming environment. Although we see the development of such general praxeologies as a pertinent aim of teaching students to use programming for mathematical inquiry, the question remains as to how the specificities of an environment could shape students' praxeological equipment. One limitation of our study is that it used existing data from interviews that were not framed by the ATD. Further investigation into students' praxeological equipment would require a revision of existing research tools and a reflection on the usefulness of other data sources (e.g., students' responses to midterms).

In relation to our past work using the instrumental approach, we see the analysis presented in this paper as complementary. For instance, using the notion of instrumented action schemes, we have so far focused on modeling operational knowledge that is developed and used across MICA inquiry projects, primarily when students program a computer environment for the purposes of their inquiry (e.g., Buteau et al., 2019). In comparison, using the notion of institutionalized praxeologies, we were brought to focus on modeling mathematical knowledge that is developed and used in particular MICA projects, primarily at stages outside of the programming: e.g., when students use their programmed computer environment to conduct the inquiry. The current study seems to open a window into other key parts of students' learning. Such complementarity warrants further reflection not only on the potential contributions of the ATD, but also on its networking with the instrumental approach.

STACKification: automating assessments in tertiary mathematics

Ben Davies[1], Teresa Smart[2], Eirini Geraniou[2] and Cosette Crisan[2]

[1]University College London, Department of Mathematics, London, United Kingdom; ben.m.j.davies@ucl.ac.uk;

[2]University College London, Institute of Education, London, United Kingdom; teresa.smart@ucl.ac.uk; e.geraniou@ucl.ac.uk; c.crisan@ucl.ac.uk

In this paper, we report on four university lecturers' first-time experiences with computer-aided assessments. They were required to automate a significant proportion of the pre-existing weekly coursework for modules in first- or second-year undergraduate mathematics using STACK. We consider lecturers' perspectives on the role of computer-aided assessments in course design for undergraduate mathematics; the knowledge of technical aspects required to implement STACK-based assessments; and the perceived merits of automated assessment for different aspects of mathematical study. We conclude with a series of reflections upon our departmental practice and the process of enculturating mathematicians into the realm of automated assessment.

Keywords: Automated assessment, instructional design, mathematics coursework, thematic analysis.

Introduction.

In this paper, we focus on the introduction of STACK (a **S**ystem for **T**eaching and **A**ssessment using a **C**omputer algebra **K**ernal) to a Russell Group University in London. In particular, we set out to study a department-wide initiative where lecturers are expected to implement the majority of coursework using STACK. Students' weekly submission of handwritten solutions to problem sheets transitioned to the use of the STACK online environment which automatically assesses their answers and provides feedback.

The COVID-19 pandemic has dramatically increased the urgency and extent to which tertiary education has transitioned online. However, we understand this to be an acceleration of changes already underway in many parts of the tertiary sector. While we position our research as having general applications independent of the global health circumstances, we must acknowledge the environment in which this data was collected. Computer-Aided Assessment (CAA) has been on the agenda for the department from which we report for several years. However, the immediacy of the transition away from traditional handwritten assessments is, in large part, the result of the urgent need for remote, contactless instruction.

Given the urgency with which lecturers were required to automate their assessments, the default workflow for the majority of modules focused on the 'translation' or 'STACKification' of existing materials into CAAs. Some scholars may argue that this workflow is inherently flawed, and that effective CAAs should be generated in isolation, free from the restrictions of human graders (Sangwin, 2013). In the interests of space, we prefer to acknowledge the pragmatism of STACKification, and conjecture that many others using STACK for the first time are likely to follow a similar workflow. The process of STACKification warrants structured investigation, independent of scholarly arguments regarding the optimal origins of CAAs.

We report on semi-structured interviews with four lecturers and two postgraduate students, employed to support the design and implementation of STACK-based assessment across the department. All participants have been involved with the project for less than one year, and none had any prior experience with STACK (or any other CAA) prior to the project. The first author of this paper is also in the department and is responsible for co-leading the development of STACK-based resources.

Assessment in tertiary mathematics, and the increasing role of CAA.

Despite decades of innovation in assessment methods and tools, closed-book written examinations continue to dominate assessments for tertiary mathematics (Iannone & Simpson, 2011). Recent decades have seen an increase in the variety of assessment methods available to practitioners, but many of these innovations have struggled to gain popularity beyond the researcher communities in which they are developed. Researchers have highlighted the value of low-stakes formative assessments (Black & Wiliam, 2010), and called for greater assessment variety across undergraduate degrees. In this paper, we focus on Computer-Aided Assessment (CAA) and its role in a balanced 'assessment diet' (Iannnone and Simpson, 2011) alongside other modes including written and oral modes.

The last decade has seen significant growth in the availability of CAA technologies, from which STACK has emerged as a major player in the assessment of tertiary mathematics (Fahlgren et al., 2021). STACK uses a computer algebra system to evaluate students' responses against a wide array of mathematical properties. Unlike many of its predecessors that invoke little more than string matching or numerical equivalence, STACK uses a computer algebra system, based on open-source Maxima, to establish numeric and algebraic properties of students' answers. While STACK can be used for summative assessment, 'the actual potential lies in the possibilities for formative assessment; eliciting evidence of student understanding and providing feedback that moves learners forward' (Fahlgren, et al., p. 74). A detailed exposition of the affordance of STACK can be found in Sangwin (2013), and on stack-assessment.org. This software is currently 'used by universities, commercial [entities] and developers in over 15 countries' (www.stack-assessment.org, Sept 13, 2021) and can be integrated with a wide suite of Virtual Learning Environments including Moodle and ILIAS.

Recent developments with STACK have included a fully integrated online module in introductory university mathematics (Kinnear, 2019), and an exploration of task design for proof-based mathematics (Bickerton & Sangwin, 2021). Kinnear (2019) outlines an exemplary approach to embedding CAA in an introductory course for tertiary mathematics students. The author notes the time- and resource-intensive process required to fully integrate the technology, but from preliminary results, concludes that these investments were worthwhile for both instructor and student. Bickerton and Sangwin (2021), on the other hand, focused on higher level concepts associated with proof and argumentation. These authors provided a suite of design suggestions for proof comprehension tasks using STACK, including faded worked examples, reading comprehension activities and example generation tasks. Again, while time intensive to generate, such tasks appear to have the potential to contribute greatly to the varied assessment diet suggested by Iannone and Simpson (2011).

In this paper, we discuss the development of CAA in STACK by first-time users in one particular department of mathematics. While we did not set out to replicate Kinnear (2019), or to explicitly implement the design suggestions of Bickerton and Sangwin (2021), these works provide an important grounding against which to compare our own progress.

Aims, Research Questions and Methodology.

Consistent with the traditions of Design-based Research (Cobb et al., 2003), the aims of this research are two-fold; namely to develop our theoretical understanding of the assessments we design as a department, and to improve upon both our understanding of the design-process, and the assessment materials we offer our students in future iterations of the relevant modules.

Our research questions for the study reported in this paper are:

RQ1: What challenges are faced by first-time STACK users when implementing CAA assessments in tertiary mathematics?

RQ2: What are mathematicians' views and approaches to implementing CAA in tertiary mathematics?

Methods.

Participants.

Four lecturers (referred to as L1 – L4) and two postgraduate students (S1 and S2) participated in semi-structured interviews with two members of the research team (also the authors of this paper). S1 and S2 were members of a larger design team including two full-time faculty and six postgraduate students employed at different times throughout the year. Each lecturer was the leader of at least one undergraduate module and was responsible for overseeing the design of their own assessments. The extent to which lecturers engaged with the design team varied substantially.

Procedures and materials.

All interviews were conducted via Zoom, running between 35 and 45 minutes, and comprised two parts. First, participants were asked a series of questions about their experiences designing and implementing STACK-based assessments. The interviewers also asked about relationships between various members of the design team; the process of 'translating' existing items into CAAs in STACK; their level of satisfaction with their existing bank of STACK-based tasks; and what they would like to improve upon in future iterations of their STACK assessment. The second part of the interview was a stimulated reflection task. One week before their interview, participants were asked to select their favourite, and least favourite tasks to which they had contributed. Interviewers then asked a series of questions about each task, probing for information about the perceived strengths and weaknesses of CAA in general.

Data analysis.

In this first instance, a member of the research team watched each interview multiple times, tidying the imperfect automated transcripts in real-time. A series of latent themes were then identified, with supporting excerpts extracted iteratively through several passes through the data. A preliminary report was then produced, highlighting four themes with supporting excerpts and commentary for review by other members of the research team. This report forms the basis of the results section to follow.

Results.

Our thematic analysis (Braun & Clarke, 2006) identified three themes related to the design of STACK-based assessments by first-time users: *1) the process of STACKification, 2) technical challenges with coding in STACK,* and *3) the role of CAA in undergraduate math.*

Theme 1: The process for STACKification.

The course lecturer had for each of their modules a set of problem sheets that they used to provide homework and assessment tasks for their students. Despite variations in other aspects of their approach to CAA, all four lecturers adopted a surprisingly similar four-step workflow for translating their existing materials into automated assessments using STACK.

Phase one: Lecturers would parse their list of existing questions to identify which they believed would make suitable CAA items. This often involved identifying answers that required limited or simple input, and items that could be coded with relatively little technical expertise. L4 noted that "you cannot simply take an exercise sheet and immediately turn into STACK. It requires some effort [to identify appropriate items]". Only L3 focused on including items that were "most critical to capture the coverage of the material" when selecting items for CAA. All four lecturers worked largely independently on this phase, although two lecturers did consult the project leadership team for advice on which items were most suitable to automate.

In many cases, the mathematical content of existing questions would be preserved, but the response required from the student would be altered to suit the STACK environment. For example, with items from the Introductory Analysis course, the lecturer would choose a short series of proofs that were important for students to know and understand. Since STACK cannot currently facilitate the evaluation of student-produced proofs, the design team proposed a series of reading comprehension activities akin to those proposed by Bickerton and Sangwin (2021) that would still assess students' understanding of the proof in the absence of a 'prove that'-style task. In some cases, a series of multiple-choice items similar to those discussed in Mejía-Ramos et al. (2017) were also appropriate.

Phase two: In consultation with the design team, 'preSTACKed' documents were produced for most items. These were most frequently written in LaTeX, and resembled pseudocode outlining the design feature a future coder should implement. These included the types of inputs required from students, the scope and placement of random variables, and the specific question text to be shown to students. In some cases, this preSTACKing phase was a lot less structured, and simply comprised an itemized list of questions to be coded.

Phase three: These preSTACKed documents were then translated into functioning code. For three of the four lecturers, these preSTACKed documents were posted on a shared workflow tracker, to be picked up by the design team. By contrast, L1 did the majority of their own coding, consulting others only when "there was some finessing that I wasn't aware or didn't know how to do".

The design team collaborated frequently, checking each other's work, and coding additional question when the member responsible did not have time. This coding process worked well when the postgraduate student was familiar with the mathematical concepts and methods being developed in the module. However, S2 noted that "some of the hardest second year modules that I didn't take…I found hard, especially when the preSTACK document was vague [and] there was a lot of having to speak to the lecturer, [asking] how do you actually do this?”. We return to this back-and-forth dialogue between designers and lecturers later.

Phase four: After initial coding was completed, lecturers were invited to review each item and encouraged to check the code for the intend functionality. Given the inexperience of the design team, several items had early bugs. In some cases, variations on correct answers were marked incorrect (e.g. an answer such as 4/2 would be marked incorrect when the desired solution was the integer 2), and vice versa. As a tool, STACK gives tremendous control to the user regarding how to assess such variations and can facilitate the vast majority of desired responses in each case. However, given the inexperience of the coding team and the speed at which items needed to be produced, bugs of this nature were frequent in the early stages of the project and caused significant problems to lecturers and students.

Open communication between the lecturer and the coding team on checking how the STACK quizzes would be seen by the students was really important. L3 noted that “There were occasional things where the solutions that have been typed in weren't in the notation that I would teach and so I changed those. Little formatting things and a bit of debugging, so I would have a go at the questions and sometimes I came across errors and got them fixed before the students hit them, but other times, of course I didn't find them until the students found them and then we had to debug them live”.

We expect that these teething issues will reduce in future iterations of these modules. However, we note their significance here because of their impact on attitudes to the value of the technology, in particular with respect to (automated)-assessment, discussed later in this manuscript.

Theme 2: Challenges in early implementations of new STACK materials.

Lecturers tended to focus on assessing procedural tasks (in the sense of Sfard, 1991) in which a numeric or simple algebraic expression could be entered by the student. We, the research team, note that in theory, STACK has the capacity to implement a wide variety of question formats accessing a range of different understandings and approaches. However, anything beyond numeric or algebraic equivalence tests proved to be a significant challenge in many cases.

L1 noted that when the answer to the problem involved surds, STACK had no difficulty when the square root was in the numerator, but when it was in the denominator and the student rationalised the denominator, STACK “could not see that this was a correct answer”. Interestingly, this excerpt doesn’t draw a distinction between the capacity of the tool, and the capacity of a given implementation. While our data does not facilitate a more in-depth discussion on this point, we conjecture that this attitude may have been a barrier to higher quality design in some cases.

And L3 noted that when students were required to type in formulae “then one function of STACK that I hadn't really realized is, if you make one mistake, one small mistake [typing in a formula] which could be just a typo, it blanks all your answers”. S1 noted the importance of students needing to be shown how to input formulae correctly in STACK, for example how to input Greek letters such as lambda and theta, and how to input terms with subscripts such as x_0.

In contrast, L3 highlight one particularly successful episode, in which the coders initially “struggled because there's more than one right answer. So, in the end they worked out a really cunning way to work out whether the student’s [solution] was correct”. S1 also recognised the need for creativity with STACK, and appeared to understand that a solution should exist, even if it couldn’t be implemented in this case. STACK recognises algebraic equivalence, but students can write the solution of a differential equation in many different ways and “you kind of have to think a bit more about all the all the possible answers that the students could give you”.

L2 also highlighted problems associated with the inputting formulae: “One of the big challenges of STACK is making sure you get it right, because the system is only good as it is accurate, so if you have a mistake in your answer in STACK, then the whole, the whole thing is pointless”.

Further professional development for lecturers and coders, and in some cases of students (as pointed out by L3) will seek to minimize the problems raised in this section. However, we note that even experienced coders have difficulties in this regard. To readers considering using STACK in the future, we recommend having a robust system of peer-review in place before AND after implementation with a student cohort.

Theme 3: The role of CAA in different content domains.

All four lecturers started with problem sheets that had been used as homework and assessment activities in their previous teaching. They felt that STACK could handle examples that required a numerical or simple algebraic answers but were reticent to explore opportunities to assess more conceptual aspects of their module curriculum using STACK. For example, S1 noted the ease of assessing calculus: “[it] was fairly straightforward because it involved fairly straightforward kind of mathematical methods so we had weekly quizzes for that”. However, they asserted that the answers needed to be “well defined”. L4 felt similarly, claiming that problems requiring students to input formulae can lead to difficulties “because formula can be written in slightly different ways and sometimes it doesn't recognize these things as the same”.

While questions that required a numerical or algebraic answer could be easily STACKified in most cases, it was more difficult to test theoretical knowledge and proofs. L1 asserted that “when it comes to proofs one would use a normal Moodle (VLE) quiz and do some kind you know very smart multiple-choice type of question”. Similarly, L2 claimed that “Not all [examples] were suitable because some of the questions involve some theorem or some proving which possibly could be STACKed or, if you like, but I couldn't see a way to do that, so I concentrated on questions with numerical answers”.

Further, L4 questioned how a simple numerical or algebraic answer in STACK could show the students had understood the theory and methods they had been taught. “[In my course] it’s not a matter of manipulating formula like in school, right. It's a matter of showing that you understand what's going on and it's somehow difficult to transform it into computer-based assessment”. This lecturer went on to query the suitability of STACK “at a serious university... In a very good math department, you have to show that you understand, then you have to write, and explain”. L4 did concede that “STACK is more suitable for an ancillary course [for non-math majors], but still, it's somehow lame even for chemists”. In contrast, however, L2 felt that if you defined the question carefully then the student would have to understand the methods and the theory in order to get the right answer. This sentiment was also echoed by L3.

These excerpts suggest that the scope and merit of STACK vary greatly for different parts of the undergraduate maths curriculum. In this manuscript, we intentionally abstain from passing judgement on the commentary of L4 and others. Here, we prefer simply to report on the perspectives offered by our participants and reflect on ways in which we can improve our offering to students in future iterations of these courses. Bickerton and Sangwin (2021) propose a series of alternatives for STACK-based assessment of proof that seek to address many of the limitations raised by L4. We acknowledge that these alternatives are time consuming to implement and not applicable in all cases. However, we suspect that none of our four lecturers are aware of this recent work and intend to provide some professional development workshops in the future. In doing so, we seek to broaden the range of tasks offered to our students and the range of conceptual understanding accessed by our STACK-based assessments.

Discussion.

From our interviews with lecturers and postgraduate students, we identified three themes with consequences for the future development for the CAAs at our university and for the wider community planning to implement CAA for the first time.

First, we enumerate the process of ‘STACKification’, in which traditionally handwritten coursework tasks can be translated into CAAs using STACK. While the process has several possible refinements, it is interesting to note the relative uniformity with which this process was used by all four lecturers. Future iterations of these courses will involve cyclic redevelopments of many items, adding new features, resolving bugs, or adding more detailed feedback.

Second, we have identified a primary challenge for first-time users of STACK associated with evaluating algebraic equivalence in various forms. In several cases, lecturers and members of the design team were aware than an alternative coding solution should exist but could not execute a solution within the time constraints afforded. Again, these concerns will diminish with time, and as a department, we now have the opportunity to revisit those items that did not function as expected.

Finally, and perhaps most importantly, we considered lecturers’ perspectives on the role of CAA in tertiary mathematics more generally. All four lecturers acknowledged that STACK had the potential to assess at least some proportion of the undergraduate curriculum. However, these were heavily weighted toward applied mathematics, and to more procedural (rather than conceptual) tasks. Of particular note was L4’s belief in the inability to assess mathematical proof using STACK or other forms of CAA. It is unclear from the data available whether these perspectives would change with further professional development, focused on the potential for STACK to assess a wider array of question formats.

One final challenge not yet discussed lay in the design and implementation of feedback. The automation of personalised feedback proved to be a time intensive process, with most lecturers providing at most a correctness evaluation and a general solution for each question. We report on this feature of our data in more detail in future publications, focusing on routes for realising the potential for productive formative assessment discussed by Fahlgren et al. (2021).

Final remarks and future development.

At the time of writing, the STACK project at our university has been running for approximately 12 months. While we have now had a large bank of STACK-based items, the process of successfully integrating CAA into our curriculum is an on-going challenge. In the future, we will develop a greater variety of question forms, with a clearer focus on the learning outcomes for students and lecturers, and a more rigorous consideration of the formative and summative roles that these assessments play in our courses. This will feature a structured research programme intended to understand students' and lecturers' experiences with CAAs, and further iterations of the design-based research cycle we began with the data reported here.

Acknowledgment

The authors would like to thank the Department of Mathematics at UCL for their financial support of this research, and our colleagues who contributed their time and insight during the interview process.

Epistemic Potentials and Challenges with Digital Collaborative Concept Maps in Undergraduate Linear Algebra

Ana Donevska-Todorova[1] and Melih Turgut[2]

[1]University of Applied Sciences HTW Berlin, Germany; ana.donevska-todorova@htw-berlin.de

[2]NTNU–Norwegian University of Science and Technology; melih.turgut@ntnu.no

This paper aims to investigate epistemological potentials and challenges of digital concept mapping in collaborative activities of pre-service teachers regarding conceptualization in undergraduate linear algebra. Design experiments were undertaken within a larger design-based project with pre-service mathematics teachers for upper secondary school in Germany to look at students' connections and translations between three modes of representations and thinking of concepts such as matrices and determinants. Besides testifying that concept maps have the potential to foster students' organization of the concepts, the results also show how collaborative digital mapping can support three kinds of transitions and students' experiences: (1) *within a digital CmapTools,* (2) *across a digital and a physical medium and* (3) *beyond a single digital resource by integrating DGS and CmapTools, which gained importance since the pandemic outrage.*

Keywords: Pre-service mathematics teachers, Concept mapping, Design research, Linear algebra, Digital tools.

Introduction

While undergraduate linear algebra for engineering and science students is based on the vector space definition and other axiomatic definitions of the concepts, courses about didactics of linear algebra for pre-service secondary school mathematics teachers usually treat the concepts in a non-axiomatic manner in Germany (Donevska-Todorova, 2018a, 2018b). Such approaches may result in the lack of *cognitive flexibility* (Alves Dias & Artigue, 1995) where students perceive many of the concepts disconnected from one to another and prevent them from getting a wider picture of what constitutes a typical axiomatic-structural undergraduate linear algebra curriculum. Hence, pre-service teachers may gain disorganized, fragmented knowledge with little connections between many of the concepts or insufficient conceptual understanding without recognizing the concepts' meanings (Donevska-Todorova, 2016, 2017).

Preventing such development has become even more challenging since the global COVID-19 pandemic. Remote teaching has challenged educators to search for adequate novel tools that may quickly and effectively transform traditional mathematics classrooms and simultaneously involve learners in resource designs that maximize their activities and engagement. It seems to us that collaborative concept mapping in the virtual space has the potential to respond to this challenge. Thus, the purpose of using collaborative digital concept maps in our teaching approach is to enable future teachers to systematically connect different modes of representation and thinking in linear algebra in an organized structure, which is in line with Papert's notion about digital tools being "vehicles" for development of "Mathematical Ways of Thinking" (Papert, 1983). We focus on the following research question: what are the epistemological potentials and challenges of collaborative digital mapping through algebraic, geometric, and axiomatic transitions and experiences with linear algebra concepts by pre-service mathematics teachers?

Theoretical framework

Regarding the representation of mathematical objects in linear algebra, Hillel (2000) addressed three modes (p. 192): the *abstract* mode, the *algebraic* mode, and the *geometric* mode. The abstract mode is referring to axiomatic definitions, structures and language of vector spaces, subspaces, linear combination, and linear independence of vectors in linear algebra. An algebraic mode refers to the use of algebra of (specifically) properties of $\mathbb{R}^n$, like algebra with *n*–tuples, the interplay between matrices and associated systems of linear equations. A geometric mode refers to the language of *2D* and *3D* geometry and geometric vectors, such as parallelogram rule with vectors, lines, planes, their intersection(s) etc. The interplay between these modes is often necessary for cognitive flexibility (Alves Dias & Artigue, 1995).

However, this is not an easy and trivial task. As addressed by Sierpinska (2000), students tend to think practically rather than theoretically. Practical thinking can be described as thinking *locally* and an effort to reason that is changed by the action itself, while theoretical thinking is about generalising and reflecting on the situation through linking the action and associated mathematical objects by using different procedures. In other words, theoretical thinking concerns concepts (i.e., definitions, the use of set theory etc.), while practical thinking is limited to the results and/or experiences in the involved action. From an epistemological point of view, Sierpinska (2000) characterizes three thinking modes referring to practical and theoretical thinking: synthetic-geometric thinking mode, analytic-arithmetic thinking mode and analytic-structural thinking mode. In the synthetic-geometric thinking mode, the learner refers to geometric properties of the action (possibly) based on 'practical' observations but does not refer to thinking on how observed mathematical objects are created. The analytic-arithmetic mode is associated with referring to algebraic features of the objects, for example, thinking and reasoning with *n*–tuples, coordinates of objects in Cartesian geometry, the system of linear equations and associated matrix algebra. The analytic-structural thinking mode requires a synthesis of progressive reasoning on different situations and mathematical objects and thinking of them as (a part of) a conceptual system. We note that the three thinking modes are in parallel to Hillel's (2000) three modes of representation.

Concept mapping in mathematics education

Several resources (e.g., Brinkmann, 2003) point out that concept maps were first introduced by Novak and Gowin (1984) as research tools for structuring an individual's knowledge. The initial intention was to use the concept maps as graphical representations of one's knowledge for research purposes in science. Other authors define the concept maps as advanced organizers with a meaningful and practical structured approach (Willerman & Mac Harg, 1991) or as an aid to instruction in science and mathematics, new teaching strategies that will enhance the understanding of those concepts which are common for both disciplines (Malone & Dekkers, 1984). The concept maps are often referred to as instruments, tools, techniques, methods, graphical displays, or networks with a very wide range of aims.

The historical development of concept mapping follows the order of their implementation in research, teaching and learning. The later tendencies lead to the implementation of concept mapping in investigations on how learners learn. Qualitative analysis of students' concept mapping has been in expansion for different purposes: suggesting teaching approaches that help students integrate new knowledge and build upon their existing naive concepts, learning by illustrating patterns of conceptual development (Kinchin, Hay & Adams, 2000), assessing conceptual understanding (Williams, 1998; Varghese, 2009). Concept maps can be used to organize information on a topic, to facilitate meaningful learning, to identify students' knowledge structures, especially misconceptions or alternative conceptions, to serve as a memory aid, to revise a topic and to design instructional materials (Brinkmann, 2003). The "theory underlying concept maps" (Novak & Cañas, 2008) points out two major important foundations of concept maps:

- *Psychological,* related to learning processes like discovery learning, rote learning, meaningful learning, etc., thus they serve as a kind of template or scaffold to help organization of knowledge and to structure it, and
- *Epistemological,* so serving new knowledge creation as a constructive process involving both previous knowledge and emotions or the drive to create new meanings and new ways to represent these meanings (Novak & Cañas, 2008, p. 9).

Related to the epistemological aspect, McGowen and Davis (2019) analysed a sequence of concept maps and corresponding schematic diagrams and together with quantitative and qualitative data found out that there are students with low gain in undergraduate mathematics who seem unable to productively integrate new knowledge into an existing structure and that they reveal radically different processes of knowledge construction and organization.

Digital concept maps as tools for dynamic synchronous systematic and structural organization of concepts through collaboration

Previous research (in the previous sub-Section) shows the variety of potential that concept mapping offers in an organization, structuring and consolidation of mathematical knowledge, yet what do their digital forms have to extend or promote differently? The following Table 1 offers answers to some insights to this question.

Table 1: Comparison of characteristics of physical and digital concept maps

Concept map	Individual's map	Collective/ Collaborative map
Physical (non-digital, e.g., paper-pencil, flipchart-marker, flipchart-stickers, board-chalk, board-stickers)	Single	Static
Digital (e g., Miro, CmapTools)	Multiple	Dynamic, synchronous, integrates e-content, DGS files, shareable, extensive, adaptable

Table 1 shows a comparison of characteristics of physical and digital concept maps including examples of digital maps such as Miro and CmapTools. Further aspects of the question are explained below in the section Results and Discussion.

Concept mapping in the teaching and learning of linear algebra

An example of a concept map for systems of linear equations in two unknowns showing lower stage algebraic methods and geometric method with lines can be found in Brinkmann (2003). Lapp, Nyman and Berry (2010) examined the connections of linear algebra concepts at the undergraduate level. They have developed two techniques for qualitative analysis of student-constructed concept maps and showed that eigenvalues and eigenvectors seem to be the most disconnected concepts from the concepts as basis and dimension in the conceptual network. Another research (Stewart, 2008) aimed to discover students' difficulties in understanding some linear algebra concepts and to suggest possible ways for their prevention, through students' involvements in tests, interviews, and concept maps. In the light of the obtained results, we hypothesized that (digital) concept maps would be a key tool to connect abstract notions belonging to linear algebra context, such as linear independence, matrix algebra and determinants etc. In other words, we focused on whether digital concept maps would coordinate geometric, algebraic, and abstract representation and associated thinking modes.

Methods

During the initial design experiments in a first design-based research (DBR) cycle with pre-service teachers at a large university in Germany, physical concept mapping was applied in a course about linear algebra and analytic geometry at the beginning and the end of the second semester. The collected data, scans of flip charts were stored, qualitatively analysed and the results suggested that the time distance of the mapping activities should be reduced, and their frequency should be increased to enable students to capture the vast number of new concepts completely and structurally.

In a second DBR cycle, in addition to physical maps, CmapTools were implemented according to the previous findings. Besides regular weekly exercises, a group of 15 students were asked to create digital concept maps with an opportunity to update them every week and finally submit them in three-time slots during the semester. They were also encouraged to collaborate in small groups of up to three students during the digital mapping, edit and advance their maps by linking a variety of resources at any time. The created maps were collected via the course in the Learning Management System Moodle where students reflected and engaged themselves in further discussions in a Forum.

Results and Discussion

Instead of reporting on quantitative data, this section represents a qualitative analysis of a case related to the research question. It offers a collection of exemplary concept maps of one group consisting of three students. The maps show students' connections of different modes of representations and thinking modes. For example, Figure 1 shows students' work regarding the link between 2×2 and 3×3 square matrices and determinants.

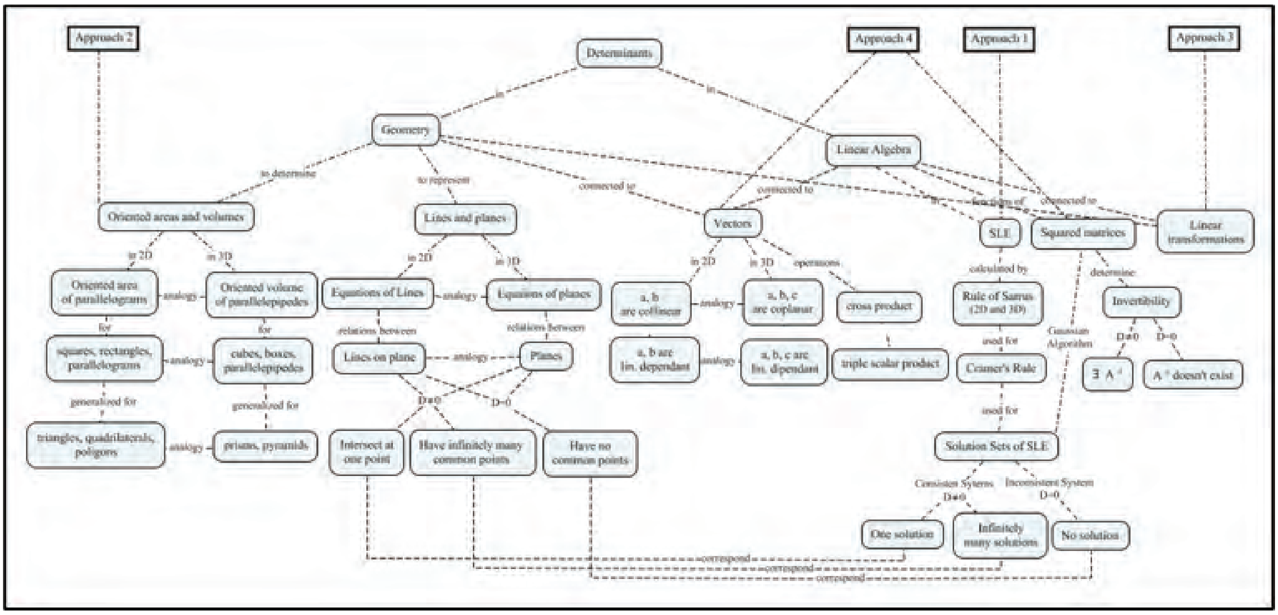

Figure 1: Students' concept map about determinants of square matrices in dimensions 2 and 3 with CmapTools

Related to the *psychological* foundation of the maps according to the "theory underlying concept maps" (Novak & Cañas, 2008) which was mentioned above, this map shows scaffolding and structuring knowledge hierarchically in seven layers of nodes-concepts and established arcs-processes of thinking. Further, related to the *epistemological* foundation, Figure 1 shows students' rich network of concepts related to determinants of matrices and their mathematical meanings. Moreover, it shows relations and transitions between Hillel's (2000) algebraic representations and modes of thinking of concepts such as systems of linear equations, linear transformations and geometric representations and modes of thinking of concepts as oriented areas of parallelograms in 2D and oriented volume of a parallelepiped in 3D geometry. Finally, this concept map represents a structured and dynamic network of epistemological connections of linear algebra concepts (1) *within a digital tool* (CmapTools).

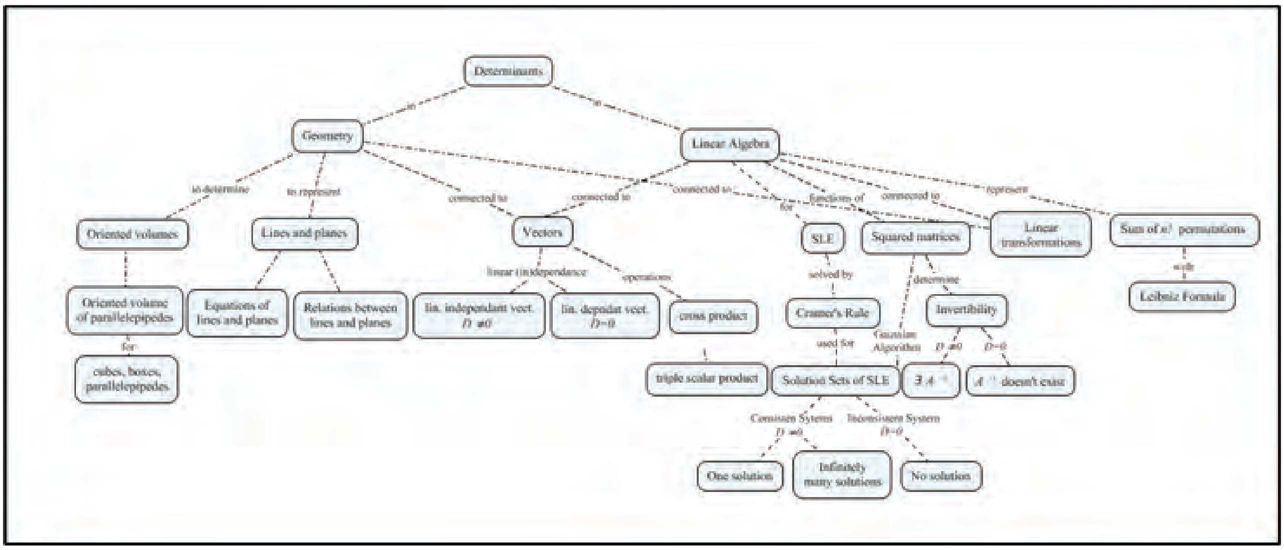

Figure 2: Students' concept map of determinants of matrices in dimension *n* with CmapTools

Likewise, the concept map in Figure 1, the one in Figure 2 created by the same group of students, shows the connections between the algebraic and the geometric representations of the concepts, yet in a generalized form for the dimension *n*. It enabled this group of students to complete their initial static flipchart-marker map, used as a sketch, with the missing concepts and relations in the digital map. The initial static map was later incorporated as a JPG file in the digital form offering possibilities to reflect on the advances and enrichment of the network. These are not only *epistemic* values of the collaborative digital concept map but also didactical and confirm the characteristics of the digital maps for easy adaptations and editing (given in Table 1).

Figure 3 describes exemplary cases regarding matrices and associated concepts, which illustrate Sierpinska's (2000) notion of students thinking of prototypes of concepts locally. This concept map is a specification and reduction of the concept in dimensions 2 and 3.

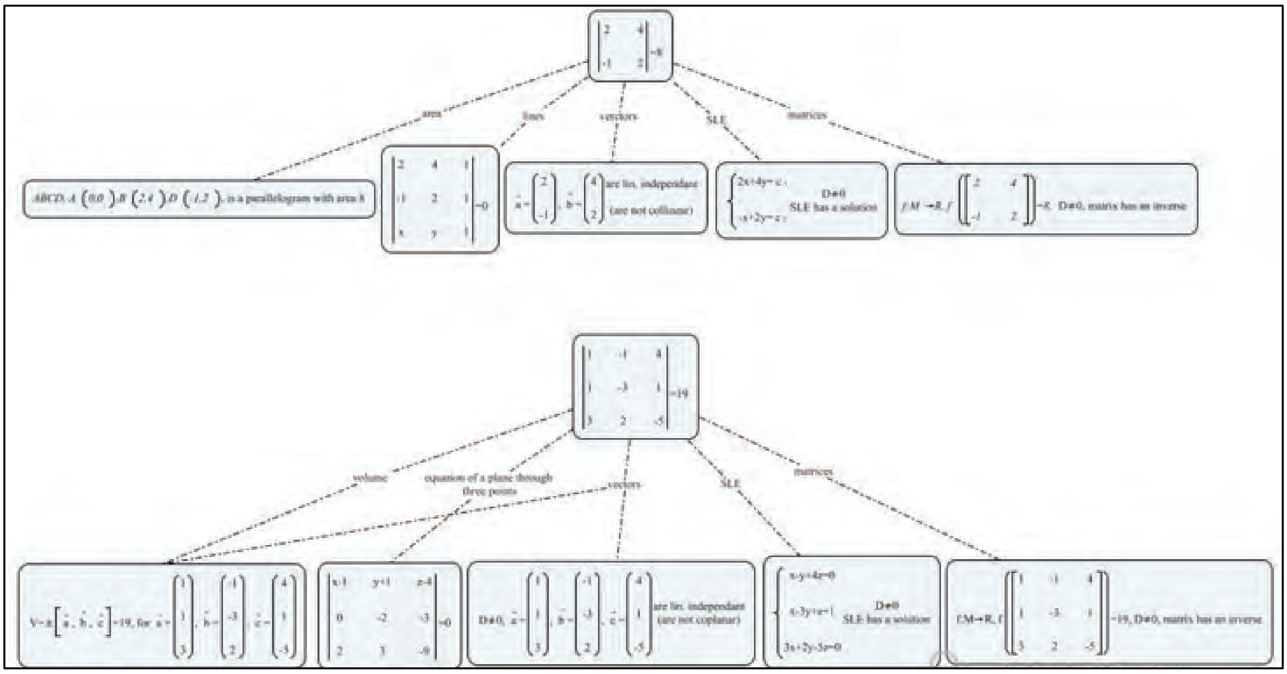

Figure 3: Students' concept maps with examples of determinants of square matrices in dimension 2 and 3 with CmapTools

These empowered students to create DGS GeoGebra files and directly link them with the map. These files enabled students' translations between geometric, algebraic, and axiomatic structural modes of representation and thinking of determinants of matrices. All three concept maps represent a collection of collaboratively created digital resources for the teaching and learning of linear algebra.

In reference to the characteristics of the physical and the digital maps presented in Table 1, some *challenges* are worth mentioning. Students' practical work showed how individual maps differ from collective ones. The synchronous engagement and the integration of the additional technology-enhanced resources were not constantly smooth to maintain. These affordances required more time and effort invested in *often adaptations*. We further consider that *'zoom in'* into the depth of each of the nodes-concepts (e.g., providing 'on click' definitions or dynamic visualizations of the concepts with other digital tools, e.g., a GeoGebra file ((3) *beyond a single digital resource of use*) in the concept maps may potentially bring one more dimension and meaningfulness of the maps.

Conclusions and further research

This paper tried to respond to the Call of the CERME12 TWG14 by tackling challenges when implementing novel approaches in the teaching and learning of undergraduate linear algebra with pre-service teachers. Based on the "theory underlying concept maps" (Novak & Cañas, 2008) we identified *psychological* and *epistemological* potentials and challenges of innovative collaborative digital concept maps in supporting conceptual understanding by connecting three modes of representations in linear algebra: algebraic, geometric, and abstract (Hillel, 2000) and the corresponding thinking modes analytic-arithmetic, synthetic-geometric and analytic-structural (Sierpinska, 2000). Concerning the research question, we have undertaken design experiments in two DBR cycles with physical concept maps and the digital tool CmapTools. Through a qualitative analysis by comparing the collected data we found a case of a group of students providing a collection of concept maps bringing into forth the *potentials* of the maps in showing connections (1) *within a digital tool* (Figure 1), (2) *across a digital and a physical medium* (Figure 2) and (3) *beyond a single digital resource of use* by integrating CmapTools and DGS (Figure 3) which enabled students to reflect, consolidate and reorganize their knowledge. To summarize, we have investigated how digital collaborative concept maps enable learners to construct, scaffold and consolidate an individual's knowledge and how they contribute to meaningful learning, effectiveness in conceptual understanding in linear algebra, negotiation of the meaning of mathematical concepts while establishing connections between them, assigning them appropriate placement in a structured and hierarchical network of concepts through its nodes and arcs. Often requiring adaptations of the maps and 'zoom in' options in the nodes leave room for further research.

Introduction and background

We report on the latest development of our efforts to coordinate analyses of individual and collective mathematical progress. We build on and extend a series of theoretical-methodological analyses aimed at networking Abstraction in Context (AiC, Dreyfus et al. 2015), and Documenting Collective Activity (DCA, Rasmussen & Stephan 2008). AiC is commonly used for the analysis of knowledge construction by individuals or small groups of students, and DCA, which accompanies the emergent perspective, is commonly used for analyzing the mathematical progress of the whole class or a small group of students (Hershkowitz et al. 2014; Rasmussen et al. 2015; Tabach et al. 2014; Tabach et al. 2020). Our research goal is to further develop a methodological approach for characterizing the interplay of mathematical progress across individuals, small groups, and the whole class. We refer to this approach as “collective and individual mathematical progress: Layering explanations” (CIMPLE, pronounced as “simple”). “Layering explanations” pertains to the use of both theories on the entire data set, and to transparently layering analysis upon analysis, unlike our previous efforts that leveraged AiC on small group work (SGW), and DCA on whole class discussions (WCD). The significance of this ongoing work lies in the identification of nuanced ways in which students’ knowledge progresses in inquiry-oriented classrooms.

The context for this study was a semester-long intact graduate level mathematics course on chaos and fractals at a State University in the USA. Ten of the eleven students were pursuing a master’s in mathematics education. The students worked in four stable groups: A (Carmen, Jen and Joy); B (Kevin, Elise and Mia); C (Soo, Kay and Shani); and D (Curtis and Sam). All names are pseudonyms. Groups A and B were video-recorded during SGW; the class was video-recorded during WCDs.

Analysis and results

In Lesson 9, students carried out the first few iterations of a recursive geometric process (given a triangle, connect its midpoints and remove – or color white – the middle triangle); if continued infinitely, this process produces the Sierpiński triangle (ST). Students were asked to imagine the ST and discuss what they could say about the area and the perimeter of the ST.

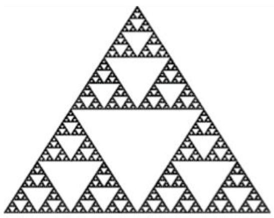

Figure 1: The ST

After 3 WCDs and 3 SGWs, the instructor (who had listened in on Group A) convened the class and asked Carmen and Joy to report on their opposite views of the perimeter. According to Carmen, as one keeps zooming in, the entire triangle is “going to be white, so there’s no area, so there’s nothing to … put a fence around; so there’d be no perimeter”. According to Joy, “if you zoom in…, there is more and more to fence; Until…" Joy was unsure whether the perimeter increases to a finite value or to infinity. Although in the preceding SGW and WCD episodes the students had made little progress constructing knowledge about the features or the length of the perimeter, Elise immediately reacted to Carmen and Joy by Connecting Area to Perimeter (CAP): "what you are coloring in *is* perimeter, to some extent". She was followed by Kevin, and later Curtis: "The perimeter of the white is also the perimeter of the black" (PW=PB); and in between Carmen: "The fence is guarding both properties". Our analysis shows that in these 2 minutes, several students constructed the CAP knowledge element (according to AiC) and PW=PB started functioning-as-if-shared (FAIS) in the class (according to DCA). In other words, the students constructed new (to them) knowledge within a WCD, and this new knowledge immediately began to FAIS in the class. This constitutes substantial mathematical progress, achieved in a pattern that is very different from the standard trajectory.

Earlier in the same lesson, the students made mathematical progress in two further patterns. In one, "Area goes to 0" passed from FAIS in Group A to FAIS in the whole class without any reaction or even question. In the other one, the everyday metaphor of "zooming in" which had earlier appeared in a movie about the fractal nature of the coast of Britain was appropriated by the students as a tool to deal with the infinite nature of the ST (as used by Joy and Carmen above).

There are certainly additional patterns of mathematical progress. We conclude that the standard trajectory is only one of many possible ones for mathematical progress in inquiry-oriented classrooms. The coordination of AiC and DCA is an efficient methodology to identify such patterns.

Design principles for gaps in worked-out examples in mathematics for science students

Lidia Feil[1] and Dorothea Strauer[1]

Keywords: Worked-out examples, modelling cycle, undergraduate students.

Learning how to apply mathematics is crucial for university level science students. Modelling tasks are especially challenging for undergraduates, since solving such tasks involves performing various actions. These actions can be described as transitions between successive states in modelling cycles (e.g., Blum & Leiß, 2006). Students often focus on calculations and neglect the actions of modelling and interpreting, even though these are important for their future studies and work. In order to support students in modelling tasks, we use worked-out examples (WOEs) with gaps and self-explanations to encourage active work with the problem at hand (Hilbert et al., 2008). Our poster shows design elements of our WOEs, in particular the different types of gaps, and the design of a pilot study with the idea of analysing how students work with these gaps (link to the poster).

Worked-out examples with self-explanations related to a modelling cycle

It is well known that beginners benefit from WOEs, especially when they include self-explanations (Atkinson et al., 2000). Some research reports the use of WOEs with gaps. For instance, Stark (1999) showed that gaps improved the students' performance in case of probability calculation, while Hilbert et al. (2008) found that gaps impaired the learning gain in the context of proving in geometry. In our opinion, the greatest advantage of WOEs is the possibility to provide a structure for a solution of a modelling task as well as to enable students to think deeply about the solution by filling in the gaps.

We have taken the modelling cycle from Schupp (1988) as a basis to structure the WOEs. Our WOEs usually start with a scientific problem in a real-world situation (see Figure 1) and contain various tasks of modelling, deducing, interpreting, and validating that correspond to transitions in the cycle. In addition, we extend the action of modelling by the translation between scientific, mathematical and daily languages as a bridge in order to better comprehend the scientific problem and the mathematical model as well. Moreover, we feel it is important to emphasize the underlying mathematics, which is, for instance, a crucial point in a mathematically deduced solution.

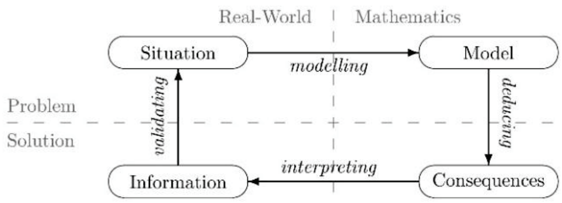

Figure 1: Modelling cycle (our representation, following Schupp, 1988)

Design principles for gaps in worked-out examples and research questions

Strauer et al. (2019) suggest four types of gaps; each of these types is used to foster the actions in the modelling cycle. *Gaps for translation:* These gaps activate the translation between scientific, mathematical and daily language to refer to the transition from real-world to mathematics and vice versa, i.e. for modelling and interpreting. *Gaps for calculation:* Students are asked to calculate some steps on their own. This type is always inserted for deducing on the mathematical side. *Gaps for mathematical terms and notions:* The students should practice the use of mathematical language, including mathematical symbols. These gaps are applied on the mathematical side of the cycle for both deducing and modelling. *Gaps at key points:* At these points, students should become aware of crucial points or general subgoals in modelling, deducing, and interpreting.

According to our experience and the students' comments during lectures and tutorials, students do not always estimate the difficulty of gaps in the same way as the designers of the WOEs.

1. What *types of gaps* in the WOEs do students find *easy/moderate/difficult*, and why?

2. To what extent do the estimates of *the difficulty of gaps differ* between the designers and students?

Design of a pilot study

We proposed the following interview study on the topic of discrete growth with first-year pharmacy and biomedical students. The designers of the WOEs set gaps of different types and estimate the difficulty of the gaps in advance. Between a lecture and the tutorial, student volunteers first complete a given WOE while thinking aloud. Second, they are asked to estimate the difficulty of the gaps and give reasons for their estimate if possible. Afterwards the designers' and the students' difficulty estimates are compared and analysed, particularly with respect to the types of the gaps.

The triple discontinuity in engineering mathematics education

Ignasi Florensa[1], Iria Fraga[1] and Víctor Martínez-Junza[1]

[1]Escola Universitària Salesiana de Sarrià, Univ. Autònoma de Barcelona; iflorensa@euss.cat, ifraga@euss.cat, vmartinez@euss.cat

This paper takes as object of study the discontinuities in mathematics education in engineering. In particular, the internal discontinuity between mathematics education and the role of mathematical activity in engineering courses, is characterised through diverse interviews with mathematics and engineering teachers of an engineering school in Barcelona (Spain). The results show that the internal discontinuity can be characterised by diverse elements that make it an institutional phenomenon further from the specific discontinuities found in previous punctual studies.

Keywords: Anthropological Theory of the Didactic, mathematics in engineering education, discontinuities.

Introduction: transition between institutions and discontinuities.

The beginning of the analysis of discontinuities in mathematics education started with the work of Felix Klein (1908) who announced the famous double discontinuity concerning the mathematical education of teachers. However, research in didactics of mathematics at university level is a relatively young field: the first works date back to 1970. From the beginning, this domain of research considered the didactic phenomena associated with discontinuities as a relevant study area.

The first discontinuity announced by Klein concerns the transition problems that students experience when they enter the university. This has been extensively studied in recent research in mathematics education (Gueudet, 2008). The second discontinuity concerns the disconnection that mathematics students experience when they join the school as teachers. At this point, they are faced with a process of transposing academic knowledge acquired at university into knowledge needed for teaching, which is far from being an easy process (Winsløw & Grønbæk, 2014).

Another field of study in didactics at university level is that of mathematics education for non-mathematicians in the field of engineering. Quéré (2019), in his doctoral dissertation, shows that the number of research works at the CERMEs in this field has been growing in the last editions.

This paper is framed within the Anthropological Theory of the Didactic (ATD, Chevallard 2000), and takes as its starting point the study of phenomena associated with discontinuities and mathematical education in engineering. The ATD approach on discontinuities considers that they are associated to a transition between institutions: discontinuities appear when the students move from one institution to another one. Analysing the existing work to date, we hypothesise that the path followed by people learning engineering experiences what we could call a triple discontinuity (see Figure 1), making an analogy with Klein's famous double discontinuity. In fact, the first and third discontinuities are homologous to those announced by Klein in mathematics teacher education. The second is the one that would be more specific to engineering education: it is an internal discontinuity in engineering education institutions due to the transition between the mathematical courses for engineers and courses in engineering courses, in line with what has been observed by Romo Vázquez (2009) and Quéré (2019).

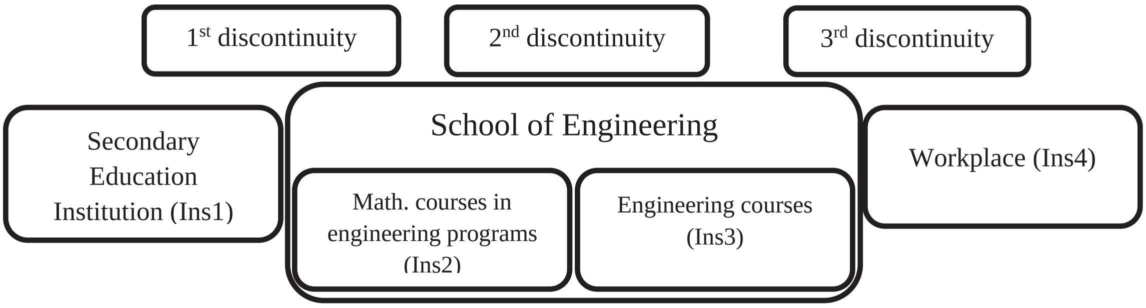

Figure 1 - Diagram of the triple discontinuity in engineering and institutions considered

Theoretical framework

Some studies referring to the ATD address the second discontinuity by analysing the different mathematical activity in the engineering courses (institution 3) and contrasting it with the activity promoted in mathematics subjects or in the workplace (institutions 2 and 4). We present in the following some of the most relevant works analysing the second discontinuity in engineering degrees as well as the theoretical tools mobilised in them.

One of the pioneer woks is Romo Vázquez's doctoral dissertation (2009) that studies the origins of mathematical education for engineers and highlights the differences in mathematical activity in mathematics courses, engineering courses and professional practices. Romo Vázquez (2009) and Castela and Romo Vázquez (2011) adopt as the main theoretical tool the praxeological model proposed by Chevallard (2000). Praxeologies allow researchers to model knowledge: they are entities formed by the inseparable combination of a praxis or know-how made of types of tasks and techniques, and of a logos or knowledge made of a discourse aiming at describing, explaining, and justifying the praxis. Romo Vázquez (2009) and Castela and Romo Vázquez (2011) identified the differences that appear in the logos block (especially in the technological environment) depending on whether the training institution or that of the practitioners is considered (mathematical courses or engineering courses).

In the ATD studies analysing the mathematical training of engineers, a key notion is that of institution and institutional position. According to Chevallard et al. (2015) an institution in the sense of ATD is just a more general conception than the general meaning: for example, a class with the students and teacher is an institution. In every institution, each person may occupy different institutional positions, for example, in the case of a class, that of student or that of teacher.

Another relevant work analysing the mathematical training in engineering is that of Barquero et al. (2014). They hypothesize that the applicationism is an essential component of the epistemological conception of mathematics in applied sciences degrees at university. Specifically, they characterise the applicationism by five indicators: (1) Mathematics are presented independently of other disciplines, (2) Mathematical tools are considered the same for all scientists, (3) Organisation of mathematical courses is based on logical concepts, (4) Applications are always presented after the basic mathematical courses and (5) Extra-mathematical systems can be constructed without any reference to mathematics. In their work, they observe, through interviews with university mathematics teachers in applied sciences, a clear applicationist conception of mathematics. In addition, the authors consider this conception as an element hindering the implementation of mathematics (and science) teaching based on modelling processes.

More recent works within the ATD framework are those of González-Martín and Hernandes-Gomes (2019) and Hochmuth and Peters (2020), both mobilising the praxeological model. Specifically, the first addresses the differences in the use of the integral in mathematics and in strength of materials textbooks while the second addresses the use of mathematics in signal theory courses.

Research questions

Considering the previous works in the ATD framework in the field of mathematics for engineers and the discontinuities as well as our hypothesis, our research question is:

What are the epistemological conceptions of these two institutional positions: first-year mathematics teachers and engineering courses' teachers? Do these conceptions reveal a discontinuity in the institution further from punctual issues already characterized?

Institutional context and interviews

The institution where the interview campaign was carried out is the Escola Universitària Salesiana de Sarrià (EUSS), a centre associated to the Autonomous University of Barcelona (Spain), where five engineering degrees are taught (electronics, mechanics, automotive, industrial organisation and renewable energies and energy efficiency). This is an institution with a tradition of implementing teaching innovation processes and where specific training courses in didactics for university teachers are offered to teachers, see for example Florensa et al. (2017).

Mathematics teaching in all EUSS degrees is concentrated in three courses. Mathematics course is offered in the first semester with 7 ECTS, Calculus in the second semester with 8 ECTS and Statistics in the fourth semester with 6 ECTS. The syllabuses of each degree can be consulted in detail on the centre's website: www.euss.cat. In order to characterise the possible discontinuity, two interview protocols were designed: one for teachers of mathematics courses and the other for teachers of engineering courses. Both interview protocols can be consulted in full at the following link (https://sites.google.com/euss.cat/cerme12).

Both interview protocols have the same structure with two common blocks and a third differentiated one. The first one characterises the academic and professional career of the person interviewed, as well as the degrees and courses in which they teach. The second block is dedicated to identify the conception of each person with respect to the applicationism described by Barquero et al. (2014). The third block aims to identify the opinions of the teaching staff on the most important elements in mathematics education in engineering in terms of techniques and type of tasks (accordingly to the praxeological model). In particular, teachers in the mathematics field are asked to identify the most important elements of the courses they teach, the most common difficulties detected in students, as well as the criteria used to design the contents of each course. In contrast, engineering teachers are asked to identify the types of mathematical tasks and techniques required in their subjects, and whether these are of a routine or algorithmic nature or whether they are related to modelling. These protocols were used to interview teachers of mathematics courses (Mathematics and Calculus) in the first year (MT, 5 in total), as well as teachers of engineering subjects (ET, 8 in total). In Table 1 the academic and professional backgrounds of the interviewees are summarized.

Table 1: Academic and professional backgrounds and teaching experience of interviewed teachers

	Academic background	**Professional background**	**Teaching experience**	**Courses**
MT1	PhD Mathematics	Academia	30 years	Mathematics, calculus, statistics
MT2	PhD Chemistry	Academia	9 years	Mathematics, engineering courses.
MT3	MSc Mathematics	Teaching (not researcher)	30 years	Mathematics, calculus, statistics
MT4	BSc Mathematics	Secondary education,	10 years	Mathematics, calculus, statistics
MT5	PhD Biochemical Engineering	Academia with some experience in industry	7 years	Mathematics, calculus, engineering courses

ET4	PhD Material Science	Vocational training, laboratory technician and academia	10 years	Materials, manufacturing processes and strength of materials
ET5	PhD in Business Administration	Academia	4 years	Strategic management and Quantitative Methods
ET6	PhD Local Development	Consultant, in academia since 2009	12 years	Quality and Industrial plant location
ET7	MSc Electronic Eng.	Academia	12 years	Electronic systems, Project Management and Digital signal
ET8	PhD in civil engineering	Academia	7 years	Physics, Strength of Materials, Machines and Fluids

Results

Interviews of teachers of mathematics courses

The results regarding the applicationist conception of mathematics education in engineering show a strong consensus except in the first question that refers to the uniformity of mathematics education in any university degree. In this question, teachers do not have a clear position (see Figure 2).

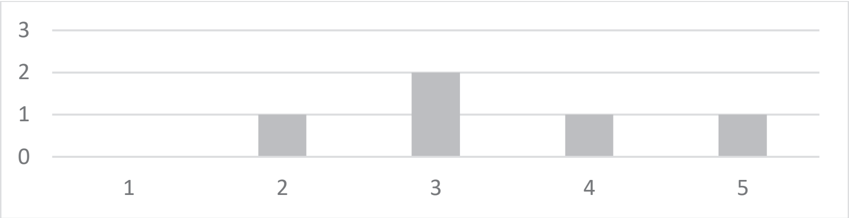

Figure 2- Answers of mathematics teachers to the statement "The mathematics taught in the first university courses of Engineering are the same as those taught in the other university degrees" with 1 being " I disagree" and 5 being "I strongly agree"

Concerning the answers to the criteria used to define the syllabus of the courses, these reveal the existence of a shared conception for the meaning of mathematics by mathematics teachers in the first years. For example, MT2 states that "the subject was already set up, but it is similar to what is offered in other centres" In the same direction, MT3 speaks of "a common profile for Engineering Mathematics" A second phenomenon that comes to light at the same time is the influence of previous curricula on the definition of the contents included in the courses. In this sense, MT4 states that "the contents of the old engineering program (3-year program before the adaptation to the European Higher Education Area standards) were adapted to the new engineering degrees" or MT1 states that "the syllabus was established with the technical industrial engineering, I suppose based on what was done in other universities" MT3 also states that "there has been continuity since the initial creation of the courses and the contents have been adapted...".

Related with the mathematical content, there are two types of answers. Firstly, MT1 and MT4 attach great importance to the ability of mathematical content to develop "abstract thinking, reasoning skills and the ability to adopt strategies" (in the words of MT1). MT4 formulates it as follows: "finding primitives is important, not because of the technique, but because of the associated mental process" Secondly, most of the interviewees propose a set of contents justifying its importance. These include finding primitives and derivatives (MT2, MT3, MT4), working with matrices (MT3, MT4, MT5) and solving differential equations (MT4 and MT5). It is important to note that the importance assigned to each content is heterogeneous and there is not much uniformity: some teachers emphasise the structuring role of algorithmic work, while others prioritise, in the words of MT4, "knowing and understanding how to solve, since calculation is mechanical and/or programmable"

Although the two groups of teachers do not prioritise the same contents on the list, there is a great consensus that the manipulation of algebraic expressions in the study of functions is the greatest difficulty that students face when learning mathematics. Other difficulties that appear are the calculation of integrals and derivatives and the confusion between vector and scalar magnitudes.

Table 2- Results of the question "Highlight from the following list of linear algebra contents the five most relevant to your course"

Contents of “Linear Algebra”	Number of votes MT	Number of votes ET

Interviews of teaching staff in engineering courses

As in the case of mathematics teachers, there is consensus in all the questions related to applicationism, except on the question whether the mathematics taught in the first years of engineering is the same as that taught in other degree courses where there is not a clear agreement on the answers.

Teachers of engineering courses attach particular importance to the interpretation of the results obtained, and decision-making based on these results, beyond the technique applied. ET1 expresses it as follows: "I am not so much interested in them finding integrals or derivatives, but they need to acquire the concept behind them and use it to solve engineering problems". ET2 also expresses in very close terms: "Mathematical elements are useful for modelling, the difficult thing is to set out and validate the model, the resolution itself is algorithmic...". ET3, speaking of the use of integrals and derivatives in a strength of materials course, states that "the bending moment that we obtain allows us to select a beam for a structure: this is what matters, beyond the algorithmic calculation" ET5 also emphasises this duality: "the convolution of functions can be very routine, but what is interesting is that it allows us to analyse, study and explain typical phenomena of electronic systems"

Characterising the phenomenon: applicationism and internal discontinuity

The results obtained on the applicationist conception in mathematics education in engineering, confirm those obtained by Barquero et al. (2014) in the field of applied sciences. Moreover, there are no significant differences between the opinions of mathematics and engineering teachers, which seems to indicate that the applicationist conception is proper to the institution.

With respect to the internal discontinuity, two points stand out. Firstly, the MTs' and ETs' interviews show some items with a very high level of consensus in the fields of linear algebra and analysis (see Table 2). The maximum consensus is obtained in solving systems of equations, finding the derivative and the integral. However, there is a significant disparity in matrix scaling and operations with matrices, as well as the determination of the graph of a given function. Another point of consensus detected in the open comments on the questions, is that training in mathematics should provide abstraction, reasoning and generalisation skills beyond working with specific content, what Chevallard et al. (2015) characterises as transcendent utility.

However, the main difference between the MTs' and ETs’ answers, lies in the role played by the solving technique as opposed to its justification. The ETs emphasise that mathematical education should have as its main goal the development of a well-defined logos around certain mathematical praxeologies rather than the work on technique. ET2 expressed it in the following way: "I am interested in the concepts of integral and derivative in contrast to them knowing integration by parts which I do not consider necessary at all". ET3 also states along the same lines: "They have to know and identify functional relationships, the variation of data, identify trends, beyond finding integrals or concrete derivatives by hand". ET4 states it as follows: "They don't have to know how to solve almost anything by hand, on the internet there are symbolic calculators: they have to know what it is to integrate and derive" ET5 puts it like this: "In practice, solving by hand is not used, there is technology available that solves it [...] On the other hand, it is more important that they know how to identify trends, analyse data" This type of discourse in which technical work is not a priority does not appear explicitly in the interviews with the MTs.

In conclusion, the interviews allowed us to identify an applicationist conception of mathematics in the institution under study. Moreover, the internal discontinuity that we hypothesised appears to be characterised by the contrast between a technicist teaching model (in the sense of Gascón, 2001), in which the raison d'être of mathematics education is mainly the resolution of exercises using concrete techniques and another model closer to the conception of mathematics as a modelling tool. These results confirm the local characterisation of the discontinuity described by Castela and Romo Vázquez (2011), González-Martín and Hernandes-Gomez (2019) and Hochmuth and Peters (2020).

Physics for mathematicians. How physics can help to develop mathematics in higher education.

Tassilo Fuchs[1]

[1]University of Bordeaux, Lab-E3D, Bordeaux, France; thorben511@gmail.com

Keywords: Higher education, mathematics, physics, anthropological theory of the didactic.

Different studies in the field of didactics have shown difficulties that arise in the teaching of mathematics in relationship with physics at university level. In her opening lecture for INDRUM 2016, Artigue (2016) recalls the work done in the 1980's by a group of didacticians, mathematicians and physicists, where no agreement could be made on the notion of differential and the way to teach it. In this study (*Groupe Maths- Physique Enst. Sup.*, 1989, page 15), the researchers show that mathematics students and teachers are very uncomfortable when they are asked about the validity of differential procedures. Recent research shows that the object 'integral' has different aspects and interpretations (sometimes common to physics and mathematics), between which the students have to juggle when they use integrals in applied contexts (Jones, 2013). This suggests that students who encounter the integral in many different applied contexts develop a deeper understanding of the whole object. Mathematical modeling in a physics context might allow to develop mathematical knowledge. The process of modeling is often described as an iterated process, where the modeling hypothesis is subject to modifications depending on the results obtained at the end of the mathematical work. This implies that the mathematical treatment has to be valid and thus legitimated by a mathematical theory.

Our global research question is: *How mathematical modeling techniques in physics can be related to classical calculus courses content?* We search how the physics modeling contexts can enrich calculus knowledge.

Modeling physics tasks involving integrals in polar coordinates to determine a magnitude sometimes makes use of a technique in which we consider surface elements delimited by two semi-lines going through the origin at an angle of $d\theta$ and two concentric circles distant of dr (where the smaller circle has radius r). This surface element is said to have approximately the area of a rectangle of side lengths $rd\theta$ and dr. The searched magnitude is then obtained if we "sum-up" these areas or a magnitude depending on these areas by the integral: $\iint m\,(r,\theta)rdrd\theta$. We tried to analyze this technique in terms of praxeology (Chevallard, 1985). The theorem that is often cited as a justifying technology to this technique is the change of variables theorem. However this theorem already needs the function to be integrated to be known, and thus it cannot be applied in such a physics modeling situation whose goal is precisely to find this function. Instead we searched if the error we get by this approximation of the area has or not an impact on the limit of the Riemann Sum. Indeed the real surface of such a surface element can be calculated using simple proportionality and the area formula for a disk: $\Delta S = r\Delta r\Delta\theta + \Delta\theta\,(\Delta r^2)/2$. Comparing this to the formula obtained by the approximation by a rectangle, we can determine the error term of the approximation $\Delta\theta\,(\Delta r^2)/2$, for which we can show that its sum can be made arbitrarily small if the partition is fine enough. This technology is embedded in the theory of Riemann integrals.

To further investigate if and how this link could be implemented at the student level, we tried to teach this missing brick to two second year mathematics students who were volunteers and interested in electrostatics. In four sessions of two hours each, we gave them an overview of the physics subject of electrostatics, divided the proof of the missing brick into subtasks in a purely mathematical context (integrate a function over a disk) so that they could do the proof and at the end we proposed them the following modeling task (standard in electrostatics courses): "Determine the force exerted by a uniformly charged disk onto a charged particle situated above its center". For the last session, only one of the students was present. He first wanted to repeat the end of the proof from the session before, to be sure to understand. After that, he followed the proof from the last time for this physics task. This modeling task contained new elements, making the task more complex. For instance, the magnitude to be calculated was a vector instead of a scalar. Here the student correctly explained that we could do the sum component by component, and thus passing to the limit do the integral component by component. He first calculated the vertical component, and then he was asked to formulate a conjecture about the horizontal components of the force. He was able to give a heuristic argument for his conjecture that they would vanish:

E2: We turn around the point […] the components er… in a horizontal direction, well it, it cancels out then.

In physics courses such simplifying techniques that use the symmetry of the objects are explicitly taught. Our student never had such courses, but he was still able to give a correct answer and an argument for this. This gives us new praxeologies to investigate.

Moving mathematically

Robyn Gandell

University of Auckland, New Zealand; rgan004@aucklanduni.ac.nz

Over the last twenty years, mathematics education research has become increasingly interested in how the body interacts with students' thinking and knowing. However, researchers in this field often theorize the body in diverse ways. From Ingold's post-humanist perspective, humans live in animate bodies which are inseparable from their thinking and knowing. Movement, for Ingold, is not a support for, or an expression of, thinking, rather human bodies think in movement. This paper studies a small group of students, as they engage with a mathematical task, to investigate students' spontaneous mathematical thinking in movement. As this study illustrates, students' spontaneous thinking in movement can offer new and valuable insights into students' mathematical knowing. These findings suggest mathematics educators may need to reevaluate what might be considered students' mathematical thinking in research and in the classroom.

Keywords: Thinking in movement, mathematics education, embodiment, post-humanism.

Within mathematics education, the links between the body and mathematical thinking are an increasing focus of research. Mathematical education researchers employ a variety of theoretical perspectives to investigate movement and thinking. Although these theories generally reject the historical western separation of mind and body in cognition, they often theorize the body from a variety of different perspectives. Recruiting Tim Ingold's (2013) post humanist theory of making, this paper investigates students' spontaneous movement and thinking. For Ingold, new things emerge from the correspondence of animate human and non-human material flows. Following Maxine Sheets-Johnstone (2011), Ingold argues thinking and movement are inseparable: animate human bodies "think in movement" (Sheets-Johnstone, p. 451).

This paper is part of research for a doctoral thesis which explores students' activities as they engage with a mathematical problem task. As part of the wider thesis, this paper investigates a different fragment from, but the same group and session as, Gandell & Maheux (2019). The focus for this paper is an exploration of students' spontaneous full body movement rather than investigating movement as a learning tool. In order to include all aspects of movement, space, body and dynamic qualities, Laban's (Moore & Yamamoto, 2012) movement elements are employed as a movement framework for this study. The aim of this paper is to investigate students' mathematical thinking in movement during a mathematical task. The paper begins with a brief background into the research and theories underpinning the research, describes the research design and movement framework, analyses a small fragment of student activity, and ends by discussing the significance of the findings.

Background

Over the last twenty years, embodiment research, investigating the role of students' and lecturers' bodies in and as their knowing, has gained traction in mathematics education (Abrahamson et al., 2020; Roth, 2016). Although challenging the long-held paradigm, separating mind and body in cognition, embodiment research encompasses a variety of, sometimes conflicting, theories (Abrahamson et al., 2020; De Freitas & Sinclair, 2014; Maheux & Proulx, 2015; Roth, 2016). In addition, many of these theories, which include sensuous cognition, cognitive psychological frameworks (for example, grounded blends, conceptual metaphors, and gesture research), enactivism, and inclusive materialism, hold a variety of diverse perspectives on the body.

As Ingold (2013) and Sheets-Johnstone (2011) explain, embodiment research often appears to continue the divide between mind and body. For example, in some embodiment research, students' movement may be dictated by specified tools (often digital tools), or students may be required to use preplanned movements, to produce a predetermined output (Abrahamson et al., 2020). In this way movement may be conceived as a demonstration of concepts held in the mind with the body positioned as an instrument of that intellectual knowing mind (Roth, 2011). For Ingold and Sheets-Johnstone, however, humans are tactile-kinaesthetic beings, not reified minds enclosed in a body package. As primarily tactile-kinaesthetic beings, humans use their bodies, from before birth and before language, to explore and come to know the world (Sheets-Johnstone). From Ingold's post-humanist perspective, humans come to know as human and non-human material flows correspond in an ongoing, ever changing, "dance of animacy" (p.101). In this way knowledge emerges from the flows of animate materials answering to each other, rather than by building representations of the world in ordered steps. So that, as Sheets-Johnstone explains, humans experience "thinking in movement" (p. 451), not by having thoughts in the mind expressed as movement, nor by having movements creating thinking in the mind, but the movement itself is the thinking.

Research design

To investigate students' spontaneous mathematical thinking in movement, this paper follows the flows of materials forward, as Ingold (2013) suggests. Working together, students offer their actions, including their movements and verbalisations, to each other as indications of their knowing (Roth, 2016). Any actions, made available to others, can then be used by researchers as a representation of the students' knowing, without resorting to presupposing students' intentions or thoughts (Roth). By micro-analyzing students' verbalizations and movements, this analysis is concerned only with the actions the students provide for each other, as they engage with a mathematical task. Thus, students performed actions are taken as their knowing, rather than guessing at students' intentions.

Movement framework

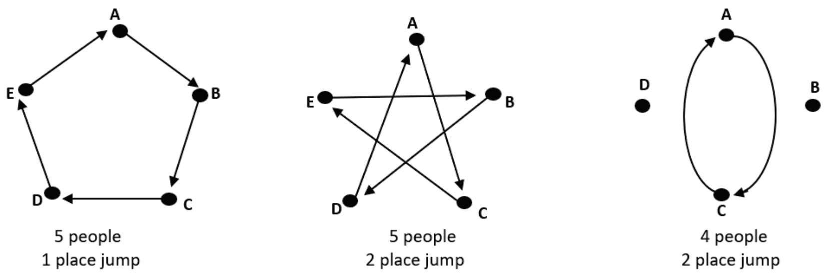
Humans, with similar bodies, share an understanding and recognition of how bodies move and how they feel as they move (Sheets-Johnstone, 2011). This shared social understanding of movement is essential for survival and reproduction in any animate social species. Typically, mathematics education research usually considers how the body moves through space. Inherent in any movement, however, are dynamic qualities which evoke sensations for both the performer and for the observer (Laban & Ullman, 2011/1966, Sheets-Johnstone). Consider how stomping heavily feels different to running lightly and how these movements might feel different for an observer. During the 1930's Laban developed detailed framework of movement elements describing both quantitative (body and space) and dynamic qualitative (effort actions) of movement. Laban's elements are now used in a variety of fields including the arts, industry, psychology research and computer interface technology. Over time Laban's framework has been adapted, however, three elements are generally described: body (parts and actions); space (reach and direction); and dynamic qualities (force and timing)

(Moore & Yamamoto, 2012). Although Sheets-Johnstone's movement descriptions are similar to Laban's elements, Laban's framework provides more detail and is more widely used in movement analysis. Thus, this paper analyzes students' movements using Laban's movement elements.

One difficulty for movement research is how to record dynamic movement in a static paper. A variety of methods have been used including Laban Notation (Laban & Ullman, 2011/ 1966), developed prior to easily available video recording, a series of still images of progressing movement and annotated still images. This paper uses still images with annotated arrows to provide some animation to the still images as Ingold (2013) describes in drawing lines.

The mathematical task

Nic watches a game where a ball is being thrown around a group of people in a clockwise direction. The number of people in the group is called the *people number*. Each time the ball is thrown in a game it is thrown in equal size *place jumps*. Each person throws the ball to the person on their left the same number of *place jumps* away. When the ball gets back to the first person the game ends.



In some games (like the 5-people 1-place jump game and the 5-people 2-place jump game) Nic notices that all the people throw the ball. In other games (like the 4- people 2-place jump game) only some people throw the ball. Nic wonders whether everyone gets to throw the ball in a 4-people 3-place jump game and a 6-people 3- place jump game.

Nic wants to make a dance using this game with people moving between each of the positions instead of the ball being thrown. Nic wants to know if everyone gets to move for different size *people number* and *place jumps*. Create and explain a shortcut that Nic could use for any size of *people number* and *place jump* size. Present this shortcut in the last 5 minutes of the session.

Figure 1: The task

As a modular arithmetic task, the modulus, n, is the people number and the place jump number is repeated addition (multiples of), m. For example, in the five-person three-place-jump game: the multiples of 3 mod 5 are (3, 1, 4, 2, 0/5). As this is the set of numbers in modulus 5, everyone gets to throw the ball (or move/swap places in the dance). A possible shortcut could be written as: if the people number and place jump number don't share a common factor everyone gets to throw the ball (move/swap places).

The setting

This paper is part of a larger thesis studying students' movement, as they explore a mathematical task and follows on from the analysis of students' mathematical problematizing reported in Gandell and Maheux (2019). For Maheux & Proulx (2015) is the posing and solving of smaller self-generated problems in response to a mathematical task. The environment and task were intentionally designed to elicit students spontaneous full body movement.

The participants, four non-maths major students aged 18 and 22 years, were recruited from a six-month tertiary bridging programme which provides entry into degree and diploma programmes. During an hour-long session, the students engaged with a mathematical task in an open room with no tables and chairs. The task (Figure 1), printed on A3 paper, was attached to one of several vertical whiteboards positioned at the edges of the room with whiteboard markers and magnetic counters. All student activity was captured by three video cameras positioned at the edges of the room. The fragment transcribed below, occurs thirteen and a half minutes from the beginning of the session, and six and a half minutes after the first fragment transcribed in Gandell & Maheux (2019). The session began with a movement warm up, led by the researcher, who then invited the students to move freely around the room. The students then alternately used the vertical whiteboard and task sheet and acted out two games from the task (a four-person three-place-jump game and a six-person three-place-jump game) in the open area of the room. In the first enactment the students used a counter as a ball, in the second enactment the students changed the game into a dance, as requested by the task (Figure 1).

Mathematical thinking in movement

At the beginning of this fragment the students have just completed acting out a six-person, three-place-jump game, which they call a six-three. As 3 modulus 6 has only two multiples (3, 0/6) only two people move, during the enactment of the game, which the students verbalize as swapping places. Returning from the open area of the room to the white board and task sheet they utter "that one doesn't work". The group, Chas, Kit, Ala and Paige, stand quietly for a few minutes. Kit first problematizes finding a formula, and then how to change a six-three game so that everyone can move.

1	Kit:	A six-two for everyone to move I think (suddenly dabs three discrete positions with this right index finger, inscribing a circular path in front and to his right side with this right arm, and gazing first between Chas and Ala then towards Ala and Paige, Figures 2 a, b and c).

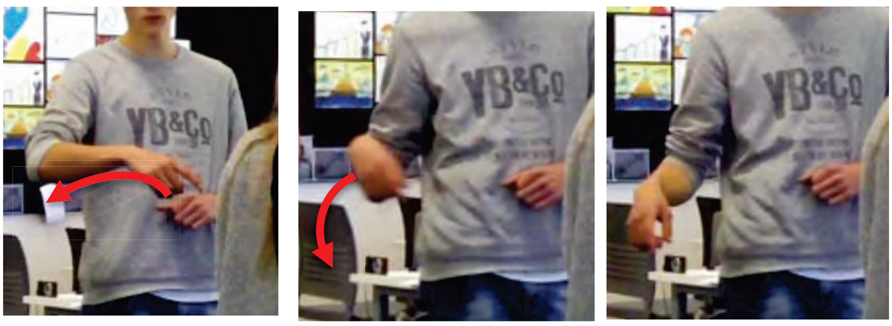


Figure 2: a) Kit dabs position one b) position two c) and position three

For Sheets-Johnstone (2011) “thinking in movement is not that the flow of thought is kinetic, but that the thought itself is” (p. 421). Thinking in movement does not require students to learn which movements will produce specified answers, or to pre-plan movements to express ideas: thinking in movement is the spontaneous activity of a dynamic thinking body. In the fragment above Kit demonstrates spontaneous, self-generated, mathematical thinking in movement providing a mathematical solution for his problematization of how many people move in a six-person two-place jump game (line 1).

In Line 2 Kit verbalizes that everyone will move, for a six-person two-place-jump game and performs a movement indicating three positions in a rough circle with his right index finger (Figure 2). Kit performs this movement very quickly, with the three positions distinguishable by the variations in dynamic qualities. The curved paths between each of the positions have a light, gliding quality, like a bounce. Kit pauses, at the end of each bounce, with a heavier and more bound quality, like a dab. Although these bounces and dabs serve to indicate different three positions to his right front and side (Figure 2), the sudden and indirect qualities of this movement give Kit’s performance the feeling of a sketch. With his movement in line 2 Kit appears to be trying out, rather than defining, the solution of three positions for the game.

Kit clearly provides a solution for the six-person two-place-jump game with his movement: a solution not available from his verbalisation that everyone moves. No previous movements in this session have sketched a solution using Kit’s bounce and dab movement, so Kit is not reproducing a movement. Thus, a new mathematical movement has emerged spontaneously from a moving dynamic body. As Kit’s movement (Figure 2) does not replicate his verbalized solution the movement cannot be a pre-planned or pre-thought embodiment of that verbalization. In line 2, then, Kit performs a mathematical solution in movement: Kit is thinking in movement as Sheets-Johnstone (2011) describes.

Evolving thinking in movement

2	Chas:	The trouble is instead of swapping (elbows bent index fingers touching, right finger traces horizontal curve forwards, left hand traces straight line backwards and up, Figure 3a) you go around (spiral trace with right arm across left, up and forwards, Figure 3b).

Figure 3: a) “instead of swapping” b) “you go around”

3	Paige:	(lifts hands to hips) yeah that’s what I was thinking
4	Chas:	(touches left and right index fingers in midline) it goes around to the next person (spiral right arm trace left, forward and up across his body) instead of swapping (index fingers touching, traces two lines right hand forward, left hand backwards and up then rolls right hand backwards under left hand going forwards, then rolls right hand forwards under left hand going back, Figure 4a). So that’s the swap (Rotates right and left hands around each

other tracing horizontal circles Figure 4b. Holds final position index fingers pointed upwards for 2 seconds, Figure 4c).

Figure 4: a) over and under rolls b) spiral around vertically c) final held position

5 Chas: From there (points right arm to left side, rotating torso and head to left, Figure 5a) goes around to (traces horizontal circle around body with right arm, rotating torso, to point to right side. Holds arm extended to right and looks back to Kit, Figure 5b) … the next person

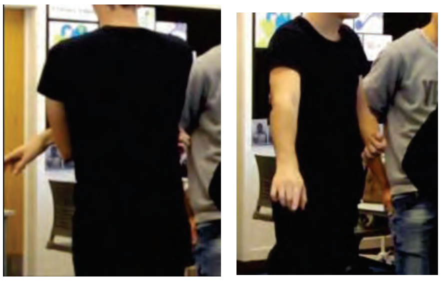

Figure 5: a) "from there" b) "to the next person"

Thinking in movement arises from a body that resonates with the world (Ingold, 2013; Sheets-Johnstone, 2011). Rather than reified minds creating symbols and representations of the world, new things, including mathematical things, emerge as tactile-kinaesthetic bodies correspond with animate material flows. Thus, thinking in movement is emergent, evolving and adapting to an ever-changing environment, and may take many different forms (Sheets-Johnstone). Chas, in lines 2, 4, and 5, demonstrates an evolving thinking in movement which contrasts with his almost unchanging verbalizations.

In line 2, Chas verbalizes and performs two problematizations which he differentiates both verbally and by using different space, body and dynamic movement qualities. For the first problematization Chas traces a line with each hand (Figure 3a) as he utters "instead of swapping back". In the second problematization Chas performs a spiral trace with his right arm (Figure 3b) uttering "you go around". The small, direct, straight line "swap" movements are performed with two hands, tracing a mainly horizontal pathway. In contrast, for the larger spiral "around" movement, Chas's right arm traces a path to the left, across his midline, then up and forward, through horizontal, vertical and transverse planes, with a sustained, indirect, light, floating, quality. Although Chas uses different words for his verbalizations, how "swap" might be different to "around" is not clear without his movements. Chas' verbalizations, then, appear to be labels supporting his movement problematizations.

In line 4, Chas begins by repeating the swap and around problematizations, with little change to his movement or verbalizations, but in reverse order. Immediately after he repeats the 'swap' movement from line 2, Chas begins a new movement (Figure 4a) rolling his hands over and under each other in vertical semi-circles. Chas then verbalizes “so that’s the swap”, as he spirals his hands around each other in a horizontal plane (Figure 4b), finally stopping and holding the position in Figure 4c. Thus, in line 4 Chas performs three distinct “swap” movements.

These “swap” movements, which are performed in quick succession, are differentiated by transforming dynamic qualities from sharp, bound and direct to more continuous, freer and indirect. In this way the “swap” movement appears to enfold the dynamic qualities of both the “swap” and “around” movements, initially performed in line 2. In addition, the movement pathways change from almost straight lines to semi-circles and finally to spirals. Although performed with two hands the spiral pathway of this final swap movement (Figure 3b) reflects the spiral of the initial “around’ movement from line 2. However, while Chas performs ever-evolving “swap” movements in line 4, he continues to verbalize these movements as a swap.

Finally, in line 5, Chas places himself in the centre of the movement and performs a large continuous, sustained horizontal curved pathway with his right arm. By combining a curved path, a sustained floating dynamic quality, and the use of one arm this final movement performs some elements of the “around” movement from line 2. However, in this movement Chas also includes elements of the line 2 swap movement, performing a more horizontal, single direction, pathway and a more direct dynamic quality. Thus, Chas’s movements (lines 2, 4 and 5) evolve and, by merging elements of both the “swap’ and “around” movements, seem to resolve the problematization of how counting around becomes swapping places in the game as a dance. Although Chas’s movements transform, in lines 2, 4 and 5, his verbalizations remain very similar, with his final verbalization indicating positions rather than referencing any resolution to his problematizations. By adapting and evolving his movements to merge his two problematizations, Chas shows how thinking in movement may evolve and change as a dynamic body resonates with an ever-changing environment.

Discussion and conclusion

For Sheets-Johnstone (2011) humans move and know the world through their tactile kinaesthetic bodies. Humans cannot remove themselves from their bodies and think in some disembodied mind. As this paper demonstrates, students’ movement is not only integral to their thinking and knowing, students think mathematically in movement. Kit’s movement illustrates how students animate bodies perform mathematical thinking: thinking that may not necessarily be articulated, expressed or made available in any other way except in movement. Similarly, Chas demonstrates how thinking in movement can emerge and evolve, even while accompanying verbalizations remain static. Thinking in movement is not about making decisions about how to move or where to move, rather spontaneous movements emerge and evolve in correspondence with an animate world (Ingold, 2013; Sheets-Johnstone).

For a long time, western mathematics education has de-privileged movement and the body in mathematical thinking. By ignoring students’ spontaneous thinking in movement, mathematics educators and researchers may be missing valuable instances of students’ mathematical thinking and knowing. As Sheets-Johnstone (2011) explains

> “thinking in movement is a way of being in the world, of wondering or exploring the world directly, taking it up moment by moment and living it in movement, kinetically. Thinking in

movement is clearly not the work of a symbol making body, a body that mediates its way about the world by language, for example, it is the work of an existentially resonant body" (p. 425).

Although many educators approach movement in the classroom in many different ways, movement is not simply a learning tool. Students' spontaneous movements provide access to mathematical thinking and knowing that may not otherwise be available. To fully understand students' mathematical thinking, mathematics educators need to develop approaches that recognize and support students' thinking in movement, rather than considering movement as an adjunct to verbalization or an expression of concepts held in a mind. In research, and in the classroom, mathematics educators need to consider movement not just as another resource for learning, providing space and support for students to move, mathematics educators also need to pay closer attention to students' mathematical thinking in their spontaneously performed movements.

Coping strategies: A rather neglected perspective of research on first year university mathematics students' goals and strategies

Robin Göller

Leuphana University Lüneburg, Germany; robin.goeller@leuphana.de

Research on undergraduate mathematics students' goals and strategies has mainly focused on students' learning and performance goals and their learning and problem-solving strategies that correspond to these goals. This paper presents results from an interview study on self-regulated learning with 18 first-semester mathematics students, which indicate that, in addition to those, well-being goals and coping strategies may provide an important contribution to understanding students' engagement with mathematics at university. These results provide approaches to a more holistic view of the everyday learning of mathematics students at universities with possible implications for research and practice, which are discussed.

Keywords: Mathematics Education, Higher Education, Learning Strategies, Coping

Introduction and theory: Students' goals and strategies

Research on undergraduate mathematics has grown steadily in recent years, particularly with regard to the transition from school to university mathematics and revealed many difficulties of students with the mathematical contents at tertiary level (e.g., Biza et al., 2016; Gueudet & Thomas, 2020). Reasons for these difficulties are considered to be the differences and ruptures between the mathematics taught at school and the mathematics taught at university, but also the institutional settings (e.g., Gueudet, 2008). For example, the proportion of time, where students have to shape and regulate their own way of learning is significantly higher at universities than at schools and, according to the study regulations of German universities, amounts to about two thirds of the learning time for the mathematics modules of the first academic year. This increases the importance of self-regulated learning at universities which will be examined in the present study with a focus on first-year mathematics students' goals and strategies.

There are many different models of self-regulated learning with varying definitions and foci (e.g., Panadero, 2017; Zimmerman & Schunk, 2011). Consistent with most of these models, self-regulated learning can be defined as *"an active, constructive process whereby learners set goals for their learning and then attempt to monitor, regulate, and control their cognition, motivation, and behavior, guided and constrained by their goals and the contextual features in the environment"* (Pintrich, 2000, p. 453). This definition shows the importance of goals in models of self-regulated learning. A distinction is often made between *learning goals* which focus on increasing competence and *performance goals* which focus on the attainment of positive judgments, e.g., good grades (Pintrich, 2000). Additionally, the dual processing self-regulation model of Boekaerts (2011) takes *well-being goals* into account that focus on preventing threat and harm to the self. This model theorizes that when tasks are appraised to be a threat to the self, *coping strategies* such as seeking social support, join with people who have the same concern, wishful thinking or working hard, are used to deal with the stressful situation (Boekaerts, 2011). Generally, we define *strategies* as goal-oriented behaviors and thoughts, which can be distinguished by the goals they aim to achieve: *Learning strategies* aim at learning, *problem-solving strategies* aim at solving a problem, *coping strategies* aim at preventing threat and harm to the self. This is in line with Weinstein and Mayer's definition of learning strategies which *"can be defined as behaviors and thoughts that a learner engages in during learning and that are intended to influence the learner's encoding process"* (Weinstein & Mayer, 1986, p. 315).

Research in university mathematics education has provided important insights into mathematics students' general learning strategies surveyed via questionnaires (e.g., Griese, 2017; Lahdenperä et al., 2019; Liebendörfer et al., 2021, 2022), students' problem-solving strategies (e.g., Pólya, 1945; Schoenfeld, 1985; Selden & Selden, 2013; Sommerhoff et al., 2021), their activities learning new mathematics (Wilkerson-Jerde & Wilensky, 2011), types of students' engagement with proofs (Selden & Selden, 2017) as well as their proof-reading strategies (Panse et al., 2018; Weber, 2015). As with any research, the explanatory power of such studies for students' actual day-to-day mathematics learning is framed by the questions asked and, possibly, limited by the study design of the particular studies. For example, when participants *"were asked to read the paper and try to understand it such that they would be able to teach it to a colleague"* (Wilkerson-Jerde & Wilensky, 2011, p. 27) the learning goal "to understand the paper" and the strategy "to read the paper" is given by study design. However, it is not clear in which situations of everyday engagement with mathematics students pursue such goals and use such strategies, or whether other goals and strategies might occupy a more prominent position.

Studies which rather try to capture students' usual everyday strategies suggest that, when working with textbooks, students' rather spend their time on searching worked out examples or for surface similarities with a procedure and rather not to read the (closed) text (Lithner, 2003, 2004; Weinberg et al., 2012). On a broader picture, it seems that first year mathematics students spend more time on searching for worked-out examples in books, their lecture notes, or on the internet or on working in peer groups trying to solve mathematics exercises (and seem to consider this their main responsibility) than trying to recall their lecture notes to understand mathematical theory (Göller, 2020, 2021; Gueudet & Pepin, 2017). This is in opposition to expectations of lecturers, who rather anticipate that students work on their lecture notes, especially on the proofs of the theorems, and then are able to work on exercises by themselves (Gueudet & Pepin, 2018). Of course, such expectations of lecturers vary and, in addition to personal conceptions, depend on the institutional setting in which the lecture takes place. Therefore, in the following, the organization of typical first semester mathematics courses at German universities will be briefly described.

Goals implied by the institutional settings of first year courses at German universities

First year mathematics modules at German universities often consist of lectures and related exercises. The lectures introduce mathematical theory, i.e., definitions, examples, theorems and their proofs are presented. The exercises are handed out weekly and worked on by students in self-study. Students submit their solutions which are corrected, graded, and discussed in a separate lesson. To pass such a module, usually a certain number of exercises (often 50% of all exercises) must be solved correctly and a written exam has to be passed.

These formal requirements imply at least two types of performance goals which are necessary to pass such mathematics modules: *Generating solutions to the exercises* and *passing the exam*. In addition, the division of the courses into a lecture and exercises may imply certain learning goals: For example, the *comprehension or understanding of the lecture contents* and the *development of problem-solving competencies* to be able to solve the exercises.

Research questions

This paper aims at investigating the everyday self-regulated learning of first-year university mathematics students within the described institutional setting based on the following questions:

RQ 1: Which study-related goals do mathematics students report in their first year of study?

RQ 2: Which study-related strategies do mathematics students report in their first year of study?

RQ 3: How can these strategies be explained as the result of a balancing of goals?

Research methods

In order to investigate these questions, problem-centered interviews (Witzel, 2000) were conducted with a total of 18 students (13 of whom were female) at up to four interview times in their first year of study. Ten interviewees (9 female: T1-T9, 1 male: T10) were enrolled in a degree program for *mathematics teachers at upper secondary level*, six (3 female: M1-M3, 3 male: M4-M6) in the degree program *Mathematics B.Sc*. and two (1 female: B1, 1 male B2) in the degree program *Business Education*. The respective interviews had a duration of about 45 minutes, were audio-recorded, completely transcribed, and analyzed using methods from Grounded Theory Methodology (Strauss & Corbin, 1990). To pre-structure the data material, passages in which the interviewees talked about their goals and strategies were identified first and then these were coded inductively regarding further subcategories (cf. Göller, 2020 for a more detailed description). The interview excerpts presented below were translated from German by the author.

Results

With regard to RQ 1, learning and problem-solving goals as well as well-being goals were reported (see Table 1) and could be identified as influential for students' strategies.

Table 1: Categories of reported goals

Category	Quote example
Performance goal: Pass exam	I said from the beginning, even when I started studying, the main goal is to pass math, nothing else matters. (T1)
Performance goal: Solve 50%	My goals are to get at least 50 percent of the points on the exercise sheets. (T2)
Learning goal: Understand lecture notes	To actually understand it. That is my goal. To actually understand what I wrote down in the lectures. Maybe not everything, that will be impossible, I think. (T3)
Learning goal: Solving ability	You also have to be able to solve exercises. (M1)
Well-being goals	Because I'd also like to enjoy the time a little and don't want to drown in stress. (T4)

Among these reported goals, the interviewees' overall focus was primarily on achieving the institutionally defined performance goals: Pass the exam and solve at least 50% of the exercises. It could be observed that especially when the achievement of these goals is in question, learning goals were inhibited or postponed to a later point in time.

The strategies were dominated by the work on the exercises (RQ 2). Thus, work with the lecture notes was comparatively rarely reported and, in many cases, even explicitly negated. A frequent reason given is that the exercises take so much time that there is no time left for working on the lecture notes:

> T3: I really don't have time to look at the lecture notes again. Well, I'm kind of geared up to try to finish this exercise sheet somehow within the week. And most of the time I sit there at ten o'clock on Wednesday evening and write down these exercises. That's basically all I'm trying to do in math, because time just isn't there.

At the same time, experiences of success when working on the exercises often occurred in the context of working through the lecture notes. But even for students who had realized this for themselves, working through the lecture notes was a question of time resources:

> M1: Sometimes I even manage to learn the topic before handing in the exercise. And that's when I notice that it really makes a difference. Because if you have learned the topic beforehand and really understood it, then the exercise doesn't take ten hours. Then it takes maybe two or so.

Table 2: Categories of strategies for exercise solutions with subcategories for "work with others"

Category	Quote example
Work with lecture notes	I start with the exercise where I think you could make good progress, to get a positive feeling. Yes, then I look in the lecture notes to see if there's anything I can use. This semester I have already been able to use the lecture notes surprisingly often. (B2)
Problem solving strategies	I always write it down: What do I have? What do I want? What do I have to show? (T6)
Use other materials	I occasionally also look on the Internet. (M4)
	Sometimes you can find something in books that helps a lot. (M2)
Work with others	And analysis, well, we do that in a group, that's much faster than doing it alone. (T7)
- Compare solutions	For example, today we also meet and do the exercises together and then talk together about who has solved and how we solved which exercise and so on. (M2)
- Teamwork	We complement each other. Sometimes he has things that I don't have, and vice versa. (B2)
- Ask for hints	And if I get stuck, I write to someone and ask if he can give me a hint. (B2)
- Comprehend solutions of others	So, when other people already solved it, that I then look at it and try to understand it for myself and write it down again. (T4)
- Copy solutions of others	Exactly, that's why we just bluntly copied some things without comprehending what was being done. (T5)

Regarding the work on the exercises, different strategies can be distinguished, which are listed in Table 2. The subcategories of *work with others* given in Table 2 can be seen as arranged in descending order for the achievement of learning goals (also from the students' perspective) and thus describe a gradual transition toward coping strategies. Regarding RQ 3, the respective situationally used strategy then depends on a balancing of situational goals and self-assessed internal (time, ability, effort) and external (materials, other people) resources. Although these strategies varied situationally, there were students who preferred to work on their own and rated related strategies rather high,

M4: I usually work completely alone, and I refuse to copy solutions anywhere, which might mean that other people then have more points, but I think I've built up more understanding by the end of the semester. That's how I would evaluate it now.

while others rather worked in groups to generate exercise solutions in teamwork:

T5: So, the other girl, who is with me then, that's more the one who also looks up a bit what we've done or something. She also has ideas from time to time about what to do about it. I think she also looks at things at home from time to time to understand. Then we have another guy. He also does some calculations on the weekend. So, he works on the things himself. He also wrote the best exam of all four of us. Then there's the guy who failed everything, he's just not the brain, but he, I don't know how he manages it, but every now and then he listens to the lecture, and then he can summarize the things that the professor explains in a totally complicated way, he can simply apply them to school knowledge in a way that every eighth grader will understand. And he always makes these simpler connections. And so, he can derive these proofs. But apparently that didn't work in the exam. And I'm the one who always looks at all the theorems. I do not do anything before or something like that, but we really sit down on Tuesday and do the exercises. Then I look at the exercises. Or get solutions or something. From someone else. Or some ideas. And I'm also pretty good at searching for definitions. So, I find definitions and find parts: Oh, this could be important. And then the girl takes that and forwards that. So, it's a good team, I would say.

One main reason for working in groups seemed to be that many students did not feel able to solve the exercises on their own within a reasonable amount of time (from their point of view):

M5: First, because of the motivation, because otherwise I would have to work on it alone. But it also helps to have the others because the ideas come from several people. You could also say that it might not be so good if you don't have all the ideas yourself, but then we wouldn't be able to finish in time. So, if I had to do it alone, then I would need much more time, much more.

Working in groups with all its sub-strategies (cf. Table 2) thus did not only address students' learning and performance goals, but also their motivation and well-being goals, i.e., it is (also) a coping strategy. The following interview excerpt provides a more detailed insight into this balancing and negotiation of different goals with regard to available resources:

T3: And with the exercises, it's pretty much the only thing I do. But even there, I have to admit, I don't really engage with it. Because we have such an exercise group now, and somebody always has the solution. And most of the time I just write it down to get my permission [50%], because there is no time for it. […]

Interviewer: But I mean, it was a little different last semester, right?

T3: Yes, but that was simply because we had no solutions [from others]. There was no other option for us. That was simply the fact. But it was actually better that way. I

> must say quite honestly. Because you don't get anything out of it. Everything just passes by. And that's exactly the problem. And actually, I have to say, somehow, I mean, I got my admission in Ana[lysis] I, too. And somehow, I understood more. So, it could have been done in Ana[lysis] II as well. And, I mean, I somehow found time to make these exercises at some time. I just have to say that at that time I sat there until two o'clock in the morning, sometimes on Wednesdays, and did math. Fortunately, I don't have to do that anymore and I'm actually glad that I don't have that stress anymore. But, as I said, I don't get anything out of it.

Discussion

This paper tries to give a qualitative insight into first year mathematics students' everyday strategies while dealing with the challenges of their study. The results indicate that a closer look at coping strategies can contribute to a better understanding of students' everyday engagement with mathematics at university. Boekaerts' (2011) theory predicts such coping strategies, as the exercises pose a potential threat to well-being because they often frustrate self-confidence on the one hand and can actually determine the success or failure of the module on the other. The results of this study highlight the importance of students' balancing and negotiation of different goals, considering their respective resources, to understand their use of learning, problem-solving, and coping strategies.

Implications for research and practice

The categories of goals and strategies presented here are based on different theoretical perspectives and research practices. Questionnaires usually operationalize theoretical considerations on general learning strategies (e.g., Griese, 2017; Lahdenperä et al., 2019; Liebendörfer et al., 2021, 2022), observational studies from research in undergraduate mathematics education often examine problem-solving strategies or proof-reading strategies in a more clinical setting (Panse et al., 2018; Weber, 2015; Wilkerson-Jerde & Wilensky, 2011). This research is undoubtedly important but seems not to represent the totality of the everyday strategies used by students. Well-being goals and coping strategies are rarely represented in common questionnaires and are rather prevented in observational studies by study design. However, based on the data presented here, they seem to offer an important perspective for a deeper understanding of mathematics learning at universities regarding the respective institutional settings and their influence on students' learning.

The requirement, e.g., to achieve at least 50% of the possible points for the weekly exercises entails that most of the time spent on mathematics is spent working on exercises. Students invest a lot of time and effort on the exercises, while working on the lecture notes is often neglected. In addition, this external pressure provokes coping strategies when students feel unable to meet the requirements on their own. From the data of this study, however, it is unclear how an omission of the 50% barrier would affect students' goals and strategies. On the one hand it seems that the emphasis on such extrinsic incentives inhibits or postpones learning goals, on the other hand it seems that at least for some students the absence of these extrinsic incentives (e.g., because of the possibility to copy solutions of others) leads to a situation in which they hardly engage with the mathematical content at all. Accordingly, further research in this direction is desirable in various institutional settings.

In the institutional setting described, exercises can be seen as an important institutional tool to regulate students' strategies. Accordingly, goals and strategies considered essential should be represented as explicitly as possible in the exercises. For example, special task formats can be considered which support the work on lecture notes, in particular the reading of proofs, if these are identified as important institutional goals. In terms of coping strategies, attention must also be paid to the difficulties involved in the exercises, to enable as many students as possible to participate in working on the exercises in a way that promotes learning and at the same time challenge all students.

[1]UR EST, Université Paris-Saclay, ghislaine.gueudet@universite-paris-saclay.fr; [2]Brock University, Canada; [3]Cinvestav, Mexico; [4]Universidad del Valle, Cali, Colombia

The instrumental approach, and in particular the concept of scheme, can contribute to our understanding of how students learn programming for mathematical inquiry at university. While most studies consider only individual schemes, in this paper we propose to investigate schemes' social aspects, focusing on the scheme of "Validating the programmed mathematics". Through a questionnaire conducted with students over 2 years, and interview data, we identify shared rules-of-action developing over time. Deepening the analysis for the case of two contrasted students, we observe that common rules-of-action can be associated with different theorems-in-action.

Keywords: Social aspects of schemes, Programming, Instrumental approach, Mathematical inquiry.

1. Introduction

The study presented here is part of a larger 5-year project, whose aim is to better understand how students learn programming for mathematical inquiry at the university level. In our previous work (Buteau, Gueudet, et al., 2020; Gueudet et al., 2020) we have shown that the instrumental approach (Rabardel & Béguin, 2005; Trouche, 2003) and the concept of scheme (Vergnaud, 2009) can contribute to this aim. This concept allowed us in particular to investigate how students develop operational knowledge (knowledge that provides means to do and succeed, Vergnaud, 2009), through instrumental geneses. We focused only on the individual level: the schemes developed by a given student. Nevertheless, at university, students learn in a social context, and most probably their schemes also comprise common elements. Some aspects of the operational form of knowledge are shared; identifying these aspects is essential in particular to inform teachers' orchestrations (Trouche 2003) in this context. The question we investigate here is: Can we identify patterns in the culture of a community of students learning to use programming for mathematical inquiry?

In terms of research, we claim that studying this issue is an important theoretical and methodological contribution, because the instrumental approach has been used mostly for studying individual learning processes. In terms of teaching, we have observed in a previous study (Buteau, Muller, et al., 2020) that insights into students' schemes can be very helpful for teachers orchestrating their learning of programming for mathematical inquiry.

Our study takes place in the context of a sequence of three university mathematics courses called *Mathematics Integrated with Computers and Applications* (MICA I-II-III) taught at Brock University since 2001 (Buteau & Muller, 2010). In these project-based courses, mathematics majors and future mathematics teachers learn to use programming for mathematical inquiry (e.g., using programming to simulate a battle between two armies; see section 5).

2. Theory and research questions

We draw from Vergnaud's (2009) theory of conceptualization, distinguishing between an operational form of knowledge (knowledge that provides means to do and succeed) and a predicative form of knowledge (knowledge that consists of means to express ideas in words or symbols). We argue that Vergnaud's theory is relevant for our study because operational knowledge is very important when learning to use programming for mathematical inquiry.

Operational knowledge's development and evolution are captured by Vergnaud (2009) through the concept of scheme, which is central in our study. A scheme is an invariant organization of activity for a certain goal and consists of four components: the goal and sub-goals; rules-of-action (RoAs), to generate action, information seeking, and control; operational invariants (concepts-in-action, which are concepts considered as relevant, and theorems-in-action (TiAs), which are propositions considered as true); and possibilities of inferences.

We also use the instrumental approach, particularly its theory of instrumental genesis, which conceptualizes the process of how users (learners) transform an artefact (a human product, designed for a goal-directed activity) into an instrument for a specific goal and situation (Rabardel & Béguin, 2005). For Rabardel and Béguin (2005), an instrument is a hybrid entity: partly an artefact and partly scheme(s).

According to Rabardel and Béguin (2005), schemes have both a private and a social dimension. The private dimension is specific to each individual, while the social dimension reflects the fact that schemes may be shared by members of social groups. The social dimension also may be a consequence of schemes developing during a process involving individuals who are not isolated; for example, classmates working on assignments in a shared space such as a computer lab. Schemes may be shared informally or prompted/promoted formally by training, such as in teaching and learning situations (e.g., through assignment guidelines, lectures, etc.).

This points to the possibility of the development of social dimensions of schemes in teaching situations. In fact, Trouche (2003) claims that through instrumental orchestration, one aim of the teacher is to reduce the variability of the individual schemes students develop, in order to strengthen the social dimensions of schemes; for instance, reflecting those shared by an intended community of practice, such as that of mathematicians (Lave & Wenger, 1991).

The above theoretical elements lead us to refine our initial question as follows: Can we identify common elements in the schemes developed by students learning programming for mathematical inquiry? For a common goal, do students share common RoAs, and if so, are these rules associated with the same operational invariants? How do these common elements develop over time, in a course, and over several years of courses?

3. Methods

In our past work, we developed a general model of students engaging in learning to use programming for mathematical inquiry (Buteau & Muller, 2010), which enabled us to identify common goals in the schemes developed by students. For this study, we focus on one such goal, namely "Validating the programmed mathematics", considered as particularly important because it associates mathematics and programming. For this goal, we further focus on RoAs because most operational invariants and inferences cannot be made explicit; RoAs are more explicitly identifiable.

We mainly draw from two types of data: a questionnaire and individual interviews. The questionnaire was given to students at the end of each MICA course over 3 years (2019–2021), and included questions on demographics, confidence levels in programming (mathematics), et cetera. Since 2020, it also included two questions seeking insights about two specific schemes. Each of these questions presented a list of RoAs in a matrix format and a 5-point Likert scale for students to answer if they used the RoA always, often, sometimes, rarely, or never. Most of these RoAs were identified in our previous work analyzing a student's activity (Buteau, Gueudet et al., 2020), and some more were added based on our experience as mathematicians researching with programming or teaching programming for mathematics investigations. The questionnaire was answered by 30 anonymous volunteer students, in addition to another 13 volunteer students whom we have been following closely throughout their MICA courses (e.g., using also individual interviews).

We used relative frequency bar graphs for responses to each of the questions and for responses regrouped into three categories (always/often, sometimes, rarely/never) in order to identify RoAs that could be considered as social. To do so, we used an arbitrary threshold of 70% of the regrouped always/often responses. We note that the sample of 43 participants is not necessarily representative of the entire MICA community but can nevertheless give insights into potential social dimensions of schemes. For triangulation purposes, we also called upon interview data. For this paper, we selected data collected in Year 2 (2019) of our research since we had the opportunity to collect data both from an instructor (Bill) and some of his students. In one of the interviews with this MICA II instructor, we showed him the list of RoAs and invited him to comment on whether, according to him, students enact the RoAs, and to elaborate about his related guidance.

Finally, we went to individual student cases. Two among eight student participants enrolled in Bill's MICA II class were selected due to their more reflective answers in interviews and for their differing profiles: Kassie is a female student enrolled in the mathematics and education program who had no programming background prior to starting her university studies and Mark is a male computer science and mathematics co-major student who had a significant programming background prior to MICA I. After each of the programming-based mathematics inquiry projects (five assignments), individual semi-structured interviews were conducted. We used guiding questions incorporating "explicitation" techniques (Vermersch, 2006) to help students relive their actions during the development of their investigation projects. Kassie and Mark's interview data were coded to identify potential elements of schemes (in particular, the "Validating" scheme) according to their RoAs and TiAs (Gueudet et al., 2020), which were then confronted with their assignment reports. The outcomes of this analysis were organized in terms of RoAs and summarized for each project in a common Excel table, to which we added Kassie and Mark's own questionnaire responses as well as the relative frequencies of the overall questionnaire responses. Using these tables, we identified individual elements of the "Validating" scheme for Kassie and Mark, respectively.

4. Identifying social aspects of a scheme

In this section, we present the results of our analysis identifying the social RoAs for the "Validating" scheme (Buteau, Gueudet, et al., 2020), as part of the process of creating a program for conducting a mathematical inquiry. We consider an aspect of a scheme to be "social" when it is shared by a social community. In our analysis, we realized that RoAs may be identified as social (or not) depending on whether the community in which they are shared comprises the students in MICA I or the students in upper MICA courses (i.e., MICA II and III). These two communities are not independent: We might even see the MICA I student community as in the process of "becoming" or "developing" into an upper year MICA community. This relates to the instrumental lens, whereby the study of students' instrumental geneses is considered as progressing over time. Hence, we will not consider as our reference community all MICA students. Note that we grouped 2nd- and 3rd-year students (into upper MICA) to have more appropriate sample sizes for comparison purposes (N=18 for upper MICA, N=25 for MICA I). This also reflects the implementation model in these courses: MICA II and III invite students to use programming skills to engage in mathematics inquiry, while MICA I is also focused on developing students' programming skills (due to their lack of background in programming).

RoA	Upper MICA	MICA I
1. I check a few times as I program by compiling with a few inputs.	94, 6, 0	72, 28, 0
2. Once I have programmed it all, I run the program with a few different inputs and compare the output with my hand calculations.	89, 0, 11	92, 8, 0
3. I compare the output of my program with that of a peer or with examples from the internet.	83, 6, 11	40, 24, 36
4. I compare my program with that of a peer.	72, 17, 11	32, 24, 44
5. I ask someone (a peer, a TA, the instructor, etc.)	61, 22, 17	52, 20, 28
6. I trust that I translate in vb.net/python what I do on paper. († This is the original wording in the questionnaire. However, we acknowledge that this formulation rather points to an operational invariant and a 'no RoA'.)	56, 22, 22	28, 32, 40
7. I use other technology (Maple, Desmos, etc.) to generate an example and compare it with the output of my program.	28, 50, 22	64, 24, 12
* I don't really know if it works. (* We label this statement differently because it is not a rule-of-action. It is more an indication that students do not have a fully developed scheme for validating the programmed mathematics.)	11, 22, 67	8, 24, 68

Figure 1: Percentages of participants who say they do the RoA always/often, sometimes, rarely/never, in response to the question "When I program a mathematics concept, I know that it works because…"

Figure 1 depicts findings from the online questionnaire, listing the RoAs in the order of highest to lowest percentage of upper MICA participants stating that they use it always or often when validating a programmed mathematics process.

While these RoAs can seem to concern programming in general, we note that the question invites the students to answer only about programming a mathematics concept. Some of the rules are directly linked with mathematics: calculating by hand (RoA 2), or with Maple (RoA 7). Moreover, when the scheme is mobilized in a specific mathematical situation, these rules are specified in relation to the mathematical contents, as we illustrate in the following section.

The top four RoAs are used by more than 70% of the upper MICA participants, suggesting that those RoAs may be social components of the validating scheme for the upper MICA community.

RoAs 1 and 2 appear to be social also in MICA I. For RoA 2, the proportions are similar: 89% and 92%, respectively. One reason for this may be that the lab and assignment guidelines explicitly encourage students to check their output with hand calculations, starting in MICA I. In contrast, for RoA 1 the proportions have a greater difference: from 72% in MICA I to 94% in upper MICA. One way to explain this is that RoA 1 goes together with the practice of coding incrementally. The MICA II instructor from our study, Bill, explains:

> Bill: They will often test. … They develop programs incrementally, so they'll write … just a couple of … a loop or something and they just [say]… see: does that make sense?

Such a skill may require time to develop. Also, the mathematics problems explored in upper MICA lead to more elaborated programs, which can encourage students to code incrementally. This is in contrast with RoA 2, where students check after the program is completed.

RoAs 3 and 4 appear to become social only in the upper MICA community. For RoA 3, the proportion increases from 40% in MICA I to 83% in upper MICA. This could be related to upper MICA students having become more confident in their own skills and more comfortable with their peers; hence they may be more willing to interact and share with their peers. We note that interaction and sharing among MICA students, as well as comparing output with examples from the internet, is also encouraged by instructors. Bill confirms that students do RoA 3 and says:

> Bill: There are places where the answers are on the internet and I encourage them to check that their program gives that output.

Similarly for RoA 4, the proportion increases from 32% in MICA I to 72% in upper MICA. Bill again confirms that students do this constantly and are encouraged to do so:

> Bill: It's a public forum. Chat, talk, discuss. … We are collaborating and I want to foster that atmosphere.

The last four RoAs do not appear to be social in the upper MICA community. Bill confirmed this in some cases: E.g. for RoA 6, Bill noted that it is not common for students to trust their translation of what they do on paper into the programming language. Finally, we note the low proportions (in *I don't really know if it works) that may be interpreted as indicating that all students already have started to develop their "Validating" scheme to a certain degree by the end of MICA I.

5. Social and individual aspects of schemes

In this section, we further analyze the "Validating" scheme for two students, Mark and Kassie. Considering this individual level allows us to observe similarities and differences when a common RoA is mobilized by different students, and to deepen our analysis of the intertwined mathematics and programming knowledge involved in this process. For the sake of brevity, we focus on assignment 4 (question 1) from the MICA II course taken by Mark and Kassie, and we select only one of the social RoAs. We also evoke other MICA II assignments that confirm the stability of the organization of students' activity and illustrate variability depending on the mathematics.

Presentation of assignment 4

In this assignment, students investigated simulations of a battle between two opposing armies using discrete equations. The assignment contained three questions that became progressively more complex. In the first question, students were told to create a program to output the day-by-day evolution of the battle represented by the Lanchester equations: $X_{n+1} = X_n - a*Y_n$ and $Y_{n+1} = Y_n - b*X_n$, where a and b are fixed parameters and X_n and Y_n represent the number of soldiers in the two armies on day n (the battle ends when X_n or Y_n is less than 1).

RoA 2: A common mobilization, different TiAs

For question 1 of assignment 4, both Kassie and Mark mobilized RoA 2: "Once I have programmed it all, I run the program with a few different inputs and compare the output with my hand calculations", which we found to be social among both MICA I and upper MICA communities. In their individual interviews, they declare for example:

Kassie: I did like the equations myself, just after like the first day of battle and kind of like, compared them with what I got with my program.

Mark: You're able to, again, at least begin on paper to kind of understand and write it out yourself of what the expected results are going to be. So, because of that, I kind of just tried to do the first few questions by hand.

We found evidence of the mobilization of RoA 2 by Kassie and Mark for other assignments as well, confirming that it is part of a stable organization of their activity. We infer that both Kassie and Mark developed a corresponding TiA, such as: "When the result I compute by hand and the output of my program coincide, my program is correct". Both this general TiA and RoA 2 take different forms depending on the specific mathematical content. In assignment 4, once the parameters a and b and the initial values X_0 and Y_0 are chosen, simple computations using the recurrence relations can provide the successive values X_n and Y_n. Students look for an exact match between the output and their hand calculations; however, they are only able to do this for a finite number of days in the simulated battle and eventually trust that the further iterations will be calculated properly too. In comparison, in assignment 1, where students adapted a program (presented in class) simulating the Buffon needle random experiment, they could compute by hand the exact probability (applying a formula given in class). They knew (law of large numbers) that the frequency computed by their program should converge towards this exact probability and used this mathematical result to check their program (in particular, Mark described his actions in this way).

In the questionnaire, while Kassie said that she "Always" uses RoA 2, Mark answered "Rarely" (nevertheless we found evidence that he used this rule on several occasions when completing his MICA II assignments). One possible explanation for this difference is that Mark is aware that a hand calculation is not always possible, depending on the mathematics involved. For example, about assignment 2, where students had to use the daily return percentages of the Dow Jones from 1950 to 2020 to compute the probability of a 2% drop, Mark said:

Mark: If you're given, uh, a mean … or a standard deviation or anything like that, um, you can't just verify your answer because you'd have, what over 50 years of data there.

It seems Mark developed another TiA associated with RoA 2: “The validation through hand calculation is only possible in some particular cases”. Thus we observe in this case that in the “Validating” scheme, even if RoA 2 can be considered as social among the upper MICA community because it seems to be shared by a majority of students, the associated TiAs are not necessarily shared: Mark has developed a TiA about the possibility, or not, to apply this rule, but we did not observe the development of this TiA by Kassie.

6. Conclusion

In our study we attempted to identify patterns in the culture of a community of students learning programming for mathematics inquiry, and more precisely to identify common RoAs in the schemes students develop. We also have investigated the development over time of these shared RoAs, and the TiAs associated with them. In this paper we focused on the scheme developed for the goal of “Validating the programmed mathematics”, which associates mathematical and programming knowledge, and RoAs for this goal that were identified in an earlier study.

Students’ answers to a questionnaire confirm that some of these rules are shared by more than 70% of the students—we consider these rules as social aspects of the “Validating” scheme. A further study of schemes developed individually by two students evidences that the same rule can be associated to different operational invariants, perhaps depending on the profile and experience of the student. We also observed evolutions between MICA I and upper MICA students. We claim that the social aspect of the teaching (the orchestration by the teacher, collective students’ work, etc.) contributed to create a community, with its shared patterns. MICA I students progressively entered the upper MICA community and aligned with its practice (Lave & Wenger, 1991) in terms of using programming for mathematical inquiry. In this university context, the horizon is given by the practice of mathematicians using programming for their own research.

The patterns of this practice were not explicitly stated in the MICA curriculum; they can be considered as operational knowledge, which is often not explicit. The teachers might be aware of some of these patterns and try to support students in addressing a goal in “proper” ways—using certain RoAs, based on certain TiAs. Nevertheless, they might also ignore some of these patterns; the identification of patterns by a research study can be helpful for them.

Most research using the concept of schemes has focused on individual schemes. However, as emphasized by Vergnaud (2009), the scheme–situation pair is a powerful tool in mathematics education research. Studying the aspects of schemes shared or not by students in a situation can also help refine our understanding of the situation. Focusing on social aspects of schemes is important to better understand what the situation is, for a group of students. We claim that using schemes not only as a theoretical tool for research but also as a lever producing interesting results for teachers requires a consideration of the social aspects of schemes, and their social-individual dialectics. In our future research we will further investigate social schemes by networking the theoretical frames of the instrumental approach (Trouche, 2003) and communities of practice (Lave & Wenger, 1991).

Aspects of complex path integrals

Erik Hanke

University of Bremen, Faculty 3 Mathematics and Computer Science, Germany; erik.hanke@uni-bremen.de

Keywords: Aspects, complex analysis, complex path integrals, definitions, partial aspects.

Introduction

Complex path integrals appear in various undergraduate mathematics curricula (e.g., for pure mathematics students, pre-service teachers, or engineers) and have many applications in pure and applied mathematics (e.g., computing Riemann integrals). Yet, there is only very little research on educational issues of complex analysis education so far (e.g., Oehrtman et al., 2019). Regarding the heterogeneity of students attending courses in complex analysis and deep curricular connections of complex to real analysis, it is relevant to analyze various ways to define complex path integrals, and how real analytic notions, which are usually foreseen earlier in mathematics curricula, can be used for that purpose. Moreover, Oehrtman et al. (2019) indicate that even experts in complex analysis struggle interpreting complex path integrals, so the epistemological endeavor undertaken here is likely to contribute to the teaching and learning of complex analysis. Hence, I address the following question: *"How can complex path integrals be defined and how are these definitions substantiated?"*

Theoretical frame and methodology

Greefrath et al. (2016) introduce the notion of mathematical "aspects": "An *Aspect* of a mathematical concept is a subdomain of the concept that can be used to characterize it on the basis of mathematical content" (Greefrath et al., 2016, p. 101; emph. and capital. orig.). For example, the *product sum aspect* characterizes Riemann integrals as limits of "product sums" and the *anti-derivative aspect* as the difference of the values of a primitive function at the upper and lower bound of integration. The last aspect actually requires an additional constraint (continuous instead of integrable integrands), and so do several characterizations of complex path integrals. Therefore, I follow Roos (2020) in distinguishing aspects from "partial aspects", which are only valid under additional constraints.

Definitions from approximately 50 textbooks from Cauchy's time to present and articles on interpretations of complex path integrals (see Hanke (2020) for some references) were analyzed with regard to the constraints imposed on the integrands (e.g., continuity or holomorphicity) and the paths of integration. In addition, I analyzed connections to real analysis as well as authors' substantiations for the definitions in order to abstract them into aspects and partial aspects of complex path integrals.

Exemplary results

Whereas the poster presents all (partial) aspects, I can only indicate four aspects (Table 1) and one partial aspect here. Assume that $f = u + iv$ is a complex function defined on the trace of a simple continuously differentiable path $\gamma: [a, b] \to \mathbb{C}$. The *product sum aspect* resembles that for Riemann integrals. Making use of the *substitution aspect*, the complex path integral is defined by symbolically substituting $z = \gamma(t)$ into $\int_\gamma f(z)\,\mathrm{d}z$. The *mean value aspect* characterizes $\frac{1}{L(\gamma)} \int_\gamma f(z)\,\mathrm{d}z$ as the average of the values obtained by rotating and dilating $f(z)$ by the unit tangential vector at z on the path of integration, not the values of f itself. The *vector analysis* aspect expresses $\int_\gamma f(z)\,\mathrm{d}z$ in terms of two real path integrals, which can be interpreted as the flow and flux of the so-called Pólya vector field $\boldsymbol{w} = (u, -v)^T$ associated to f along and across the path of integration. Therefore, there is a risk of confusion in the last two aspects in terms of what is averaged or which vector field occurs. One of the partial aspects is the *residue partial aspect*, which characterizes the complex path integral for closed paths and holomorphic integrands as a finite sum of residues.

Table 1: Four aspects of complex path integrals

Product sum aspect: $\int_\gamma f(z)\,\mathrm{d}z$ is the limit of complex Riemann sums $\sum_{k=1}^{n} f\left(\gamma(\xi_{n,k})\right)(\Delta\gamma)_k$, where $a = t_0 < \cdots < t_n = b$ ranges over the partitions of $[a,b]$, $(\Delta\gamma)_k \coloneqq \gamma(t_{k-1}) - \gamma(t_k)$, and $\xi_{n,k} \in [t_{k-1}, t_k]$ are tags.	**Mean value aspect:** $\frac{1}{L(\gamma)}\int_\gamma f(z)\,\mathrm{d}z$ is mean value of $(f \circ \gamma) \cdot (T \circ \gamma)$ on the trace of γ, where T is the unit tangent vector at the path of integration
Substitution aspect: $\int_\gamma f(z)\,\mathrm{d}z$ is the complex number $\int_\gamma f(\gamma(t))\gamma'(t)\,\mathrm{d}t$.	**Vector analysis aspect:** $\int_\gamma f(z)\,\mathrm{d}z$ is equal to $\int_\gamma \boldsymbol{w}\,\mathrm{d}\mathbf{T} + i\int_\gamma \boldsymbol{w}\,\mathrm{d}\mathbf{N}$, where $\boldsymbol{w} = (u, -v)^T$.

[2]Université de Montréal, Canada; a.gonzalez-martin@umontreal.ca

Calculus and mechanics are closely connected disciplines. However, students are not always able to establish links between them or use knowledge from one to solve problems in the other. In this paper, we study students' solutions of two tasks: a familiar mechanics task and a similar yet unfamiliar calculus task. Our results indicate that while students had acquired praxeologies from mechanics suitable to the mechanics task, they had difficulties transferring these praxeologies to the task presented in a calculus context.

Keywords: Calculus, mechanics, anthropological theory of the didactics (ATD), derivative task, college mathematics.

Introduction and research problem

Calculus and physics have been closely linked since the birth of the former: the emergence of the notion of derivative is tied to the formalisation of velocity and acceleration as concepts. Taşar (2010) points out that "in the educational literature [velocity and acceleration] emerge as nodes of difficulties", but also that "students experience great difficulty when they need to transfer knowledge between these two domains" (p. 142).

International literature has identified a number of difficulties that students face in grasping the notion of derivative (e.g., Montoya Delgadillo et al., 2018; Orton, 1983). Taking into account different representations of the derivative (graphical, verbal, symbolic, paradigmatic physical, and others), Zandieh (2000) observes in particular that if a student understands the derivative in one context, this does not mean that they can solve tasks in another.

The notion of "transfer" has been studied in the literature, initially from a cognitive perspective examining the transfer of knowledge from one situation to another, and more recently from the perspective of the *Actor-Oriented Transfer* (AOT) (e.g., Lobato, 2012; Roorda et al., 2015). With AOT, transfer is defined as "the influence of a learner's prior activities on his activity in novel situations" (Lobato, 2012, p. 233). From a cognitive perspective, the fact that students fail to intuitively transfer knowledge from mathematics to physics has been highlighted in the physics education literature (e.g., Christensen & Thompson, 2012; Planinic et al., 2019). As for mathematics education, our literature review of the main international journals identified only two studies that focus explicitly on the links students make between each domain. In the first study, Marrongelle (2004) provides evidence that students can use physics to solve calculus problems. In the second one, Roorda et al. (2015) use AOT to study the transfer of procedures between mathematics and physics in both directions (from the traditional cognitive perspective, transfer is "usually expected to occur from mathematics to physics" [Planinic et al., 2019, p. 235]). In Roorda et al. (2015), the participants did not tend to explicitly mention links between the formulae learned in physics and the results obtained through symbolic differentiation in mathematics. However, they were able to establish further relationships between the procedures learned in both courses over the long term.

Hitt and González-Martín (2016) and Rasmussen et al. (2014) state that research on the teaching and learning of the derivative in relation to physics is still scarce, calling for more studies in that area. In particular, they highlight a lack of research in mathematics education examining teachers' and students' practices at the intersection of both disciplines. To address this issue, in her PhD, the first author of this paper examines practices related to the use of derivatives in calculus and mechanics courses at the college level. In this paper, we present some preliminary results of this ongoing work. Our research is divided into three main stages: (1) a praxeological analysis of calculus and mechanics textbooks (Hitier & González-Martín, 2021); (2) an analysis of teaching practices, through interviews with mathematics and mechanics teachers and in-class observations of differential calculus and mechanics courses; (3) an analysis of student practices using a questionnaire and task-based interviews. In order to shed light on the complex relationship between the two disciplines, our research aim is to study the similarities and differences between the way the notion of derivative is used in mathematics and mechanics courses, and the resulting impact on students' learning.

In the first stage, we observed that while the different representations of the derivative considered by Zandieh (2000) appear in the mechanics and calculus textbooks analysed, the practices studied do not seem to consider the difficulties inherent in shifting among these representations. We also observed that the practices employed in the context of one-dimensional motion were different in calculus and mechanics, relying on the limit definition and differentiation formulae in calculus, while applying given formulae in mechanics (Hitier & González-Martín, 2021). In this paper, we provide preliminary results from the third stage of our research, focusing on two tasks included in the students' questionnaire (see Methodology). We aim to answer the following research question: How do the praxeologies that students use when solving an unfamiliar calculus task relate to the praxeologies they use when solving a similar but familiar task in a mechanics context?

We note that in the international literature, certain studies remove the physics context from mechanics tasks, using a graphical representation to create calculus tasks (e.g., Christensen & Thompson, 2012). Their results "suggest that students have difficulties conceptualizing mathematics tasks that are common to the ways in which [they] ask questions in physics courses" (p. 5). However, we have found no example where essentially the same task is presented both with its physics context and without it. The tasks discussed in this paper do exactly this, and it is in that sense that we consider them to be "similar".

Theoretical framework

As stated above, we are interested in analysing practices related to the use of derivatives in two different courses (calculus and mechanics), in particular when solving a similar task in each discipline. We draw on the Anthropological Theory of the Didactic (ATD—Bosch et al., 2020), which considers human activities as institutionally situated. In ATD, knowledge is seen as embedded in practices which are conceptualised through the key notion of *praxeology*. Praxeologies are formed by a quadruplet $[T/\tau/\theta/\Theta]$, where T refers to a type of task to perform, τ to a technique that allows the completion of the task, θ to a rationale (called "technology") that explains and justifies the technique, and Θ to a theory that includes the rationale. These four components form two blocks: [T/τ] is the practical block that describes tasks and ways to solve them (*know-how*), and [θ/Θ] is the knowledge or *logos* block that describes, explains, and justifies what is done.

Additionally, ATD distinguishes between the *knowledge to be taught* (i.e., predetermined praxeologies that appear, for instance, in textbooks), the *knowledge actually taught*, and the *knowledge actually learned* (Bosch et al., 2020). In our analyses, we refer to our study of calculus and physics textbooks (identified as *knowledge to be taught*) and connect it with the students' responses (as evidence of *knowledge actually learned*). Finally, we consider a task to be familiar when it is part of the *knowledge actually taught* (it is also generally part of the *knowledge to be taught*).

Methodology

Our research is taking place at a large Canadian college (College *A* hereinafter). In Québec, students attend colleges after finishing high school and before entering university. Pre-university science programs are four-term, two-year programs. At College *A*, science students usually take their differential calculus and mechanics courses in their first term. On top of the *Regular Science* program (R), College *A* offers an *Enriched Science* program (E) featuring extracurricular activities, such as weekly seminars. Enrolment in the *Enriched Science* program is primarily based on motivation and interest. College *A* also offers two other programs (O): an *Explorations Science* program (consisting mostly of remedial courses) and continuing education classes at night or on the weekend.

During the fall of 2020, all courses were taught online due to the Covid-19 pandemic. That term, the college established two cohorts of students: one Enriched (EP, 37 students) and the other Regular (RP, 35 students). Each cohort attended calculus and mechanics courses together. A number of other students were not assigned to specific cohorts. The cohorted students followed the same curriculum as the non-cohorted students, with the calculus and mechanics teachers working in collaboration and sometimes attending each other's classes. At the end of the term, between the final classes and the beginning of the examination period, we sent an online questionnaire to all science students at College A (approximately 1,200 students). We chose to use an online questionnaire despite its limitations, due to the pandemic and the fact that students were not physically present at the College throughout the 2020–2021 academic year.

The questionnaire was divided into three main sections. The first included questions concerning the student's profile (the name of their program, whether they were attending a calculus and/or a mechanics course, etc.). The second section consisted of three contrasting questions addressing the students' views on calculus and mechanics, inspired by Halloun (2004)'s Inventory of Basic Disposition. The third section included seven questions containing tasked to be solved, focusing on either calculus or mechanics. Among them were two pairs of similar questions, with each pair containing one calculus and one mechanics question. In this paper, we focus on one of these pairs (Question 4 and Question 7, see Figure 1).

Question 4 is considered a familiar question in mechanics. As our textbook analysis (Stage 1 of our research project) revealed, such tasks are part of the praxeologies developed in mechanics courses.

Question 7 is similar to Question 4: the velocity v is replaced by a function f, so that the acceleration a becomes the derivative f'. However, this "translation" comes with a few adjustments. We considered the absolute value of f in Question 7 for two reasons. First, *speeding up* and *slowing down* refer to the variation of speed, which, in one-dimensional mechanics (the content considered in our study), is the absolute value of the velocity. Second, without the absolute value, Question 7 could become a familiar task in differential calculus, likely prompting students to use learned calculus praxeologies. Another important difference: to avoid an explicit connection between both questions, we used different terms: "not moving" for Question 4 and "constant" for Question 7. We are also aware that "not moving" in mechanics means $v = 0$, whereas f constant allows for more possibilities for f. We did not deem this difference to be crucial in the resolution of the task.

Question 4	Question 7
An object, with velocity v_x and acceleration a_x is moving on a straight line. In each of the situations, state whether the object is *speeding up, slowing down, not moving*, or there is *not enough information to decide*. $v_x > 0$ and $a_x > 0$. | $v_x > 0$ and $a_x < 0$. | $v_x < 0$ and $a_x < 0$ | $v_x < 0$ and $a_x > 0$. For each of the situations, explain your reasoning.	In each of the situations, state whether $\lvert f(x) \rvert$ is *increasing, decreasing, constant*, or there is *not enough information to decide.* $f > 0$ and $f' > 0$. | $f > 0$ and $f' < 0$. | $f < 0$ and $f' < 0$. | $f < 0$ and $f' > 0$. For each of the situations, explain your reasoning.

Figure 1: Question 4 and Question 7 of the online questionnaire

Of the students who received the invitation to take the online questionnaire, 179 accessed it and 62 answered at least one of the questions in Section 3. Question 4 was answered by 27 students; of these 27 students, 23 also answered Question 7, while four students skipped Question 7 but completed the rest of the questionnaire. To preserve anonymity, we identified the participants with numbers, preceded by letters corresponding to their academic profile ("N" for students who had already passed differential calculus and mechanics, "O" for Explorations Science or continuing education, "R" for students in the Regular program, "E" for students in the Enriched stream, adding "P for students in a paired group). We conducted a thematic analysis of the students' answers to each question, identifying the main elements of their praxeologies (mainly, their techniques and the rationales provided). We then cross-referenced the categories that emerged from our analysis of each question.

Data analysis

Question 4

Only a few participants had difficulties answering this question correctly (see Figure 2 or Figure S1 for a more detailed distribution of the answers). Consistent with our analysis of textbooks, the data indicates that this content is part of the *knowledge to be taught*: the students' praxeologies match the textbook praxeology, and we observe that the students use rationales present in their textbooks. For instance, one of the textbooks used in mechanics at College *A* (Serway & Jewett Jr, 2014), invites the reader to "think about the signs of velocity and acceleration by imagining a force applied to an object and causing it to accelerate" (pp. 32–33). Some examples of rationales are:

> when a and v are the same sign, the object is speeding up. If they are opposite signs, the acceleration is against the movement, which means that the object is slowing down. (EP6)

> when acceleration and velocity have the same sign then the object is speeding up and when they

are opposite signs (or their vectors are in the opposite direction) the object is slowing down. (N1)

We note that these rationales were also present in the mechanics teaching practices we observed in class. In this case, the *knowledge to be taught* also seems to be the *knowledge actually learned* by most of the participants.

Question 7

In contrast with the results of Question 4, the results of Question 7 (see Figure 2 or Figure S2 for a more detailed distribution of the answers) confirm that this is an unfamiliar question in calculus, with participants displaying greater difficulty in answering correctly. With the exception of one student who mentioned the first derivative test (RP13), the rationales used to support correct answers are common to rationales for Question 4 (referring to the sign or using the idea of (co)variation). Many participants develop techniques related to the use of rules based on the signs of the derivative, but only a quarter of them do so successfully. This could be because they have memorised the rules without truly understanding their meaning (which could in fact be understood using knowledge from mechanics). The majority of the students who use rules based on the signs of the derivative refer to the relationship between the sign of the derivative and the variation of the function (part of the *knowledge to be learned* in calculus), without clearly considering the absolute value of the function *f*. For example, RP5 states:

> If $f'(x)$ is bigger than 0, then it is increasing. If f' is smaller than 0, it is decreasing. The sign of f does not matter.

R3 goes further in her explanation, linking the sign of the derivative with the slope of the graphical representation:

> […] This is because a function will have a positive slope when it is increasing, and therefore a positive derivative. The opposite applies for decreasing.

Here also, the sign of the function, and therefore its absolute value, is not taken into account in the student's reasoning.

Cross-referenced results of Questions 4 and 7

Figure 2 provides an overview of the answers to Questions 4 and 7. To simplify the coding, each response was coded in only one category. We can see that of the 24 students who answered Question 4 correctly, only seven answered Question 7 correctly. Additionally, none of the students who failed to answer Question 4 correctly was able to answer Question 7 correctly.

In both questions, when students refer only to the sign(s) or to vector direction (e.g., EP5, O2), the rationale is relatively poor, as it comes down to the technique itself. For instance, EP3 wrote: "In mechanics, we saw that whenever the acceleration is of opposite sign to the velocity, the object was slowing down". We observe that this type of rationale, typical of mechanics courses, allows students to be successful in the familiar task (Q4), but it mainly leads to failure in the unfamiliar task (Q7). These findings are consistent with those of our textbook analysis (Hitier & González-Martín, 2021), as well as with other studies on the use of calculus in other disciplines, such as engineering. Many results that depend on calculus are proved once and then taken for granted, indicating that students may learn the explanations by heart without fully understanding them (e.g., Faulkner et al., 2020; González-Martín, 2021; Hitier & González-Martín, 2021).

Question 7 \ Question 4	Idea of variation	Idea of acting on movement	Referring to vector directions	Referring only to the **signs** of v and a	"Not enough information" in the case $v<0$ & $a>0$*	Depending only on the **sign of** a	"Not enough information" for all cases*	Total	
Idea of (co)variation, taking the absolute value into account	R2	O3						2	7
First derivative test, taking the absolute value into account			RP13					1	
Referring only to the **signs** of f and f' (correct)			N1	EP3 R4 RP7				4	
Referring only to the **sign of** f' (correct-inconsistent)						E1		1	3
Referring only to the **sign of** f' (incorrect-inconsistent)				EP5				1	
Constant in the case $f<0$ and $f'>0$			N2					1	
Referring only to the **sign of** f' (incorrect)		RP5 RP6 EP6	O2 RP8 RP14	N3 EP7				8	13
Graphical argument		EP2	R3 RP11					3	
Concavity mixed with variations				O1				1	
Unclear explanation		RP10						1	
-- No answer				RP9 RP12	EP4		R1	4	4
Total	1	5	9	9	1	1	1	27	
	24				1	1	1		

* No rationale given in the response.

Figure 2: Summary of responses for Question 4 and Question 7

We also note that although the students were not asked to make explicit connections between Questions 4 and 7, two students (R2 and, to a lesser extent, RP7) did so. For Question 4, R2 and O3 provided the most detailed rationales. Remarkably, R2 does not use the vocabulary *speeding up* or *slowing down* but provides explanations in terms of the variation of the absolute value of the velocity (the only participant to do so). Below is an excerpt of her rationale:

> for i and iii: since both v_x and a_x are in the same direction, there is no change in direction, so there is no decrease of the absolute value of velocity. […]
>
> iv: the absolute value of the velocity will decrease until zero, then the velocity will increase in the positive direction. (R2)

Her ability to rephrase Question 4 in terms of the variation of the absolute value of the velocity might have allowed her to identify the link between the two questions. Regarding Question 7, her rationales are:

> i and iii: since f and f' have the same sign, the abs value of f will continue to grow; f' will not subtract from the absolute value of f.
>
> ii and iv: since f and f' have different signs, the abs value of f will decrease until it reaches zero. After that point, f will increase in the direction of f'. (R2)

In her explanation, we see the expression "f' will not subtract from the absolute value of f" as hinting at the "idea of acting on movement" that we found in the other students' rationales for Question 4.

We believe that this provides evidence, as observed by Roorda et al. (2015), that students are able to establish certain links between the knowledge learned in the calculus and the physics courses.

Final remarks

In this paper, we analyse students’ solutions to two tasks: a familiar mechanics task and a similar yet unfamiliar calculus task. As in the work of Marrongelle (2004), we observe certain students using praxeologies from mechanics to solve the calculus task. However, those students make up only a small fraction of the study’s participants. Even if we consider that the students who provided correct answers to Question 7 (*referring only to the sign of f and f'*) might also have seen the link between the two questions without mentioning it explicitly, they still represent less than a quarter of our participants. In fact, our analyses tend to indicate that, for the calculus task, most students develop techniques based on results from calculus without giving any real sense to them. These techniques allow students to solve familiar calculus tasks but seem to lead them to failure when faced with unfamiliar tasks. Connecting these results with our textbooks analyses (Hitier & González-Martín, 2021), we see important implications for the teaching of calculus and mechanics. Praxeologies in calculus seem to foster the development of practices whereby results and formulae are learned without necessarily connecting them with a physical meaning or an interpretation. On the other hand, although derivatives are used in mechanics, the praxeologies rely heavily on given formulae and the link with calculus is obfuscated. Figure 2 shows that the small number of successful rationales in mechanics does not translate to successful rationales when solving a similar calculus task. This sheds some light on students’ difficulties in transferring knowledge between mathematics and physics, as discussed in the introduction. These difficulties may be related to praxeologies in both disciplines, which do not establish explicit connections between the two. This is consistent with Planinic et al.’s (2019) view that “students’ almost exclusive reliance on formulas in physics presents […] an important obstacle for the development of students’ deeper reasoning in physics and sometimes even an obstacle for the application of their already existing knowledge and reasoning developed in other domains” (p. 243). In this vein, Taşar (2010) also noted that the transfer of knowledge between the two domains seems problematic. We believe our results help to reveal institutional reasons for these difficulties in transferring knowledge between the two disciplines, as a consequence of institutional choices to organise separate praxeologies in each one.

In the previous paragraph, we mentioned the possibility that students may have seen the link between Questions 4 and 7 without mentioning it. The fact that the questionnaire was completed online could have affected the students’ ability to develop their rationales. We acknowledge this limitation and we hope to gain further insights through the analysis of the students’ interviews. This analysis, as well as other parts of our study, will be the focus of future publications.

Investigation of the connections within proof in complex analysis lecturing

Thomais Karavi[1] and Angeliki Mali[1]

[1]University of Groningen, the Netherlands; t.karavi@rug.nl, a.mali@rug.nl

Studying teaching in lectures at the university level is a topic of particular interest in mathematics education as lectures are still the predominant mode of teaching at the advanced level. In this study, the aim is to examine the teaching of mathematical proofs in a complex analysis course offered to second-year bachelor students of mathematics and science, using the commognitive framework. We focus on the mathematical discourse for proof teaching and specifically on the proving routines for the connections among the arguments within the proofs. In particular, three sub-routines were identified: setting the proof, applying, and computing. The lecturer performed these routines for the students intending for meaningful connections within the proof. We conclude by providing implications for education and future research.

Keywords: Proof teaching, lecturing, complex analysis, commognition, routines

The commognitive framework (Sfard, 2008) highlights, among other issues, the fine aspects of teaching in lectures that concern the communication of proof in lecturers' mathematical discourse for teaching. Routines have an important role in both teaching and learning mathematics; they are the patterns that appear repeatedly within a discourse as results of rules, which indicate the *when* and *how* one should perform the pattern (Lavie et al., 2019). While starting engaging with mathematical discourse, the routines of a learner (namely rituals) are process-oriented and relate to performance. Lavie et al. (2019) asserted that one of the teaching goals might be to help learners move toward outcome-oriented routines (namely explorations). A shift of the focus of the learners from the process to the outcome could be identified by addressing the *changes* in their performance (Lavie et al., 2019). When it comes to teaching for the facilitation of the changes in the performance of the learners, the researchers could seek for the characteristics of routines in the lecturer's mathematical discourse for teaching that aid the learner's move toward explorations.

In this study, we focus on the teaching that aims at the facilitation of changes related to proof production. In doing so, we seek for characteristics in the proving routines of the lecturer while teaching in lectures. The proving routines are the patterns that appear in the discourse of the lecturer while proving. In our case, the changes are intended for the students but are performed by the lecturer and identified as characteristics of the routines. The focal point of this study is on one of the changes, the *change of bondedness* (Lavie et al., 2019). The change of bondedness, in this study, is the move from a list of unrelated arguments within a proof to a sequence of arguments related to each other. Thus, bondedness, as a characteristic of the proving routines of the lecturer's discourse, is concerned with the connections between the different arguments of a proof. As the lecturer of this study stated at the beginning of a lecture:

> I urge you to take some notes and carefully look at how the various statements I'm going to make relate to one another, which one implies which one, what are the essential assumptions in each theorem.

The connections among the different arguments within the proof are an important aspect of proof production because the formal proof consists of sequences of arguments where the last is the theorem, which is aimed to be proven (Tall et al., 2012). Within the sequence, axioms and other results (theorems, lemmas, definitions) are used. Tall and his colleagues presented a macro level description of the connections, whereas with commognition we are seeking for the identification of the connections at the micro level by focusing on the routines governed by bondedness within a proof. Also at a macro level, Lew et al. (2016) identified the key points in the presentation of a proof by an exemplary lecturer and it appeared that the students did not recognize them. One explanation was that the students mainly focused on what was written on the blackboard and not on the verbal explanation of the key points by the lecturer.

The use of the commognitive framework seems promising to highlight a communicational aspect of university teaching even if there is a lack of dialogue in this context. For example, Kontorovich (2021) highlighted the communicational aspects of the lecturer’s feedback and the importance of didactical discourse on proof (DDP) for the reflection on the given feedback not only for mathematicians but also for all the communities related to proof and proving. Thus, studying the teaching of proof by using commognition adds to the discussion and understanding of the attempts of the lecturers to communicate mathematical proof with the student in university lectures. Not directly focused on a proof-oriented course, Viirman (2014) studied the teaching practices of lecturers during the teaching of functions in introductory university courses. The researcher identified the different routines in the mathematical discourse of the lecturers and provided a categorization of construction routines (which aim at the creation of new endorsed narratives) and substantiation routines (which focus on the decision to endorse an earlier presented narrative). He distinguished the emerging routines into types; for example, the different types of substantiation routines included definition verification, proof, and claim contradiction. In the follow-up study (Viirman, 2021), the courses analyzed were introductory, so proof and proving were not central. However, the study of proving routines is fruitful in analyzing mathematical activity at university, because proof is core of many introductory courses at the university level. In this study, we focus on the proving routines of a lecturer to get insights into making connections within a proof.

Methodology

This study is part of a wider ongoing doctoral project that aims to characterize proof teaching in proof-oriented university courses. For this study, we investigated proof teaching in online lectures of a second-year complex analysis course. Formal proof raises difficulties for the students. It is important to highlight how the lecturer attends to the connection among the different arguments for the facilitation of students to endorse a proof. The connections in our case indicate the intended change to bondedness. Thus, our research question is “How does bondedness within proof emerge in the proving routines of the mathematical discourse of proof teaching of the lecturer?”

The lecturer in this case study was a theoretical mathematician with less than five years of teaching experience. The course concerned a group of bachelor students enrolled in mathematics or science (physics, astronomy) degree programs. In total, 242 students were registered, while between 30 and 80 students attended the live (online) lectures, which were recorded and students had the possibility to watch anytime. In this course, complex valued functions were defined in the complex plane and their properties were explored. The lectures were based on the textbook while the lecturer referred to the chapters and the topics that were covered in each lecture. The data were generated from the transcripts of five (out of 16) live lectures. The data analysis had two stages and we used the commognitive framework (Sfard, 2008) for the identification of the proving routines in the mathematical discourse for teaching of the lecturer.

In the first stage of the analysis, firstly, we identified the mathematical narratives, sequences of utterances that describe objects, processes, or relations among them, which the lecturer presented in the lectures. These narratives concerned definitions, the statement of the theorem, lemmas, proofs, examples, exercises – problems, remarks (comments of the lecturer on the statement of the theorem which were used in the proof), or notes (comments of the lecturer after the proof). The identification of the narratives assisted in the selection of the episodes. For this study we analysed ten episodes. Each episode had a duration of five to 45 minutes and included the narratives relevant to the teaching of proof. For example, the most common episodes included the narratives: theorem, proof, remarks. Then, we highlighted keywords and phrases of lecturer's discourse, relevant to proving. They were related to the mathematical aspects of proving (e.g., "the first thing we're going to do is replace this simple closed contour"), and the pedagogical aspects of proving (e.g., "let's see how you go about proving this"), and lecturer's comments about proving (e.g., "to make things formal and nice"). Also, the visual mediators, visual objects that are employed for communicational purposes (graphs, notations, interaction with the online environment), were identified. The visual mediators were of two kinds, either pre-existed in the slides or were created on the spot by the lecturer. The first stage ended with overarching proving routines. Some of the routines were "making connections within the arguments of the proof", "presenting a proving technique" (i.e., proving by contradiction), and "generalising to the complex plane".

In the second stage of analysis, we focused directly on the overarching routines. Doing thematic analysis, we used open coding for analyzing the episodes in Atlas.ti software because previous literature is limited on this topic. The coding was necessary for the rectification of the routines and the characterization of each routine. Within the routines of stage one, we identified, through constant comparisons, sub-routines. In this study, we focus on the proving routine "making connections within the arguments of the proof" which is closely related to the change of bondedness. Within this overarching routine, we identified three sub-routines namely: *setting the proof*, *applying*, and *computing*.

Results

The first sub-routine, *setting the proof*, was used to connect the statement of the theorem with the intended outcome of the proving process and the proving strategy (i.e., an outline of the arguments that will lead to the desired conclusion). In this paper, we focus on the former. The lecturer, when performing this sub-routine, either drew analogies with the real case which was familiar to the students or discussed a proving strategy. For example, an analogy with the real case appears in the following excerpt where the lecturer introduced the fundamental theorem of calculus for the complex plane to the students:

> So, if you recall from calculus [writes the formula on the right corner of the slide], you know, the fundamental theorem says that integral of f of a continuous function on an interval a b [meaning: $\int_a^b f(x)dx$], equals $F(b) - F(a)$ where F is any anti derivative of f on this interval. So, we have basically the same statement here… The proof is essentially a simple application of the fundamental theorem of calculus in the real case.

The lecturer, in this excerpt, reminded the students of the theorem in the real plane after presenting the statement of the fundamental theorem in the complex plane. The proof that followed after the excerpt, was described as an application of the theorem that the students were familiar with. The lecturer in that case did not explain a new proving strategy but connected the proof with a familiar theorem to students and placed this theorem within a familiar proving strategy to them.

The next example comes from the Laurent series theorem, which statement appears in Figure 1.

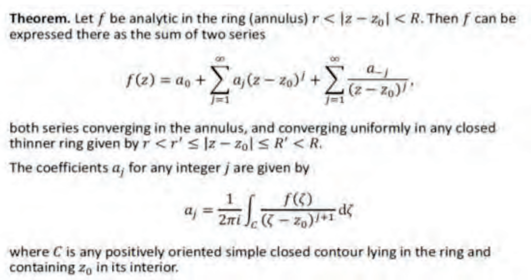

Figure 1: Slide presented for the Laurent series theorem

The excerpt of the lecturer's discourse highlights the case when a new proving strategy is needed:

> So, we start with a little theorem whereby we consider functions that are, well, we already know a name for them, analytic functions, that are expressible as a power series in some domain, right? And we said that if we have an open disk, then an analytic function on it, and its Taylor series are in sort of one-one correspondence… that's what we talked about in the previous lecture. So now, we will be interested in considering something slightly different that would be any annuli… So, we will be interested in these and functions which are expressible on them as power series, because it will let us slightly expand the family of functions that interests us, because you know, functions can have singularities.

In the excerpt, the lecturer discussed the statement of the theorem by bringing results from the previous lectures; the students were familiar with the case of the open disc. Now the problem changes to the case of any annuli and to general functions with singularities. Then, to describe the annuli, he made the visualization on the top right corner of the slide [Figure 2].

Also, the lecturer added examples about the different types of functions that related with the case that was described in the statement:

So, easy example would be something like $1/z$ at the origin, and so forth.

Next, the lecturer discussed a proving strategy to tackle the case of the annuli:

So, we will be interested in functions with that kind of property that there is some bad point. And then, in a sense, the natural thing to look at is, well, you remove a small disk, okay, and then the function will be analytic, that's the idea right.

Within this sub-routine, the lecturer discussed the statement of the theorem and used visualizations for its exemplification, formulated the problem that the proof will answer, and sometimes gave some examples. We showcased the lecturer's intention of focusing on connections within a proof in the introduction of this paper. In particular, the lecturer's excerpt showcased that one of his intentions was to "carefully look" at the relations among the statements he made. Given this intention, it seems reasonable that the sub-routine *setting the proof* happened mainly at the beginning of the proving process, and the lecturer set the scene for the proof that followed. Thus, the lecturer connected the statement of the theorem with the strategy they would follow to prove the theorem, building on familiar or new arguments. Within this sub-routine, the discussion and the visualizations around the statement of the theorem were connected with the other intention of the lecturer to "carefully look" at "the essential assumptions in each theorem". Indeed the sub-routine *setting the proof* placed the theorem within known theorems and results from that or previous courses and made connections between the results that appeared within the proof and the intended outcome of the theorem.

Next, is the sub-routine *applying*, which had three aspects. The first aspect concerned the introduction of a result (definition, theorem, lemma, preposition, axiom, remark, note, example). The second was the connection of this result to an argument, not shaped yet, with the form of this result that was suitable for the specific case in order to proceed with the argument. The third aspect was related with the development of the result. In this sub-routine, the lecturer elaborated on a visualization, described and applied results. The following excerpt is an application in the Laurent series theorem. The lecturer introduced the result, Cauchy's integral formula in that case, which he intended to apply (first aspect of this sub-routine). Next, he elaborated on that with the visualization [Figure 3] (second aspect of this sub-routine). By the end of the excerpt, the lecturer described the outcome of the application that $f(z)$ can be expressed in terms of values on the boundary as was already written in the slide [Figure 3] (third aspect of the sub-routine).

So, for any z, which is inside the annulus, Cauchy's integral formula applies. Now, mind you, you can think of these if we say that $C1$, so this can be a little bit confusing, perhaps, when we say a positively oriented circle, in just in in a vacuum that's just counterclockwise oriented circle. But there is also orientation of a boundary where we said the positive orientation means that if you reverse it, you're going if you reverse the boundary, the set is on your left side. Well, of course, for the outer circle, its counterclockwise orientation on the annulus indeed corresponds to that orientation consistent orientation that the set is on the left side right, but if you reverse the inner circle, counterclockwise, the set the annulus is on the right side. So, it is also possible to think of this minus sign as coming from the sort of wrong orientation on the smaller circle not consistent with the annulus. Well, at any rate, reserved which is properly inside, you can use Cauchy's integral formula to express $f(z)$ in terms of values on the boundary.

In this excerpt, the lecturer used a result, Cauchy's integral formula, to proceed to an argument related to an intended outcome within the proof, $f(z)$, as an expression of terms of values on the boundary. The statement of the theorem had an important role in this sub-routine as it facilitated the emergence of the results. Indeed the lecturer used and explained the orientation of C described in the statement of the theorem. Taking into account the statement of the theorem and the ideas formulated at the beginning of the proof, he then brought and applied the aforementioned result to have a specific outcome. In this excerpt, the visualization was the same with the one in Figure 2 but was of different nature. At this sub-routine the visualization assisted the lecturer to describe how the use of Cauchy's integral formula can be applied. However, in the sub-routine *setting the problem* the visualization was used to describe the statement and set the picture of the statement and the problem that was needed to be solved with the proof.

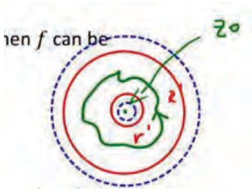

Figure 2: Visualization for the exemplification of the theorem's statement

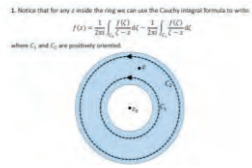

Figure 3: Slide used for the presentation of the theorem's proof

The applications within the sub-routine *applying* happened mostly after the verbal representation of the proving process and the explanation of the reasons why the result can be applied. Looking at the lecturer's excerpt in the introduction of this paper, his intention to "carefully look" on how the statements related and implied one another explains his focus on the verbal representation of the reasons why a result can be applied and related with the arguments that needed to be shaped for the proof. Moreover, the students could see the application from the beginning of his verbal representation because it was also written in the pre-written slides. We interpret that this choice of the lecturer is connected to his intention to relate the statements, as the attention is moving from an application to the reasons why an application (here Cauchy's integrals formula) is valid. In a nutshell, the sub-routine *applying* indicated how one uses a result for a specific proof.

The last sub-routine we present is *computing*. Computing relates to either algebraic or logical manipulations and the connections appeared within and among the arguments. The algebraic manipulations had to do with substitution or division of quantities. The logical manipulations indicated the equivalences among the arguments. These connections happened when all results within the proof were set, so in the final version. An example of the lecturer doing the algebraic or logical manipulations (i.e., rearrangement of terms, subtraction of terms) is the following from the fundamental theorem of calculus for the complex plane:

> So, if said zero is the initial point of γ_1 or the initial point of the whole contour, this integral equals $F(z_1) - F(z_0)$, that's the first integral. $+F(z_2) - F(z_1)$ is the second integral, this is just the antiderivative at the endpoints, the endpoints z_1 and z_2 of this contour γ_2 and so on.

$$\int_{\Gamma} f(z)\mathrm{d}z = \int_{\gamma_1} f(z)\mathrm{d}z + \int_{\gamma_2} f(z)\mathrm{d}z + \cdots + \int_{\gamma_n} f(z)\mathrm{d}z$$
$$= (\cancel{F(z_1)} - F(z_0)) + (\cancel{F(z_2)} - \cancel{F(z_1)}) + \cancel{\cdots} + (F(z_n) - \cancel{F(z_{n-1})})$$
$$= F(z_n) - F(z_0)$$

Figure 4: Fundamental theorem of calculus computations in lecture slide

In the excerpt, the lecturer proceeded to the computations that led to the intended outcome of the theorem. To support his verbal explanation, he crossed the terms in the pre-written slides and circled the remaining terms [Figure 4]. An example of the lecturer doing the logical manipulations is the following from the Laurent series theorem. The explanation was verbal and in the slides, only the inequality appeared:

> And, of course, the opposite inequality holds in that case, namely $\zeta - z_0$ is less than $z - z_0$ in absolute value, which is just to say that if you take ζ on the boundary, $C1$ which is closer to the center, that's going to be, well, ζ is going to be closer than an arbitrary to the center than an arbitrary point, which is inside the annulus. So the inverse hold.

The lecturer in this excerpt explained why an inequality was true. The logical manipulation appeared in the colloquial of arguments that are connected with logical laws; equivalence in this case.

The connections in the sub-routine *computing* are within arguments and between arguments and the statement of the theorem. The lecturer's intention to relate arguments, found in the excerpt in the introduction of this paper, is at a different level in this sub-routine compared to the previous sub-routines, because the arguments are connected with each other or connected within. The computations led to the argument that was expected to be proved and as such they are connected with another intention of the lecturer to bring the "essential assumptions in each theorem" that can give the intended result.

Discussion

In this study, we discussed the proving routines of a lecturer's mathematical discourse for proof teaching. The proving routines indicated connections within a proof and related to an intended change, for the students, from a list of unrelated arguments to bondedness within a proof. We identified three sub-routines, *setting the proof, applying,* and *computing*. The first connects the statement of the theorem with the intended outcome of the proving process and the proving strategy (i.e., an outline of the arguments that lead to the desired conclusion). It appeared mainly at the beginning of the proving process. The second connects the argument that is about to be developed with the results (definition, theorem, lemma, preposition, axiom, remark, note, example) that are needed to be applied in order to proceed with the argument. The third one is the connection between the different arguments of the proving process and the statement of the theorem. With the use of commognition we shed light on the relations between the different arguments of the proving process and the lecturer's associated routines. In our search for bondedness as a characteristic of proving routines, we identified sub-routines, which gave a micro-level analysis of the connections within a proof in the discourse of the lecturer. These sub-routines may facilitate students' understanding of the connection between the statement of the theorem, the arguments and the intended outcome of the proof.

In previous studies, Lew et al. (2016) interviewed students and found that they did not attend to the key ideas of a proof when those were delivered verbally by the lecturer. Viirman (2021) criticised such an approach of a one-time interview and suggested an investigation for a longer period, because students need time to accumulate the key ideas of a proof and change their performance. In the current study, which is part of an ongoing project, taking into consideration that a prolonged period of data collection is needed, we focused on one lecturer for a period of five lectures. We were able to identify in a micro level some connections within proof that were present in the discourse of teaching of the lecturer. In contrast, Tall et al. (2012) discussed proving in a macro level as a linear process. In our micro-level analysis, we found that formal proofs, as appeared in lectures, were more than a sequence of arguments. Within the arguments, we found the three sub-routines that intended to connect the arguments with the statement of the theorem (sub-routine: *setting the proof*), with previously presented results, which were also shaped for the development of arguments (sub-routine: *applying*) and with each other via algebraic or logical manipulations (sub-routine: *computing)*. Thus, we conclude that commognition offered a rich description of the teaching of proof and contributed to understanding communication of proving in lectures. A follow-up study is about the characteristics in the proving routines of the students during a semester. Such studies could only but help lecturers take a closer look at their teaching and raise their awareness about their proving routines, which sometimes they perform tacitly.

[2]The University of Auckland, New Zealand; s.greenwood@auckland.ac.nz

We report on an ongoing project in a cross-level topology course, where students have been provided with opportunities to prove the same mathematical statement in different social situations. This paper focuses on a pair of students who proved a statement collaboratively before one of them volunteered to re-prove it at the board for the whole class to observe. We offer a commognitive analysis of students' discursive activity in each situation and trace the transformations of their proof throughout the process. This process is discussed with a focus on students' mathematics learning.

Keywords: Commognition, graduate students, proof and proving, topology, university mathematics.

Introduction

In their comprehensive overview of the mathematics education literature, Stylianides et al. (2017) identify three broad perspectives in the area of proof: the cognitive – proving as problem solving, the constructivist – proving as convincing, and the social – proving as an activity that is embedded in communities. Within the latter, typical proof-related tasks (e.g., constructing or presenting a proof) are not viewed in isolation but as constituents of a broader mathematical activity. Stylianides et al. (2017) further explain that "If a student or teacher produces a proof, research in this perspective would frequently place emphasis on the meaning of this artifact and how that individual and members of his or her community could subsequently use it" (p. 247).

Stylianides et al. (2017) describe the social perspective as less developed, not yet coherent, and lacking "common, widely used concepts" (p. 248). These descriptors seem especially appropriate in the university mathematics education literature where the cognitive and the constructivist perspectives dominate the area of proof. This situation opens the space for socially-oriented studies on how proof is practiced in university classrooms. Stylianides et al. (2017) propose considering these practices in relation to the mathematics community.

Much has been written about proof in the mathematics community. For instance, Rav (1999) stresses that "the intricate role of proofs [is] in generating mathematical knowledge and understanding, [that goes] way beyond their purely logical-deductive function" (p. 6). He associates this role with "inventing methods, tools, strategies and concepts" (Rav, 1999, p. 6) for solving problems.

We suggest that proof often actualizes its intricate role when mathematicians prove collaboratively, participate in research seminars where proofs are communicated, engage with published proofs, et cetera. These are structured situations with particular rules of the game that shape the course of a mathematical activity and yield proof transformation. In the case of a new proof, the transformations often occur through interactions between the proof constructors and outsiders to the construction process. For instance, as a response to the feedback from reviewers and editors, the constructors can revise the proof. Alternatively, a familiar proof can be restructured in a way that makes it more readily available “to build on it”. Morgan (1998) highlights the importance of the media through which mathematics is conveyed, which draws attention to instances where a proof transfuses from one communicational channel to another (e.g., from oral to written). Accordingly, we propose that proof transformation is a multifaceted process that can unfold in various social situations.

This paper comes from our ongoing project that unfolds in a proof-based course in topology (Kontorovich, 2021). This relatively advanced mathematical context has received limited attention in TWG14 (for an exception, see Stewart et al., 2017). Our project features a sequence of classroom situations where students develop proofs individually or in small groups, share them with the whole class at the board, and receive feedback from their peers and the course teacher. The project’s overarching aim is to explore opportunities for mathematics learning that emerge when students engage in progressive transformations of a proof. In this paper, we analyze an interaction between two students as they collaboratively constructed a proof, and the subsequent public re-proving of the same statement by one of them at the classroom board.

Theoretical framework

Our project is grounded in the *commognitive framework* (Sfard, 2008). This framework has been acknowledged for its capability to account for the complexity of university mathematics education and for offering tools to analyze learning and teaching in fine grain (e.g., Nardi et al., 2014). Commognition posits that mathematics as a whole and its particular disciplines (e.g., topology) can be construed as a *discourse*. Discourses are distinguishable through *keywords* (e.g., “Hausdorff space”) and their use, *visual mediators* (e.g., diagrams) and their use, endorsed narratives (e.g., a proof), and *routines* (e.g., proving). A person’s participation in a discourse is viewed as a patterned activity, when features of one’s public communication that remain relatively stable across interactions with different interlocutors constitutes a *personal discourse*.

Lavie et al. (2019) introduce the notion of a *task situation* to refer to “any setting in which a person considers herself bound to act—to do something” (p. 159). Then, they define “a routine performed in a given task situation by a given person is the *task*, as seen by the performer, together with the *procedure* she executed to perform the task” (p. 161, our italics). A procedure can be constructed through abstracting the commonalities of steps that a performer undertakes in similar task situations. Having no access to the performer’s interpretation of a task situation, one approach to deducing their task is attending to what the implemented procedure achieved.

The task situations at the heart of our project invite students to prove mathematical statements. We propose that in university mathematics classrooms, the keyword “proof” is often used to refer to a narrative that is targeted at endorsing a statement. This substantiating narrative is expected to unfold as a sequence of utterances (or sub-narratives), each either an “accepted fact”, or derived according to a well-defined set of rules (e.g., deduction, induction). Sfard (2008) comments that “routines of substantiation are probably the least uniform aspect of mathematical discourses. The very term *endorsement* may be interpreted differently by different people” (p. 231–232, italics in the original). These intrapersonal differences may emerge in students’ interpretation of which elements of their substantiating narratives constitutes a “classroom fact” and when a substantiation is required. We associate these interpretations with students’ tasks (cf. Lavie et al., 2019). We also note that the same dilemmas feature in the mathematics community, when different resolutions were offered in different historical periods. Even today the approaches to proof vary greatly across mathematical communities.

Whether the narrative "truly" endorses the statement or not, is a matter of social sanctioning. Manin (1977) writes that "a proof becomes a proof after the social act of 'accepting it as a proof'" (p. 48). In a similar vein, we use "proof" as a discursive label that is allocated by a particular community to a substantiating narrative (Kontorovich, 2021). This community can be as small as the person who constructed the narrative in the first place.

Lastly, Sfard (2008) defines *learning* as a lasting change in one's discourse. This change can be triggered by *learning opportunities* – "circumstances that call for, and support, *a change* in the learner's participation in a discourse, a transformation that would bring him or her closer to the discourse required by school curricula" (Chan & Sfard, 2020, p. 3, italics in the original). Chan and Sfard distinguish between opportunities for a change in *the learner's command of the discourse* and for a change in the *discourse* itself. Within the former, the learner becomes more fluent in the target discourse by realizing the opportunity to mathematize according to its rules. In the latter, the learner enriches their discursive repertoire of endorsed narratives and routines. Students' discourses are expected to get closer to the university version of a topological discourse in our project.

The case of Grace and Jonah

The project data comes from a semester-long course in a large New Zealand university. The course cohort consisted of six students: four were studying towards post-graduate degrees in mathematics, and two undergraduates were in their final year of a mathematics major. This was the only course in topology offered by the university's mathematics department, and it covered standard topics in point-set and algebraic topologies (e.g., continuity, convergence, homology). For illustrative purposes, we selected a case where transformations in students' proof were evident.

The data is extracted from the lesson on Hausdorff spaces, which took place towards the end of the first third of the semester. At the beginning of the lesson, the teacher defined Hausdorff spaces as those where every two elements can be separated by open sets (i.e., for each $x \neq y$ in X there are open sets $U, V \subset X$ such that $x \in U, y \in V$ and $U \cap V = \emptyset$). After discussing this definition and specific examples, the students self-divided in pairs, and the teacher invited them "to have a go at proving" that if $f: X \to Y$ is a continuous one-to-one function and Y is Hausdorff, then X is also Hausdorff. The protagonists of our case are a doctoral student, Grace, and an undergraduate, Jonah. They collaborated for nearly 4 minutes before the teacher asked "who is ready to present?"; then, Jonah volunteered to prove the statement at the classroom board.

The data corpus consisted of video-recordings of students' activity and written work. We embarked on the analysis with two questions: "*what routines did the students implement in each task situation?*" and "*how did their proof transform in the progression from one task situation to another?*" After transcribing the data, we examined students' activity to identify routines implemented in each task situation. We scrutinized the utterances to delineate substantiating narratives and routines before characterizing discursive similarities and differences between them. To present the findings, we begin with analyzing students' collaboration, and then turn to Jonah's mathematizing at the board.

Collaborative work

1	Jonah:	Okay, so… [sketches two ovals for the sets X and Y in his notebook]
2	Grace:	So we want to show that in X, yeah
		[Jonah completes the diagram reproduced in Figure 1]
3	Jonah:	That’s basically it.
4	Grace:	[a] Yeah, that is kind of it, right? [b] Well, if they weren’t disjoint…
5	Jonah:	[a] Oh, that’s true. [b] Sounds really simple.
6	Grace:	It’s almost too simple. [pause of 5 seconds]
7	Jonah:	I feel like, I feel like something’s missing.
8	Grace:	Yeah, I feel like something is missing as well. [pause of 15 seconds]
9	Grace:	So the function is from X to Y. You have two points here [in X], let’s call them little x, little y. [notates the points on the sketch]
10	Jonah:	Oh, doesn’t it imply that these two actually are in the same… You have an intersection.
11	Grace:	Yeah, that’s seems wrong because then it [the statement] is true for all functions. Oh, but the fact that it is a continues function…
12	Grace:	But why do we need one-to-one? I feel that we got to use that.
13	Grace:	So, so… Let’s actually do this super logically. We start with two points.
14	Jonah:	Yeah.
15	Grace:	We want to put an open set around each.
16	Jonah:	Yeah, yeah.
17	Gemma:	We go to $f(x)$ and $f(y)$.
18	Jonah:	Yeah, yeah.
19	Grace:	We put an open set here and here, which we can do because it is Hausdorff.
20	Jonah:	Yeah.
21	Gemma:	We can pull these back and get two open sets here [pre-images in X].
22	Jonah:	Yeah.
23	Grace:	If there was a point in this intersection but it can’t get mapped to two points.
24	Jonah:	Yeah.
25	Grace:	One-to-one means that these two… Oh!!! These two can’t get mapped to the same point. Because if they got mapped to the same point, this argument wouldn’t work. It has to be two different open sets. That’s why [1:1].
26	Jonah:	Oh, wait, what? I still don’t see where the one-to-one.
27	Grace:	So our argument would fail. If f wasn’t … because of if f wasn’t one-to-one, then you could have $f(x)$ equals $f(y)$.
28	Jonah:	Oh, oh, oh [as if realizing this]… Yeah.
29	Grace:	[a] And then you definitely couldn’t do this picture. [b] So I think that’s where it happened.
30	Jonah:	Okay. Right, right. That’s kind of subtle.

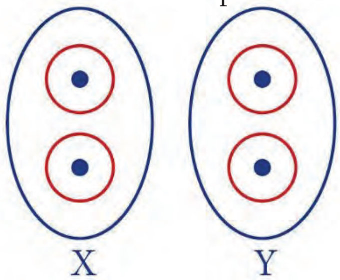

Figure 1: Jonah's diagram

The presented transcript features three rounds, differing in task situations and students’ routines. In the first round in [1-5], Jonah sketches a diagram that both students treat as a visual mediator of a proof of the assigned statement. Note that in [2] Grace appears to commence the construction of the substantiating narrative, but once Jonah completes the diagram the construction is relinquished. Accordingly, we suggest that generating a verbal version of the proof was not within the students’ task (in this round). This suggestion explains why the mathematically experienced students endorsed a diagram as “basically it” and “kind of it” in a proof-requiring task situation.

In [3-8], the pair implements what we term as a *proof-monitoring* routine: a procedure of “looking back” at the previous discursive activity with the task of assessing whether or not it can be sanctioned as a proof of the assigned statement. Herein, the students monitor the diagram visually and only the routine outcomes are articulated: Grace and Jonah both do not identify issues with their never verbalized proof. Notwithstanding, both agree that “it” (the diagram, the proof, or their construction) was “too simple”. In tune with our approach to proof, we interpret the appearing tension between not identifying an issue with their work and being not satisfied with it as students monitoring not only their previous activity but also how it appears to them in the broader context. For instance, they could recall that the task situation was set up by a research mathematician in a cross-level course. Within this view, it may seem unlikely that the dyad could generate a proof just in seconds.

In [7-8], the wholistic “it” turns into a focused “something’s missing”, and the identification of a potentially problematic element turns into a task for the second round. Pursuing this task seems impossible without narrating the proof, and this is what happens in [9-11]. We refer to these students’ utterances and actions as the implementation of a *proof-growing* routine: a procedure through which a substantiating narrative is not constructed “from scratch” but becomes more extensive, elaborate and detailed based on previously conducted work. In this case, Grace uses Jonah’s diagram to name the sets and points, and in [10] Jonah appears to rephrase Grace’s utterance from [4b].

This round’s task is completed in [11-12] with Grace identifying that their (still partially narrated) proof does not capitalize on f being one-to-one. This identification is not unlike the one in the previous round where the problematic spot was also not detected in proof-monitoring. The progress is in students delineating an element that they expect to feature in the substantiating narrative, and that it is currently not there. This recognition illustrates that a proof-growing routine can impact the substantiating narrative, not only by broadening its previously recognized constituents with new details, but also through its expansion to elements that were not addressed beforehand.

But why do Grace and Jonah expect the function’s injectivity to play a role in their emerging proof? Both appear to agree that their work substantiates the assigned statement “for all functions”, and injective functions are a subset of “all” – so why wouldn’t the pair see their proving mission as accomplished? As before, we propose that the students’ proof-monitoring went beyond *their* discursive activity to account for how this activity may appear in a broader context. For instance, drawing on their previous experiences, they could be driven by such considerations as “a teacher would not provide a redundant condition” or “we would be asked to prove a stronger version of the statement if it was possible”.

In tune with the above, delineating the role of the function’s injectivity becomes the task for the third round. The [13-30]-section features proof-growing and proof-monitoring, but the students’ interaction changes: Grace leads the implementation of both, narrating one proof element at a time, while Jonah endorses her statements. In [25], this interaction bears fruit: Grace realizes that their diagram had highlighted the function’s injectivity at the start, by depicting $f(x)$ and $f(y)$ as distinct points. Thus, in this round, their substantiating narrative grew by generating a verbal utterance about a visual element of the diagram. To appreciate what comes next, note that other parts of the diagram, especially those substantiating the Hausdorff-ness of X, did not feature in students’ discussion.

Jonah’s mathematizing at the board

Due to space limitations, we present an abbreviation of Jonah’s work at the board (for the full transcript see Kontorovich et al., in press). Jonah approached the board leaving the notebook with his much-discussed diagram on the desk. He stood facing the board and with his back to the class throughout the process, often blocking the board with his body. Figure 2 shows a snapshot of Jonah's board when he finished.

Jonah began by articulating every word in the sentences that he wrote on the board. The first three lines in Figure 2 were generated in this way. The fourth line emerged in silence. Then, Jonah appeared hesitant: he stopped writing and his gaze oscillated between the target statement and what he had written to that point. He took a step aside and sketched a diagram with two ovals, points x and y, and dotted circles U and V. After a few seconds, he giggled and smiled as if embarrassed, went back to his desk and returned with his notebook featuring the original diagram presented in Figure 1. After a quick glance at it, Jonah exclaimed "oh yeah!" and generated lines (5-6). Then he returned to the diagram on the board and completed it (see Figure 2). He wrote the lines (7-8) in silence, and instantly went back to his seat while cracking a smile to the video-camera.

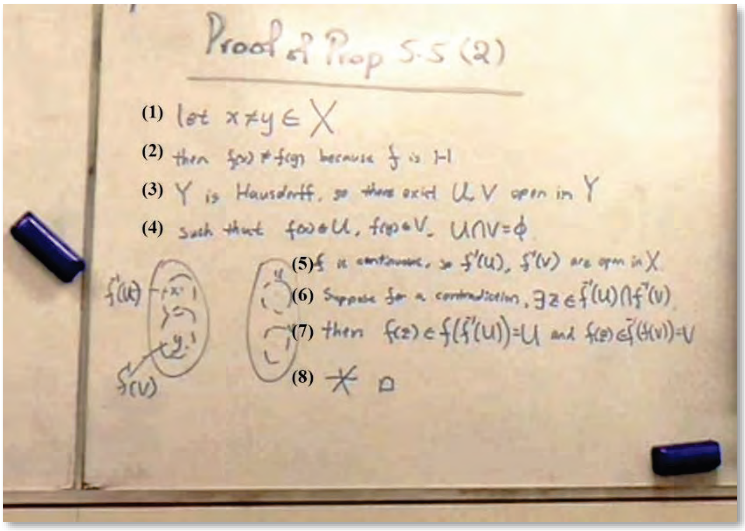

Figure 1: Snapshot of Jonah's board (numbering added)

In terms of routines, there is a visible change in how Jonah proceeded with his proof in this task situation: from *utterance-duplicating* in the first three lines, where he articulated what he put on the board as he wrote, to *silent writing* towards the end. We propose that while proving publicly for peers and the teacher to observe, Jonah mathematized for himself. This explains him investing almost no effort in elaboration on his text and eventually "turning off" the oral component – when one is communicating with themselves, the talk is loud even when all others hear is silence. Furthermore, his task appears to generate a written and self-contained proof, only parts of which were earlier discussed with Grace. Given that Grace did most of the "heavy lifting" in the earlier generation of the substantiating narrative, Jonah's proving appears as a self-imposed challenge of constructing the board narrative on his own. This is in tune with him volunteering to prove at the board, initially leaving his notebook behind, and using it half-heartedly when getting stuck.

The transition from collaborative work to the board entailed a transformation of the proof in terms of *restructuring*, *formalization*, and *growth*. Indeed, recall the insight on the function's injectivity in [25-29]. The dyad clarified it in the third interactive round and referred to it as a matter of contradiction (see [25,29a]). On the board, Jonah transformed this element into the symbolic "$f(x) \neq f(y)$", eloquently substantiating it with f being "1-1" (see line (2)). The formalization aspect can be captured through what Sfard (2008) terms as *reification*: a discursive process in which humanized formulations about processes turn into a talk about mathematical objects (e.g., [19] vs line (2), [21] vs line (5)). Perhaps the most visible instance of proof growth is evident in the transition from "if there was a point in this interaction […] but it can't" in [23] to the deductive sequence in lines (6-7), where Jonah declares his intention to obtain a contradiction and explicates the steps that do so.

Summary and Concluding Remarks

Focusing on a single mathematical statement, we analyzed the progression of students' proof between two task situations. Collaborative work on a statement "from scratch" and its consequent proving at the board are distinct social circumstances, and thus, it is barely surprising that different substantiating narratives emerged in each of them. What seems less obvious is what transformations a narrative can go through when "rolling over" such task situations. In the presented case, the proof was restructured, it grew previously not articulated elements and became more formal and elaborate. We acknowledge that these developments relate to the shift from the oral to written communicational medium, at least partially. Indeed, academic mathematical texts are renowned for being dense with terminology and symbols, modest in their use of "grammatical words", and having impersonal and authoritative formulations (e.g., Morgan, 1998). Then, it may be expected that such an experienced mathematics student as Jonah would write in this way in the presence of a mathematically mature audience.

Can these transformations count as evidence of Jonah's mathematics learning? The answer depends on whether Jonah's discourse underwent a lasting change, which is out of the research scope in this paper. Our analysis captures the short-term developments in Jonah's communication: from his limited contribution to the generation of a substantiating narrative in the first task situation to a fully-fledged narrative in the second. Some may argue with our claim about Jonah's discursive development, noting that he was the one to generate the original diagram and declare "that's basically it". He delivered on this declaration at the board after a short glance at that diagram, something that may be explained by him as "holding the proof in his mind" all along. We remind the skeptics that commognition operates with communication that rests in a publicly accessible space and it recognizes the effort that is often needed to switch from inner dialogue with oneself (i.e., thinking) to conversing with others (e.g., recall how Jonah got stuck at his board proof). In the minimal case, by volunteering to mathematize at the board, Jonah realized a learning opportunity to change his command of an academic topological discourse. Indeed, he not only mathematized through using conventional keywords, symbols, narratives, and routines, but he did that at the board, which is characteristic to research mathematics.

A somewhat similar argument can be made regarding Grace's discursive development. Throughout the interaction, Grace led the proof growth to broaden its components and expand it to new elements. Specifically, Grace's discourse was enriched by a narrative about the role of the function's injectivity in the assigned statement, a condition that initially appeared redundant.

Two interrelated aspects of the students' interaction are noteworthy. First, the case illustrates how a substantiating narrative can develop through the alternation of proof-monitoring and proof-growing. Students' monitoring is interesting since its first two implementations did not remove a blind spot in the proof, even though the dyad was convinced that this spot existed. We accounted for this conviction by proposing that the pair monitored not only their activity but also how it may appear in a broader context. The inaptness of their activity within this broader context explains why the students kept growing their proof further. This account illuminates how social considerations can permeate what could be expected to be a "purely logical-deductive function" (cf. Rav, 1999) of proof-monitoring.

Second, the students knew that in their topology course and beyond, a request for a proof is tantamount to generation of a written self-contained narrative. Yet, the dyad referred to a wordless diagram as “basically it” and “kind of it”. This illustrates that students’ familiarity with “a certain kind of action” (Lavie et al., 2019, p. 159) that the task setters expect does not always prevent students from pursuing a different task. Lavie et al. refer to “task” as “a person’s interpretation of a given task situation” (p. 161), but this case shows that it can be a deliberate choice. Janah’s proof at the board offers a colorful example that the choice of an alternative action in one task situation is not necessarily evidence of one’s incapability to undertake an expected action in different circumstances.

Students' development of mathematical language regarding definitions

Julian Körtling[1] and Andreas Eichler[2]

[1]University of Kassel, Germany; jkoertling@mathematik.uni-kassel.de

[2]University of Kassel, Germany; eichler@mathematik.uni-kassel.de

Research showed that university students struggle with the mathematical language, particularly when beginning mathematics studies. Therefore, we investigate a group of 15 mathematics students from a German university that were interviewed at seven different times during their first year of study to describe the process of their language development. Focusing on the aspect of definitions as a specific part of mathematical language, our results imply three types of students with respect to their development of mathematical language. Students of the first type seem to have an adequate understanding of mathematical language from the beginning. By contrast, students of the third type have severe problems and show no real development, whereas students of the second type start also with severe problems, but show improvement during their first year of study. The main aim of this paper is to describe and analyze the development of a student belonging to the second type.

Keywords: Language, definitions, transition, university students.

Introduction

The transition from school to university is strongly influenced by a transition from school-mathematical language to university-mathematical language. According to Gueudet (2008, p. 244), the mathematical language at universities can be seen as a gatekeeper that ensures or impedes access to the mathematical community: "It is the language of advanced mathematics, required to enter the mathematical community, and to communicate inside this community". Furthermore, Seaman and Szydlik (2007) describe the development of the mathematical language as part of mathematical sophistication, by which they mean the "enculturation into the community of practicing mathematics" (p. 170). Mathematical language at universities is the basis of stating and using mathematical definitions, understanding mathematical concepts and developing mathematical argumentations and proofs (Moore, 1994). Schleppegrell (2007, p. 140) stated: "the language [of a discipline] and learning [a discipline] cannot be separated". This deep dependency of language and mathematical learning is widely accepted in mathematics education research (e.g., Morgan, 2005; Pimm, 1987; Tabach & Nachlieli, 2015). However, research showed that university students struggle with the mathematical language, especially when beginning mathematics studies (e.g., Gueudet, 2008). The students' difficulties with mathematical language could be understood as a potential reason for the high drop-out rate in mathematics studies (e.g., Heublein, 2014).

Whereas the topic of language and mathematics has been studied from various perspectives, especially in recent years, research concerning the development of mathematical language as a main part of students' mathematical sophistication, is sparse. Therefore, we contribute to this line of research with a project conducted within the Competence Center for Higher Education in Mathematics (khdm, www.khdm.de) that has the aim to investigate the process of mathematics students’ development of mathematical language within their first year of studies. In this paper, we focus on definitions as a specific part of mathematical language that seem to provide a specific obstacle for mathematics students (Alcock & Simpson, 2002; Moore, 1994). For example, Edwards and Ward (2008) have shown, that many freshmen in mathematics are unable to understand and apply mathematical definitions correctly, which can lead to further problems, e.g. with proofs (cf. Moore, 1994). Other studies showed similar results for prospective mathematics teachers, who were not able to formulate precise definitions (Özyildirim & Sahiner, 2017; Zazkis & Leikin, 2008). To conclude, our main question for this paper is the following:

> What development of the mathematical language do students show within their first year of study?

Construct and content of mathematical language

Characterizing the mathematical language and its key features, one usually finds a subdivision into word, sentence and text level (e.g., Prediger et al., 2019). Mathematical symbols can be understood as specific linguistic entities and therefore they can be assigned on the word level (Meyer & Tiedemann, 2017). Symbols in mathematics are used as abbreviations for mathematical objects or technical terms and without them, many abstract objects, constructs and thus meanings could not be described and grasped (Schleppegrell, 2008). Besides symbols, the mathematical vocabulary (technical terms) is to be classified on the word level. Compared with everyday language, mathematical vocabulary can be divided into three categories (cf. Maier & Schweiger 1999; Monaghan, 1999): The first category includes words that are not used in everyday language (e.g. “bijection”), the second words that are used in everyday language with largely similar meanings, for example “completeness”. Words that occur in both registers but have different meanings are assigned to the third category (e.g. “field” or “series”).

On the sentence level, there are certain norms and rules about how mathematical symbols may be linked with each other and may be linked to words. For this, it is possible to establish references between different concepts and objects and to express mathematical relationships (Maier & Schweiger, 1999). Furthermore, special patterns of grammar and syntactical structures like using long and dense noun phrases, passive voice and the verbs “be” and “have” are typical for mathematical language (e.g. Schleppegrell, 2008; Maier & Schweiger, 1999). Definitions as an important element of mathematical language are to be located at the sentence level. Mathematical definitions – in contrary to definitions in general - do “have the property that everything satisfying it belongs to the corresponding category and that everything belonging to the category satisfies the definition.” (Alcock & Simpson 2002, p. 28). Definitions in mathematics do not include more properties than necessary to describe the relationship or the object that should be defined. Further, usually only previously defined terms are used. Grammatically, in the (conditional) subordinate clause the condition or premise is presented and in the main clause the consequence resulting from the premise, the conclusion, is described (Meyer & Tiedemann, 2017). Regarding the transition from school mathematics to university mathematics there are changes concerning mathematical definitions (cf. Chesler, 2021): In school mathematics, objects and terms mostly have an experimental or descriptive basis, using less formalism and a more informal language instead of the exact terminology (Reiss &

Nagel, 2017), whereas “they are specified by formal definitions and their properties reconstructed through logical deductions” (Tall 1992, p. 495) in university mathematics.

Mathematical theorems are another important element of mathematical language, which often consist of more than one sentence and are therefore located at the text level (Meyer & Tiedemann, 2017). Besides theorems, proofs are of course assigned to the text level. Generally, properties of technical jargon such as completeness or precision are also characteristically for mathematical language.

Method

The students were analyzed concerning their language development in a longitudinal setting at seven different times in their first year of study and were interviewed at these seven times. The group of students we interviewed comprises 15 students (of which ten were female and five male), all beginning with their mathematics studies (prospective mathematics teachers (upper secondary school) and mathematics students). We obtained them through convenient sampling and they were paid for making the interviews in the same way student workers are paid. The interviews lasted about 30 to 60 minutes and were transcribed completely. In the interviews, among other aspects, the students were asked to read specific mathematical sentences providing theorems or definitions, to formulate specific theorems, to describe the meaning of mathematical objects or to give definitions. One of the tasks was to give a definition of the term function (other terms that should be defined were for example linear combination and divisibility). The interviewer asked the participants to write down the definition and to read it out loud afterwards. If necessary, the participants were asked, how a particular phrase or term in their definition should be understood. If the interviewer noticed that the participants had difficulties in defining the term, he asked them to try to explain these difficulties.

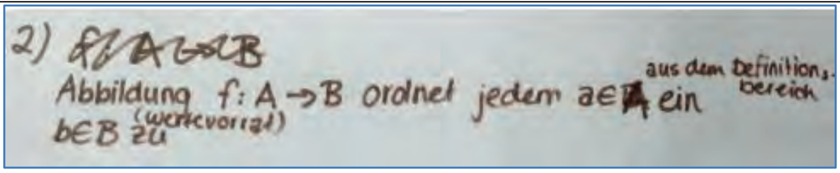
To evaluate the collected data, we developed a coding scheme on the basis of preliminary interviews for analyzing the definitions provided by the students (cf. Kuckartz, 2016). These codes were used to describe differences among the students and to identify developments in the students’ mathematical language use. We coded the students’ use of symbols and technical terms with the following codes:

- the number of symbols, quantifiers, variables and arithmetic operators
- the number of sets and symbols for set operations
- the number of technical terms

In addition, we coded failures that are apparent in the students’ written answers. As failures we coded

- the number of undefined variables,
- missing parts of a definition,
- erroneous terms

After coding the students written answers, we analyzed and compared, what the missing parts and erroneous terms in the students’ definitions exactly were. An example for our coding process referring to a student’s solution concerning the definition of the term function is given in Figure 1: The student used eleven symbols overall in her definition. In detail, she used two (different) variables that are defined ($a \in A$ and $b \in B$), six symbols for sets or set operations ($A, B, \in$) and one calculus symbol ($\rightarrow$). She further used four technical terms and there are no erroneous terms in her definition. Finally, the aspect of the uniqueness of the assignment is not mentioned explicitly (the student wrote “ein” which translates to “a” or “one” but not “genau ein” which translates to “exactly one”), so based on the written answer we coded that as a missing part of the definition. For each excerpt of students' expression, we show the original expression and a translation.



2) Image $f: A \rightarrow B$ assigns every $a\epsilon A$ of the definiton set a $b\epsilon B$ of the value set

Figure 1: Example of the definition of the term function from a student (first type, fourth interview)

Besides being asked to give and write down definitions of specific terms, the students were asked by the interviewer to explain what characterizes mathematical definitions in general and what differences they see between definitions and theorems. The interview transcripts were analyzed and coded following Mayring's procedure of inductive category development (cf. Mayring, 2014).

Results

From the perspective of qualitative analysis on the basis of the codes described above, we identified three types of students with respect to the development of mathematical language regarding the questions and tasks in the interviews about definitions. Students who can be summarized to a first type (three out of the 15 participants) use mathematical language from the beginning with little or no errors. They use technical terms correctly, the variables that they used are defined and they rarely use irrelevant terms in their definitions. Still, a development of mathematical language can be observed among these students. In the course of their first year of study, their definitions become more precise by avoiding ambiguous terms and an adjustment of word orders. On the other hand, students who were unable to formulate the required definitions in the first interview, or at most incomplete and incorrect definitions, can be summarized to a third type (seven out of the 15 participants). These students start at a low level and hardly any development is seen in their use of mathematical language when trying to define the requested terms over the course of the interviews. Instead of generally valid definitions, students of this type can usually only give examples, so most of their definitions are no sentences in a linguistical sense. Besides that, they often do not define the variables they use and use fewer technical terms than students of the other two types. The second type is represented by students, who have difficulties at the beginning with the use of mathematical language and, therefore, especially with defining mathematical objects. Still, a positive development can be observed during their first year of study. Out of the 15 participants, five belong to this type.

As mentioned before, we focus on a student representing the second type who showed heavy difficulties referring to her mathematical language at the beginning of mathematics studies and analyze her development. Table 1 shows the definitions of the term function from the first, fourth and last interview of a student of the mentioned type. In the first interview, she only managed to write down three symbols (two symbols for sets and one calculus symbol) and besides the fact that not all functions are from $\mathbb{R}$ to $\mathbb{R}$, it remains unclear how this even exemplifies a function. The student seems not to be able to connect her expression of an assignment with more information that it could become a meaningful mathematical sentence. Being asked what characterizes definitions in mathematics and what differences between theorems and definitions are, the student answered the following in the first interview: "A definition [...] that is, that one, […] has an assumption and that one somehow tries to explain by a solution in a mathematical way. [...] I would say a theorem, um, a theorem is basically a formula perhaps. [...] The theorem was rather that one writes down this formula and with defining, it was rather that one deduces something.”. A definition for her at that point was an “(explained) assumption” and “something deduced” – an ambiguous and vague description that she could not explain further.

Table 1: Examples of a student’s definition of a function (first, fourth and last interview)

Interview 1:  IR —> IR	
Interview 4:  Eine Funktion projeziert Elemente von einer Menge ~~in~~ auf ~~die~~ eine andere Menge. Dabei können die Abbildungen surjektiv, injektiv ~~also~~ oder ~~auch~~ bijektiv sein.	A function projects elements of one set to another set. The mappings can be surjective, injective or bijective.
Interview 7:  2) seien A und B nicht leere Mengen, dann ~~kann~~ kann eine Abbildung gefunden werden, die a ∈ A ein f(a) ∈ B zu ordnet. Eine ~~Abbildung~~ Abbildung ~~wird~~ wird dabei Funktion genannt, wenn A, B ∈ IR, C ist.	2) be A and B non-empty sets, then a mapping can be found that assigns $a \in A$ to a $f(a) \in B$. Thereby, a mapping is called function if $A, B \in \mathbb{R}, \mathbb{C}$.

Her definition from the fourth interview is at least a complete sentence, but she used no symbols this time. We coded six different technical terms instead, but three of them are irrelevant for the definition of the term function (e.g. surjective). There are no erroneous terms in the definition, but she used the ambiguous formulation “to project” and furthermore, the aspect of uniqueness is missing. In her fourth interview, she describes definitions first as “basis for proofs” and then as “basis for theorems”, so it seems that at least the deductive character of mathematics has become clearer to her and she can better distinguish definitions and theorems from each other: “A definition is there to give a mathematical proof. [...] Well, a theorem is, so to speak, when I (...) want to prove something and for this proof I then apply various corollaries, I think they are called, and lemma and perhaps also definitions. [...] And the definition is so to speak what I use for the theorem.”.

She managed to produce a more elaborated definition in her last interview (Table 1). In that definition, she used fifteen symbols (the variable she used is defined) and three different technical terms, but we coded again the aspect of the uniqueness of the assignment is missing explicitly. She explains the following about definitions and theorems in general in her last interview: “[...] when you have a term or an expression, that the definition is simply a more detailed explanation of that term or expression. And a mathematical theorem [...] basically just, um, a statement or rule. [...] If you have previously defined something, a term, the theorem simply serves to explain how you calculate with this definition". She describes more concretely what she thinks a definition is ("definitions explain terms") and expresses more clearly, that for her theorems are based on definitions.

The question of what characterizes a mathematical definition could not be answered correctly or only vaguely by almost all participants at the beginning. However, differences between the three types can be observed here as well, and these differences continue to manifest themselves over the course of the first year of study. While students of the first type at least usually answer in their first interview that definitions, unlike theorems, do not need to be proved and must be unambiguous, students of the second and third type are usually not aware of the difference between theorems and definitions, cannot answer the question at all or give a nonsense response. Nevertheless, a positive development can be observed among those students who can be assigned to the second type as described below, whereas for students of the third type it seems not to be clear, even in later interviews, what characterizes definitions in mathematics.

Discussion

We investigated students' development of a mathematical language as a crucial part of students' mathematical sophistication in our study and focused in this paper on the students' ability to formulate mathematical definitions, for what a precise and elaborated mathematical language is necessary (cf. Moore, 1994; Zazkis & Leikin, 2008; Chesler, 2021). As mentioned above, our results indicate a division into three types of students. On the one hand, the students we assigned to the first type already seem to have a good knowledge of the mathematical language at the beginning of their studies. They are able to define familiar terms linguistically correctly and almost without errors and the mathematical language does not seem to be a barrier when they access new content. They quickly adapt to the conventional mathematics language and the deductive structures of university mathematics experienced in their courses and lectures. Therefore, it is reasonable to assume that they do not need specific language support to master their mathematics studies successfully. By contrast, students of the third type are unable to formulate adequate definitions in most cases and have serious problems with using mathematical language. They make errors in linking symbols to each other and use more colloquial paraphrases. It should be noted that during their first year of study the majority of students we assigned to the third type dropped out of their mathematics studies (five of seven). For those in this group who participated in all interviews and did not drop out of their studies, we assume that they will have low chances of success in their studies, particularly because of their difficulties with mathematical language.

The students of the second type are to be classified between these two groups. Here, a positive development can be observed in the course of the interviews as we presented before in more detail, but even at the end of their first year of study, they are still far from being able to use mathematical language adequately and reach the goal of mathematical sophistication. Especially at the beginning of their studies, mathematical language seems to be a barrier for them. Together with the higher pace in university lectures compared to school classes and the new content, a cumulation of different transition problems can occur (cf. Gueudet, 2008). Another noticeable aspect is that students in this group sometimes try to use new mathematical symbols quite quickly and they succeed in doing so to some extent. However, whereas students of the first type seem to have grasped the meaning of the symbols they use, it is at least debatable whether students of the second type actually already use all symbols meaningfully. Following Berger's (2004) hypotheses, this form of functional use and imitation could help students to learn using mathematical language correctly - but it is not clear whether these students will succeed by the end of their studies and achieve the linguistic sophistication that is necessary without specific opportunities for support or whether they remain on the level of imitating phrases based on school mathematical knowledge. Therefore, we assume that these students seem to need substantial support for developing their mathematical language. One possible option could be to discuss failures in using the mathematical language appropriately so that their failures could be used in a productive sense (Loibl & Rummel, 2014). To reveal the relevance of a sophisticated mathematical language, it could also be helpful to confront these students with examples where an ambiguous school-related language is not appropriate. Whereas students of the first type at least have the right idea of what characterizes definitions in mathematics, it turned out that this is not clearly the case for students of the second type. Thus, another supportive measure could be a learning unit that points out the importance of definitions in mathematics and in which the students practice defining.

Due to our small sample and the qualitative approach, we cannot generalize our results or quantify how many students belong to one of the types. However, the results of our study imply that a larger group of students has problems with developing a sophisticated mathematical language.

A link between a second course in calculus and engineering applications: what the students think about.

Maria Antonietta Lepellere

University of Udine, Italy; maria.lepellere@uniud.it

Keywords: Mathematical Modelling, Problem Posing, Engineering Mathematics, Thematic Analysis

Theoretical background and aims

One of the problems in the early years in an engineering curriculum is that mathematics is taught as a separate subject and, in many cases, the students do not recognize the mathematics they use (Kent & Noss, 2003). Modelling activities are usually recommended to bridge the gap between mathematical content and engineering practices (González-Martín et al., 2021). Problem posing offers opportunities to connect mathematics to students' interests. Moreover, within a classroom community, students could be encouraged to pose problems that others in the class might find interesting or novel. Students' beliefs about the relevance of mathematics are considered as one of the factors that can play an important role in their attitude and motivation (Hannula et al., 2016).

To help student to recognize the relevance of mathematics and make it more interesting, as volunteer supplementary problem posing work, assigning as incentive of 3 over 30 extra bonus points to add to their final grade, to Civil and Environmental Engineering (University of Udine) students were asked to find possible applications of the topics of the course (i.e. differential and integral multivariable calculus and differential equations and systems), to engineering and to present them to the class as completion and support of the standard lessons (see also Lepellere, 2021). At the end of the academic year, we also asked to students who participated to the project to write a report about their impressions of the work done. Thematic analysis technique (Braun & Clarke, 2021) was carried out to identify benefits do students report participating in the project. An anonymous survey on the Moodle platform was also administered. The research questions were: what kinds of application will the students choose? Does participating in the project affect students' belief that knowledge in analysis is relevant to engineering? What benefits do students report participating in the project gave them?

Results

Twenty-five students, out of seventy-five, prepared and presented their project: 46% chose a modelling of real problem; 38% a topic connected to other courses (rational mechanics, construction sciences and hydraulics); 21% presented a simplified extract of a research article. Twelve students wrote a report. From its analysis, three important themes emerged: enjoyment; to challenge understanding; to improve connections of mathematical concepts in other contests. Eleven students expressed positive enjoyment, as: *It is a good idea to motivate students to go beyond the classic lesson study…* Just one student said: *However, I cannot claim to be satisfied*. Eleven students said that it challenges students' understanding: *This forced us to understand the proposed arguments more fully… from a previous study of the subject I did not understand its essence and its applicability in real contexts…* Just one student said: *it did not help me in the study of the subject*. It helps to make connections of mathematical concepts in other contests: *It allowed us to broaden our knowledge and get closer to aspects of engineering that perhaps in other cases would not have been of personal* *interest… It has allowed an easier understanding of the same topics seen in other courses allowing a considerable simplification of the learning phase…* Seven students spontaneously highlighted their beliefs about mathematics: *abstract topics…, a very theoretical subject in itself…, many concepts are delicate to understand…* There was no lack of critical issues: *It took me a long time to find something… it is not always easy to find precise, certain, and secure information… it is easier for students who have already attended more "technical" courses… I had a hard time developing the idea and find a conclusion…* About the survey, to the multiple-choice question: What do you think of the supplementary work on applications proposed during the course? Only 5% (2 out of 40) wrote the project is not useful, 85% find it useful, but just 7.5% would make it mandatory, 10% would extend the project even at the end of the course given the excessive workload during the semester.

Conclusions

Despite the efforts that teachers do to make calculus more attractive for future engineers, by offering application examples, often related to physics, the students continue to show little interest in the discipline, deeming it “too abstract”. Furthermore, the students are not always able to connect the topics covered in class with those of other courses, sometimes the simple use of a different “language” confuses them. However, it is difficult to propose alternative activities, as evidenced by the fact that while they consider the proposed project useful, they prefer it to remain optional. But if the students are stimulated, they are able to pose and solve problems using mathematical modelling too. From the analysis of the data, we can conclude that the activity had a positive impact on students’ beliefs that mathematics is essential for the continuation of their studies and career as engineer.

We present a study about statistics university education focusing on study and research paths. An SRP is a didactic proposal based on the inquiry of questions, introduced as a research and teaching tool within the Anthropological Theory of the Didactic. Our research addresses the problem of the SRPs' ecology in the first courses of statistics considering the conditions and constraints enabling or hindering the proposal to be implemented in a sustainable way. We perform a qualitative analysis of consecutive experimentations of the same type of SRP using the methodology of didactic engineering. In this paper we highlight the last stage of didactic engineering, the a posteriori analysis, and develop the analysis of the SRPs ecology at four levels: epistemological, didactic, pedagogical and school. In the results we emphasise the impact of the SRP in the course organisation and point out its strength of being both a research and teaching tool.

Keywords: Study and research path, anthropological theory of the didactic, project-based learning, statistics, ecology.

Introduction

Statistics has rapidly evolved during the past two decades, primarily thanks to technological developments that brought out the possibility and the need for collecting and effectively analysing massive amount of data. Such a change in the profession requires adaptations of the teaching of Statistics that keeps up with its application. A similar cause in architecture resulted in the beginning of a reform of its teaching back in Italy in the 16th century (Knoll, 2014). Knoll locates the origins of the Project Method as an instructional approach for "the academisation of a profession" and not the result of "abstract philosophical deliberations" (Ibid.). Throughout centuries, the method evolved, penetrating various branches at all educational levels and is continuing to adapt, grow and being disseminated. Nowadays, the most common expression for the method's successor is "project-based learning" (PBL) (Batanero et al., 2013; Harmer, 2014).

The research works assuming the PBL pedagogical model in statistics teaching has grown steadily these past decades. These research works address two main aspects: first, its founding principles and second, the description of diverse teaching experiences (Markulin et al., 2021a). In addition, Batanero et al. (2013) propose implementing projects and investigations, bridging the relationship between the mathematical concepts and alive statistics environment, as a method to develop a "statistical sense" of the students. They show that the project fosters not only technical knowledge but a strategical one too (to know when to use a specific content or analysis tool).

As a contribution to the field of statistics education, our research follows the line of research within the Anthropological Theory of the Didactic (ATD) on the study of the ecological conditions in the design, implementation, analysis and development of a new type of instructional format – study and research paths (SRPs) – based on the continued inquiry of problematic questions (Chevallard, 2015).

In a way, SRPs include aspects of project-based learning (PBL). However, they also provide new perspectives and methodologies currently not elaborated in the PBL literature (Markulin et al., 2021a). The question addressed in an SRP has a main goal to generate an answer, regardless of the knowledge mobilised during the inquiry, while in PBL the central aim is meeting a specific piece of knowledge. This communication forms part of the first author's doctoral work on the advancement in the dissemination and impact of the SRPs in university education of statistics for non-mathematics students. We particularly analyse the didactic ecology of SRPs, that is, the conditions that allow their implementation in the classroom, and the constraints of all kinds (epistemological, pedagogical, school and social) that hinder their generalised development.

Research framework

During the past 15 years, a line of research has been developed within the ATD to study the conditions needed for a change of the prevailing pedagogical paradigm. We are now in the paradigm of visiting works, where syllabi are usually a list of themes, topics or disciplines to learn, without necessarily knowing why it is important to learn them. The new paradigm considers knowledge as a tool to question the world and elaborate answers to the questions raised.

To analyse the conditions for transitioning to the new paradigm, the ATD proposes to design, implement, analyse and develop a new type of didactic device: SRPs. This proposal is based on organising teaching and learning processes taking the study of open questions as the central activity. These *generating questions* are posed to students in order to develop answers under the direction of a teacher or team of teachers. The process of elaborating the answers will give raise to research activities (such as: searching for information, collecting data, comparing the information collected, producing partial answers, etc.) and study activities to understand the information collected, acquire and be able to mobilise new tools of analysis. In that sense, the paradigm of visiting works is being replaced by a new paradigm: questioning the world. An important aspect to highlight is that in SRPs, the study of new knowledge or know-how is integrated into the research process (Bosch, 2018; Chevallard, 2015) and that they do not oppose transmission and inquiry.

The research follows the line of implementations of SRPs in chemistry, business administration (BA), medical sciences and mechanical engineering and continues in the case of statistics in BA degrees. These investigations show different modalities of SRP's integration in the courses and their management using different tools originated in didactic research, such as question and answer maps, research and study dialectics and the methodology of didactic engineering (Barquero et al., 2020).

Research questions

The emphasis of this communication, and the doctoral work it forms part of, is to address the problems associated with teaching statistics at the university level in a moment where knowledge in this field is evolving rapidly. We investigate actions that can and do appear in the process of the change from the traditional teaching of statistics towards the acknowledgment of the evolution of the profession and its application in the teaching of it. Our research questions are:

- What conditions can be established in a current degree of business administration (in Spain) to organise a first course of Statistics in the transition between paradigms (where the students' work is led by the need to answer some questions instead of the need to visit some works)?
- What constraints appear at the epistemological, didactic, pedagogical and school level?

To answer these questions, we rely on the literature about similar teaching proposals, their design and implementation, as well as on our own research experiences.

Methodology

As said before, this work is framed in a wider research project intending to study the ecology of SRPs at higher education institutions. More specifically, our research group has been implementing SRPs in experimental sciences (Barquero et al., 2011), engineering (Florensa et al., 2018; Bartolomé et al., 2018), and business administration (Markulin et al., 2021b) among others. The first approach to study the conditions and constraints governing the implementation of SRPs at higher level takes a macro-didactic point of view and assumes as an object of study the collaborative work needed between researchers and lecturers to design and implement SRPs at higher education. Previous research showed that the ecological fragility of the implementation of SRPs is due to the fact that in most experiences the researcher and the teacher are the same person (Florensa et al., 2019). Our work intends to explore how this collaborative work, materialised in teams of researchers and teachers, can address this issue and to what extent this collaborative setting may enhance the long-term viability of SRPs at higher education. Our proposal is not far from the practitioner-researcher collaboration as described by action research method that faces similar challenges concerning this situation where the researcher and the teacher are close collaborators or even the same person (Townsend, 2014).

The second approach is the study of the ecology of SRPs by designing, implementing and analysing SRPs at higher education level, in particular in the fields of mathematics and engineering (STEM). We follow Florensa's (2018) proposal on the use of Didactic Engineering (DE) to do so. In fact, one of the main particularities of SRPs compared to other PBL proposals (Markulin et al., 2021a) is the existence of this four-phase methodology (Barquero & Bosch, 2015). The first phase is the *preliminary analysis* where the institutional conception of knowledge is explicitly characterised in order to identify the foundations of the didactic phenomena addressed. The second phase is the *a priori* analysis of the SRP that will include not only the selection of the generating question but also a new proposal of the knowledge at stake considering it as a consequence of the inquiry process. The third phase is the *in vivo* analysis concerning the implementation and observation of the SRP as well as the data collection. Finally, the fourth phase is the *a posteriori* analysis. The main work is to analyse collected data, to compare the a priori analysis with the actual activity experienced, to describe the different roles played by teachers and students and to highlight the constraints and conditions identified during the implementation.

In this work we adopt this second approach, and we analyse the implementation of three SRPs in a second-year course on statistics in Business Administration degree at IQS School of Management (Barcelona, Spain). We present here the last phase of the DE methodology, this is the analysis of empirical material generated during the implementations (further details on the design and the implementation of the SRPs can be found in Markulin et al., 2021b; Bosch et al., in press). The first implementation was done during the year 2019-20, the second during the year 2020-21 and the third implementation is ongoing (fall semester of year 2021-22). We have collected and analysed different students' productions (weekly reports, final reports), we have also conducted naturalistic teachers' observations, and students have filled in surveys. The survey had been previously piloted in other SRPs implementation (Florensa et al., 2018) and can be found here (https://sites.google.com/view/cerme12-statistics-srp-ecology). To complete this information, we have conducted semi-structured interviews with students focusing on students' experience regarding: the aim of the study, data gathering, teamwork, assessment, etc.

Results and discussion

In this section we present and discuss the results obtained during the last phase of DE methodology. We propose an overview of the a posteriori analysis structured in four levels of didactic co-determinacy: epistemological, didactic, pedagogical and school (Chevallard, 2015). For each level we present the conditions and constraints detected during the implementations of the SRPs. An overview of the results is also shown in Table 1.

Epistemological level

The different implementations of the SRPs have caused important modifications at the epistemological level. Changes at this level are very challenging as they tend to modify the curriculum, or at least to heavily modify the previous conception of knowledge. This modification contrasts with the prevailing epistemology at the institution: that is the conception on what statistics is and the attributed raison-d'être. Even if the adoption of the European Higher Education Area standards led to competence-based curricula, the institutional conception, often implicit and ill-defined, remains in terms of conceptual organisations and pieces of labelled knowledge.

For the case of statistics, we consider it as an area where its epistemological modification towards a knowledge conception in line with the paradigm of questioning the world is favourable. First, because scholarly knowledge is evolving rapidly, especially in the past 20 years with significant technological developments and a shift in the way of collecting and dealing with data. Secondly, because statistics is placing the focus of the course more on the interpretation of the results than on the mathematical procedures that are at the foundation of the calculations, and this fact enables a better fit with the degree of BA and nurtures the motivation for the field. Nowadays, there is no shortage of questions and problems to pose when proposing any activity or project in the teaching of statistics.

However, this favourable situation is not without a challenge: a transposition work needs to be done to reorganise the praxeological components of the statistics organisations. This didactic transposition process should consider the selection and adjustment of the scholarly knowledge to become the knowledge to be taught. In the process, new technologies in the ATD sense will get elaborated to adapt into better correspondence with the statistics software as well. Epistemologically, the area is compliant with the creation of new exercises and teaching proposals. Nevertheless, teachers can have a lack of legitimacy to "invent" new teaching materials and knowledge organisations. In our case, such a constraint is not an issue thanks to the freedom that the teacher-researcher has for transforming the knowledge to be taught according to some didactic and epistemological principles.

Interviews with the students revealed their views on the project and the area of statistics in general: "I think I learned more in the project than in the rest of the course", "I learned that you could know something about subjective things about people and that, if you could do it with vegetable diets, you could also do it with other subjects, such as politics."

Didactic level

On the didactic level, we consider a crucial point that the community of study takes the SRP's generating question seriously. The need to produce an answer is, in fact, the generating force of the whole inquiry process and points to the direction for the final answer to be presented. However, the variables governing this process are difficult to identify and of diverse natures.

The first variable identified is the origin of the dataset, this is if the dataset and the survey are given (external) or produced by the community of study (internal). In the first two SRP implementations, the survey was composed by the marketing experts and the students were in charge of collecting the data. We considered that this external origin would engage students because of its closeness to a real setting. However, in the interviews we found out that the external origin of the survey led to students' detachment mainly because of the difficulties to understand its structure and questions: "At the beginning the questions seemed strange. But when we started analysing with graphs and summaries, we started understanding it." Consequently, for the third implementation, we plan to build the project survey together with the students, making it more a product of internal descent to encourage the involvement, making the structure more understandable than in the previous implementations.

On the other hand, the receiver and validator of the question and its answer can be inside the course, the institution or from outside the education setting. We administer a combination of internal and external receiver/validator, depending on the step of the project. Derived questions and the feedback provided based on the intermediate students' reports are validated by the course teachers, while the final answers are presented for the external jury (members of the institution and the external client). The validation of the results is announced beforehand using an evaluation rubric which forms part of the established didactic contract. Furthermore, the case studies during the course, before the project, help introduce (or train) didactic strategies and devices that are later vastly used in the project activity. An example of such a strategy is a practice of always starting with a Q_0 that is open and needs to be studied in several sessions, meaning it is presented as an activity that requires deep attention and investigation by the students and cannot be solved within 20 minutes or even in one session. The teacher is then a guide in the process and not an instruction giver.

Pedagogical level

As the business requirements for our students require collaborative work, most of the students' activities during the statistics course we present are carried out as teamwork. On top of that, the idea of an SRP by the ATD proposes raising above the individual work. It encourages connecting, interfering, brainstorming and advancing in a problem setting by interaction within and between groups. Case studies that form the course before the project, apart from being managed in teams, cherish investigative environment and set pace to the statistical activity. They have a fixed duration of two weeks and always end with a submission of a team report that is afterwards corrected by the teachers. The culmination of the project, on the other hand, occurs in a session of posters or presentations, depending on the conditions the course is going under (pre-pandemic project finished with poster sessions in the classroom, during the pandemic project finished in online presentations). Although the project is being organised and driven by the problems that are considered relevant for the students' degree, statistics remains a topic from a group of courses based on quantitative methods. On average, this brings a pre-established aversion of the students towards the course and a lack of dedication in its components. However, the inclusion of a project is perceived as a valuable stimulation for some of the low-motivated students, as noted in the interviews: "It makes a huge difference; what we will encounter tomorrow, the fact that our work is going to have an impact on the work of different people".

Table 1: An overview of the SRPs conditions and constraint and their evolution

	CONDITIONS	CONSTRAINTS	EVOLUTION
Epistemology	° Flourishing area of research ° Area of knowledge in fast evolution ° Importance in BA ° Facility to modify the knowledge to be taught	° Prevailing epistemology: difficulty to accept new organisation of knowledge ° Didactic transposition work needed to adapt new areas of knowledge	From SRP1 to SRP2: ° Re-scheduled detaching from traditional organisation (kept during SRP1) → Planning SRP3: continue the praxis from SRP2
Didactics	° External Q_0 proposed by real companies - partners ° Report writing ° Final assessment	° Data are given ° Difficulty to incorporate new tools by students ° Didactic contract based on external validation of answers	From SRP1 to SRP2: ° Incorporation of intermediate reports allowing to give feedback to students ° The project was initiated earlier in the course → Planning SRP3: continue the praxis from SRP2
Pedagogy	° Teamwork ° Calendar of the course: case studies ° Oral presentation	° Low degree of students' engagement ° Lack of creativity	From SRP1 to SRP2: ° COVID pandemic heavily affected the development of SRP2 ° Explicit management of the process of study in the second edition.
School	° Assessment ° Computer availability ° Use of free software R ° Moodle, MS Teams ° Teacher's accessibility ° Small groups	° Private university: complaints on changing the terms of didactic contract	The school stays the same

School level

At school level, we present our institutional setting, a private university, shows no or few changes from one SRP implementation to another. A direct consequence of the COVID19 pandemics was the implementation of the MS Teams for all the teachers and students. There were also vast investments in the technological equipment to ensure the quality and synchronous teaching and interaction, but no other changes. Teachers have the autonomy to arrange assessment of the course (two to three teachers depending on the implementation, well connected and easy to agree between themselves) and to adapt it from one year to another. They also have freedom with the calendar organisation of the course (no need to be in accordance with teachers of other courses or with the instructional organisation). The students' attendance is compulsory, and they are organised in relatively small groups (big teacher-student ratio compared to usual university groups). Each student owns a personal computer and is required to always carry it. In Statistics we introduce R software, more precisely its user interface R Commander, and use it in every session. For the provision of the materials, we use a learning platform Moodle. Implementing the SRP in a private university modified its initial schedule due to the students' requirements for extending the pre-SRP sessions devoted to statistical inference. Conditions are certainly different in this respect in Spanish public universities.

Conclusion

The consecutive implementations of SRPs in statistics for BA students allow us to transform the Statistics course in several aspects. The didactic phenomenon at stake becomes questioned before and after every implementation, providing new perspectives both from the epistemological (the profession) and the didactic (reorganisation and enrichment of didactic devices) point of view. In a way, already by seizing to detect the phenomena in the foundation of the professional area, occurs the questioning of the educational setting and puts the basis for the design of the SRP. Furthermore, according to the teachers' observations, every implementation that was experienced suffered from different or repeated obstacles. Such constraints bring to consciousness the impact of different didactic strategies or influences originating in other levels, whether epistemological, pedagogical or the school. For example, in the statistics course presented, the case studies facilitated certain skills that appear in the SRP as well. However, this situation can be a limitation, for instance, when a certain activity appears in the project but is not previously encountered during the case studies. The analyses of each implementation support the common findings and stimulate the design of the following implementations of the SRP and the course in its entirety. The long-term viability of the SRP implementations to this Statistics course is still under study. In addition, a major ecological change will take place in 2022-23 when the researchers will not be involved in the course anymore.

In the line of the SRPs developments, we cannot avoid stating that an SRP is a transformative and questioning instrument, not only for the students but also for the teachers who design the course. We observe that the implementations of SRPs progressively influence the organisation of the program. If it was first included as a complement to a course typically structured according to the logic of the contents, it gradually gained more prominence and made the content subordinated to the anticipated needs of the research. This goes in favour of extending the unit of analysis of the SRPs' methodology to the entire course of Statistics.

A university mathematics transition programme designed to increase student engagement with mathematics support

Claire Mullen[1] and Anthony Cronin[1]

[1]University College Dublin, Ireland; claire.mullen@ucdconnect.ie; anthony.cronin@ucd.ie

This paper describes preliminary findings from the ongoing project known as MathsFit, a suite of online and in-person mathematics supports designed for in-coming first-year university students of service courses. We describe the rationale of the project, some engagement metrics, and present results from the first year of the programme. Early results indicate that MathsFit does improve student engagement with the mathematics support services available. Plans for the next iteration of MathsFit, based on these results, will also be discussed.

Keywords: Undergraduate students, diagnostic teaching, sector transition, mathematics support.

Introduction

Diagnostic testing of incoming university students has been occurring for at least 30 years (Lawson et al., 2002; Hyland & O’Shea, 2021) and often leads to the identification of students at-risk of underachieving in mathematics courses with the objective of supporting these students as early as possible in their transition to university mathematics (Gillard et al., 2010; Ní Fhloinn et al., 2013). However there have been no attempts, that the authors know of, at developing best practice in terms of how and why such testing should be conducted and what follow-on supports are most effective given varying institutional, socio-cultural and didactical contexts. In this on-going project MathsFit, a blend of in-person and digital supports, we employ an action research methodology of cyclical critical reflection using learning analytics, student interviews, and student survey response data.

Literature Review

The growing ‘Mathematics problem’ (Hawkes & Savage, 2000), i.e., the difficulty students, especially service students, experience in the transition from secondary to university mathematics has led to a number of initiatives in universities worldwide to support such students. Common measures include the expansion of mathematics supports such as drop-in centres and extra organised support tutorials (Lawson et al., 2019), the creation of bridging or preliminary courses, some of which have been discussed in previous CERME conferences (Kürten & Greefrath, 2015; Biehler et al., 2011), and diagnostic testing which has been researched extensively in the UK and Ireland (Gillard et al. 2010; Hyland & O’Shea, 2021). Diagnostic testing can allow for the identification of students who would most benefit from additional mathematics support during their initial time at university and beyond, commonly known as ‘at-risk’ students. Lee et al. (2008) used diagnostic test results among other variables to predict the performance of students in later mathematical exams. Other uses for diagnostic testing found in a survey of UK institutions by Gillard et al. (2010) include tracking changes in student profiles (e.g. Faulkner et al., 2011), informing students and staff about the students’ mathematical competencies and guiding the development of additional support services.

There are two parts of diagnostic testing that necessitate sound learning design principles – the test itself and the follow up support (Savage et al, 2000; Lawson et al. 2002). In choosing the mathematical topics to include in a diagnostic test, the mathematical expectations for students at university are communicated (Hyland & O'Shea, 2021) and a connection to their previous mathematical learning is made. Other design decisions, including whether the test is paper-based or electronic, and if questions are multiple-choice or not, affect the efficiency of the marking process and thus the speed of follow-on support. Follow up support can vary, with most including recommendations to engage with the mathematics support available (Hyland & O'Shea, 2021; Gillard et al. 2011). Personalised and/or monitored support has a significant positive effect on students' engagement with offered support (Gallimore & Stewart, 2014; Burke et al. 2012). Large online systems with automatically marked multiple choice diagnostic tests followed by a personalised, gamified online remediation course that allows immediate feedback and increased student choice have also been successful (Sharma et al., 2019). Ensuring diagnostic test results provoke action by students and university staff is the key theme across the literature on how diagnostic testing can aid students' transition to university mathematics.

Rationale

The rationale for implementing this project at this time were numerous. Firstly, quantitative research conducted on visits to the University College Dublin's Maths Support Centre from 2015-2020 showed that the majority of students attending the centre achieve high grades in the courses they sought support for (Mullen et al., 2021a). Conversely those students who failed mathematics courses, particularly in the first semester of first year typically did not attend the MSC or if they did it was often on only one occasion and late in the semester. Thus, it was conceived that new strategies to engage and support these under-performing students were needed beyond existing measures of advertising and promotion of the service. Secondly, given the significant disruption caused by the COVID-19 pandemic on second-level students' mathematics education from March 2020 there was a concern among MSC management that the mathematical preparedness of incoming university students may not be as strong compared to pre-pandemic times. Thirdly, given the disruption to state examinations and the delay to the collation and awarding of teacher awarded grades, university students started later than usual. This meant a reduction in instruction from 12 to 10 weeks. Combined with the fact that first-year final university examinations could not proceed in the traditional fashion, these students needed to be assessed within this same 10-week period. These factors persisted for the 2021/22 student cohorts also.

Methodology

In year one, MathsFit targeted two of the largest service modules taught by the UCD School of Mathematics and Statistics, Mathematics for Business (515 students) and Mathematics for Agriculture (371 students). These student cohorts come into university with very similar mathematical prior learning standards and university entry requirements, with Business requiring slightly higher matriculation points. A 30-question diagnostic test, referred to as 'Proficiency quiz' in communications with students, assessing fundamental concepts was devised by the authors. Existing diagnostic tests from Ireland, the UK, and Australia were consulted. The motivation was for students to reach ~~a~~ mastery level in the basics of mathematics fundamentals; Arithmetic and Trigonometry, Algebra, and Functions and Calculus. Questions were chosen on the basis that (i) they were taught in the Ordinary Level Leaving Certificate course (the state terminal second-level school examination sat by all school leavers in Ireland), (ii) they would be required in the forthcoming university courses, and (iii) they were a mixture of both procedural and conceptual questions. Figure 1 shows the first question of the Algebra and seventh question of the Functions and Calculus sections. All but two of the questions were multiple choice with five options: the correct answer, three distractors (based on common misconceptions), and 'I don't know'. Non-multiple-choice questions (such as Q1 shown below) were included to avoid 'process of elimination' type responses via the multiple choices offered. We included 'I don't know' as an option throughout to discourage random guessing and to differentiate between students who made errors in their solution and those who could not approach the question.

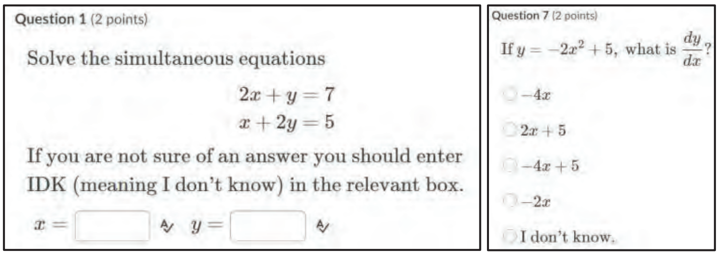

Figure 1: Question 1 of the Algebra and question 7 of the Functions and Calculus sections of the MathsFit Quiz

The quiz was delivered online through the Quiz feature of the university's VLE Brightspace and students had 45 minutes (15 minutes for each section) to complete the quiz. In advance of the quiz students were shown an introductory video welcoming them to the university and explaining the rationale of MathsFit. The quiz counted for 3% of the continuous assessment grade for the Business module and did not count for credit in the Agriculture module. Demographic information including students' entry route to university and feedback on the students' experience of the quiz were collected through pre and post quiz surveys.

Utilising Intelligent Agents and Release Conditions features of the VLE, each student was sent a personalised email within 24 hours of their first attempt which included their results for each of the three sections, their overall result and a set of feedback instructions detailing how they may like to remediate. The email wording of these remediation factors was pre-programmed and dependent on their quiz score, which had five bands of classification. For example, those students who did most poorly were invited to book a one-on-one maths support session with a tutor to discuss their quiz and work through the areas they scored poorly on. Those students who scored the highest grade possible were invited to lead a study group of their peers under the facilitation of a senior MSC tutor. All students who did not score in the highest band were invited to retake the MathsFit quiz the week after their first attempt so that they may gain the extra academic credit, in the Business case, or refresh their mathematics, in the Agriculture case. This allowed us and the students to measure their improvement and further identify students who still score poorly after being offered initial support.

Results

446 Business and 254 Agriculture students gave their consent to participate in the study. There were 164 Business (37%) and 185 Agriculture (73%) students scoring in the lowest band. Only 11 Business (2.5%) students and no Agriculture students scored in the highest band. In terms of the specific mathematical areas tested students scored best on Arithmetic and Trigonometry and worst on Functions and Calculus. Figure 2 below displays the results by topic area for both attempts for the Business student cohort and for the first attempt of the Agriculture students. The second attempt results of the Agriculture students were not included due to low participation (n=13).

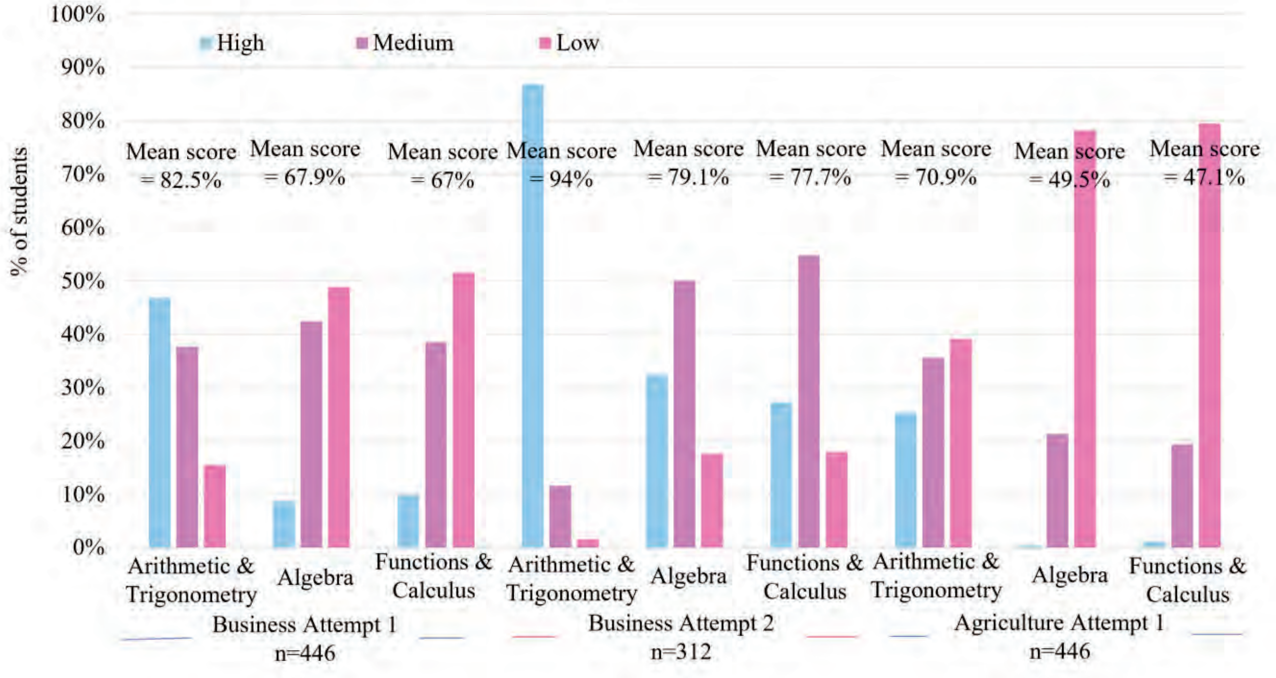

Figure 2: MathsFit Business and Agriculture Results by Section

The pre-quiz survey included a question on how well students felt they had covered their second-level mathematics curriculum and what topics they may not have covered sufficiently or at all. 38% of Business students and 34% of Agriculture students were unsure if they had covered the curriculum while 30% and 38% of Business and Agriculture students respectively were certain they had not. The post-MathsFit quiz survey results for Business students indicated that 11% did not have enough time for the Arithmetic and Trigonometry section, 46% did not have enough time for Algebra, and 27% did not have enough time for Functions and Calculus. The corresponding percentages for Agricultural students were 18%, 36%, and 31% respectively. Answers to these questions may explain in part, why the majority of students fell into the 'Low' category in the Algebra and, Functions and Calculus sections, calculus especially being a topic only covered in the Leaving Certificate curriculum, while other topics would have been covered prior to that. The module lecturers were informed about these results including students' particular struggles with exponents and features of functions (e.g. range) to aid their conceptions of students' prior knowledge and thus their teaching.

To assess the predictive nature of MathsFit, linear regression analysis was performed on the Business students' MathsFit data and other continuous assessment data from their Mathematics course. Both attempts at MathsFit were positively correlated with all the assessment components (six quizzes and two exams, all taken online). Students' first attempt at the MathsFit quiz had a correlation coefficient of 0.48 with their final percentage grade (see Figure 3). Their second attempt had a correlation coefficient of 0.53 with their final percentage grade (see Figure 4). Stepwise linear regression found the best model to predict students' final percentage using MathsFit data from both the quiz and the survey contained ten highly significant terms including their MathsFit second attempt result (denoted MF2 in the regression equation below), their gender, their degree, their Leaving Certificate result (H1 is the highest possible grade achievable), whether they thought they had covered the curriculum, and whether they had enough time in the Algebra section.

Final Percentage = 22.6533 + (0.61 × MF2) + (9.02 × H1) + (4.2 × H2) + (3.93 × Female) − (3.36 × NotSure, Covered Curriculum) + (0.3 × Yes, Covered Curriculum) + (6.5 × Other Degree) + (3.65 × H5) + (2.28 × A Enough Time).

The model had an adjusted R-squared value of 0.3816, which means 38.16% of the change in Final Percentages can be explained using this model, similar to Lee et al.'s (2008) model. In particular, for every 1% increase a student scored on MathsFit, the model predicted a 0.6063 increase on the Final Percentage. Of 446 students, the model correctly predicted 433 of the students passing. It incorrectly predicted 11 students would pass, however they failed (false positive rate of 2.5%). It also incorrectly predicted 2 students would fail, but they passed (false negative rate of 0.45%). This model shows that MathsFit data can be used to identify at-risk students; however, linear regression may not be the best model to capture the trend. The quartile-quartile plot (Q-Q plot) for this model reveals a straight line for the middle values, but deviation at either end, particularly the lower end which means the residuals are not normally distributed. It implies that the model is working well for students in the middle range, but not well for students with lower marks, unsurprising as the model assumes normal distribution and the data is left skewed. Despite not being the best possible fit, this linear regression model shows that the data gathered through MathsFit, like other data from diagnostic tests (Lee et al., 2008, Gilliard et al., 2010) can be used to identify students at risk of failing and hence those in need of support.

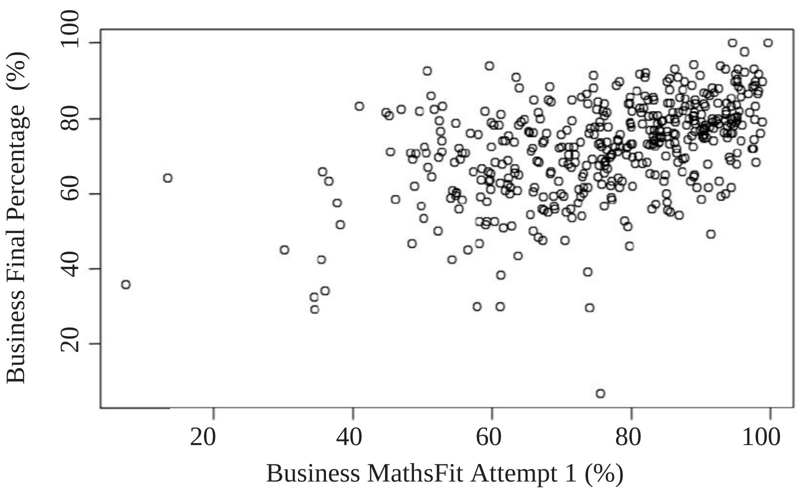

Figure 3: Correlation between Business students' MathsFit Attempt 1 results and final percentage

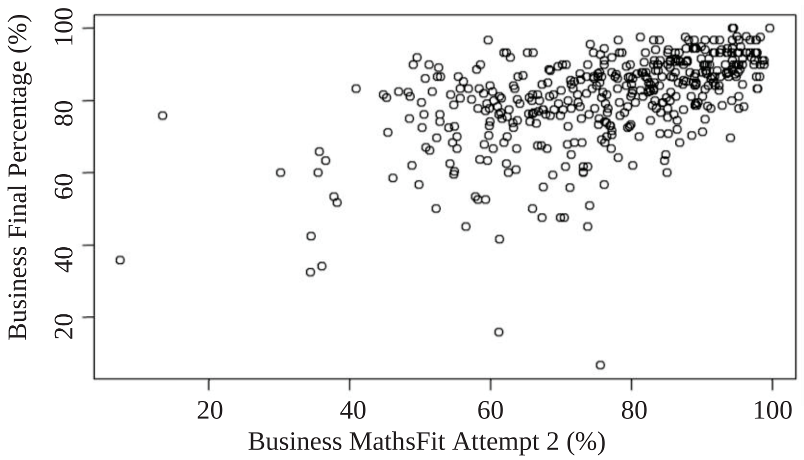

Figure 4: Correlation between Business students' MathsFit Attempt 2 results and final percentage

Analysis of visits to the university's Mathematics Support Centre (MSC) by Mathematics for Business and Mathematics for Agriculture students was completed to investigate the potential effect of MathsFit. Some 17 of the 51 Maths for Business students identified as needing support most (scoring 'Low' in all three quiz sections) visited the MSC, a positive beginning but engaging this cohort still requires attention. Comparing the percentage change in number of visits from the academic year 2019/20 to 2020/21 for those two courses to the 200 other courses using the MSC reveals a positive impact of MathsFit. The average percentage change in number of visits per course from 2019/20 to 2020/21 was -60% due to the sharp drop in visitors caused by Covid-19 and the move to online support provision (Mullen et al., 2021b). The 14% drop in visits for Mathematics for Agriculture and the 166% increase in visits for Mathematics for Business are thus above average. In particular, Mathematics for Business was one of only 20 courses whose number of visits increased in 2020/21 in comparison to 2019/20. Some of this increase in visits can probably be attributed to the impact of MathsFit, but other factors also may have played a role, such as, the course lecturer's increased advertising of the Mathematics Support Centre when lecturing online in 2020/21 in comparison to lecturing in person in 2019/20. MSC visits have been proven to positively impact students' grades both in UCD (Mullen et al. 2021a) and in other international contexts (e.g. Lee et al. 2008) so this increase in MSC visits by Business students due to MathsFit is a positive outcome.

Next steps

In September 2021, MathsFit was extended to incoming first-year students of five service courses including Calculus for Science, Introduction to Calculus for Engineers and the Business and Agriculture modules targeted in 2020. This involved approximately 1,600 students. Based on the authors' analysis of the first iteration of MathsFit, four of the five course coordinators agreed to award 3% of their continuous assessment for MathsFit. For comparison purposes a core set of 15 questions was common across all five MathsFit student cohorts, though the Engineering and Science quizzes were assessed at a higher cognitive level than the Business and Agriculture quizzes due to the mathematical requirements of these courses.

Analysis of the survey (39 respondents - 29 Business / 10 Agriculture) conducted in June 2021 found that students felt being asked to take a quiz in the first week of university without preparing for it was not student-centred. Hence, this year participating students had the option to engage in a refresher course before (and after if necessary) attempting the quiz in their first tutorial. Both the refresher course and quizzes were delivered using the open-source e-assessment tool Numbas (https://www.numbas.org.uk/). This allows for corrective feedback and multiple attempts (in the refresher course context) and a randomization of question~~s~~ variables. Hence students get multiple opportunities for practice and do not see the same quiz if a second attempt is necessary as was the case with the static quiz in Brightspace. Due to public health restrictions in Ireland, lecture and tutorial slots must be capped at 45 minutes and so it was necessary to shorten the quizzes to 24 questions. Discriminant analysis and correlation analysis was conducted on the 2020 answers so that the questions with the lowest discriminant indices and/or highly correlated with another question were removed from the 2021 version of MathsFit.

Conclusion

MathsFit has reached one objective in that it had a positive impact on the number of student visits for the Business course involved in the study. It has also alerted lecturers to the gaps that some of their students have in terms of mathematical preparedness for university mathematics, in particular exponents and the range of a function. Finally, it has targeted the students who are most in need of timely mathematics support and introduced them early to the services on offer. Clearly the carrot of offering even a small percentage of credit for mastery within MathsFit had a significant impact on engagement with the second attempt and subsequent mathematics support engagement among the Business students.

Acknowledgments

We would like to acknowledge the Maths Support Centre tutors who helped test the MathsFit Proficiency quiz questions and helped design the refresher courses in both years of the study.

Keywords: Technology uses in education, mathematics instruction, teaching mathematics, teacher competences, teacher behavior, teacher professional development

Introduction

The two technology groups at CERME (TWG15 and TWG16) adopt a broad view of technology resources in mathematics education to include tangible devices (hardware), and the associated applications (software), within the context of learning and teaching. TWG15 addresses the related issues that mostly concern teachers and teacher education. Previous discourse at ERME conferences embraced a wide variety of research topics, theoretical and methodological approaches. Most recently, this has focused on: teachers' uses of students' (digital) productions; sorting and organising digital content such as: simulations, applets and Open Educational Resources (OERs); the teaching of computational thinking in, and through, mathematics; teachers' choices and beliefs concerning technology use; and the ever-challenging process to develop useful theories and new pedagogies. The group is keen to learn more about actual uses of technology in classrooms (and beyond) to understand both the prevailing classroom practices and the implications of this on policy, practice and theory. The Covid-19 pandemic offered such a context and two papers (Barlovits, Kolokytha, Ludwig & Fessakis and Ramirez) and one CERME12 award-winning poster (Bini) reported such research from Chile, Germany and Italy respectively.

The group concluded the following perspectives and suggestions for future research. Continued effort is needed to enable wider understanding of the theories and methods applicable to this domain. More specifically, a greater awareness of the epistemologies that underpin these theories and methods, particularly when adopting more than one frame and/or attempting to network them in some way. The prevalence of quantitative studies led the group to conclude that increased attention is needed to the sampling of research participants and their associated characteristics, which can greatly impact the research claims that can be made when reporting findings. In addition, the roles and activities of participants within research studies is also an area of growing interest for the field. Finally, the nature of innovation within the field of technology in mathematics education results in many future research opportunities that have both pedagogical and mathematical implications, and make this a vibrant area for study.

Organisation of TWG15 and its sub-themes

TWG15 accepted 22 papers and 6 posters for presentation at the conference, which reported research from 20 countries (Argentina, Austria, Canada, Chile, China, Denmark, England, France, Germany, Ghana, Greece, Ireland, Israel, Italy, Norway, Portugal, Spain, Sweden, Turkey & United States). Each paper was allocated to one of six sub-themes and all authors of papers recorded 5-minute presentations of their papers, which were made available for asynchronous viewing by all CERME participants. In each TWG session, the allocated video presentations were broadcast prior to the TWG discussions. Each Sub-theme chair structured the whole group and breakout group discussions around key ideas that emerged from the related papers. In the text that follows, we summarize these ideas and suggest implications for our field of research. We conclude with 'hot topics' for the TWG15 community, which emerged from our final collaborative discussions.

Sub-theme 1: Theoretical frames for investigating the teaching of mathematics with technologies (Chair: Melih Turgut)

Tools and technologies for teaching and learning mathematics continually change. Accordingly, it naturally takes time for teachers to adapt the use of technologies in classroom practice, a process that is known to be challenging. Alongside, pedagogies also evolve and emerging theoretical/conceptual perspectives are needed to provide insights on how to integrate both new technologies alongside new functionalities of well-adopted tools. Many theoretical and conceptual frameworks have been developed to help understand the inevitable gaps between teachers' existing content and technological knowledge, and the processes through which new technologies transform classroom practice. The TWG15 papers provided a broad spectrum of emerging theoretical perspectives for designing and understanding teaching practice. We underline two main applications of theories: (i) as more deductive research frames, such as Ruthven's *Structuring Features of Classroom Practices* (SFCP) (Ruthven, 2009) (Simsek, Bretscher, Clark-Wilson & Hoyles), Gueudet and Trouche's (2009) *Documentational Approach to Didactics* (Basturk-Sahin & Tapan-Broutin), and Koehler and Mishra's *TPACK* (2009) and TPACK developments (i.e. Bray & Oldham; Lyublinskaya & Du; Meier & Oliveira); and (ii) as multiple frameworks that are merged to offer new theoretical/conceptual lenses, such as: Verillon and Rabardel's (1995) *Instrumental Genesis* and Robert and Rogalski's (2002) *Double Instrumental Approach* (Haspekian & Fluckiger), and *TPACK* and Valsiner's (1997) *Zone Theory* (Lindenbauer, Lavicza & Weinhandl).

Barlovits et al. propose a set of "design requirements" for the development of mobile environments for teaching distance mathematics, where they combine a community of inquiry lens, with e-pedagogy and mobile learning models. Gonscherowski and Rott conduct an interview study to explore pre-service and in-service teachers' argumentation and justification regarding digital tool use in mathematics education. Gonscherowski and Rott consider a combined analysis tool; teaching phases and classification of the use of digital tools (Clark-Wilson, Robutti & Thomas, 2019) and they further elaborate different levels of *decision-*

making competencies about appropriation of the digital technologies. Haspekian and Fluckiger combine the five components of the Double Approach (Robert & Rogalski, 2002) with notions of instrumental distance and didactic landmarks to analyse teachers' instrumental geneses when integrating programming in their practices. Their combined analysis addresses teachers' difficulties, which mainly concern '... the changes that ICT introduce[s] at cognitive and meditative levels'.

Sub-theme 2: Methodologies and methods for investigating the teaching of mathematics with technologies (Chair: Alison Clark-Wilson)

The TWG15 papers and posters predominantly report empirical research that spans a diversity of methodologies. Each study is underpinned by the respective researchers' epistemologies, which frame their thinking on what it is possible to know and conclude from their research findings. Consequently, this TWG session encouraged participants to think critically about if, and how, the application of research methods in different studies did (or did not) shed light on the chosen phenomena, and in accordance with the selected theoretical frame.

The majority of studies adopted qualitative research designs that sought to reveal aspects of the different phenomena at hand: (i.e., Engelhardt & Roth; Meier & Oliveira; Vilchez & Lemmo; Speer & Eichler; Tortoriello & Veronesi). Common qualitative methods included questionnaires, surveys, observations, interviews (individual, focus group), and document scrutiny/analysis. In some cases, data is analysed to present findings quantitatively. For example, in the study by Lyublinskaya and Du, a novel data visualization method reveals interesting characteristics of pre-service teachers' development of TPACK over time.

The second most common method used in the studies (i.e. Gavor, Clark-Wilson & Hoyles; Kristinsdóttir, Hreinsdóttir & Lavicza; and Lindenbauer, Lavicza & Weinhandl) is the increasingly used *design (or design-based) research approach* (Bakker, 2018). At the heart of such an approach is the aim to research innovations (i.e. design new materials or approaches) for which existing theories and methods might not be appropriate. Instead, more 'humble' theories inform iterative cycles or research that involve different methods to enable the theoretical, methodological and practical knowledge to emerge.

Two mixed method studies were presented. Fan and colleagues propose a mixed method approach to answer the question: How do mathematics secondary school teachers in China use digital resources in their teaching? They design a questionnaire for teachers about their uses of digital resources, before, during and after lessons, according to the three dimensions (content, function and infrastructure). The results are analysed quantitatively, alongside a sample of follow-up interviews, which are analysed qualitatively. The quantitative results show that more than one half of the teachers use digital resources often or always, and especially during lessons. However, they less frequently use resources after lessons, and the variety of resources used before, during and after is still limited. Interviews are used to ask the reasons for the use of specific resources. Segal and Biton's study, conducted in Israel, research teachers' perceptions of their work in the Whatsapp environment, also using questionnaires and interviews, and additionally Whatsapp messages and observations of four teaching groups.

Results of this study are at two levels: for students, in feeling free to make mistakes without fear, and for teachers, who gained in their professional technological knowledge.

The three studies by Thurm, Geraniou and Jankvist, Müller and Wachte, and Sharkia and Kohen all adopted quantitative designs.

Finally, TWG15 discussed how well we paid attention to, and made explicit in our research, our methods for sampling the participants of our studies. The prevalence for 'opportunity sampling' of pre- and in-service teachers, was acknowledged as a concern when set alongside claims for wider application or generalisation of research findings.

Sub-theme 3: Teachers' different roles in diverse educational settings (Chair: Ornella Robutti)

There is a recent increase in research concerning the role of teachers within in educational settings and processes. From being recognized as a "dimension" in studies on mathematics teachers (Robutti et al., 2016), to becoming one of the four fundamental themes of ICMI Study 25 *Tools and resources used/designed for teacher collaboration and resulting from teacher collaboration* (Robutti et al., in press). TWG15 interpreted teachers' roles within the different institutions as: prospective teachers (e.g., undergraduates in mathematics courses with a clear aim in preparing future teachers); pre-service teachers (e.g., participants of university-led teacher education program); in-service teachers (e.g., within their professional work context, or in formal projects); teacher educators (e.g., participating in formal or informal teacher education settings). The papers presented below relate to teachers in the aforementioned roles, focusing on the different types of involvement for teachers as participants in the research.

One role is teachers as *designers* of tasks using technology (Guerrero-Ortiz & Camacho-Machín; Speer & Eichler; Fahlgren, Szabo, & Vinerean): teachers are protagonists and have an active role in the design of tasks. Another role for teachers is that which is presented by Lyublinskaya and Du. In their study mathematics pre-service teachers are *learners* of technologies to be used in teaching mathematics. Their learning trajectories are analysed using the TPACK frame within the institutional context of a non-discipline-specific online educational technology summer course. The findings show that the pre-service teachers grew in their discipline-specific TPACK, under the influence of personal and contextual factors. The study demonstrates an innovative use of TPACK, combined with digital timelining analysis, to describe teachers' growth in professionalism as dynamic processes.

Jacinto and Carreira show another kind of teachers' involvement in the research: as *problem solvers*, with the use of technology. Contextualising the teacher's approach to technology in the general lens of *humans-with-media*, the study questions the role of technology within the mathematics teachers' problem-solving processes. The study reports the gain in the teacher's competences according to the MPST model, facilitated through the different micro-cycles in the overall process.

A community of inquiry comprising teachers as *participants* constitutes another kind of involvement: active participation is a distinctive feature of the community, intended not only in presence but also at distance. The ASYMPTOTE project (Barlovits et al.) is presented as an evolution and adaptation of the MathCityMap system in the COVID-19 pandemic era. The particular setting of the technology, which uses the idea of decision trees, enables teachers to design differentiated tasks for students in a flexible way, directing students to different learning paths, according to their performances.

Sub-theme 4: Innovations in technology for teaching mathematics (Chair: Daniel Thurm)

Technologies in mathematics education are constantly evolving. “New” innovative technologies emerge and become over time more established technologies. For example, dynamic geometry systems, computer-algebra systems, or function plotters - technologies which were considered “new” in the 1990 – have by now a strong research base. However, even for those technologies there is still much to be understood with respect to teaching and learning which, is evidenced for example by the papers of Fahlgren, Vinerean, and Szabopaper (task design for dynamic geometry environments) or Jacinto and Carreira (problem solving using spreadsheets). At the same time some TWG15 papers focused on more emerging technologies, e.g., videogames (Vilchez & Lemmo), WhatsApp-messenger (Segal & Biton), videos in a flipped classroom setting (Sharkia & Kohen) and multitouch environments (Bakos).

Vilchez and Lemmo presented research on a game-based approach, concluding that the selected videogame has potential to support the teacher to scaffold students’ relational thinking during whole-class discussions. In particular, the authors hypothesize that observing students play the videogame might implicitly help teachers to orchestrate classroom discussions.

Another emerging technology not so widely investigated from the perspective of the teacher is WhatsApp. Segal and Biton’s research focuses on opportunities for learning and teaching that can be created using WhatsApp as a social network. While teachers report positively on many aspects of using WhatsApp some teachers felt limited to generate collaboration between students, as they would in a regular class. From the researcher’s point of view, decentralized learning made it difficult for the teachers to capture the learning processes of the students.

Sharkia and Kohen investigate how online videos in a flipped classroom setting can effectively utilize an Inquiry-Based Learning (IBL) approach. For this they analyze seven filmed lectures from an advanced mathematics course. The discussions during the TWG15 session suggested extending the investigation to include the students’ views and experiences, since IBL is fundamentally a student-centered practice.

Bakos focuses on teaching and learning with the app TouchTimes, which is a multi-touch iPad application. By using the notion of double instrumental genesis, Bakos examines how teachers experience TouchTimes as learners, alongside their subsequent transitions to adopting it as a didactical instrument. The paper highlights that the notion of instrumental distance can be a promising way to examine the impact of integrating emerging digital technology on mathematics teachers’ practices.

The TWG15 papers evidence how the constant emergence of technological innovations brings some recurring challenges for the educational research community. For example, new technologies might require new pedagogies, for which existing theories may neither be sufficient, nor sensitive enough, to detect new phenomena. Conversely, there is the challenge to relate research on emerging technologies to research on established technologies and the "old" theories (Jankvist & Misfeldt, 2021). The TWG discussed how the research community can respond to the accelerated emergence of "new" technologies and in what way "new" technologies demand and/or inspire "new" pedagogies. It was suggested that looking back at the characteristics of technologies which remain constant might help to us to better connect our research to existing knowledge and practices. For example, focusing on dynamic mathematical representations could be a common theme across different technologies. Finally, it was highlighted that use of (and research on) digital technologies is often inherently linked to a particular mathematical concept or topic. Hence, for researchers and teachers alike, the challenge to grapple with both the mathematics and the tool is very real, as clearly described in the paper authored by Bakos.

Sub-theme 5: Pedagogical approaches and mathematical content (Chair: Gülay Bozkurt)

As indicated in the previous theme, technology use demands different pedagogical approaches, which are also likely to be affected by the aspects of mathematics that is being taught. Hence, in this theme, we focused on elaborating the foci of *pedagogical approaches* and *mathematical content* in our studies. The studies discussed in the TWG15 indicated a great variety in both their pedagogical framing and the particular aspect(s) of the mathematics curriculum such as: developing problem solving skills in algebra (Jacinto & Carreira); integrating computer science in mathematics education (Haspekian & Fluckiger); encouraging modelling activity in proportions and areas (Guerrero & Camacho); and improving distance education (Barlovits, Kolokytha, Ludwig & Fesakis). Within the TWG15 discussions on this theme, we particularly focused on perspectives pointed out in the three papers by: Abu Raya and Olsher; Bretscher; and Simsek, Bretscher, Clark-Wilson and Hoyles.

The paper of Abu Raya and Olsher explores the potential of a technological environment (STEP) on formative assessment as a process of teachers' pedagogical approach. They particularly examine the effect of accessible learning analytics on teachers' formative assessment practices, by providing them with means to respond to student submissions. The FaSMEd framework is adopted as an analytical lens through which to focus on teachers' interactions with the STEP environment's learning analytics. The researchers explore the impact of this on both class discussion, and the content for teaching functions. Findings indicate that teachers use all the technology's functionalities, enabling them to advance learners' understanding through a class discussion that deployed the five key strategies of formative assessment interactions.

Bretscher examines one teacher's knowledge about a particular aspect of geometry, circle theorems, focusing on his transition between dynamic and static technologies through which he would support students' related conceptual understanding. The researcher uses the TPACK framework to explore such knowledge with a particular focus on comparisons between angle definition and measurement within GeoGebra, and a paper-and-pencil environment. The author's analysis of a clinical interview with the teacher, reveals an example of this teacher's dilemma on defining angles in GeoGebra indicating his technological content knowledge

(TCK). Bretscher concludes “mathematical knowledge for teaching using technology is always situated, since the technological context in which it is being applied is central to its meaning”.

Simsek, Bretscher, Clark-Wilson and Hoyles apply Ruthven’s (2009) SFCP framework into teachers’ domain specific practices. They select the construct of curriculum script in their aim to characterize teachers' knowledge regarding key aspects of their practice. Focusing on three different teachers’ classroom practices and interview accounts in the context of English secondary schools, this study highlights differences in both the quantity of teachers’ anticipated or identified misconceptions about geometric similarity in their curriculum scripts, and the ways they use the dynamic mathematical technology in addressing such misconceptions.

Emerging “hot topics” relevant to the TWG15 community

During the final session, the TWG15 divided into self-identified breakout groups of early, mid and late career researchers/practitioners for the purpose of reflecting on the implications of the TWG15 session inputs (and associated discussions) for our field. Each group generated and discussed a long list of personal ‘hot topics’, prior to agreeing those that are summarized below.

Early career researchers want to get to know and deepen knowledge on theories that were introduced within the different papers’ frameworks and the group discussions, e.g., on TPACK and (Double) Instrumental Genesis as major theories; or specific theories like FASMEd as possible components of theoretical frameworks. Also, this group is keen to learn more about how these frameworks are operationalized within the respective research methodologies. The group also want to explore more the social, political and economic aspects of the use of technology within mathematics teaching, from both teachers’ and students’ perspectives (i.e. the availability of technology, the learning opportunities offered, etc.).

Mid-career researchers identified a methodological hot topic, which concerns the design of research instruments that capture mathematical and digital competences for teaching and/or the associated knowledge and beliefs/orientations. This seems important both for conceptualizing what the competences are, and for supporting teachers’ professional learning. Associated with this, how to develop methods to help them understand whether such knowledge is associated with improved pupil outcomes? On a theoretical level, the selection of theoretical framework(s), how frameworks are put to use (operationalized) within studies and, in the case when multiple frameworks are used, how they are synthesized (e.g., examining the resulting data from different perspectives) is also an ongoing hot topic. Finally, the group acknowledged the need for research designs that include strong connection, communication and collaboration with pre-service and in-service teachers to enable both a deeper understanding of teacher characteristics and practices, and to be able to develop more impactful teacher education and development programmes/initiatives.

Late career researchers identified the hot topic of how best to identify and connect theories, frameworks and methodologies. The group poses three questions, “What are the considerations that guide us as researchers in choosing a theoretical framework?”; “Are the existing theoretical frameworks suitable for the purpose of analyzing the research data?”; and “How to merge different theoretical frameworks for the analysis and characterization of findings, including mergers between theories on the integration of technologies in teaching and research and theories from other fields?”. For example, Segal and Biton’s study, which explores teachers' perceptions of the contribution of teaching and learning in the WhatsApp environment, implies that theoretical frameworks from the field of social sciences might be profitable. A second hot topic concerns the need for methodologies that take account of the evolution of teachers’ practices over time, a perspective that demands a mixed (quantitative/qualitative) study design. Finally, the group was most concerned about the need for studies that conclude findings that can be applied directly to teachers practices and/or support the design of teacher education/preparation programmes.

Teachers’ formative assessment practices when interacting with learning analytics

Kholod Abu Raya[1] and Shai Olsher[1]

[1]University of Haifa, Israel; kholodmoed@gmail.com, olshers@edu.haifa.ac.il

Conducting a student-centered discussion in a mathematics classroom is not a trivial task. Teachers must follow their students’ work, then use the relevant information to conduct a meaningful discussion. This challenge is greater when digital environments are involved, or when students work remotely and submit their work only online. A possible solution to this challenge may come in the form of accessible learning analytics (LA) that can assist teachers to gain insight about their students’ work. In the presented case study, which is part of an extended research project we focus on the interaction of teachers with LA and the formative assessment practices of teachers when dealing with students' answers to example-eliciting tasks in a digital environment.

Keywords: Teacher dashboard, topic-specific learning analytics, online formative assessment

Rationale and Background

Conducting mathematics lessons based on students’ ideas and on analysis of their answers is a good example of meaningful student-centered teaching. Using this analysis, teachers are required to conduct class discussions that promote formative assessment (FA) interactions. We focus on formative assessment, conceptualized as “all those activities that are undertaken by teachers, and/or by their students, which provide information to be used as feedback to modify the teaching and learning activities in which they are engaged” (Black &Wiliam, 1998, p.7-8). In technology-enhanced learning settings, teachers are required to assess their students’ work in multi-participant classes and direct their teaching accordingly, often in real time. Studies show that teachers who integrate digital systems in their classes choose to do so based on their usual habits and views on teaching mathematics in general (Drijvers et al., 2010). At the same time, the technological learning environments can provide an immediate picture of students' work for teachers. Each environment offers different learning analytics (LA) in the form of a single display that aggregates various indicators about learners, learning processes, and learning contexts into one or multiple visualizations (Schwendimann et al., 2016). In the meantime, it remains a challenge to provide a meaningful LA to teachers in real time. Numerous technological learning environments have been developed to provide teachers with an immediate snapshot of students' work for example, DESMOS and TI-Nspire (Clark -Wilson, 2010). Another example is STEP, a formative assessment platform that uses example-eliciting tasks (EETs), with more than one correct answer, to support conceptual learning. Students are asked to construct an example that meets or contradicts certain conditions, after which the environment analyzes the answers according to mathematical characteristics (Olsher, Yerushalmy, & Chazan, 2016). STEP provides teachers with accessible statistical data and helps them shift from focusing mostly on errors to making decisions based on the analyzed data (Olsher & Abu Raya, 2019).

In this study, we explore the effect of accessible LA on teachers' formative assessment practices, by providing them with means to respond to student submissions based on the LA. We explored the potential of a technological environment on teachers' formative assessment using the FaSMEd framework evolved to describe the use of technology in formative assessment. The three-dimensional FaSMEd framework extends Black and Wiliam’s (2009) model, which includes five FA processes: (a) clarifying and sharing learning intentions and criteria for success; (b) engineering effective classroom discussions and other learning tasks that elicit evidence of student understanding; (c) providing feedback that moves learners forward; (d) activating students as instructional resources for one another; and (e) activating students as the owners of their own learning. The FaSMEd model takes into account three main dimensions: the five key FA strategies, three main agents (teacher, student, peers/group), and functionalities by which technology can support the three agents in developing the FA strategies. The three categories of the functionalities of technology are: sending and displaying (SD) when technology is used to support communication among the agents of FA processes, processing and analyzing (PA) includes all the functionalities that support the processing and the analysis of the data collected during the lessons, and providing an interactive environment (PIE) are functionalities of technology that enable to create a shared interactive learning environment where mathematical/scientific contents could be explored (Aldon, Cusi, Morselli, Panero, & Sabena, 2017). Aldon and Panero (2021) use the FaSMEd framework to demonstrate that different FA practices of the different participants (teacher, students) are not necessarily similar during different parts of a learning activity, and for different ages levels. In this study we hypothesize that teachers' practice is affected by the type and design of data that LA offers teachers, which means that the functionalities of each report affects teachers` formative assessment practices.

Methodology

This study examines teachers’ interactions with LA as well as its effect on class discussion and on changes in the contents of teaching the topic of functions using STEP. The lessons were conducted in Israeli middle schools (grades 8 and 9) during the 2020-21 school year. The research question is: What formative assessment processes do teachers use when they interact with LA when evaluating student answers to EETs in a digital environment?

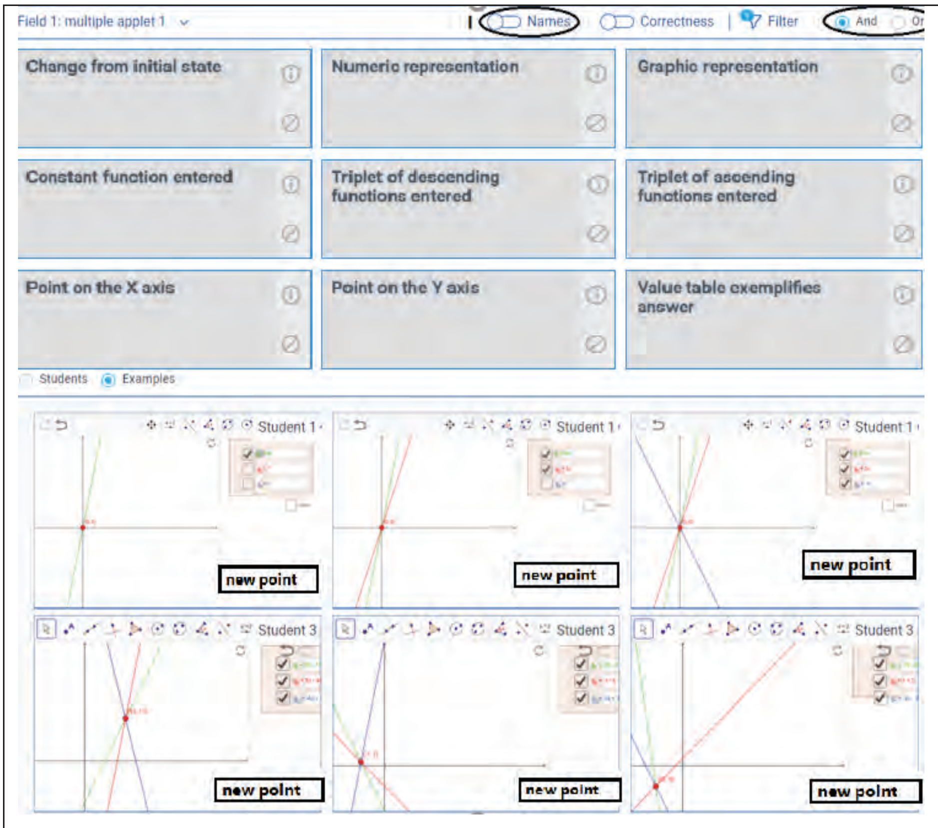
Sample

Three 8th and 9th grade teachers, experienced in teaching using the technological platform, participated in the study. The teachers had attended a professional development program and used the platform in their classes, which made them appropriate candidates for the study.

Research tools

The research tools included STEP reports and video records of the teachers using the reports. Teachers used STEP in their classrooms as part of their routine teaching sequence and conducted a discussion after the students completed the activity based on the STEP reports. The lessons were video-recorded, and the teachers were interviewed to clarify various decisions and actions that were noted during the lesson. The STEP teacher dashboard produces six types of reports: tables, grids, histograms, Venn diagrams, perceptual landscapes, and bubble reports (Abu Raya & Olsher, 2021). Each interactive report was designed to address specific pedagogical needs. Mathematics teachers were introduced to the design principles of STEP and its usage ideas in professional development programs. In this report we focus on four of the reports: table, grid, histogram, and Venn diagram, and present separately the goals and mechanisms of each report.

The grid report presents a snapshot of student submissions in a collage (Figure 1) that resembles those of other platforms (e.g., TI-Nspire). This report makes available to the teacher the work of the students in the classroom, allowing the teacher to filter student work based on predefined characteristics. The filtering mechanism is similar to that of e-commerce websites. For example, users looking for a small black purse can check each one of the characteristics for the relevant meta-data category (size, color). The grid report allows teachers to choose one or several characteristics as either present or absent and to create "and" and "or" relations between them (Figure 1), making possible in-depth analysis of submissions based on their characterization. The interactive report also enables teachers to choose a picture by clicking on it and to display the interactive diagram that the student submitted. Filtering helps the teachers detect various phenomena in the students' work, as opposed to merely scanning the snapshots to identify characteristics relevant for the ensuing classroom discussion.



1. presents a snapshot of student submissions in a collage

2. allows teachers to filter student work based on predefined characteristics.

3. allows teachers to choose one or several characteristics as either present or absent.

4. enables teachers to choose a picture by clicking on it and to display the interactive diagram that the student submitted.

Figure 1: Grid report with filtering activated, name display button (I), and/or buttons, (II).

The table report displays a row for each student, and a column for each characteristic, indicating which characteristics are present in each student submission. Presentation is similar to that of conventional spreadsheets. The goal of the report is to provide information about submissions of student in class, especially about characteristics that are prominent in each submission.

The histogram report presents a distribution of the characteristics across submissions. Each characteristic is represented as a bar whose height corresponds to the number of submissions having that characteristic (Figure 2a). The report provides a visual representation of the frequency of each characteristic of a task in students' submissions. Clicking a column brings up a filtered grid report below the histogram, allowing the teacher to further analyze student work directly.

The Venn diagram shows the relations between characteristics in the students' submissions (Figure 2b). It displays up to three characteristics simultaneously, each color representing a different characteristic. The Venn diagrams show the distribution of more complex phenomena in student submissions, which could not be captured by a single characteristic but only in the relations between several. The diagram provides an indication whether certain characteristics coexist. It also displays numeric values that enable determining the phenomena that are more prominent in students' work. Similarly to the histogram report, clicking on a part of the diagram displays a filtered grid report according to the selected region, for example, the intersection of three characteristics.

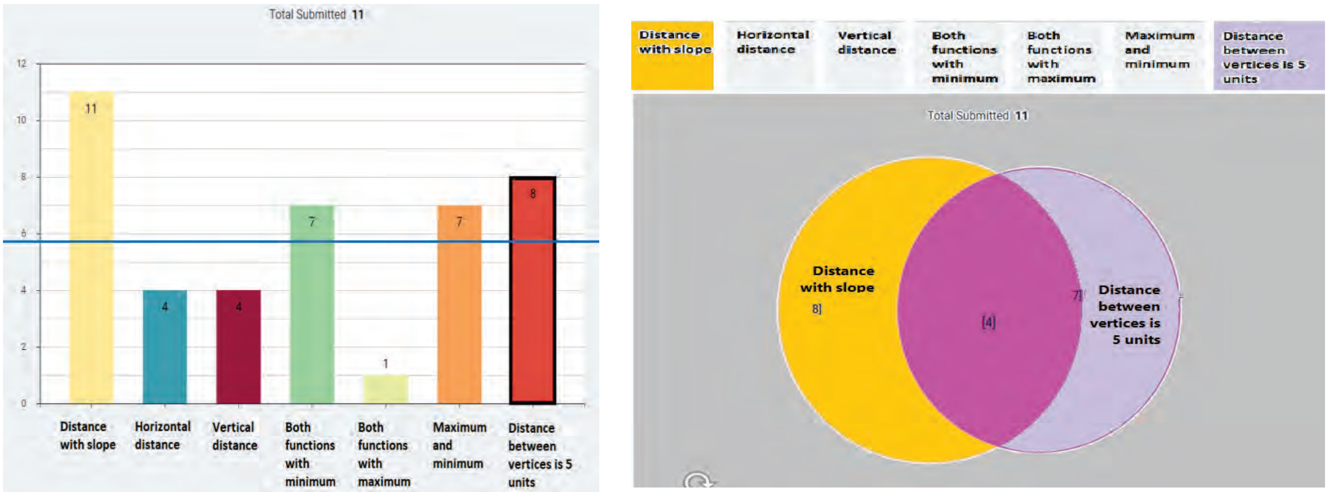


Figure 2: Histogram report (a) and Venn diagram (b)

Data sources and analysis

Data sources include student submissions for the tasks, interviews with each of the teachers, conducted after the class discussion that followed the students' submissions, and classroom observations. Each teacher assigned five tasks in five separate lessons. We used the FaSMEd analytical framework to describe the findings.

Findings

The findings show how teachers conducted formative assessment in their teaching using the data they obtained from the different reports. Below we describe the teachers' use of each report, focusing on the different report functionalities, indicating the role of these affordances in describing the FA properties that teachers focused on in the ensuing discussions.

Grid report

The use case for this report concerns a task asking students to find a linear function equation from two given points, which was assigned in the course of an 8th grade mathematics lesson. The students were asked to "Construct a linear function whose graph passes through the two given points. If you believe this cannot be done, explain why." The interactive diagram that was provided included multiple linked representations of the function, and the students could choose the different points by pressing a "New points" button that generated semi-randomized pairs of points (Bagdadi, 2019).

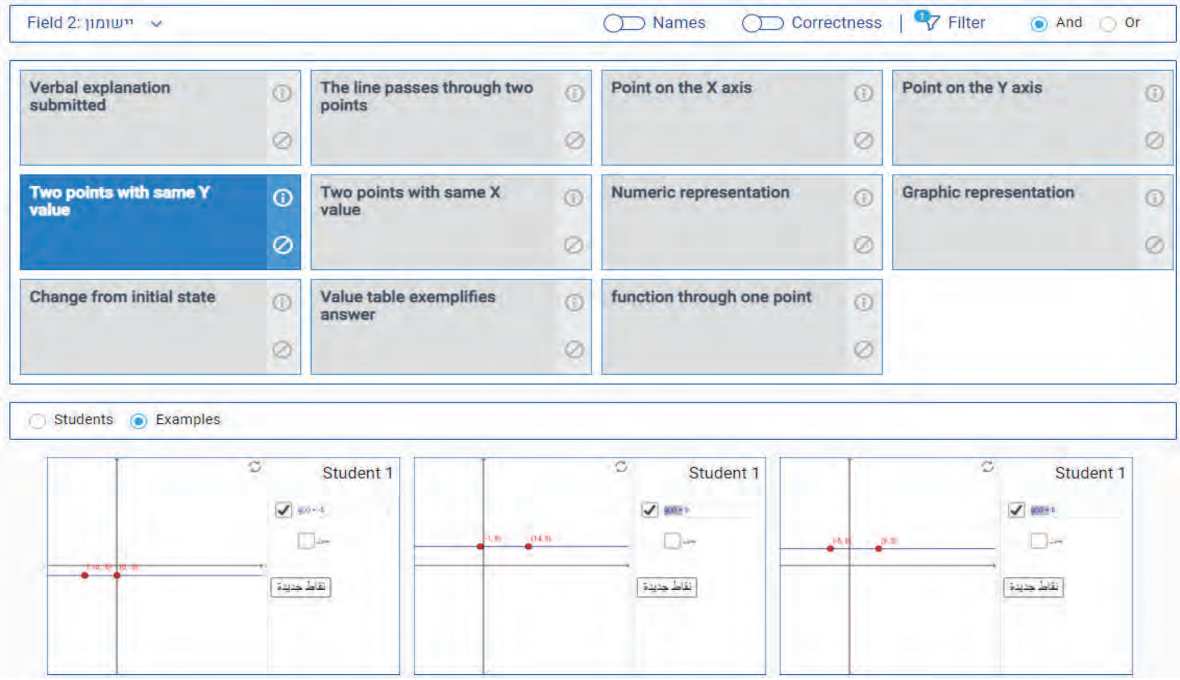

Figure 3: Filtered grid report presented during classroom discussion

The teacher chose to address the characteristic "Two points with same Y value," based on the analysis (PA) provided by the platform. The teacher *clarified and shared learning intentions and criteria for success.* She indicated that "this characteristic describes a constant function and helps students solve this type of a task efficiently, saving them time" (Asala, questionnaire). Analysis of the classwork reveals that the teacher presented examples of student submissions with this characteristic (Figure 3). In the process, the teacher used an interactive component of the report (PIE) to choose a filter based on the automatic analysis and displayed students' work (SD). Next, the teacher decided to give students tasks for discussion to *elicit evidence of their understanding*, *organizing an effective classroom discussion* based on the data she collected from the report. Lesson observations reveal that she asked students questions like "What did these students do?" "What type of function do you get in this situation?" "Do you think it [constant function] is easier [than a function with a slope]?"

"How would you find the equation?" The teacher also addressed student submissions in which the two points coincide, which enabled students to submit non-constant functions. Generally, it was apparent that the teacher *activated students as instructional resources for one another and as the owners of their own learning.* The teacher indicated that this choice of points helped students understand that an equation can be written without calculating the slope and plugging in the X and Y values of the points. The teacher used the different functionalities of the report to *provide feedback that takes learners forward*. In general, the grid report offered the three functionalities of technology that enabled teachers to relate to all the five FA strategies (Figure 4a).

Table report

The use case for this report concerns a task asking students to find several linear functions that intersect a given point and also intersect the positive part of the Y axis. The task was part of an 8th grade mathematics lesson. The students were asked to "choose a point and construct several expressions of linear functions whose graph passes through the given point and intersects the positive part of the y-axis." Based on the report (PA), the teacher found that none of the students paid any attention to the table of values provided in this task ("numeric representation" characteristic in the table). She later said: "I chose to pay attention to this characteristic because none of the students used the table. In addition, it was important for me to emphasize that the table helps illustrate characteristics of the function" (Asala, questionnaire). Observation of the lesson revealed that the teacher used the report to *clarify and share student learning intentions* and to *orchestrate the discussion*. The teacher continued to *provide feedback that takes learners forward* by showing the students how the table of values could assist them in verifying their solutions by displaying an additional report, the grid report (SD). This report is limited to two functions of the technology, *sending and displaying* and *processing and analyzing* (Figure 4b). Although teachers can use the analysis provided by this report to activate the students, our current findings do not indicate that they did so.

Histogram report and Venn diagram

The use case for these reports concerns a task involving quadratic functions, specifically, identifying the extremum and calculating the distance between two extrema of two different quadratic functions. The task was formulated as follows: "Functions f(x), g(x) are from the family y=a(x-p)^2+k. Claim: there is only one situation for the functions f(x) and g(x) in which the distance between the extremum points of each function is 5 units. If you think this claim is true, provide the algebraic expression of each function. If not, use the interactive diagram to create five examples of different functions." The teacher used the histogram to *clarify learning intentions and criteria for success*: "I presented the grid for each characteristic separately and we discussed the effect of the parameters for each characteristic" (Ranya, interview). She noticed that most of the students gave correct answers, and that most of the students provided a distance that was not a vertical one, something she did not expect (PA). Following this insight, she presented (SD) the filtered grid report for the characteristic "vertical distance" and *conducted a discussion around it*. Next, she used the filtered grid report of a distance that has a slope (i.e., not vertical/horizontal) to *share the students' work* (PIE) (Figure 2a).

The Venn diagram was used for the same task. Indeed, it was the histogram report that encouraged the teacher to use another representation of the data from her classroom. In the histogram report, the teacher noticed that most of the student submissions were correct, and that most of the submissions had distance with a slope (PA): "The histogram showed that most of the students gave examples with a slope, which was strange for me since they didn’t study the distance formula yet. So I turned to the Venn diagram to see the intersection between the characteristics” (Ranya, interview). On the Venn diagram (PA), the teacher checked the interrelations between the two characteristics (PIE) (Figure 2b) and noticed that only 4 out of 11 submissions were both correct and with a slope. She said: “I chose to look into this characteristic. Even though there were many submissions with a slope, they were not correct, since they calculated the distance only according to the X values” (Ranya, interview). One student used the Pythagorean theorem and calculated the distance based on the length of the hypotenuse. Following this insight, the teacher asked this student to reveal her solution (SD) and used it to explain to the other students why it was not correct to calculate the distance the way they did, *activating students as instructional resources for one another and as the owners of their own learning*. Based on the analysis and on the interactive reports, the teacher gathered valuable information about the students’ learning that assisted her *to manage an interesting discussion* about a rare correct solution of one of the students. In the course of this discussion, she provided feedback to the whole class about the common mistake. In general, these two reports offer the three functionalities: sending and displaying (SD), processing and analyzing (PA), and providing an interactive environment (PIE), of the technology to teachers. By using these functionalities, the teachers can apply the five strategies of the FA (Figure 4c). By clicking on any characteristics in these reports, the platform provides additional information about the student's works, which helps the teacher *give effective feedback and serves as a powerful resource for activating the students*.

Summary and discussion

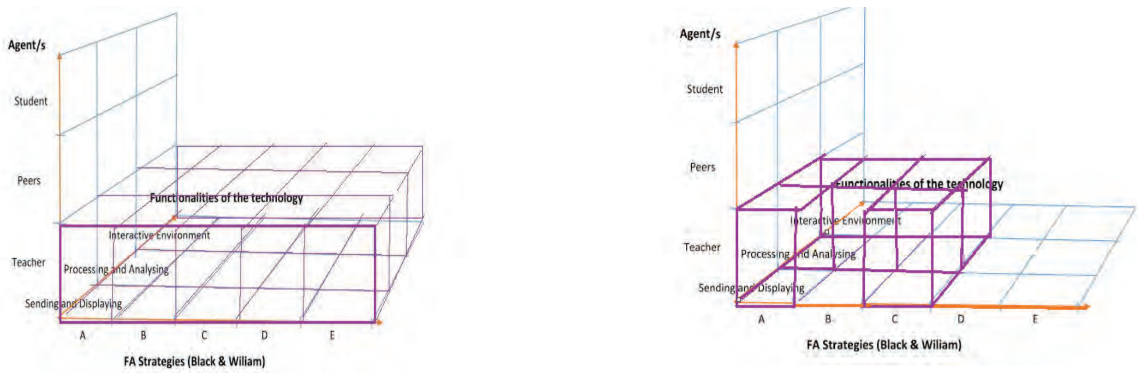

Figure 4: Grid report and Venn diagram interactions (a) and table report interactions (b)

In this report, we used the FasMed framework to describe the FA practices of teachers interacting with LA based on students' answers to EETs in a digital environment. LA were accessible by means of different interactive reports. The use cases presented show that in using the reports, teachers resorted to different strategies, ranging from locating work with specific characteristics to discovering meaningful complicated logical conjunctions of characteristics. In the grid report, students’ work is accessible in a single report, and teachers could filter student work according to pre-designed characteristics. Teachers used all the functionalities of the technology, which enabled them to advance learners in the course of a class discussion that deployed the five key strategies of FA interactions (Figure 4a). By contrast, the table report provided only the functionalities of sending and displaying, and of processing and analyzing. Teachers used these functions to clarify, guide the discussion, and provide feedback. (Figure 4b). The histogram and Venn reports offer correlations between the different characteristics, and grids of students answers for the correlation they chose. In these reports, findings show that teachers used all three technological functionalities for effective FA that also included all five strategies (Figure 4a). The examples show how the design principles of each report served teachers in different ways and demonstrate the role of interactive environment in the teacher's FA. At the same time, other facets of the interaction and of FA characteristics remain to be further investigated. By enabling the teacher to display the students work (SD), then to click on one of the columns in the histogram report (PIE) then get the filtered grid (PA), STEP demonstrates a wide range of opportunities to use technology in teacher's formative assessment practices.

Primary teachers implementing *TouchTimes*

Sandy Bakos

Simon Fraser University, Canada; sbakos@sfu.ca

After integrating TouchTimes (hereafter, TT) into their teaching practice, four primary school teachers (K–5) in British Columbia, Canada share their experiences, both as learners of this relatively new technology, and as teachers utilising TT as a tool to guide and support student learning. Using the notion of double instrumental genesis, I examine how these teachers experienced this digital technology from 2018–2021, both as learners themselves, as well as their subsequent transitions to thinking about and adopting it as a didactical instrument for teaching mathematics. The aim of this research was to identify and highlight specific ways in which these teachers adopted technology-enhanced mathematical learning, managed obstacles they experienced during personal instrumental genesis and how instrumental distance affected their professional instrumental genesis.

Keywords: Touchscreen technology, TouchTimes, instrumental distance, double instrumental genesis.

There are a wide variety of resource options available for the teaching and learning of primary school mathematics. Physical (hands-on) objects have been used to support the development of mathematical understanding for many years and, with the emergence of touchscreen devices which are better suited to the as-yet developing fine motor skills of younger students, digital technology is becoming a more viable resource to primary school classrooms (e.g. Sinclair & Baccaglini-Frank, 2015). Integrating technology into their teaching repertoire and becoming adept at leveraging the opportunities that technology can offer for teaching and learning remains challenging for many teachers (Trigueros et al., 2014), and this is also the case when implementing TT in primary school classrooms (Sinclair et al., 2020). The notions of *instrumental distance* and *double instrumental genesis* (Haspekian, 2014) are useful for examining the impact of integrating digital technology on mathematics teachers' practice.

TouchTimes (Jackiw & Sinclair, 2019), a multi-touch iPad application, enables primary school children to experience relational and functional aspects of multiplication through engagement with two different microworlds, *Grasplify* and *Zaplify*. While using their fingertips to create and transform pictorial representations of multiplicative situations on an iPad screen, the children receive immediate visual, tactile and symbolic feedback from TT in response to their actions.[1]

The design of TT focuses on the two quantifying dimensions that comprise the multiplicative relationship; the first being the unit of measurement (the multiplicand), and the second involving the quantity of that unit (the multiplier). Multiplication from this perspective involves "a count of a [larger] unit for which a relationship to another, smaller unit, is already established" (Davydov, 1992, p. 12). The design of Grasplify is influenced by Davidov's (1992) double change-in-unit approach to multiplication that is grounded in measurement. The first unitising occurs when the multiplicand is established (in Grasplify, this is the creation of the pips) and the second occurs when determining the number of units to be used (the number of pods). Rather than repeated addition, both Grasplify and

1 For further information on *TouchTimes*, view this short video demonstration. https://youtu.be/JkznPdu8RkA

Zaplify focus on doubling, tripling, etc., a design choice influenced by the relational and functional aspects of Vergnaud's (1983) work on the conceptual field of multiplication.

Theoretical framing

The instrumental approach extends Vérillon and Rabardel's (1995) theory of instrumentation of human tool-use into the domain of mathematics education, utilising its focus on instrumental genesis for analysis of technology-mediated teaching/learning (Artigue, 2002). There is a two-way process during instrumental genesis, in which a physical object or tool, defined as an artefact, influences the user (*instrumentation*) whilst the user adjusts to the tool (*instrumentalisation*). It is during this process that the artefact develops into a functional instrument for the user. This progression is even more complex in the case of teachers, who must engage in what Haspekian (2014) terms *double instrumental genesis* when adopting unfamiliar technology for teaching. Initially, a personal instrumental genesis occurs when teachers first engage with an artefact as learners themselves. As the artefact becomes an instrument for mathematics, teachers then engage in a professional instrumental genesis as they appropriate and construct the technology into a didactical instrument for use with students. Haspekian declares, "The teacher's professional genesis with the tool is much more complicated as it includes the pupils' instrumental genesis" (p. 254).

In examining the sustained integration of technology into mathematics teaching, Haspekian also refers to the notion of *instrumental distance* between the digital technology and the mathematics. This relates to the gap between 'current school habits' and the didactical experiences offered by the technology, and can include the computer transposition (how the computer mediates the mathematical concepts in question, as per Balacheff, 1996), institutional, didactical or epistemological changes that occur when a tool is introduced into mathematics teaching. The gap must be large enough to make the benefits of adopting the technology apparent, but not so large as to discourage teachers from its integration.

Given that TT was developed specifically for mathematics teaching, and that none of the teachers had any prior experience using it, double instrumental genesis provides a way to examine how these teachers experienced this digital technology as learners themselves, as well as their subsequent transition to thinking about it as a didactical tool for teaching mathematics and the effects of instrumental distance during the process of integrating TT. The research questions specifically relate to these ideas. (1) During their personal instrumental genesis of TT, were there specific problems or obstacles related to either the technology or the mathematics it represents, encountered by the primary school teachers interviewed? (2) How did the instrumental distance between prior ways of teaching multiplication and using TT affect the evolution of these teachers' professional instrumental genesis of TT? In order to respond to these questions, I draw on data gathered during interviews with these four teachers about their experiences implementing TT as a teaching tool in primary classrooms.

Method

Three of the teachers are primary school generalists, and one is a former secondary mathematics teacher, who is now a mentor teacher that works with K–12 teachers in her school district to improve mathematics teaching. Their teaching experience ranged from 9–24 years, each had a master's degree, and all were working in grade 3 or 3–4 classrooms in British Columbia, Canada when utilising TT. Each teacher had volunteered to provide feedback for a larger, multi-phase project, in which the author is part of, involving the implementation of TT in primary school classrooms, and to contribute to the development of tasks and assessments to be used with it.

The teachers were initially introduced to TT during the first meeting of this larger project, which was videorecorded. With the exception of Leah's first reaction to TT (which is used as a comparison to her later thoughts about TT that emerged during the interviews), the data in this paper has been taken from 60–80–minute semi-structured interviews with each of the teachers individually (one for each teacher), which were conducted via Zoom in June through August of 2021. Having observed that teacher responses in the larger research group meetings would often build from the ideas shared with each other, it was hoped that this may also occur by interviewing pairs of teachers together. Therefore, two additional interviews were conducted where the four teachers were interviewed in pairs (one interview for each pair). In each interview, the teachers were asked about their initial experiences with TT as learners, their thoughts about how TT presents multiplication, how they used it as an instructional tool and their observations related either to TT or to its mathematical representations, as well as what they noticed about student learning during the implementation of this digital technology. Each interview was transcribed in its entirety and the resulting transcripts were then analysed for common themes that emerged based on the experiences shared by the four teachers.

Data analysis and results

With my research questions in mind, the data was analysed with two specific aims. The first was to identify instances of obstacles or challenges related to the personal instrumental genesis of TT shared by each teacher, while the second was to look for specific examples of instrumental distance that influenced the evolution of each teacher's professional instrumental genesis. I first categorised the experiences of instrumental genesis of TT as either personal or professional, while noting any obstacles or challenges shared prior to examining the examples of the latter more closely to determine if instrumental distance was apparent and, if so, whether the resulting gap was related to computer transposition, institutional, didactical or epistemological changes. I wanted to understand better the challenges these teachers experienced with TT as learners themselves, as well as what factors influenced the integration and use of TT into each teacher's mathematical teaching practice. I will now discuss five specific challenges in the teachers' double instrumental genesis.

(a) Leah: "Grasplify is backwards". A member of the research group, Leah's initial encounter with TT occurred during our first teacher–researcher team meeting. While using the app, she noticed the multiplicand × multiplier = product ordering displayed by TT and stated to the group that this was "backwards". Leah shared how she would refer to the textbook to guide her teaching. The textbooks that she referred to all showed 4 × 3 as four groups-of three, and were always in the multiplier × multiplicand = product ordering. Grasplify however, displays the equation in the opposite order, where 4 × 3 is four, three times (see Figure 1).

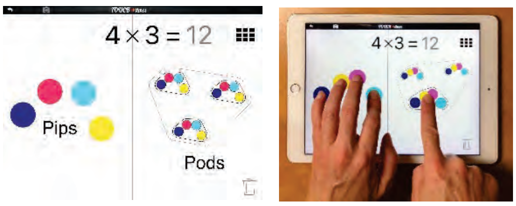

Figure 1: (a) Pips and pods; (b) Grasplify display of 4 × 3 = 12

Leah’s reaction to this ordering occurred during her first exposure to Grasplify, and was immediate. Though she was still learning how TT functions, and in the very first stage of personal instrumental genesis, this obstacle intertwined with her professional instrumental genesis and how she could use Grasplify with her students. The instrumental distance between the computer transposition and the epistemological aspect of Leah’s personal representation of multiplication and how she taught it was significant from her first use of the Grasplify world and continued to be problematic for her.

When I interviewed her three years later, Leah mentioned again how she “couldn’t get past the groups-of thing and it was so huge for me”, but explained that, “if I really believe in […] how this [app] works and what multiplicative thinking means, it doesn’t matter what happens next. It’s what happens in their [her third grade students’] thinking.” She went on to say, “I was so stuck on this groups-of thing and then I started thinking about, well, what does multiplication mean? So, it really changed my thinking about what it [multiplication] means.” It was through discussion in the TT teacher–researcher group, and during Leah’s use of Grasplify in her classroom, that the instrumental distance began to narrow. She explained that the commutative property makes the order of the factors irrelevant, so the product will be the same. Observing her own students using TT was what was most convincing for Leah, who noted that students, “didn’t know any different, and so they were understanding it [the ordering] the way it was, and it didn’t matter”. The most significant growth in Leah’s personal instrumental genesis occurred as a result of her professional instrumental genesis, rather than preceding it, as often occurs when implementing new digital technology in the classroom.

Another challenge that Leah described involved the impermanence of the pips and pods on the iPad screen. When first using Grasplify with her students, she was projecting it onto the wall for all to see. At that point, she only had access to one iPad with TT on it, and was engaging in teacher-led prediction tasks. For example, she would create pips and pods on the screen and asked the students to predict how she would double the product by only changing the pips (see Figure 2). Leah shared her frustration when, each time she removed her pip-making fingers, it would reset the screen. This left her ‘stuck’ at the front of the classroom and unable to view the predictions students were making on their mini-whiteboards. However, once multiple iPads were available for student use, she noted how the impermanent nature of the pips and pods forced her students to think more carefully about what they were doing, adding an element of concentration and a bit of planning that resulted in a more “metacognitive aspect to it. It’s not just playing […], it’s thoughtful play”. This aspect of the technology and how it affected Leah’s ability to use it and monitor student progress, created an obstacle for her professional instrumental genesis. It was not until she observed how this lack of permanence affected student engagement with the tasks, that the instrumental distance grew smaller.

Figure 2: Doubling task progression

(b) Rachel: It was not intuitive. When first using TT, Rachel did not find the app to be intuitive. She described it as hard to use and admitted to having difficulty thinking of ways to use it with her students. As was observed with Leah, Rachel’s personal and professional instrumental geneses were closely intertwined and the instrumental distance was initially large, making TT difficult for her to adopt and implement without assistance. It was through the shared experiences of other teachers within the teacher–researcher group, the teacher discussion about what they had difficulties with or found valuable when using TT with their students, as well as the provision of task ideas to be used with students, that helped Rachel overcome these initial obstacles and begin using Grasplify in her classroom. She explained that she needed teacher tasks that were already developed to support her initial implementation of TT and also suggested the creation of short videos to help other teachers better understand the app and the tasks that can be used with it. Rachel described the benefits of being part of a cohort of teachers who were talking more deeply about multiplicative thinking, their experiences teaching with TT and its accompanying tasks and how this influenced her thinking about the properties of multiplication and being more purposeful about this in her own teaching. The instrumental distance narrowed over time, and although TT was not initially intuitive to use as a teaching tool, its use began to change the way she thought about and taught multiplication.

(c) Amy & Rachel: Using Grasplify in the "opposite way". As these two teachers continued to use Grasplify with their students over the course of two school years, the ways they described using it were becoming more personalised, reflecting on-going professional instrumental genesis. When discussing Grasplify as a teaching tool, the differences between traditional methods of teaching multiplication and those afforded by TT were described as beneficial by both teachers. When interviewed together, the pair would often elaborate on and extend each other's ideas. They explicitly stated that TT is not the only model that they use with students when teaching multiplication, that it is simply one model. Going further, both described teaching multiplication using other models in comparison with how they used TT. Amy commonly begins by writing a multiplication equation on the board for all to see. After writing 3×2, for example, she would then proceed to use manipulatives or drawings to create three groups-of two, or the applicable array or area model or a number line drawing for skip counting. She was starting from the symbolic mathematics and then working to create either physical or visual representations that explained what the symbolic mathematics meant. Whereas when using Grasplify, Rachel described using it in the "opposite way". When asking her students to skip count to twenty, she was, "not necessarily looking to show a model for that equation, […] the equation is there, but you're trying to get at concepts that might be harder to get by just drawing something"[2].

Amy pointed out that Grasplify provided a visual representation of multiplication for students that is difficult to demonstrate using physical manipulatives or drawings and that, because Grasplify is constantly changing and moving, it encourages more open-ended thinking and discussion. For her, "the emphasis is on the exploration because the answer is already provided by TT and therefore that isn't where the focus is". She used other models when she wanted the focus to be on the answer. Rachel agreed and reiterated that she wanted her students to notice what happens when they add or remove fingers, how that relates to what is happening within the pods and then how this influences the numbers within the equation and the product itself. She was trying to enhance her students understanding of multiplication in a different way, through the growth of pips spreading across the pods. Rachel used these types of tactile experiences with immediate visual feedback, to "enhance

[2] For a more detailed description of Leah and Rachel's classroom implementation of Grasplify, see Bakos (in press).

students’ comprehension of multiplication in ways that are different, you know harder to get at through pencil and paper or even manipulatives”.

Teaching with TT begins with students exploring the app, noticing the effects of their fingers on the pips and pods, then later, using intentional questioning, she directs student attention towards the mathematical symbols that are also visible on the screen. Student experience with the multiplicative models takes place first and then she builds her teaching on connecting such experience with symbolic mathematics. The more operational approach of starting with an equation and explaining it through a multiplicative model and using Grasplify to provide dynamic and relational experiences with multiplication was a complete inversion of their approach to teaching multiplication and yet this was what Amy and Leah both welcomed about the digital technology. It was not seen to be detrimental: rather it was considered advantageous for student learning.

(d) Kate: Transitioning across multiplicative models. Of the four teachers I interviewed, Kate was the only one who had utilised both of the TT microworlds with her students. The use of the two different multiplicative models represented by Grasplify and Zaplify allows for examining what I term *intra-instrumental distance*, in that there are two related tools and a possible distance between them.

Kate was very purposeful in taking advantage of this *intra-instrumental distance*, wanting students to learn what multiplication is and for them to understand the different representations and how to go between them, while also recognising “that multiplication is the common theme” in the different multiplicative models embodied through Grasplify and Zaplify. She engaged students in activities that explicitly directed attention towards comparing and contrasting both worlds. For example, after sharing screenshots of the same multiplication sentence represented by Grasplify and Zaplify (see Figure 3), students were asked to describe how these were the same and how they were different. Kate would sometimes provide screenshots of a multiplication equation in one microworld and ask students to draw what that equation would look like in the other. Kate’s goals were for students, “to make connections between the two different worlds, make connections between the symbols, the equations, the representations, because at the end of the day, I wanted them to know how to multiply and what multiplication was, so it kept coming back to that one idea”. Kate’s professional instrumental genesis involved her prioritisation of the symbolic mathematics and the instrumental distance between TT and her epistemological beliefs of what was important for students to learn mathematically, she very intentionally kept narrow. The learning activities that she designed for students prioritised the symbolic and representational models of multiplication and how TT could be used as a vehicle to drive students towards those goals.

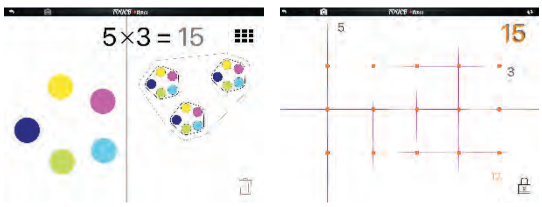

Figure 3: (a) Grasplify multiplicative model; (b) Zaplify multiplicative model

After engaging the children with various TT tasks for a few weeks, Kate described how she projected some examples of different representations of multiplication onto the board and found it “really powerful” when the students could easily identify Zaplify or Grasplify in the models, even though the models projected were taken from another teacher resource. “Switching back and forth between the models connected to the different representations. So, when they see an array model, they’re connecting it to Zaplify or when they’re seeing the groups-of, they’re seeing it as pips and pods.” For Kate, this would be useful when transitioning into what she referred to as “the more formal symbolic type of math” that most teachers teach. She explained that this is beneficial to students because when they move on to another teacher, they can carry their TT experiences into other contexts and that multiplication would still make sense.

(e) Amy, Leah & Rachel: How Grasplify shaped their teaching. Both Amy and Rachel would sometimes have students create drawings to depict what they had learned after completing a task using Grasplify. Amy used these drawings as a formative assessment tool to “see what they noticed. Like did they notice the colours? What were they able to pick up on? What did they attend to?” Of importance to Rachel was determining what her students were seeing and what they understood from TT, so that she could use this information to plan what experiences she needed to provide during the next class. Her goal was not on students transferring this knowledge to an equation: rather, her goal was to know more about what her students, both individually and collectively, understood from that day’s task and to try to glimpse what it was that *they* were seeing.

As her students used Grasplify to “play with” and learn about multiplication, Leah would watch what they were doing. She explained how, even if students were not always going in the direction she had hoped for, that she was better able to understand where they were coming from and that she could redirect with a different question to get them thinking about the relevant mathematical concept that was emerging from their explorations. Leah found that, “TT allowed me to actually see how kids were thinking about multiplication”, in comparison with her traditional teaching where she would show students what to do and expected them to mimic this.

Discussion and conclusion

Throughout the process of double instrumental genesis, all four teachers became increasingly responsive to the teaching opportunities that emerged from student experiences with TT. For Leah in particular, the reaction of her students to Grasplify significantly influenced how the instrumental gap continued to narrow. The mathematics learning that her students were engaged in influenced her comfort with using digital technology with which she was initially very uncomfortable. She explicitly shared that, “one thing that affected me is the conversations I had with the kids as a teacher”.

For Rachel, she was not focused on memorising facts or writing equations, and therefore TT meets her where she is concerned, which is about providing new meanings for multiplication. The use of Grasplify allowed her to provide learning experiences with visual representations of multiplication that were dynamic and with which students could interact in a relational way. The limits of static drawings and the difficulty for children to build multiplicative situations out of physical manipulatives without error was very visible for Rachel.

The process of double instrumental genesis was not straightforward for these teachers during their integration of TT. Although there was an initial experience of learning to use the digital technology personally, for these teachers, it was difficult to differentiate between their personal and professional instrumental geneses. Their reactions to TT and the manner in which it presents multiplication were clearly related to how they would use it as teachers to promote student learning. The instrumental gap narrowed significantly as these teachers used TT with their students. When Leah's students were not having difficulty with the multiplicand × multiplier ordering, she began to re-evaluate her own thinking. When Kate's students were able to identify the multiplicative models experienced in TT to static drawings of multiplicative models, the *intra-instrumental distance* narrowed for her.

Although obstacles were encountered by these teachers during their personal instrumental genesis of TT, the instrumental distance between previously used ways of teaching multiplication and the relational experiences with multiplication offered by TT were either embraced as positive differences or narrowed as the teachers' professional instrumental genesis of TT advanced.

Acknowledgment

I would like to thank Dr. David Pimm and Dr. Nathalie Sinclair for their guidance and support.

Designing mobile environments for mathematics distance education: The theory-driven development of the ASYMPTOTE system

Simon Barlovits[1], Alexandra Kolokytha[2], Matthias Ludwig[1] and Georgios Fessakis[2]

[1]Goethe University, Institute for Mathematics Education and Computer Science, Frankfurt, Germany; barlovits@math.uni-frankfurt.de

[2]University of the Aegean, Department of Preschool Education Sciences and Educational Design, Rhodes, Greece; psed21005@aegean.gr

Distance teaching and learning due to the Covid-19 pandemic was perceived as a major challenge by both, teachers and students. With new ways of instruction emerging in a matter of days, the resulting instruction formats – summarized in the term Emergency Remote Teaching (ERT) - could not fully meet the needs of online teaching and learning in Spring 2020. With a particular focus on the reported problems of mathematics distance education during the Covid-19 pandemic, this paper firstly aims at providing a theoretical framework for the development of mobile environments for distance math class. In doing so, we refer to the Community of Inquiry (CoI) model and e-pedagogy to deduce design requirements for online learning environments. Secondly, the ASYMPTOTE system is introduced. Based on the theoretical considerations and the discussed Covid-19 experiences, necessary further developments and requirements for the project are identified.

Keywords: Covid-19, design requirements, distance education, mobile learning, online systems.

In the following, a theoretical framework for mobile learning environments aiming at mathematics distance education is provided. Hereby, we refer to the Community of Inquiry, online learning and practices of online instruction as well as mobile learning. The theoretical framework is used to evaluate the present status of the ASYMPTOTE system and to identify needed further developments.

Theoretical Framework

Community of Inquiry

A well-known approach for the design of digital educational environments is the Community of Inquiry model (CoI), which is based on Dewey's (1897) assumptions made on the value of social interaction and collaboration to the learning process. The constructivist model describes learning in online communities – composed of teacher and students – by the interplay of three core elements: cognitive presence, social presence and teaching presence (Garrison et al., 2000).

Cognitive presence in online environments is considered as a holistic multi-phased process initiated by a triggering event. According to the practical inquiry model, it is followed by an individual exploration which result in a reflection process – and thus in the creation of new concepts. Afterwards, the skills and knowledge acquired are practiced in real situations (ibid.). Thus, cognitive presence is defined "as the exploration, construction, resolution and confirmation of understanding through collaboration and reflection in a community of inquiry" (Garrison, 2007, p. 65).

Social presence describes the ability to position oneself in the online environment as real person (Garrison et al., 2000) and to collaborate in the digital world by establishing personal and purposeful relationships (Garrison, 2007). The main aspects of social presence are the expression of emotions, the open communication and group cohesion in the online format (Garrison et al., 2000).

Teaching presence – mainly referred to the instructor's role – includes firstly the design of educational experiences, i.e. organization of the course as well as design of learning activities and assessment formats. Secondly, teacher presence involves a facilitation function during the lesson (ibid.). Thirdly, direct instruction is considered to be a part of the teaching presence (Garrison, 2007). All three functions of teacher presence focus on the goal "to support and enhance social and cognitive presence for the purpose of realizing educational outcomes" (Garrison et al., 2000, p. 90).

Viewing educational experiences as the result of successful interplay between all three elements, CoI assumes that knowledge construction in online settings depends on the ability of instructors and learners to create forms of perceived presence despite spatial separation (Shea & Bidjerano, 2009).

Online Learning

According to Allen and Seaman (2013), online learning can be defined as a course that is mostly or entirely delivered online, so that typically no face-to-face meetings are conducted. From an e-pedagogical perspective, three different instructor roles can be taken in online environments: Teachers can firstly act as excessively active leaders of students' learning progress or secondly be in a reactive position as facilitators which only respond to students' questions. Thirdly, and preferably, they take the position of a reasonably active mediator, i.e., instructors engage and interact without directly guiding students' learning progress (Serdyukov, 2015).

Even though online learning is from its origin an independent and self-determined process, the need of critical support for the online learner is highlighted in e-pedagogy. To address the demand of social interaction, four forms of organization can be identified: interaction can be enabled by both, text-based and video-based communication, either in synchronous or in an asynchronous setting (ibid.).

Principles for Online Instruction

The value of social interaction for online teaching is also highlighted by Sorensen and Baylen (2009) who adapted the *principles for good practice* of Chickering and Gamson (1987) to online instruction settings. The seven principles for teaching in online environments can be summarized as follows:

1 Enabling student-teacher interaction
2 Facilitating cooperation among students
3 Empowering active learning
4 Providing prompt feedback
5 Managing time on task
6 Communicating high expectations
7 Respecting diverse ways of learning

As shown by Fiock`s (2020) literature review on empirical studies about instructional strategies in online communities, the three core elements of CoI can be related to each of the seven principles. Consequently, the seven principles can be seen as a starting point for implementing instructional activities which consider the CoI model in school praxis (ibid.). In this paper, we understand the seven principles of online instruction as design principles for the creation of educational online environments in line with CoI.

Mobile Learning

Mobile learning can be defined as learning progress facilitated by the use of mobile devices, such as smartphones. Characteristics are the portability of devices as well as their possibilities for communication and interactive representations (Kearney et al., 2020). In a meta-study, Sung et al. (2015) report a positive mean effect of using mobile device on students' learning. The authors emphasize learning environments that offer broad functionalities including authoring tools for teachers to flexibly adapt the system to their own instruction (ibid.).

Mobile apps can promote students' learning progress in numerous mathematical areas, e.g., arithmetic and geometry. Further, the use of apps in math class can foster problem solving strategies or mathematical programming skills. Additionally, the embedding of mobile learning in math education tends to have a positive influence on students' motivation and enjoyment (Drigas & Pappas, 2015).

State of the Art: Mathematics Education in Covid-19 Pandemic

Due to the Covid-19 pandemic, abrupt changes of instruction were needed to deal with the crises circumstances. Within only a few days, new teaching practices were rapidly established (Hodges et al., 2020) mostly by the help of digital media and internet-based communication (Crompton et al., 2021). This temporary shift without appropriate time for designing online teaching courses is described as Emergency Remote Teaching (ERT) (Hodges et al., 2020). Hereby, several challenges concerning mathematics education are reported from a teacher's point of view:

Empirical cross-national research highlights the issue of assessment. Concerning the formative assessment, teachers reported problems in diagnosis as well as individual feedback and support (Aldon et al., 2021; Barlovits et al., 2021; Drijvers et al., in press). During distance education in Spring 2020, instructors mainly focused on procedural skills rather than conceptual understanding (Drijvers et al., in press). In addition, teachers reported difficulties in finding adequate forms of summative assessment (Aldon et al., 2021).

Furthermore, it arouses the question of how to implement inclusive distance education in which students can participate at their individual achievement level (Aldon et al., 2021), especially underachieving students (Barlovits et al., 2021). In addition, teachers reported a lowering of the course level through an increased rate of standard and reproduction math tasks (ibid., Aldon et al., 2021) and an infrequent use of modeling or reasoning tasks (Drijvers et al., in press).

Also, social factors are emphasized in research on mathematical distance education during the ERT phase. Here, the interaction between teacher and student (Aldon et al., 2021; Barlovits et al., 2021) as well as among students, e.g., in form of peer instruction (Drijvers et al., in press), is perceived as challenging. The general ability of fruitful content-related social interaction in math class seems to be dependent on the ratio of synchronous distance education (ibid.)

Moreover, with regard to the finding that teachers paid more attention to the use of general tools, such as video conferencing systems, than on the use of tools designed for math education (Barlovits et al., 2021; Drijvers et al., in press), the availability of technical equipment and the handling of accessible tools must be taken into consideration in the context of distance education (Barlovits et al., 2021).

From the outlined empirical studies, we derive four requirements for digital tools in math distance education during Covid-19 pandemic. An appropriate digital tool in math education has to (i) enable appropriate formative assessment, (ii) promote inclusive forms of teaching and foster different performance levels, (iii) address the issue of social relatedness and (iv) follow a low-barrier approach concerning technical requirements. Being aware that only a few challenges that arose due to crisis situations are presented here, these four design requirements are considered in the following analysis.

Theory-based Design of a Mathematics Online Environment

Mathematical learning in fully online learning environments differs substantially from traditional classroom instruction since it involves a greater amount of asynchronous and self-directed instruction and a lower degree of collaborative work (Choi & Walters, 2018). However, following CoI and the seven principles for online instruction, the opportunity for a teacher-learner interaction and the student collaboration is clearly emphasized. Following the assumption that ability of successful social interaction in math class depends on the number of synchronous lessons (Drijvers et al., in press), online environments should enable *synchronous distance learning*, *direct interaction* and *collaboration* in mathematics distance learning.

Both, the seven design principles as well as the challenges of Covid-19 math distance education, underline the importance of *immediate feedback* and *adaptive design* of learning environments to support and challenge learners at their individual level. Concerning the lack of technical equipment or challenges in its handling (Barlovits et al., 2021), a *mobile learning* approach seems promising due to the high rate of smartphone ownership in Europe and worldwide. Regarding the instructor role, online environments should enable the teacher to act as a *mediator* (Serdyukov, 2015).

The ASYMPTOTE Concept

Based on these considerations, the ASYMPTOTE[1] project is presented as one example for the development of a synchronous mobile environment in the context of the Covid-19 pandemic.

The project aims at the development of a cost-free, open-accessible and low-barrier tool for mobile distance learning in mathematics education. Due to availability and handling of the environment, it is designed for smartphones and tablets. In order to set up this tool for distance mathematics education in a reasonable time, the already existing MathCityMap system (Ludwig & Jablonski, 2019) will be adapted to the needs of online education. The stand-alone system ASYMPTOTE will be available at the beginning of 2023. In the following, the features of MathCityMap are evaluated in light of the theoretical considerations for online instruction. Subsequently, based on the theoretical framework, steps for the further development of ASYMPTOTE are identified.

The MathCityMap System

The MathCityMap system – developed for mathematics outdoor education using the math trail method – consists of two components, namely a web portal for teachers and smartphone app as

[1] Adaptive Synchronous Mathematics Learning Paths for Online Teaching in Europe. Erasmus+ Strategic Partnership; co-funded by the European Union from 03/2021 to 02/2023 (grant no. 2020-1-DE01-KA226-HE-005738).

working space for students (Gurjanow et al., 2019). In the MathCityMap app, students can easily download samples of tasks via code. The app displays the tasks (Figure 1, left; here: task for distance education), shows up to three hints during and a sample solution after the task solving process on demand. Further, an immediate answer validation in form of a systemic feedback is implemented.

Besides these asynchronous features, the web portal offers teachers within the Digital Classroom the possibility for a real-time monitoring of the students' working progress on both, class and individual level. In addition, a chat function is implemented for a one-to-one synchronous communication between instructor and student (Figure 1, center right and right).

By using MathCityMap in the context of distance education, students work on digital learning paths, i.e., internet-based task sequences to be completed independently at their own performance level with the help of hints and result checks (Roth, 2015). Different answer formats such as values or vectors, cloze texts, or multiple-choice selection are available for task creation. For a detailed description of how the MathCityMap system has been adapted for distance education, see Larmann et al. (2021).

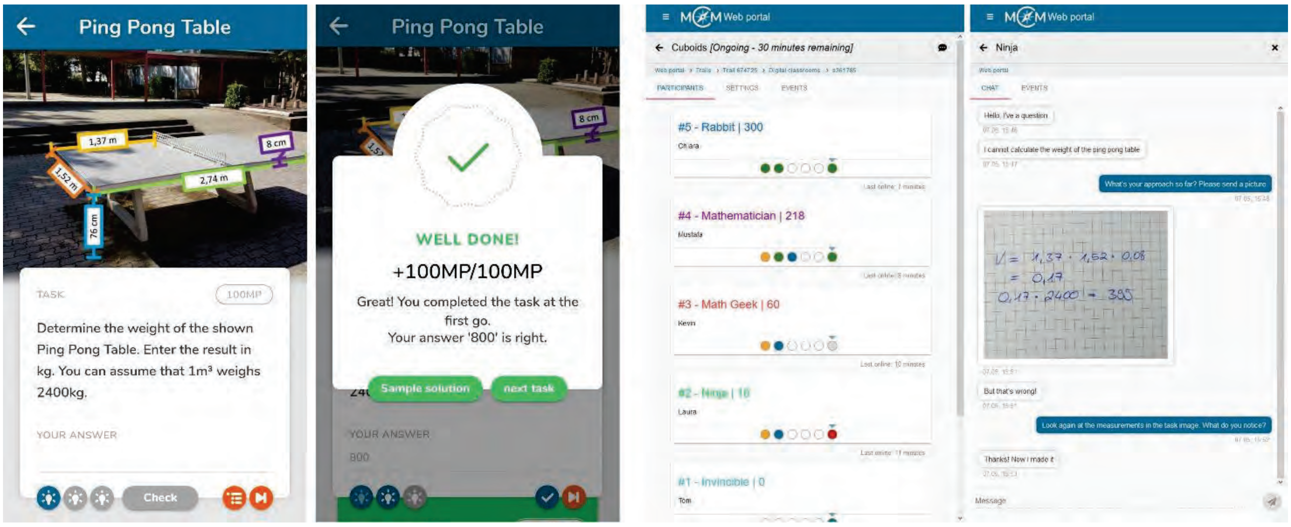

Figure 1: MathCityMap used for distance education from the student's perspective (app; left) and the teacher's view (Digital Classroom in the web portal; right)

From MathCityMap to ASYMPTOTE

Following the considerations for math education online environments, we evaluate the present status of MathCityMap and derive steps of further developments for ASYMPTOTE.

Features of MathCityMap based in line with the identified design requirements: As for *student-teacher interaction*, the chat function of the Digital Classroom provides a possibility for a dialogue between the instruction and the student. Therefore, shown by Larmann et al. (2021), students often start the communication with the teacher to receive feedback on their solution process. Further, teachers can send messages to the whole learning group.

The system provides *prompt feedback*: the student's numerical or text input is immediately validated by the system (Figure 1, center left). In addition, the possibility to send images and audio messages via chat allows teachers to provide individualized support to the student in the sense of formative assessment. Since the systemic feedback distinguishes between correct and incorrect solutions, instructors gain more time to analyze solutions. Thus, the interplay of systemic and individual feedback follows the idea of semi-automated feedback (Fest, 2011).

For student's *time on tasks*, Sorensen and Baylen (2009) highlight well-structured and -planned lessons as well as the value of teacher's time management. Within MathCityMap, a structured setting by using digital learning paths is provided on which students work in a predefined time slot synchronously. Within the Digital Classroom, instructors can monitor student's individual working progress, track student's engagement and directly contact students via chat if needed. With the monitoring function of the Digital Classroom and the semi-automated feedback, the MathCityMap system seems to address the need of mathematical distance education for formative assessment.

To further encourage the student's *time on task* and to *respect mutual ways of learning*, the system offers the ability for teachers to select available digital learning paths or to create own digital learning paths related to the individual needs of their class. Thus, according to Sung et al. (2015), it provides teachers the ability to make adaptations needed for their own classes. Additionally, MathCityMap enables the structuring of complex tasks in manageable subtasks. While upper-performing students can work on the task at a whole, under-archiving students can be guided through the solution process by the subtasks. Also, the online learning setting itself (Serdyukov, 2015) as well as the concept of digital learning paths (Roth, 2015) respect different paces of learning and levels of performance.

Further developments for ASYMPTOTE based on identified design requirements: Within the ASYMPTOTE project, the possibility to create adaptive learning paths will be developed. Following the idea of decision trees, teachers will be able to define so-called status indicator tasks. Depending on the quality of learner's solution, the app will allocate the next task according to the student's performance. Through the definition of several indicator tasks, the content level of the digital learning path can be more and more adapted to the individual level of the student. Moreover, to facilitate learning for students with disability, a read-out-loud mode and a zoom function will be implemented. Tasks, which are formulated in easy language, will be specially marked. Also, tasks will be translatable in various language which might help to bridge language barriers.

The *high expectations* in online education can be addressed through the use of challenging mathematical tasks. These addresses in particular the focus on standard and reproduction math tasks (Aldon et al., 2021; Barlovits et al., 2021) and the infrequent use of modeling or reasoning tasks (Drijvers et al., in press). Within the ASYMPTOTE project, a broad database of open-accessible tasks and learning paths from lower secondary to university level will be created with a special focus on modeling, problem solving and reasoning tasks.

For enabling *communication* and *collaboration* between students in line with CoI and addressing the issue of students' social relatedness in math class, a teamwork mode will be developed. This involves setting up a group chat for synchronous and text-based interaction (Serdyukov, 2015) to support collaborative task processing, discussion and reflection. Whether this type of interaction is sufficient, of course, will depend on the embedding of the lesson conducted with the ASYMPTOTE system. The authors suggest a joint preparation phase and a post-discussion via video call.

Active learning will be fostered by the ASYMPTOTE system by the provision of complex tasks on a variety of topics from lower secondary to university level as well as the teamwork mode. Since

ASYMPTOTE can be considered as an adaptive tutoring system, however, active learning is not additionally promoted by manipulative and interactive tasks: the system does not provide an integrated dynamic geometry software or computer algebra functionalities.

Conclusion

This paper presents a theoretical framework for mobile learning environments aiming at distance mathematics education. It is referred to the Community of Inquiry model, e-learning and online teaching practices as well as mobile learning. Based on the theoretical considerations, design requirements for distance learning systems for mathematics education are developed – also in line with reported challenges of distance mathematics education during Covid-19 pandemic.

Furthermore, the ASYMPTOTE system is introduced, with technical development scheduled to be completed by the beginning of 2022. The system is characterized by an adaptive, synchronous and mobile learning setting. Based on the theoretical framework, we evaluate the present status of ASYMPTOTE and identify needed demands of further developments. Due to the theory-based development of ASYMPTOTE, the mathematics online environment can be considered as a promising tool for mathematics distance education. Thus, we expect that the system will make a substantial contribution to the improvement of online instruction in math class. To which extend the system addresses the issue of social presence in online environments (CoI) and how it affects teachers' and students' perception of the distance situation, has to be investigated by future research.

Investigation of the usage of digital and non-digital resources in the transition from being teacher candidate to teacher

Burcu Nur Baştürk-Şahin[1] and Menekşe Seden Tapan-Broutin[2]

[1]Bursa, Turkey; burcu.n.basturk@gmail.com

[2]Bursa Uludag University, Turkey, tapan@uludag.edu.tr

This study aims to investigate the resource usage of teachers from the beginning of their careers. For this reason, first, we examined the digital and non-digital resources of the teacher candidates. After two years, we studied with the same group to examine their resources while they were teachers. In this phase, we utilized Documentational Approach to Didactics (Gueudet & Trouche, 2009) as the framework and we designed the study as a case study with two mathematics teachers that were mathematics teacher candidates. We used the reflective investigation method. As a result, teacher candidates used digital resources in a more personalized way. When they became teachers, it was observed that they tended to use interactive e-books. Also, teacher candidates tended to use university textbooks and the resources that their advisors suggested. When they became teachers, they tended to use the resources that the ones accurate for the national exam system.

Keywords: Documentational approach to didactics, resource usage, teacher candidates, teachers.

Introduction

Teachers utilize both digital and non-digital resources in their teaching. Also, their usage of those resources can switch according to certain variables, such as classroom conditions, student attention, etc. While using those resources and selecting and organizing them, teachers are actually designing both their lessons and their resources at the same time (Brown, 2009). However, not only teacher affects the lesson and the resources, but also, the lesson and the resources can affect the teacher. This is an interrelationship between the teacher and the tools (Trouche et al., 2020).

Some of the resources diffuse the teacher's teaching day by day, but others can fade away. This happens with or without the consciousness of the teacher, but there are certain factors affecting teachers' choices. In this study, we aim to investigate the teachers' non-digital resources as well as digital resources and we try to examine the factors affecting usage of them in transition from being teacher candidate to teacher. The problems that guide this research are in the transition from being teacher candidate to teacher:

- What are the resources the use of which has ended and continues?
- What are the resources whose usage schemes remain the same and change?

Theoretical Framework

Considering that the resources used by teachers can be both digital and non-digital, it is important to use a theoretical framework that allows examining all kinds of resources in such a study that examines the resources used by teachers in the transition from being teacher candidate to teacher. For this reason, Documentational Approach of Didactics (DAD) (Gueudet & Trouche, 2009) framework was used to guide this study.

For a better understanding of the framework, one would need to clear all the concepts special to the framework. The first of those concepts is a resource. A resource can be thought such as a tool (Adler, 2000), but it is more than a tool according to DAD. For example, teachers' drawings on the blackboard can be a resource (a tool) and also students' responses can be a resource, too. Teachers use several resources in their daily work for teaching. This work can include selecting, modifying and creating new resources. According to DAD, this work is called documentation work and the outcome of it are teacher documentation. In their documentation work, teachers utilize both the text resources (e.g. textbooks, teacher guiding books, workbooks) and digital curriculum resources (e.g. digital interactive books, technological tools).

One of the concepts of DAD is a document and it consists of resources and their usage schemes (Vergnaud, 1998). A scheme is a teacher's stable organization of their activities, for a given class of situations. A scheme has four components: (i) the aim of the activity, (ii) operational invariants, (iii) rules of action, (iv) possibilities of inferences. In DAD, schemes are considered as usage schemes of resources. All the resources of a teacher, form their resource system (Ruthven, 2007). When the resource system is associated with the usage schemes, they form the document system together.

In this study, DAD was chosen as the framework because it allows us to evaluate a larger collection, considering not only digital resources but all kinds of resources available to teachers. This holistic approach is thought to lead to a broader view of the relationship between the teacher and resources (see Figure 1).

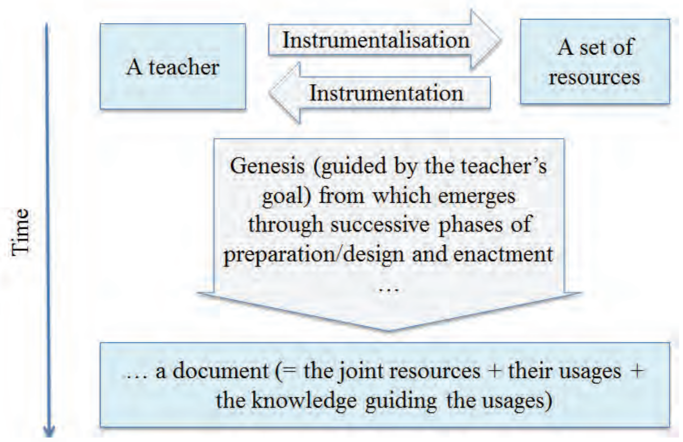

Figure 1: Documentational genesis process in DAD (Trouche et al., 2020, p.3)

As seen in Figure 1, DAD focuses on the relationship between teachers and their resource system. As well as special concepts, there are special names of the processes for teacher's relationship with resources. When the requirements of the resources influence teachers' practice, the process is called instrumentation. When the teachers' aims and knowledge lead to their choices and changes on their resources, the process is called instrumentalization. And the DAD suggests that these processes work both ways. In time with the ongoing instrumentation and instrumentalization processes and the usage schemes of the resources, teachers create documents which is called documentational genesis.

Research Design

In this study, we utilized qualitative research methods to be able to investigate the usage of the resources in detail. The study was designed as a case study. And reflective investigation approach was adopted as a data collection method.

Participants of the case study

In this study, we studied with two teacher candidates and followed them when they started teaching. The teacher candidates, Mary and Keira (pseudonyms) were not the best technology users or with the most resources. Mary and Keira were willing to share their work with resources and were able to introduce their usages in detail. Also, they were volunteering for the lesson preparation sessions as an extra activity. That’s why we chose them for this study to investigate their resources. So the sampling method is criterion sampling method and the criterion are: (i) Being in the last year of undergraduate education in the 2016-2017 academic year, (ii) those who have taken the courses "Field Papers in Mathematics Education" and "Teaching Practice", (iii) to be appointed as a teacher to public schools affiliated to the Ministry of National Education (MoNE) in 2018, (iv) being volunteer for the study.

Mary

Mary is a teacher who has drawn the attention of researchers with her studies even before the research. She came to the fore during her student years in terms of both the scores she got from the exams of the courses related to mathematics teaching and the emphasis she made on the notes she took during the lessons. Another remarkable point about Mary is that she attends classes like a teacher. She has become a student who feels like she will tell her students what she has learned after leaving the class. Mary has been a student who has attracted the attention of the instructors, especially while teaching lessons that require exemplary lectures. During the example lecture, she had no problems while controlling the class and giving appropriate answers to the questions asked. She was also able to use applications such as the Cabri Geometry on the smartboard in the teaching practice as needed and gained the appreciation of her mentor teachers. It is noteworthy that there is great diversity in her teaching practice file in terms of resource use. Mary generally accepted teachers as resources, even contacted teachers who own resources shared on websites, tried to learn how they used these resources, and sought alternative teaching methods for different courses.

Keira

Keira is a teacher who has come to the fore with her desire to use different materials in teaching lessons during her student years. Keira, like Mary, has shown outstanding success in teaching lessons, especially drawing attention to designing and using teaching materials that can be used in lessons. The teaching materials designed by Keira drew attention as they were suitable and durable for student use as they would be used in the classroom, and she stated that he wanted to use these materials when she became a teacher. She showed outstanding success both in teaching courses and in pure mathematics courses. She was able to successfully use smartboard applications in her teaching practice course. In addition, Keira's resource system is quite extensive, often containing resources for different teaching materials. In addition, Karen also used the resources recommended by her mentor teacher in her teaching practice and added them to the resource system.

Method of data collection

We utilized the reflective investigation method which is suggested by Gueudet and Trouche (2009) for those to use DAD. There are some principles of the method (Trouche et al., 2020, p. 6):

- Broad collection of the resources,
- Long-term follow-up,
- In- and- out-of-class follow up,
- Reflective follow up,
- Confronting teachers' views on the documentation work and the materiality of it.

According to these principles we utilized semi-structured interviews, schematic representations of resource systems (SRRS), teaching practice files, interviews on the lesson preparation, lesson observations, and recall sessions. Semi-structured interviews and SRRS diagrams were handled together, because we used the semi-structured interview to understand the resource system better. All the interviews were audio-recorded. The SRRS diagram is a data collection tool that is "not structured for the researcher but it is structured for the participant" (Trouche et al. 2020). In other words, we did not structure the diagrams, they did draw their own SRRS diagrams to explain their resource system.

Table 1: Data Collection Methods according to the Reflective Investigation Method

Reflective Investigation Steps	Data Collection Methods
Broad collection of the resources	SRRS diagrams
Long-term follow-up	Teacher candidate and teacher observations
In- and- out-of-class follow up	Teaching practice files
Reflective follow-up	Interviews and Observations of the lessons and lesson preparations
Confronting teachers' views on the documentation work and the materiality of it	Recall Session

Teaching practice files were used as a written interview about what they realized in their teaching practice classes. This data collection tool did not use when the time they were appointed as teachers. Semi-structured interviews were used instead.

Both before their teaching practices and teaching sessions, we interviewed them about how they planned their lessons, then we observed them in the lessons. In the observation, one of the researchers took field notes and the lesson was video-recorded, too. After the lesson observations, we planned a recall session to get the interpretations of their own lessons.

Data collection procedure

Data collection of this study started in the 2016-2017 education term. In 2016-2017, teacher candidates were in their teaching practice year and the first data was collected. Afterward, a two-year break was given for the appointment of teacher candidates and for obtaining official permissions from their schools. And in the 2019-2020 term, data collection has completed while they were teaching in their own classes (see in Figure 2).

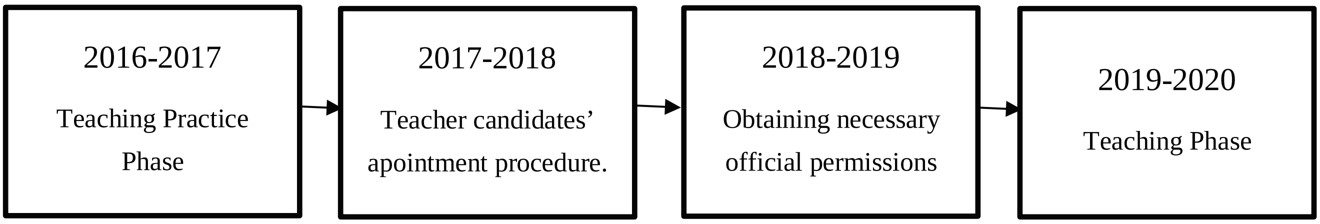

Figure 2: Data collection procedure

Teaching practice files of pre-service teachers who took the course were collected and analyzed. At this stage, the files of all teacher candidates who took the course were examined. However, after the participants were determined, the files of the selected participants were included in the study. Each participant's lesson was observed for 4 hours before the teaching period and 25 hours after being actual teachers, during the lesson observation, the researcher sat in the back rows like a student and took notes and did not interfere with the process. In addition, the lessons were recorded in order to prevent data loss and to be able to re-examine during the analysis. After all the lesson preparations, observations, and interviews, a recall session was organized in order to realize reflective remarks.

Data analysis

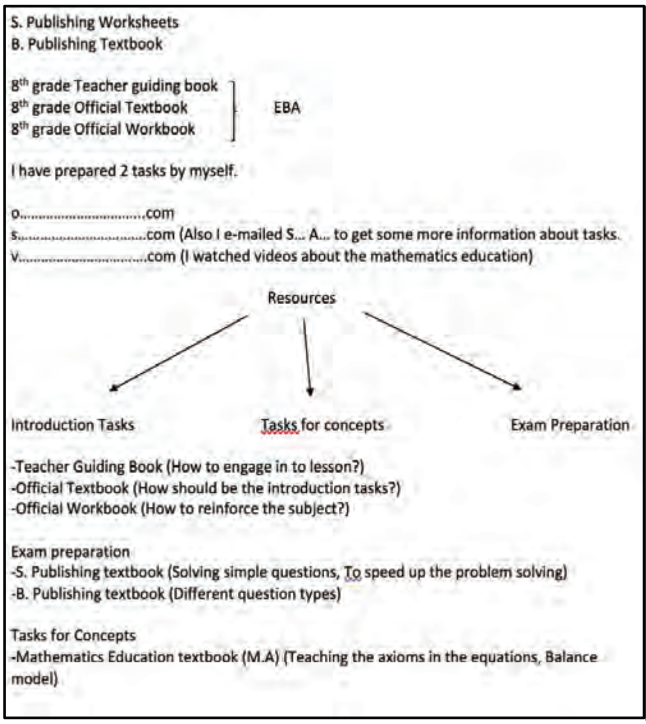
The audio-recordings and video-recordings of the interviews and lessons were transcribed. Initial coding was based on the resources and their usages of the participants. We focused on DAD's key processes- instrumentation and instrumentalization. When we realize that there could be such a process, we coded it accordingly and checked it in the recall session. Because there were a lot of data collection tools, we followed the instrumentation and instrumentalization processes during the coding. This is in line with Yin's (2009) approach about using a framework to be able to do systematic coding.

The use of various data collection tools was in order to enhance the trustworthiness of the findings. Triangulation was employed to cross-check the conclusions. The triangulation was between the interviews, observations, and recall sessions.

Findings

Teacher candidate phase

When Mary and Keira were teacher candidates, they were using smartboards in their teaching practice lessons. However, they both did not mention it in their SRRS diagrams (see Figure 3 and Figure 4).



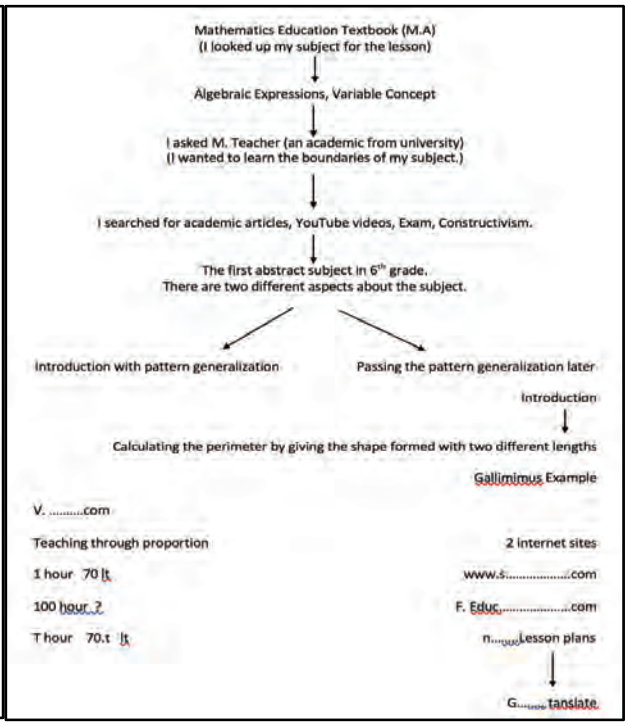


Figure 3: Mary's SRRS diagram **Figure 4: Keira's SRRS diagram**

In Mary's lesson in her teaching practice, she used a balance system to emphasize the inequality concept. Even if she utilized a special program in the smartboard, she used only the pictures to demonstrate the systems she would like to exemplify.

In Keira's lesson in her teaching practice, she used a picture and brought concrete material in the class. She utilized a special program in the smartboard, but she generally used the smartboard just for demonstration. Additionally, she used a concrete material of the picture she shared on the smartboard.

In the interviews, they both mentioned that they used a specific smartboard program to be able to teach an effective lesson. And they emphasized that both of them designed their sessions all by themselves. They mentioned only the resources they used while designing.

Teaching phase

Mary and Keira utilized the smartboard in their teaching, too. But this time, they both mentioned smartboard in their SRRS diagrams. In the teaching phase, according to lesson observations, they used interactive e-books in their lessons. But, while Mary's students have also textbook of the same e-book, Keira used the e-book only on the smartboard. Mary stated her situation as follows:

Researcher:	Mary, you use an e-book on the smartboard. But, as I see, the students follow the lesson from their own books. Did you arrange it?
Mary:	Yes, I asked them to buy this book. I also get the same book's teacher book version and e-book. Thankfully my students were able to get the book. Time is so important for us. And thanks to this e-book, I can complete all the aims in the curriculum. I also use another textbook with this e-book. When I want to give different examples about the national exams, I use that book. At that time, I close the smartboard and write the questions on the blackboard.

As it can be understood from the transcript, Mary combines the e-book with another book. But she used them for different aims. When she wants to solve harder questions for national exams, she closes the smartboard and the e-book for a while. In this situation, we can see the instrumentation process of DAD.

Also, Keira mentioned that her students could not get the students' book. That's why she explained that she could not use the students' book in the class. But she used the e-book for demonstration.

Researcher:	Keira, you use an e-book on the smartboard. But the students have another book, not the same as the e-book?
Keira:	Yes, I asked them to buy the students' book. But some of my students get and others were not able to buy the book. So, I cannot use the students' book in the class, but I use the e-book. At least I don't have to write the questions to solve on the board. I am already late in the curriculum.

It can be understood from the transcripts that they use the smartboard to gain time for the goals of the curriculum. When examining the transcripts, we can see that Keira limited her own usage of the e-book, because the students' book is not available for her students. This points out to instrumentation process of DAD. There were some notes on the teachers' book of Keira, which shows some definitions of mathematical concepts. In this case, we were able to see an example of the instrumentalization process, that Keira used her own definitions for the mathematical concepts in the teacher's book of her e-book.

Discussion and Conclusion

In this study, we aimed to investigate the digital and non-digital resources in the transition from being teacher candidate to teacher. As a result, one of the resources, the smartboard, remained the same for both of the participants. However, the usage of it differentiated when started teaching. They used interactive e-books in their teaching, even if they did not use any e-books before. Also, the way both participants use these e-books is different from each other. Mary, for example, used the smartboard for speeding up the problem-solving. However, Keira used it both for the e-book and as a music and video player. They basically explained that their initial aim is to be able to catch the curriculum (Şahin, 2010). In their opinion, the curriculum is congested and they have to catch the curriculum as well as they have to catch their colleagues.

In this study, instrumentation and instrumentalization processes were also detected. According to their own aims and knowledge, they were able to revise their resources (instrumentalization process). For example, Keira was noted her own definitions for some mathematical concepts on the e-book she used. Also, she noted some rhymes about divisibility rules to remember them quickly. And Mary noted her own draft exam questions on her teachers' book. And she presented them using the smartboard.

Also, they were able to revise their own lesson practice to use that specific resource they aimed to use (instrumentation process). For example, Mary used another textbook for the national exams, and she needed to close the smartboard for this usage. Since she was not able to use the other book on the smartboard, she closed it and continued with the blackboard. Even if she stuck to the e-book most of the time, she changed her own practice.

Therefore, it can be said that they used the smartboard just for demonstration while they were in the teaching phase. They did not use its qualifications as a smartboard. So, we can say that they used the smartboard as a resource when they were teacher candidates, but they just used it as an educational technology when they were teachers (Adler, 2000).

Another result is that teacher candidates tended to use university textbooks and the resources that their advisors suggested. When they became teachers, they tended to use the resources that their colleagues used and the ones accurate for the national exam system (Gueudet et al., 2013).

Acknowledgment

We would like to acknowledge to the 2211-A scholarship program for PhD students of TÜBİTAK for their precious support while doing this research.

MathMemeThon: how mathematical memes bring teachers and students together during Italy's pandemic lockdown

Giulia Bini[1]

[1]Department of Mathematics, University of Turin, Italy giulia.bini@unito.it

Keywords: Mathematical memes, boundary objects, learning across contexts, distance learning.

Introduction: a tale of two cultures

The global switch to distance education imposed by the Covid-19 pandemic in 2020 and 2021 dramatically exposed teachers' difficulties to engage students in a distance-learning setting, as acknowledged by recent studies (Bakker & Wagner, 2020; Fondazione Agnelli, 2021). Indeed, these difficulties are more related to the existing technological and cultural discontinuities between 21st-century learners and teacher-centred educators (Bronkhorst & Akkerman, 2016) than to the distance-learning setting enforced by the pandemic. Feedback collected from Italian teachers posting in social media groups on Facebook and from personal acquaintances evidenced that the majority of teachers simply moved their usual teacher-centred lessons from in-person to distance mode, resulting in one-way lessons with teachers lecturing passive students (often with no camera on), which dramatically failed in engaging learners. In other words, the pandemic just amplified malfunctions that were already there, making them clearly observable. It acted as the PCR, the Polymerase Chain Reaction used in molecular biology to amplify DNA samples: now these malfunctions are evident and we can observe them and act on them. One possible way to act on them, bridging the discontinuities and engaging students both in-person and in distance-mode learning settings, is by challenging the dichotomy between the two cultures represented by in-school formal learning and out-of-school informal learning. This can be done, among others, by importing a product of the out-of-school digital culture, such as mathematical Internet memes, into the in-school formal learning environment.

What are mathematical Internet memes?

Internet memes are digital objects pervasive on the Web (221 million occurrences of the hashtag #memes on Instagram in February 2022) created by Internet users adding original humorous captions to existing popular images. Mathematical Internet memes are mathematical mutations of Internet memes: they combine mathematical and memetic elements to produce hybrid representations of mathematical statements, endowed with an epistemic power to initiate argumentation processes among users inside dedicated online communities (Bini et al., 2020). Despite these evident potentialities, mathematical memes are still widely understudied in mathematics education.

The activity: theoretical framework, research question, methodology and results

In 2020, Bini and Robutti conducted an exploratory study on mathematical memes as boundary objects (Star & Griesemer, 1989) between the communities of students and teachers during in-person school activities. The purpose of this work is to move forward along this line of research, investigating if mathematical memes can "fulfil a bridging function" (Akkerman & Bakker, 2011, pp. 133) between students and teachers also in distance-mode settings. The study is guided by the research question: Can mathematical memes act as boundary objects between students' informal out-of-school culture and teachers' formal in-school mathematical culture in distance-mode activities? Mathematical memes' boundary-crossing nature has been taken into account in two different ways in designing the activity: (1) the task design requested students to create a composite object, i.e. a mathematical meme *and* a presentation providing a brief insight into the mathematical content, and (2) during the activity the author acted as a boundary broker, facilitating the "processes of translation, coordination and alignment between perspectives" (Wenger,1998, p. 109). The result is MathMemeThon, a distance learning activity with mathematical memes, structured as a team competition inspired by a computer hackathon. The activity took place in the second quarter of the 2020/21 school year, involving 7 class groups of 9th grade students (15yo) and 2 class groups of 10th grade students (16yo), for a total of about 180 students and 6 teachers from 3 different institutes located in Piedmont, in the north of Italy. It developed in three online meetings of 2 hours each, where students teamed and competed creating mathematical memes and presentations, and sharing them online on Padlet walls. Students' productions were then presented remotely via WebEx to a jury of experts made up of teachers, Master and PhD students of mathematics, who judged the productions evaluating the mathematical and memetic content and the quality of the presentation. Memes were then shared on the project's Instagram page (https://www.instagram.com/lifeonmath/).

Observations of the interactions and feedback from teachers and students showed that, even in the distance learning setting, the hybrid language of mathematical memes succeeded in connecting the two communities: teachers appreciated the idea of communicating mathematics through an object "very close to the world of students", and students valued the fact "it was necessary to give importance to the mathematical content but at the same time to find the right idea to create the meme".

An exploration of the use of structured reflection tasks to surface prospective teachers' awareness of TPACK

Aibhín Bray[1] and Elizabeth Oldham[2]

[1]Trinity College Dublin, the University of Dublin, Dublin, Ireland; brayai@tcd.ie

[2]Trinity College Dublin, the University of Dublin, Dublin, Ireland; eoldham@tcd.ie

Keywords: Reflection, TPACK, prospective teachers.

Introduction

This study focuses on undergraduate mathematics students in an Irish university who choose to take a module on mathematics education – as part of their academic course, not in an initial teacher education (ITE) programme; thus, the students can be considered as *prospective teachers*. Among the assessment elements for the module is a small component consisting of tutorial exercises. One exercise sets out some structured, technology-facilitated mathematical tasks, involving use of a spreadsheet (Excel), a function graphing and dynamic geometry package (GeoGebra), and a simple programming language (Scratch); the students do the tasks and then post written reactions and reflections to the module's discussion board. The tasks are framed for the students by the overarching idea that – appropriate – use of technology can support, enhance or change teaching and learning, and also by Taylor's (1980) simple but enduring *tutor, tool, tutee* classification (with the tutorial exercise involving the tool and tutee roles). However, the students have not been introduced to the Technological, Pedagogical and Content Knowledge (TPACK) framework (Herring et al., 2016).

Although the section of the module is short (two or three lectures and one tutorial exercise), it has produced insightful reflections from participants over the years. This prompted the research question: Do the tasks involving structured activities and reflections enable prospective teachers, in particular those who took the module in 2019-2020, to surface tacit awareness of components of TPACK?

Theoretical framework

The theoretical framework for the study is founded in the various technological components of TPACK (Herring et al., 2016): Technological Knowledge (TK), Technological Content Knowledge (TCK), Technological Pedagogical Knowledge (TPK), and Technological Pedagogical Content Knowledge (TPACK). The latter denotes the knowledge required by teachers for the effective integration of technology into their teaching in any content area. Teachers who display TPACK demonstrate a good understanding of the complex interplay between technological, pedagogical and content knowledge, by teaching content using appropriate pedagogical methods and technologies.

Methodology

Ethical clearance was granted, and signed consent forms were returned by 18 of the 25 students taking the module in 2019-2020. Fourteen of them contributed to the discussion board for this task.

Directed Content Analysis (Hsieh & Shannon, 2005) was used on the texts of the (n=14) posts, using the definitions of the four technological components of TPACK as outlined on www.tpack.org. Thus, the analysis aimed to identify instances where the students displayed TK, TCK, TPK, or TPACK.

Results

In total, 48 sections of text were coded in relation to the TPACK framework. Of the 48 codes, 15 showed evidence of students' TPACK, for example (from student 7):

> These graphing programmes certainly have a role to play in the teaching of school mathematics. Such educational tools help students to visualise mathematics in a more relatable manner, hence strengthening the understandings of mathematical concepts. For instance, first-year groups were introduced to Scratch and encouraged to learn about geometric shapes and their properties by using the tool, thus making the learning of abstract concepts more meaningful.

Here the student is clearly considering the role of technology in relation to different representations of content, as well as showing an understanding of how it might change the way the students learn. Regarding TCK, there were 16 instances, such as the following, in which student 12 reveals an understanding of how GeoGebra can be employed to create new representations of content:

> …very valuable as a tool in teaching maths, especially in terms of coordinate geometry and the links between algebraic expressions and their geometric realisations. For example, it could […] be used to explore the relationship between the coefficients of a function and the shape [of] its graph.

A further 12 sections of text were coded as TPK, illustrating both a knowledge of how technology can be used in teaching and an understanding of how its use may change teaching and learning. Student 5 posted:

> … the students being able to visualize it easier because of the spreadsheet would help and it might also help students that are not very good at computations in maths gain confidence if they could see that they could understand what's happening even if they couldn't do the calculations by hand.

Only five instances of TK were identified, such as (from student 6): "When creating worksheets, GeoGebra is a very accessible tool which makes diagrams clear and easy to paste into a document." This is indicative of an appreciation of how technology can be used for a simple educational goal.

Conclusions and implications

This research has identified the potential of using structured tasks, followed by reflection and analysis, to surface prospective teachers' awareness of TPACK concepts. We propose that the process could be effectively integrated into ITE programmes to expose students to the framework in a way that makes it accessible and personal. Having completed the structured tasks and reflections, the students would be introduced to the TPACK framework and asked to analyse their own reflections. We aim to conduct further research using this model with post-graduate students enrolled in ITE.

Teachers' knowledge for supporting transitions between dynamic digital technologies and static environments

Nicola Bretscher

University College London, Institute of Education, London, UK; n.bretscher@ucl.ac.uk

This paper explores teachers' knowledge for supporting students to transition between technologies, for example, moving between using dynamic digital technologies and using static environments for mathematics. The TPACK framework is used to explore such knowledge through an examination of one teacher's frustration with the 'rigidity' of angle definition and measurement in GeoGebra, expressed in a task-based interview on circle theorems, compared with the relative 'flexibility' of a static environment. The nature of the central TPCK construct is discussed and implications for teacher education are identified.

Keywords: teacher knowledge, dynamic technology, circle theorems

Introduction

This study investigates the nature and content of teachers' mathematical knowledge for teaching circle theorems using dynamic digital technologies, such as GeoGebra. The specific knowledge required for teaching mathematics with technology has been a long-term interest in TWG15 (Clark-Wilson et al., 2019). Less commonly, research has focussed on teachers' knowledge for supporting students to bridge or transition (Geraniou & Mavrikis, 2015) between technologies, for example, moving between using dynamic digital technologies and using static environments for mathematics. Hence this study focuses on investigating what knowledge enables teachers to support transitions between dynamic and static environments in their teaching of circle theorems. The main research question is: what is the nature and content of teachers' mathematical knowledge for teaching circle theorems using dynamic digital technologies? The sub-question is: what knowledge enables teachers to support transitions between dynamic and static environments?

Theoretical background

Mathematical knowledge for teaching, as defined in this study, is when tacit knowledge-in-action (Ruthven, 2014) is underpinned by and coincides with a teacher's articulated knowledge that provides for "a rational, reasoned approach to decision-making" (Rowland et al., 2005, p. 260). The *Technological Pedagogical and Content Knowledge* (TPACK) framework is suitable for this study because the framework enables a focus on teachers' mathematical knowledge for teaching *situated* in a technological context (Mishra & Koehler, 2006). In this study, the central TPCK construct is viewed as a new domain of synthesised knowledge, that is, a transformation (Rowland et al., 2005) of mathematical knowledge for the purpose of teaching using technology. This paper focuses on the dyadic construct TCK (technological content knowledge) as a means of exploring, by comparison, the nature and content of the central TPCK construct. Mishra & Koehler (2006) define TCK as knowledge about how technology and content influence and constrain one another; that is, how the mathematical content can be changed by the application of particular technologies. For example, dynamic digital technologies, such as GeoGebra, embed mathematical rules in their design, constraining the user to obey these rules e.g. by imposing an explicit order in constructing geometric figures (Jones, 2000). This mathematical rigidity may be fruitful in supporting the user to appreciate and explore the rules embedded. By contrast, a static environment, such as paper-and-pencil, is relatively flexible, allowing the user to draw mathematical 'sketches' without the necessity of obeying a specific set of mathematical rules. An appreciation of how different environments provide contrasting representations of mathematics exemplifies the TCK construct. An appreciation of how to capitalise on such contrasting representations for the purposes of teaching, e.g. to support pupils' transitions between environments, would exemplify the TPCK construct. Adler's (1999) dilemma of transparency provides a means of explaining why teachers' knowledge might enable them or not to support transitions between dynamic and static environments.

Methodology

As part of a larger doctoral study (Bretscher, 2015), four case study teachers were selected, as self-described technology enthusiasts confident in the use of technology, to take part in semi-structured interviews based around a GeoGebra file on circle theorems. As enthusiasts, the case study teachers were likely to display mathematical knowledge for teaching using technology. The semi-structured interviews provided a common situation across which the case study teachers' mathematical knowledge for teaching using technology could be contrasted. Examples of TCK were identified where a teacher's articulated knowledge and knowledge-in-action coincided to place emphasis on technology and mathematical content when addressing a situation involving a synthesis of mathematical, pedagogical and technology knowledge. The case study teachers were prompted to show (knowledge-in-action) and discuss (articulated knowledge) how they would use diagram D1 presented in the GeoGebra file (see Figure 1) to demonstrate that the angle at the centre of the circle, subtended by an arc, is double the angle at the circumference subtended by the same arc.

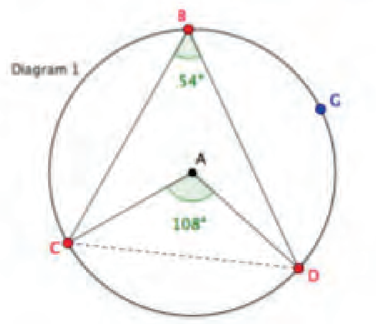

Figure 1: Diagram D1 in the GeoGebra interview file on circle theorems

Diagram D1 was designed to be similar to resources found on a web-search. Circle theorems were chosen since it is a topic, in the English mathematics curriculum, which is commonly identified with the use of dynamic geometry software (Ruthven et al., 2008). It was therefore reasonable to assume that the case study teachers would be familiar with technological resources similar to D1 and might even have previously used such resources in their own teaching. Thus, they would be likely to have some mathematical knowledge for teaching circle theorems using the GeoGebra file, even if they were unfamiliar with the particular software. In addition, the topic of circle theorems is at the apex of geometry in the compulsory English mathematics curriculum, hence it provided a potentially challenging context even for experienced teachers who were both mathematically and technologically confident.The semi-structuring of the interview allowed some flexibility to respond to events during the interview, whilst maintaining an overall structure that would allow for and facilitate comparison. Both the visual and audio aspects of the GeoGebra interviews were recorded and analysed. This paper focuses on one of these case study teachers, Edward, whose expression of frustration at the way angles are measured in GeoGebra provided a particularly illuminating example of TCK.

Defining angles in GeoGebra: Edward's dilemma

The analysis presented in this section focuses on an indicative example of TCK, from Edward's interview, as a means of exploring the nature of the central TPCK construct.

Edward was prompted to question how angles are defined for the purposes of measurement in GeoGebra by unexpected configurations of D1 appearing during dragging, displaying the 'incorrect' angle at the centre (see Figure 2). After experimenting by dragging points C and D, Edward concluded the angle measured at the centre was dependent on the relative position of points C and D. More specifically, in GeoGebra the angle measured at the centre in D1 is defined by specifying the ordered triad of points CAD and measured anticlockwise from the line segment AC to the line segment AD. Thus, when the relative positions of C and D are reversed, as in Figure 2, the angle appears to 'flip' between being less than 180 degrees and being reflex.

D1 had been designed so that, whilst the angle at the centre could become reflex, the angle measured at the circumference was constrained to be less than 180 degrees whatever the relative position of points C and D. Hence the 'correct' angle at the circumference in relation to the circle theorem was always displayed, however some configurations of D1 displayed the 'incorrect' angle at the centre. Edward's questioning of how the software defines and measures angles and his realisation of the angle at the centre's dependence on the relative positions of C and D is an example of TCK because it shows a developing understanding of how the GeoGebra software models geometric concepts and relations.

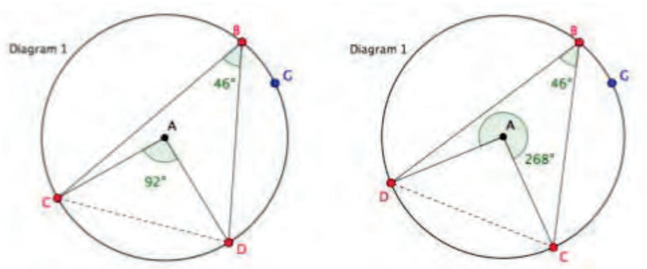

Figure 2: Angle measurement and reversing the relative positions of C and D

For Edward, the software's definition and measurement of angles was a source of frustration, appearing idiosyncratic in the way D1 'flipped' between displaying the correct and the incorrect angle at the centre. He argued:

E: ... this is sort of a function of how the software works isn't it, rather than a ... is that bringing out anything useful mathematically that ... that's just a bit annoying the way it does that, isn't it?

His frustration with angle definition in the software led him to suggest that, for proof, he would prefer a static environment: “I’d project this on the whiteboard […] and then mark on the angles that I want”. Implicitly, Edward compared the difficulties he faced understanding how angles are defined in GeoGebra to the flexibility of being able to mark the angles that he wants in a static environment. Diagrams presented in software such as GeoGebra are constrained to follow the rules for defining angles that have been programmed into that piece of software. One of the affordances of drawing diagrams without digital technologies is that the relevant angles of the circle theorem may simply be marked on a diagram with a brief stroke of a pen or pencil, without needing to consider how they are defined precisely. It is not that a precise definition of the angles does not exist or is not necessary in a paper-and-pencil environment, of course, but that often it does not appear necessary to give it explicit consideration.

A case where it might be necessary to give explicit consideration to a precise definition of the angles, even in a static environment, would be when giving a full statement of the circle theorem, rather than a commonly-used, abbreviated form such as ‘the angle at the centre is double the angle at the circumference’. For example, a full statement of the circle theorem is ‘the angle subtended at the centre by an arc is double the angle subtended at the circumference by the same arc’. The difference between the abbreviated form and the full statement is in the specification that the two angles must be subtended from the same arc. More specifically, using the full statement of the theorem clarifies which is the ‘correct’ and ‘incorrect’ angle at the centre.

In his initial discussion of D1, Edward assumes the angles are defined as being subtended by the chord CD:

E: ... so what it shows is the angle subtended at the circumference by chord CD is always twice the angle at the centre, irrespective of where B is.

Defining the two angles as subtended from the chord is unproblematic as long as the two angles remain in the same segment; however, when they are in opposing segments the theorem appears to break down (see Figure 3 a and b).

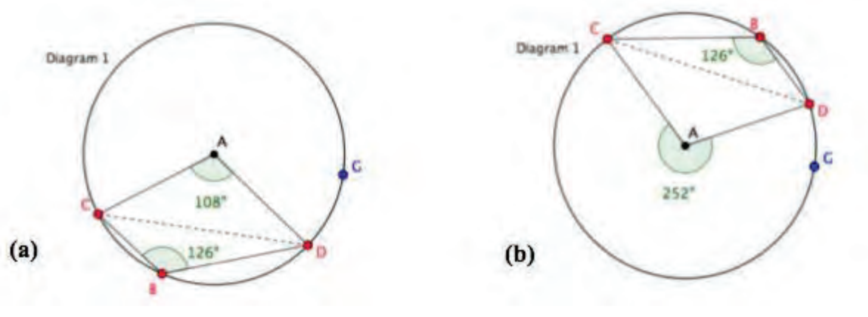

Figure 3: Angles in the opposite segments with (a) the ‘incorrect’ angle at the centre displayed and (b) the ‘correct’ angle at the centre displayed.

The situation where the two angles appear in opposing segments occurred twice during Edward’s GeoGebra interview. Firstly, as depicted in Figure 3 (a), it occurred where the ‘incorrect’ angle at the centre is shown, assuming the angles in the circle theorem are defined as being subtended from the same arc. He had anticipated this case to some extent. Thus, for Edward, this case was not unduly problematic and did not disrupt his statement of the circle theorem defining the angles as subtended from the chord CD, as the quote below suggests:

E: And then if you drag B this side [onto the minor arc CD], then suddenly it goes from 54 to 126. So ... uh ... what's happening there? So ... uh ... what's happening there is the angle on the other side of the 108 is now double the angle at the centre, the angle at the circumference ... but it's not showing on the diagram, the computer's not showing that other angle ... but you can calculate it as 360 – 108, so 252. And 252 is double 126. Yeah.

Instead, he called this case a "complication", suggests "ignoring" it at least initially with pupils, and refers to the 'correct' angle at the centre, measuring 252 degrees, as "the reflex angle". His treatment of the case in Figure 3 (a) as a sort of deviant example or extension of his statement of the circle theorem, where the angle at the centre is reflex, avoided a mathematical critique of his definition of the angles being subtended from the chord. However, the situation arose for a second time, similar to Figure 3 (b), where the 'correct' angle at the centre is shown, assuming the angles in the circle theorem are defined as being subtended from the same arc. This time, the situation was unexpected and troubling for Edward. In particular, it led him to question his previous definition of the central angle as being subtended by the chord CD. The following quote indicates his struggles as he attempted to find a correct mathematical interpretation of this configuration of D1, see Figure 4 for the numerical example he discusses at the start:

E: Um ... so ... let's take an example ... so 94 doubled is 188, so it's still true that ... so that angle is twice that angle. But uh ... how do you know it was that angle ... so the computer is kind of showing you the right angle for what it's working for isn't it? But in words, how do you explain what that angle is, it's not really the angle that chord CD is subtending at the centre is it? Because it's that ... chord CD is subtending that angle at the centre, so suddenly you have to say it's the other angle, the reflex angle at the centre that's subtending. So... so CD is subtending 99 at the circumference and, ... er ... the reflex angle is 198 yeah. Uh ... which is not a very good explanation. [E laughs]

At the end of this quote, Edward tries to re-state the theorem using a particular numerical example, taking into account his realisation that the 'correct' angle at the centre was not, as he previously assumed, the angle subtended by the chord CD. He struggles, eventually settling for "the reflex angle", whilst acknowledging this seemed inadequate.

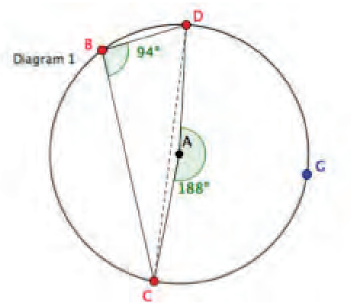

Figure 4: Edward's angle definition dilemma

Returning to Edward’s frustration at the apparently idiosyncratic way GeoGebra defined and measured the angles in D1, the discussion above shows that instead of being “just a bit annoying”, the way GeoGebra defines and measures angles *does* bring out something mathematically useful. The variation in whether the ‘correct’ or ‘incorrect’ angle is displayed in D1 provides a means of discussing how angles are defined in other contexts and, in particular, how the angles referred to in the (abbreviated) ‘angle at the centre is double the angle at the circumference’ circle theorem are defined precisely in a full statement of the theorem. Articulating a strategy to use the way GeoGebra defines angles to raise these issues for the purposes of teaching circle theorems would be an example of TPCK. Such a strategy would not appear to depend on integrating pedagogic knowledge with TCK. Instead, it requires mathematical knowledge regarding the precise definition of the angles in a full statement of the angle at the centre circle theorem. Hence, TPCK appears to be mathematical knowledge, abstract in the sense that it generalises across particular technological contexts and mathematical topics. For example, a precise definition of the angles in a full statement of the angle at the centre circle theorem should hold both in the context of using GeoGebra or a paper-and-pencil environment.

However, TPCK also appears simultaneously to be mathematical knowledge *situated* in the context of teaching using technology. The issue of how angles are defined appears more salient and even surprising – for Edward at least – in the context of GeoGebra. In addition, at the time, the high-stakes GCSE (General Certificate of Secondary Education) examinations in England only required pupils to state an abbreviated form of the circle theorems. As a result, it is possible that the case study teachers were unaware of a precise definition of the angles in a full statement of the angle at the centre circle theorem. Hence, an individual teacher’s TPCK may also be seen as situated in the examination system and national curriculum of the country in that teacher is working. This argument suggests that TPCK is a synthesis of mathematical, pedagogical and technological knowledge, highlighting its situated nature as a transformation of mathematical knowledge for the purposes of teaching using technology.

In summary, the central TPCK construct is exemplified as having teaching strategies for exploiting the opportunities that arise from contrasting and complementing the affordances and constraints of different technologies, in this case, the mathematical rigidity of angle measurement in GeoGebra relative to the flexibility of paper-and-pencil environment. Using such teaching strategies and making affordances and constraints of technologies explicit to pupils should support them in transitioning between different technologies.

Discussion

In this section, I apply Adler’s (1999) dilemma of transparency to explain Edward’s frustration further and so identify implications for teacher education. Adler (1999) uses Lave and Wenger’s (1991) notion of transparency to describe teachers’ dilemmas in negotiating the dual visibility and invisibility of talk as a resource in the practice of school mathematics. In this paper, the notion of transparency is applied to the use of technology as a resource in the practice of school mathematics. Adler (1999) describes Lave and Wenger’s use of the metaphor of a window to explain their notion of transparency:

> Lave and Wenger (1991) used the metaphor of a window to clarify their concept of transparency. A window's invisibility is what makes it a window. It is an object through which the outside world

becomes visible. However, set in a wall, the window is simultaneously highly visible. In other words, that one can see through it is precisely what also makes it highly visible.

Thus, technology as a teaching resource for mathematics needs to be simultaneously both visible, so that it can be noticed and used in the practice of school mathematics, and invisible so that attention is focused on the subject matter of mathematics and not solely on the technicalities of the environment. The particularities of using a specific technology to teach mathematics influences the mathematics that can be taught. For example, sketch diagrams in paper-and-pencil environments are relatively flexible in that they do not have to obey fixed rules in relation to defining and measuring angles. The flexibility of the paper-and-pencil environment affords the user the freedom to imagine they are working in an ideal mathematical world, where geometric relationships embedded in figures can be imagined without being weighed down by rigid rules of construction and where perfect circles, exact angle measurement, circle theorems and proof 'exist'. Diagrams in GeoGebra appear more mathematically rigid in this respect, hence Edward's irritation with the software. However, this rigidity can be useful in forcing attention to mathematical details, such as defining angles, which the sketch diagram in a paper-and-pencil environment allows the user to elide. Similarly, the window frame, its shape and positioning on the wall, influences which part of the outside world can be seen. Thus, teachers need to understand the significance of the particular technology for the mathematics they are teaching: the technology requires teachers' explicit attention, it needs to be visible. In this sense, mathematical knowledge for teaching using technology is always situated, since the technological context in which it is being applied is central to its meaning. Simultaneously, technology should enable the teaching of mathematics, in this case the GeoGebra software should enable the teaching of circle theorems and should thus be invisible. It is the window through which mathematical knowledge can be seen: the GeoGebra software is a means of controlling numerical and geometric variation so that pupils are exposed systematically to examples of the circle theorem. Here, mathematical knowledge for teaching using technology appears more abstract, allowing teachers to make mathematical connections across technological contexts.

Adler's description of a dilemma of transparency where the teacher manages talk as a classroom resource, so that it is neither too visible for pupils, obscuring the mathematical subject matter, nor too invisible so that they are unable to access it, has some explanatory value for this study. However, here, the dilemma is managing technology so that it does not become too visible for teachers, obscuring mathematical knowledge for teaching using technology, nor too invisible, so that teachers assume that technology can be used unproblematically for teaching mathematics. For example, on the one hand, Edward's irritation with the definition and measurement of angles in GeoGebra indicated that the software was too visible for him. In this case the GeoGebra software obscured his access to mathematical knowledge for teaching using technology, leading him towards rejection or restriction of technology use. On the other hand, the case study teachers' lack of awareness of how dragging imposes a particular order on how different configurations of the circle theorem arise (reported elsewhere, e.g. in Bretscher, 2015) provide an instance where technology seems too invisible. Here, the unintentional pedagogic structuring of mathematics suggests that the technology has become too invisible, with an assumption that technology provides unproblematic access to mathematical knowledge for teaching. The implication for teacher education is that they need to help teachers manage the dilemma of transparency. That is, just as teachers need to making affordances and constraints of technologies explicit to pupils, teacher educators need to make affordances and constraints of technologies explicit or ‘visible’ to teachers. In addition, teacher educators need to support teachers in identifying teaching strategies that exploit the contrasts and complementarities of different technologies, such as dynamic digital technologies and static paper-and-pencil environments, so that the technology becomes ‘invisible’ and just another resource for teaching mathematics.

How do pre-service teachers evaluate dynamic worksheets for learning functional relationships?

Alex Engelhardt[1] and Jürgen Roth[2]

[1]University of Koblenz-Landau, Campus Landau, Germany; engelhardt@uni-landau.de

[2]University of Koblenz-Landau, Campus Landau, Germany; roth@uni-landau.de

The appropriate choice of media is a key task in lesson planning. In the past years, there have been several studies which indicated potential in the use of digital media in the classroom. Nevertheless, these technologies are rarely used in everyday teaching. While one initially thought that this was due to the lack of infrastructure, it seems to be more due to a lack of skills. For this reason, the present study investigates what skills teachers need in order to teach functional relationships with dynamic worksheets, what skills pre-service teachers already possess and how these can be fostered.

Keywords: Dynamic worksheet, (technological) pedagogical content knowledge, pre-service teacher training, functional relationships, qualitative research

Theoretical background

Lesson planning is a daily and important part of teachers' work. Here, the choice of appropriate media is a key task, especially when the aim is on achieving mathematical learning goals. From a theoretical point of view, dynamic worksheets have high potential for developing functional thinking as seen with Lichti & Roth (2018). A dynamic worksheet consists of an applet (dynamic figure constructed with GeoGebra which is often embedded in a web page) and accompanying tasks and/or explanations (Hohenwarter & Preiner, 2008, p. 318).

The ability of evaluating dynamic worksheets for learning functional relationships

With the TPACK model, Mishra and Koehler (2006) have created a framework for what teachers need to know in order to use technology in a meaningful way. In order to adapt this framework to the ability of evaluating dynamic worksheets for learning functional relationships, the special features of developing functional thinking were brought into connection with the features of dynamic mathematics software like GeoGebra. In addition, e-learning principles according to Mayer (2009) were considered, as the extraneous cognitive load in dynamic worksheets "should be small in order to foster more effective learning of mathematical concepts" (Hohenwarter & Preiner, 2008, p. 314). As a result, five main aspects are identified: Learning goals, representations, interactivity, tasks and multimedia principles. These five main aspects and their sub-aspects have been validated by experts (N=14) for adequacy and completeness.

Research questions

The study aims to describe how pre-service teachers engage in evaluating dynamic worksheets and enhance pre-service teachers' ability of evaluating dynamic worksheets. Resulting research questions are:

1. How do pre-service teachers engage in the evaluation of dynamic worksheets?
2. How does training influence the way pre-service teachers engage in the evaluation?

3. To what extend can the ability of evaluating dynamic worksheet be promoted?

Method

Data collection runs in two parts. During the entire duration, the students' screen is recorded. In the first part, the students are encouraged to think aloud, as this method enables the reconstruction of thought processes (Wallach & Wolf, 2001) and thus resembles a simulated lesson preparation.

Specifically, the students are asked to evaluate a dynamic worksheet in relation to a given learning goal for its use in the classroom. In the second part, a pre-structured guide is used to give students a reflection scheme as a scaffold. In this way, differences within a data collection can be investigated and the data collection itself can serve as a learning opportunity. Data will be collected at three different times during a teaching-and-learning-lab course in which students are trained to evaluate and develop dynamic worksheets.

Data will be analyzed with qualitative content analysis (Kuckartz, 2018), with the aim of a potential type-building of how students proceed when evaluating dynamic worksheets. In addition to the interview and think aloud data, students' topic-specific PCK and CK, previously GeoGebra experience and teaching experience are collected as secondary features.

Expected Results

A pilot study indicated that students tend to address only superficial features of applets, especially in earlier stages of the course. Deepener argumentations and suggestions for improvement were more frequently found in later stages of the course. Furthermore, it seems that in later stages of the course students find relations between different aspects.

Prospective teachers designing tasks for dynamic geometry environments

Maria Fahlgren[1], Attila Szabo[2], and Mirela Vinerean[1]

[1]Karlstad University, Department of Mathematics and Computer Science, Sweden; maria.fahlgren@kau.se, mirela.vinerean@kau.se,

[2]Stockholm University, Department of Mathematics and Science Education, Sweden; attila.szabo@edu.stockholm.se

The paper examines the quality of digitized tasks designed by 10 (small) groups of prospective upper secondary school teachers as part of a geometry course assignment. The results indicate that a small instructional intervention, addressing the planning and implementation of tasks in digitized task environments as well as how to stimulate students to make mathematical generalizations, led to a relatively high proportion (8 out of 10) of high-quality tasks designed by the prospective teachers.

Keywords: Task design, dynamic geometry environment, prospective mathematics teacher.

Background

Dynamic Geometry Environments (DGEs) have been used as educational tools for several decades (Sinclair et al., 2016). Mainly, it is the dragging function that is regarded as the defining feature of a DGE. By dragging points linked to geometrical objects, students can interact with these objects to search for regularities and invariances and to generate conjectures (e.g. Leung, 2011).

However, to utilize the potentials provided by DGEs, there is a need for carefully designed tasks. Indeed, designing DGE tasks or even evaluating existing tasks is not easy for teachers (Trocki & Hollebrands, 2018). To address this issue, researchers suggest models or principles for designing tasks that take advantage of DGEs as tools for exploration that might lead to conjectures, explanations and proofs (e.g. Fahlgren & Brunström, 2014; Leung, 2011). For example, Leung (2011) suggests a task design model composed of three epistemic modes that resemble different phases of the proving process: exploration, re-construction and explanation. These three modes are sequentially nested in the sense that one mode is a precursor for the next mode, which in turn, is a cognitive extension of the previous one. In this way, "…this task design model can be seen as a vehicle to carry the acquisition of mathematics knowledge." (Leung, 2011, p. 328).

In recent years, there has been an increasing interest in how to support teachers in their process of designing DGE tasks (e.g. Komatsu & Jones, 2019; Trocki & Hollebrands, 2018). While the study by Komatsu and Jones concerns specific task design principles to engage students in heuristic refutation, Trocki and Hollebrands provide a more generic framework with the intention to serve as guidance for teachers "…both for identifying and for writing high-quality tasks for DGSs [i.e. DGEs]." (p. 111). This framework, entitled the Dynamic Geometry Task Analysis Framework, is inspired by Smith and Stein's classification of tasks based on the level of cognitive demand that they require (Smith & Stein, 1998) as well as theories linked to various technological action linked to DGEs. Although Trocki and Hollebrands demonstrate the effect of the framework on teacher knowledge for recognizing and designing DGE tasks, they argue that this is only the beginning because there is a need for more research on investigating the usefulness of the framework (Trocki & Hollebrands, 2018).

Bozkurt and Koyunkaya (2020) address this request by investigating how prospective mathematics teachers (PMTs) developed their task design skills in DGE during a period of 14 weeks. Their study involved three cycles: (a) seminars on task design, followed by design of DGE tasks, (b) implementation of peer micro-teaching, followed by task revision, and (c) implementation in classrooms. Besides using Trocki and Hollebrands' (2018) framework as instructional material to develop the PMTs' skills in designing DGE tasks, the framework was used as a research tool to analyse task prompts as well as the questions posed and responses made by the PMTs during their teaching practices (Bozkurt & Koyunkaya, 2020). The micro-teaching cycles revealed that the PMTs were unable to reach neither the mathematical depth nor the technological actions that they planned for. However, Bozkurt and Koyunkaya found an improved development in PMTs' classroom practices after the micro-teaching. Having participated in each other's micro-teaching lessons, including follow-up discussions, the PMTs revised and developed their DGE tasks. Accordingly, Bozkurt and Koyunkaya suggest micro-teaching as an important component in teacher education courses aiming to develop PMTs' technology integration skills (2020). Moreover, they confirm the usefulness of the framework by Trocki and Hollebrands, both as instructional material and as a research tool.

In a similar study, Gulkilik (2020) examined DGE tasks designed by PMTs. The focus of this study was to examine in detail how PMTs' DGE tasks supported students' "…acquisition of mathematics knowledge"…(p. 2). To enable this, Gulkilik used Leung's (2011) model for task design. The PMTs were introduced to Leung's model and asked to analyse sample DGE tasks to examine their potential of engaging students in activities such as exploration, re-construction, and explanation, which relate to the three epistemic modes in Leung's model. In line with Bozkurt and Koyunkaya (2020), the PMTs implemented their designed tasks in micro-teaching with peers acting as students. To analyse the PMTs' tasks, Gulkilik developed a coding manual with descriptors related to each of the three epistemic modes as well as the transition between them, which enabled "…a continuous description of how PMTs guided students to mathematical understanding in DGE tasks." (2020, p. 13). One prominent finding was that the focus of the PMT tasks was on the construction of geometrical objects, i.e. without using pre-constructed sketches. Instead, the tasks included step by step instructions to build robust constructions, i.e. constructions were the properties are perceived under dragging. In this way, Gulkilik argues, the focus of the PMTs' tasks were limited to observe and explain invariants in the first constructed object, and "…did not utilize the potential of DGE to engage students in terms of exploration, re-construction, predicting, conjecturing, or proving…" (2020, p.13), i.e. activities for knowledge acquisition in DGE according to Leung's model (2011). Overall, the literature highlights the need for more research on task design within DGE to utilize the potential of the technology to reach a deeper mathematical understanding (Sinclair et al., 2016).

Dynamic Geometry Task Analysis Framework

Trocki and Hollebrands' (2018) framework consists of two components: mathematical depth and technological affordances (see Table 1). Central in the framework are the prompts, i.e. questions or directions that require written (or oral) responses and/or technological actions. Besides the prompts, a DGE task most often includes a pre-constructed or partially constructed sketch of a geometrical object (Trocki & Hollebrands, 2018).

Table 1: Dynamic Geometry Task Analysis Framework (Trocki & Hollebrands, 2018, p. 123)

Allowance for Mathematical Depth		Types of Technological Action	
Levels	**Descriptions**	**Afford -ances**	**Descriptions**
N/A	Prompt requires a technology task with no focus on mathematics.	N/A	Prompt requires no drawing, construction, measurement, or manipulation of current sketch.
0	Prompt refers to a sketch that does not have mathematical fidelity.	A	Prompt requires drawing within current sketch.
1	Prompt requires student to recall a math fact, rule, formula, or definition.	B	Prompt requires measurement within current sketch.
2	Prompt requires student to report information from the sketch. The student is not expected to provide an explanation.	C	Prompt requires construction within current sketch.
3	Prompt requires student to consider the mathematical concepts, processes, or relationships in the current sketch.	D	Prompt requires dragging or use of other dynamic aspects of the sketch.
4	Prompt requires student to explain the mathematical concepts, processes, or relationships in the current sketch.	E	Prompt requires a manipulation of the sketch that allows for recognition of emergent invariant relationship(s) or pattern(s) among or within geometrical object(s).
5	Prompt requires student to go beyond the current construction and generalize mathematical concepts, processes, or relationships.	F	Prompt requires manipulation of the sketch that may surprise one exploring the relationships represented or cause one to refine thinking based on themes within the surprise (adapted from Sinclair (2003, p. 312).

While the levels (0 to 5) of mathematical depth that a prompt allows reflect the progression of cognitive demand, the descriptors for technological actions (A to F) reflect the potential of using a DGE. It is the degree of coordination of mathematical depth and technological actions that indicate the quality (low, medium, high) of a DGE task (Trocki & Hollebrands, 2018).

Trocki (2015) reports findings from case studies involving three in-service teachers and three prospective teachers. Mainly, the research setup involved three parts: (a) design of a DGE task (with a given learning goal), (b) a tutorial session introducing the framework, and (c) redesign of the DGE task. By using the framework, Trocki found that all tasks redesigned by the participants increased their ranking to the highest level. Among the initial versions of the task, all (except for one) ranked medium in quality. Based on these findings, Trocki and Hollebrands suggest that the framework can serve as a useful tool in teacher education programs (Trocki & Hollebrands, 2018).

We had occasion to investigate this issue as part of a geometry course for prospective secondary and upper-secondary mathematics teachers. In contrast to the studies by Bozkurt and Koyunkaya (2020) and Gulkilik (2020), we only had a very limited amount of time at our disposal; one and a half week (over 6 weeks). Accordingly, we designed a small intervention, where the PMTs were asked to design DGE tasks as part of the course assignment. This paper aims to gain insight into what impact a small intervention might have on PMTs' abilities to design DGE tasks by exploring the following research question: *What quality of DGE tasks designed by PMTs can we expect of the instructional intervention?* As Bozkurt and Koyunkay's (2020) study, this paper is also guided by Trocki and Hollebrands' (2018) framework.

Method

The study was conducted in spring 2020 in the context of a geometry course for PMTs in secondary and upper secondary school (ages 14–18) in Sweden. In total, 24 PMTs were enrolled in the course. Although the main aim of the course was to develop PMTs' content knowledge, in this case, both Classical Euclidean and Non-Euclidean geometries, there were some seminars on geometry teaching embedded in the course. Particularly, these seminars intended to develop PMTs' skills in planning and implementation of tasks in digitized task environments (such as DGE), as well as their abilities to stimulate each students' learning in the ordinary classroom, including those students who easily reach the knowledge requirements. The instructional intervention addressed both these issues by offering a seminar that introduced geometrical tasks whose numerical solutions could be developed into general results on giftedness and one homework with a follow-up seminar on task design in DGE. After the intervention, as part of the course assignment, the PMTs were asked to design (in pairs or small groups) DGE tasks for (upper) secondary school for all students at different levels of knowledge. Preliminary versions of the tasks were trialled by peers, who provided both oral (at a small seminar) and written responses. The PMTs were then expected to revise and provide a final version of the DGE tasks. Although the participating PMTs were familiar with dynamic mathematics environments as learners of mathematics, the role as task designers were new to them.

The intervention

The mentioned seminar, based on a systematic review (Szabo, 2017) was performed by the second author of this paper, and highlighted the importance of designing tasks that offer opportunities for students to reach general solutions, thereby addressing students performing at higher qualitative levels. To achieve this, we suggested using DGE tasks, in which the participants were encouraged to explore mathematical relationships, to make and verify conjectures, to generalize (if possible) and eventually to construct a proof (Fahlgren & Brunström, 2014). To introduce the ideas behind Trocki and Hollebrands' (2018) framework, the PMTs were encouraged to perform a homework as a preparation for a follow-up seminar. As a basis for the homework, we used three versions of a sample task, provided by Trocki and Hollebrands, to demonstrate various levels of DGE task qualities. These tasks address "…the same two learning goals: 1) justify that opposite angles of parallelograms are congruent; 2) justify that the diagonals of parallelograms bisect each other." (p.127). Each of the tasks consists of a combination of a sketch of a parallelogram and some associated prompts for students to achieve the learning goals. The homework included a brief introduction to the task, of which three versions, A, B and C were provided, and the two learning goals (as described above), followed by some prompts (see Figure 1). At the follow-up seminar, the PMTs discussed the homework in small groups before a whole-class discussion. The focus of these discussions was on to what extent the three versions of the task took advantage of the DGE. For example, which of the versions (A, B, and C), if any, encourage students to explore and discover mathematical relationships.

(a)	Start by constructing a parallelogram in GeoGebra. Make sure that your construction is robust, i.e. that the properties of the parallelogram are perceived even when one of its vertices is dragged.
(b)	Perform the three versions (A, B and C) of the task. Reflect on possible constraints and opportunities that each version entails for a student to achieve the learning objectives.
(c)	Reflect on the quality of the different versions of the tasks by considering the following questions: • How is the potential of the DGE utilized? • What is it that makes one task of higher quality than another?
(d)	How can the task be adapted for students who easily reaches the knowledge requirements? Give suggestions.

Figure 1: The homework prompts

Data collection and analysis

The unit of analysis was the DGE tasks (both the preliminary and the final version) designed by 10 groups (A to J) of PMTs, and the written responses from peers. Each task included a number of prompts for potential students. Some tasks also included pre-constructed (manipulable) sketches. For each task, all prompts were coded with Trocki and Hollebrands' (2018) framework. The coding process was done independently by two of the authors of this paper and then comparisons were made followed by discussions (between all authors) until full agreement was reached. Although the framework was straightforward to use, some subtleties emerged, which are also recognized by Trocki and Hollebrands (2018). First, the distinction between the mathematical depth codes 4 and 5. According to Trocki and Hollebrands, the

> [c]hoice of the word *explain*, as opposed to *justify* or *prove*, was deliberate, in that it serves expose the student to the need *for* explanation as opposed to a particular type *of* explanation (e.g. deductive proof). The code is also based on research that emphasizes a need for students to explain what they notice when using a DGS. (p. 124)

Another subtlety concerns the technological action codes E and F. To sort this out, we needed reexamine Trocki´s original work (2015). A prompt is considered a code E when it "…requires manipulation and directs the student on what to notice." (p.173), while a code F was used if the manipulation is based on a student conjecture, i.e. "…not on a preconceived conclusion on behalf of the task writer."(p.174) .

When all prompts related to a task have been coded, they are assessed holistically to define the quality of the task ackording to the three levels described by Trocki and Hollebrands:

> **Low:** The task *does not* contain a collection of prompts that co-ordinate mathematical depth and technological actions in such a way as to *require* the student to make generalized conclusions based on emergent invariant relationships that go beyond a static sketch.
>
> **Medium:** The task contains a collection of prompts that co-ordinate mathematical depth and technological actions in such a way that *may encourage but does not necessitate* that the student make generalized conclusions based on emergent invariant relationships that go beyond a static sketch. (2018, p.126)
>
> **High:** The task contains a collection of prompts that co-ordinate mathematical depth and technological actions in such a way that *requires* the student to make generalized conclusions based on emergent invariant relationships that go beyond a static sketch. (2018, p.125)

For each of the 10 DGE tasks, all associated prompts were coded by indicating the level(s) of mathematical depth and the type(s) of technological action (see Table 1). This coding generated 10 individual summary tables, which formed the basis for ranking the task quality. To illustrate the coding process, we use one of the tasks, designed by Group D (see Figure 2).

Prompt	**Code (within brackets) and Explanation**
1. Create an arbitrary quadrilateral (convex) with the tool "Polygon". Remove the labels on the sides of the quadrilateral. Then mark the midpoints on each side of the arbitrary quadrilateral. Use the "Polygon" tool to construct the inscribed quadrilateral.	**(1,A,C)** To "create an arbitrary quadrilateral" (coded A) and to "mark the midpoints" (coded C) in Prompt 1, the students need to recall the definition of a (convex) quadrilateral (coded 1).
2. Formulate a hypothesis for the type of geometric figure that is created when the midpoints are connected. Write down your hypothesis on paper. Also, try to drag the corners of the original quadrilateral, before formulating your hypothesis.	**(2,3,D)** Students are asked to drag (coded D) the figure created to formulate a hypothesis (coded 3) about the type of geometric figure it represents (coded 2).
3.After formulating your hypothesis, read the length of the sides and measure the angles of the inscribed quadrilateral. Also, try to drag the corners of the original quadrilateral to see any relationships. Does this result agree with your hypothesis? What type of geometric figure did you get and what characterizes one? If your result is incorrect, justify why and state what assumptions you made that were incorrect and what should have been your correct conclusion. Write down all conclusions on paper.	**(3,4,5,B,D,E,F)** The codes of technological action emerged due to the requirement of measuring the angles of the inscribed quadrilateral (coded B), and then to drag (coded D) the corners to obtain multiple examples (coded E) from which one can generalize to "…see any relationships" (coded F). Concerning the mathematical depth, the students are encouraged to consider relationships in the current sketch (coded 3), and to justify (coded 4) the hypothesis from Prompt 2. Since the prompt requires the student to go beyond the current construction and generalize the mathematical relationships, it receives a code 5.
4. Formulate a hypothesis about the relationship between the area of the inscribed quadrilateral and the area of the original quadrilateral. Write down your hypothesis on paper. Also, try to drag the corners of the original quadrilateral to try to see connections before formulating the hypothesis.	**(2,3,D)** Coded in the same way as Prompt 2.
5. Measure the area of the inscribed quadrilateral and the original quadrilateral. Drag the corners of the original quadrilateral to discover interesting relationships. Does the result agree with the hypothesis that you formulated in point 5? Write down your conclusions on paper.	**(3,5,B,D,E,F)** Coded in the same way as Prompt 3, except for code 4. In contrast to Prompt 3, Prompt 5 does not require the student to justify the conclusion (code 4).

Figure 2: Analysis of one of the DGE tasks (Group D) designed by the PMTs

Since the task includes prompts that co-ordinate mathematical and technological actions in ways that requires students to draw generalized conclusions (code 5) based on emergent invariant relationships that go beyond a static sketch, we ranked the quality of the task as 'high'. During the quality ranking process, we compared and contrasted our interpretations with those made by Trocki (2015).

Results and discussion

Table 2 shows our task ranking of the DGE tasks designed by the 10 groups (A-J). Notably, there was no difference in terms of task ranking between the preliminary and final versions of the DGE tasks. The reason for this might be that the written feedback provided by peers foremost concerned clarification of the DGE tool instructions and/or formulations of questions. We also (in Table 2) indicate whether the tasks provide students with manipulable pre-constructed sketches or step-by-step guidance for constructing geometrical figures.

Table 2: Overview of the results

Group	A	B	C	D	E	F	G	H	I	J
Task rankning	High	High	High	High	High	High	Medium	High	High	Medium
Pre-constructed sketch?	No	Yes	No	No	Yes	Yes	No	No	No	No

As seen in Table 2, 8 (out of 10) tasks ranked high, which indicates that the instructional intervention worked well. However, these results should be interpreted with caution. Besides the subtleties concerning the coding of prompts indicated by Trocki and Hollebrands (2018), the subjective nature of the task ranking method must be taken into consideration. In contrast to Trocki's (2015) study, the tasks designed in this study aimed to address different learning goals, which made the holistic analyses of the prompts associated with a specific task challenging due to fewer comparison opportunities between the tasks. So, for example, to distinguish between 'may encourage but does not necessitate' (medium') and 'requires' (high), was not straightforward. Consequently, we argue that this perspective may affect the validity of our study. Therefore, the relatively high proportion of high-quality tasks designed by the PMTs can be questioned. Still, the tasks ranked as high quality according to the definition (Trocki & Hollebrands, 2018), indeed include prompts that coordinate mathematical depth and technological actions. For example, in this study, the tasks ranked 'high' all offered opportunities for students to reach a generalization beyond the DGE sketch (Code 5) by directions for technological actions such as dragging to recognize invariants in the sketch (Code D and E). A possible explanation for the relatively high proportion of tasks including generalization-making prompts might be the first seminar in the intervention. This seminar highlighted, among other things, the importance of encouraging mathematical generalizations as a way to challenge high-achieving students. Nevertheless, reconsidering the comparatively small size of the instructional intervention, we argue that it was successful in that most of the PMTs designed DGE tasks were ranked at high quality, at least according to Trocki and Hollebrands' (2018) framework.

Moreover, Table 2 shows that several groups did not provide pre-constructed sketches in their tasks. This is in accordance with Gulkilik's (2020) finding that PMTs' tasks provided students instructions to make (robust) constructions on their own. There are several possible explanations for this result. In previous courses, the participating PMTs experienced, as learners, tasks designed for dynamic environments (although not DGE) that offer construction guidance rather than providing pre-constructed sketches. Further, the homework (see Figure 1) prompted the PMTs to make a robust construction before examining the sample tasks, which might have influenced their task design. Moreover, in contrast to previous studies utilizing Trocki and Hollebrands' framework (e.g. Bozkurt & Koyunkaya, 2020; Trocki, 2015), the PMTs in this study were not introduced to the framework itself. Instead, they were asked to examine the quality of three sample tasks, as the PMTs in Gulkilik's (2020) study. Since Trocki and Hollebrands' framework is strongly influenced by the work of Sinclair (2003), who provides guidance for designing tasks utilizing pre-constructed DGE sketches, the introduction of the framework to the PMTs might affect their choice of providing pre-constructed sketches, which was the case in Bozkurt and Koyunkaya's (2020) study.

To sum up, despite its limitations (e.g. no data was collected during the intervention), this study adds some different perspectives to the emergent research field of DGE task design (Sinclair et al., 2016), particularly in teacher education programs (Trocki & Hollebrands, 2018). This study confirms the usefulness of Trocki and Hollebrands' (2018) framework as instructional material, although not necessarily by presenting the framework itself but by asking teachers to evaluate the quality of sample tasks. As a suggestion for further research, we propose deepening this study by analysing all steps of the intervention, not only its outcome (in this case the designed DGE task and associated written responses from PMTs). We also suggest comparing the usefulness of this framework with the suggested operationalization of Leung's model by Gulkilik (2020) to analyse the educational potential provided by DGE tasks.

Investigating Chinese mathematics teachers' use of digital resources before, during and after mathematics lessons

Lianghuo Fan[1, 2], Sicheng Xie[1], Jietong Luo[1], Na Li[1] and Shuhui Li[1*]

[1]East China Normal University, China; [2]University of Southampton, UK

Abstract: This paper aims to investigate mathematics teachers' use of digital resources (DRs) before, during and after mathematics lessons. The data were collected from a questionnaire administered to 146 secondary mathematics teachers from 11 schools in China and follow-up interviews with 19 of them. The results revealed that the majority of teachers often or always use DRs in their teaching, especially during lessons. In particular, teachers frequently searched online for rich exercise problems before lessons, displayed PowerPoint slides during lessons, and used online test makers after lessons. There still existed a digital divide between secondary schools in rural and urban areas of China in teachers' use of DRs. Teaching experience had a significant impact on teachers' use of DRs before lessons.

Keywords: Chinese mathematics education, digital resources, mathematics teachers, ICT.

Introduction

With the fast development of information and communication technology (ICT), growing attention has been paid to promoting educational modernization in mathematics education. Given the growing availability and variety of ICT, in particular, digital resources for mathematics teaching and learning, along with relatively little research available on teachers' use of digital resources, there is a clear need for a greater understanding of how digital resources impact mathematics teaching and learning, especially from teachers' perspectives and practice (Pepin et al., 2017; Remillard et al., 2021). Drawing mainly on Remillard et al.'s (2021) work, we use the term *digital resources* (DRs) to refer to a broad array of digital applications, tools, media, systems and platforms that provide teachers with digital textbooks, exercises, Dynamic Geometry Software (DGS) files, videos and other resources to empower mathematics teaching before, during and after lessons.

In this study, we aim to examine Chinese mathematics teachers' use of various DRs and the factors that influence their use. The research questions are: (1) How do mathematics teachers from secondary schools in China use digital resources in their mathematics teaching? (2) Are there differences in the use of various digital resources by different groups of mathematics teachers?

Literature Review and Conceptual Framework

Prior research showed that teachers' use of DRs varied in different educational contexts. For example, Ibieta et al. (2017) surveyed 6932 secondary teachers in Chile and found that 91% of them always used DRs for "search and preparation of resources." A study with 514 Chinese teachers conducted by Shi and Li (2015) reported that only 0.8% of the participating teachers never used computers in class. In addition, researchers have examined mathematics teachers' usage of particular DRs, some

[*] Corresponding author. Email: shli@math.ecnu.edu.cn.

of which were content-based (Vermeulen et al., 2017), function-based (Engelbrecht et al., 2020) and DR infrastructure, e.g., devices and Internet (Trouche & Drijvers, 2010).

In terms of the process of teachers' teaching, earlier studies have revealed that mathematics teachers use DRs before, during and after lessons with different instructional purposes. Before lessons, DRs play a crucial role in teachers' lesson preparation. Teachers nowadays have access to various resources for lesson planning, such as videos (Oechsler & Borba, 2020) and DGS files (Bozkurt & Uygan, 2020). Forgasz (2003) found that 40 of 96 Australian secondary mathematics teachers used DRs (mathematics software) for lesson planning. In China, Wang et al. (2019) reported that teachers in rural schools commonly used DRs for lesson planning. During lessons, teachers utilize different functions of DRs to present instructional materials. Devices used by teachers are not limited to computers, Interactive Whiteboards (IWB), projectors and tablets (Trouche & Drijvers, 2010). Bretscher (2013) reported that 85% of 188 English secondary mathematics teachers used IWB and 63% of them used digital projectors in almost every lesson. In contrast, a similar study with Spanish mathematics teachers revealed less frequent use of IWB (Gómez-García et al., 2020). After lessons, teachers mainly use DRs for assessment, e.g., automatic assessment (Joubert, 2013). However, the use of DRs outside the classroom, while more frequent, has been less studied (Ibieta et al., 2017).

In Chinese educational contexts, researchers have reported that there has been little empirical work about the types of DRs available for use in education and which DRs are used by teachers in China, especially those in rural areas (Wang et al., 2019). In a large-scale survey of teachers in 2168 schools in China, Lu et al. (2015) pointed out that there were significant differences in uses of multimedia courseware between teachers from urban and rural areas. These studies revealed that some digital divides existed between urban and rural schools in China. However, researchers' knowledge about mathematics teachers' use of DRs remains vague, particularly about the difference between rural and urban schools. In this regard, we hope that the current study, with a more holistic view of mathematics teachers' use of DRs in their mathematics teaching, can contribute to filling the gap and deepen our understanding of what and how DRs are actually used and what are the associated influencing factors.

Table 1: A conceptual framework on teachers' DR usage before, during and after lessons

Dimension	Before lesson	During lesson	After lesson
Content	PowerPoint slide, micro-lesson video, digital teacher manual, etc.	N/A	Problems
Function	Individual lesson planning, collective lesson planning, etc.	Displaying, screenshotting, drawing, virtual teaching aid, etc.	Assigning homework, teaching reflection, etc.
Infrastructure	Devices: computer, tablet, smartphone.	Devices: computer, tablet, IWB, etc.; Internet: online, offline, mixed	Devices: computer, tablet, smartphone.

In order to obtain a relatively comprehensive picture of teachers' use of DRs, we conducted a survey of the literature concerning DRs, e.g., digital textbook, DGS file, flash file, short video, online test maker (OTM), automatic grading, and devices like computer, tablet, IWB, smartphone, in education and more particularly, mathematics education. We also identified other related DRs, e.g., micro-lesson video, digital teacher manual, screenshot, digital handwriting note and online assessment, through our experience and observations. Partly based on a multi-layer model for analyzing "eSchoolbag," a personal learning tablet containing DRs for teaching and learning school subjects (Zhu & Yu, 2011), we categorized DRs in three dimensions: content-based, function-based and DR infrastructure, and investigated specific DR usage in the process of teachers' mathematics teaching, that is, before, during and after lessons. Table 1 lists examples of DRs in the conceptual framework that we established for this study.

Methods

This study adopted a mixed-methods approach. Following the conceptual framework, we designed a questionnaire to collect the data about teachers' uses of DRs. The first part captured the profile of the participants, and the following three parts questioned the use of DRs before, during and after lessons, respectively, with items corresponding to the DRs mentioned in Table 1. Each item was measured by a 4-point Likert scale, with 4 for "always; more than 4 lessons per week", 3 for "usually; 3 to 4 lessons per week", 2 for "sometimes; 1 to 2 lessons per week" and 1 for "never". Open-ended questions were used to collect more information about the most frequently used DRs, the difficulties encountered when using DRs and the specific functions of DRs that they were most satisfied or unsatisfied with.

Additionally, interviews captured the reasons or examples for teachers' use of specific DRs. Questions were asked such as: "For DRs use before lessons, you rated 4 for item 1, while 3 or 2 for the rest. Are there any reasons why you use this more frequently? How do you usually use it?" We also conducted a pilot test (n= 8 teachers) to refine the instruments and ensure reliability and validity.

Table 2: Profile of participating teachers (*n*=146)

Characteristic	School Location	Gender	Educational Background	Title[1]	Teaching Experience (Year)[2]
Participants	Urban: 105 (71.9%); Rural: 41 (28.1%)	M: 56 (38.4%); F: 90 (61.6%)	Bachelor: 116 (79.5%); Master & Doctor: 30 (20.6%)	Junior: 59 (42.1%); Intermediate: 57 (40.7%); Senior: 24 (17.1%)	(0,5][3]: 43 (29.7%); (5, 20][4]: 58 (40.0%); >20: 44 (30.3%)

Note: All percentages are based on valid responses. [1]*n*=140. [2]*n*=145.[3]5 years or less. [4]More than 5 years and less than 20 years. M=Male; F=Female.

Overall, teachers from 11 secondary schools, 7 urban and 4 rural, in 6 cities of China: Shanghai, Hangzhou, Nanjing, Jinan, Yiyang and Changde, participated in this study. We received 146 questionnaires back (response rate: 94.1%; see Table 2 for the profile of participants) in June, 2021 and conducted interviews with 19 teachers (referred to T1 to T19) from June to August, 2021.

Findings

Use of DRs before lessons, during lessons, and after lessons

Table 3 shows how often teachers used various DRs for lesson planning. 65.7% of 102 participants always or often used DRs before lessons (*M*=2.82). Digital exercises (including problems from national/regional exams) received the highest rating (*M*=3.25), and 80.4% of them always or often used exercises. This result was not surprising since rich problems could be downloaded online by teachers. For example, T17 mentioned that when she prepares lessons, she first downloads exercises online and then designs teaching activities accordingly. In comparison, flash files received the lowest rating (*M*=2.08). Only 4 teachers always used flash files, and 24 teachers never used flash files. During the interview, T11 reported that it was difficult to obtain suitable flash files. Regarding functions, teachers used individual lesson planning (*M*=2.89) most frequently, followed by collective lesson planning (*M*=2.75) and analysis of students' prior learning (*M*=2.51). T10 and T12 explained that individual lesson planning helped them build their own lesson plan database, which was beneficial to their long-term professional growth. Computers (*M*=3.37) were the most frequently used devices before lessons, followed by smartphones (*M*=2.36) and tablets (*M*=2.14).

Table 3: Frequency of using DRs before lessons and functions used during lessons

Rank	Content before lessons	Mean	SD	Function during lessons	Mean	SD
1	Digital exercise (*n*=112)	3.25	0.77	Displaying* (*n*=105)	3.39	0.74
2	Digital textbook (*n*=107)	3.08	1.07	Touching, writing and erasing (*n*=103)	3.20	0.87
3	Digital teacher manual (*n*=109)	3.06	1.00	Drawing (*n*=103)	2.87	0.87
4	PowerPoint slide (*n*=111)	2.87	0.82	Supporting interactions (*n*=99)	2.67	0.97
5	DGS file (*n*=110)	2.35	0.81	Saving handwriting notes (*n*=101)	2.50	0.98
6	Micro-lesson & short video (*n*=110)	2.32	0.77	Screenshotting (*n*=97)	2.43	0.90
7	Picture and GIF (*n*=110)	2.17	0.76	Virtual teaching aids (*n*=99)	2.34	0.93
8	Flash file (*n*=104)	2.08	0.78			

Note: *The "displaying" function combines five items, including displaying PowerPoint slides, DGS files, or using an IWB, projector or students' tablets/computers to display teaching content.

During lessons, 78.2% of 96 participants always or often used DRs during lessons (*M*=3.14). 53.3% and 44.7% of the teachers always used displaying contents (*M*=3.39) and touching, writing and erasing (*M*=3.20), respectively. In contrast, only 12.1% of them always used virtual teaching aids (*M*=2.34). During the interview, 12 teachers indicated that displaying DGS files was a good way to teach geometry and functions. Some teachers said that they were not quite proficient to use many functions of DGS. In terms of devices, teachers used computers (*M*=3.16) and IWBs (*M*=2.93) more often than smartphones (*M*=2.04). Challenges like (1) pop-ups and advertisements, (2) switching displays, (3) equipment and network error and (4) deviation issues of devices received similar ratings, between 2.15 to 2.41. For the internet connection, teachers used offline (*M*=2.43), mixed (*M*=2.38), online (*M*=2.34), in a similar frequency. 19 teachers mentioned in the open-ended questions that the instability of the Internet caused great inconvenience.

The results revealed that 55.1% of 78 participants always or often used DRs after lessons (*M*=2.56). It is highly related to recent policies as teachers were not allowed to assign digital homework after class (Ministry of Education, 2021), as mentioned by five teachers during the interview.

Regarding various functions, teachers used online test maker (OTM, e.g., ProProfs Quiz Maker) most frequently (M=2.48). T5 said she would download exam papers and adapt them for exercises; T10 said that OTM allowed him to organize and produce high-quality exam papers. In contrast, the automatic grading (M=1.82) was rarely used, probably due to the low accuracy (stated by three interviewees) and limited types of problems (mainly multiple-choice), as T2 said: “It was not meaningful to me as students can check the answers of multiple-choice questions on their own.” Furthermore, OTM is rather well-developed, while other functions were not user-friendly and helpful to teachers. For content, online problems from previous High School Entrance Examinations (HSEEs) (M=2.64) were used most frequently, while original and self-design problems were used least frequently (M=2.29). As T10 commented, problems from HSEEs were regarded as “well-designed” and “of high quality,” while the quality of original or self-designed problems was doubted. Problems from digital textbooks, teacher manuals, exercise books and resource books were used almost equally frequently (M=2.46~2.53). For problem sorting criteria, knowledge (M=2.90) and chapter and section (M=2.88) were used most frequently. Overall, teachers used tablets (M=1.82) less frequently than computers (M=2.79) and smartphones (M=2.13) after lessons.

Differences in the use of DRs by different teachers

Table 4 lists items with statistically significant differences from the chi-square tests. Before lessons, digital textbooks and exercises were used significantly less frequently by teachers with experienced teachers (more than 20 years) than less experienced teachers. In the interview, T2 pointed out that he didn’t search exercises online as he had accumulated enough exercises over the past 30 years, which was “what makes us (experienced teachers) different from novice teachers.” T13 said that experienced teachers relied on printed textbooks more heavily than novice teachers. It can be inferred that experienced teachers are more familiar with printed resources and reluctant to use digital ones. Besides, female teachers used digital exercises significantly more frequently than male teachers; teachers with graduate degrees used digital exercises significantly more frequently than those with bachelor degrees. Teachers from rural schools used tablets significantly less frequently than their counterparts from urban schools, which may be related to the availability of tablets. T16 from a rural school said in the interview that there was no tablet available in his school. During lessons, female teachers adopted the online mode significantly more frequently than male teachers. Teachers from urban schools used DRs offline in the whole class at a significantly higher frequency than those from rural schools. After lessons, there were statistically significant differences between teachers from urban and rural schools in many aspects, especially in OTM. T14 and T16 from rural schools both mentioned the lack of devices in their students’ homes, implying a relatively low frequency of DR usage. Gender differences were found in manual grading and sorting problems by the level of difficulty, in which female teachers used them more frequently. Teachers with graduate degrees selected problems by the year of exams more frequently than those with bachelor degrees.

Table 4: Items showing statistically significant differences in frequencies of DRs use between teachers

Dimension	Before lessons	During lessons	After lessons
Content		-	Digital textbook: 8.335*(SL); Digital teacher manual: 18.109***(SL)

	Digital textbook: 13.564*(TE); Digital exercise: 6.381*(G), 8.479*(EB), 9.655*(TE)		*Sorting mathematics problems by:* 1. Mathematics knowledge: 15.646**(SL); 2. Level of difficulty: 12.980**(SL), 8.551*(G); 3. Chapter and section: 15.122**(SL); 4. Upload time: 17.274***(SL); 5. Year of exams: 18.831***(SL), 11.054*(EB)
Function	-	-	Online test maker: 33.864***(SL); Manual grading: 10.409*(SL), 9.237*(G); Teaching reflection: 11.683**(SL)
Infrastructure	Tablet: 9.220*(SL)	ON: 11.233*(G); OFF: 11.005*(SL)	Computer: 18.405***(SL)

Note: SL=school location; G=gender; EB=educational background; TE=teaching experiences; ON=online; OFF=offline. *p<.05, **p<.01, ***p<.001.

Conclusions

Overall, more than one-half of mathematics teachers in our study often or always used DRs, especially during lessons. However, teachers' use of DRs is still limited in variety. Mathematics teachers used DRs at a relatively low frequency after lessons, compared to their use of DRs before and during lessons. This result was consistent with the finding reported by Ibieta et al. (2017) that teachers in Chile used DRs more frequently outside the classroom for class preparation before lessons.

Before lessons, digital exercises, individual lesson planning and computers were the most frequently used DRs by mathematics teachers. From the content-based perspective, digital exercises were the most frequently used DRs, which was partly due to the influence of high-stake examinations (see also Leung, 1995). Moreover, the finding that teachers used DRs with complex procedures (e.g., DGS, GIF and videos) at a relatively low frequency was in line with an ecological metaphor in which simpler technologies requiring little adjustment to existing practices are more frequently used (Zhao & Frank, 2003). Thus, teachers' limited proficiency in designing DGS files and other dynamic resources leads to the low frequency of using these types of DRs. Also, it was consistent with the finding that teachers mainly used DRs for presentations during lessons, as well as the findings of Bretscher's (2013) study where presentation-oriented software dominated English mathematics teachers' IWB use. The frequency of teachers' use of a particular function varies, which is affected by their proficiency in that function. Thus, more professional development programs regarding how to use DRs efficiently are needed to support teachers in this aspect. And future research on how DRs are used in mathematics classrooms in various contexts may produce new possibilities of integrating DRs effectively. After lessons, the relatively low frequency of teachers' use of DRs was largely related to policies, as well as limited and helpful functions of DRs. The well-developed and user-friendly exam/test production was used most frequently, possibly due to the high-stake examinations.

Overall, experienced teachers tended to use digital exercises and textbooks less frequently than less experienced teachers before lessons. There were statistically significant differences between urban and rural school teachers in tablet use before lessons, adopting the offline mode during the whole lessons, and in most of the aspects of using DRs after lessons, which indicated some digital divides between urban and rural schools in China. More support in terms of providing devices professional training programs for effective use of DRs are needed, especially for rural schools in China. Meanwhile, the flexibility of professional training programs should be maintained among different regions, as teachers may evolve in different ways in the same training (Prodromou et al., 2018).

Acknowledgment

This study was jointly supported by two research grants by East China Normal University, one from its "Happy Flowers" Strategic Research Fund (Award No: 2019ECNU-XF2H004) and the other from the Asian Centre for Mathematics Education (Award No: 92900-120215-10514).

Background

In 2018, the Ghana Tertiary Education Commission revised the teacher education curriculum to a 4-year Bachelor of Education, which specifically identified the use of dynamic mathematics technology (DMT) as a pedagogical tool in the preservice teacher mathematics curriculum to ensure college graduates are well-equipped to leverage digital technology for the teaching of mathematics and science (UEW, 2018). DMT for the purpose of this research refers to technology offering different linked mathematical representations (geometric shapes, graphs, tables, algebraic expressions) that teachers and pupils can manipulate and by doing so, engage with the underlying mathematical concepts and relationships.

Problem Statement

Research studies have reported the many ways that dynamic mathematics technologies can support deep and lasting learning by offering learners connected multiple representations -graphs, tables of values and equations (Clark-Wilson & Hoyles, 2017) and by providing tangible mathematical objects to explore shape enlargement or angle changes (Dick & Burrill, 2016). However, due to the absence in Ghana of courses on teaching mathematics with technology, coupled with mathematics teacher educators' lack of training, knowledge and confidence, preservice secondary mathematics teachers leave college without the adequate training and exposure to dynamic mathematics technology. Hence, they are mostly unable to use dynamic mathematics technology for teaching mathematics both to improve the reasoning and creative problem-solving skills of secondary school students and to expose secondary students to mathematical opportunities in the digital age.

Research Aim

My research aim is to investigate how to foster the integration of dynamic mathematics technology within secondary mathematics teacher education in Ghana by improving the mathematical pedagogical technological knowledge (MPTK) (Thomas & Hong, 2013) of mathematics teacher educators in the colleges of education.

Research Questions

My research will investigate mathematics teacher educators MPTK within the context of known underuse of Dynamic Mathematics Technology in mathematics classrooms across the forty-six (46) colleges of education. The questions below will guide the study.

- RQ1 How do the current Ghanaian mathematics teacher education curriculum conceive the integration of dynamic mathematics technology?

- RQ2 What are the obstacles to the integration of DMT for Ghanaian mathematics teacher educators?
- RQ3 What are the design features of professional development course for mathematics teacher educators that support them to use DMT in ways that become embedded in their practice and lead to effective teaching?
- RQ4 What is the impact of the professional development course on the mathematics teacher educators' MPTK?

Theoretical Framework

This design-based research study will adapt the *Conversational Framework* pedagogic theory (Laurillard, 2002) to create an online asynchronous professional learning course for mathematics teacher educators to improve their mathematical pedagogical technological knowledge (MPTK). Laurillard's framework argues that teaching is a dialogue and shows what it takes to learn using the ideas of instructionism, social learning, constructionism, and collaborative learning.

Methodology

The study will be an exploratory mixed methods design that would adopt a design-based research approach. Semi-structured interviews will be administered first to the curriculum designers and policy makers followed by a survey questionnaire for mathematics teacher educators. The analysed data from the interviews and questionnaires will inform the design of the intervention - an online asynchronous professional learning course on a particular DMT- the *GeoGebra* application (GeoGebra, 2021) for the teaching of geometry. In the final phase, the impacts of the course on mathematics teacher educators' MPTK will be evidenced.

Acknowledgment

I am grateful to GNPC Foundation for the financial sponsorship toward my studies at UCL, to my research supervisors and the mathematics teacher educators I intend to work with.

Digital competencies of pre-/in-service teachers—an interview study

Peter Gonscherowski[1] and Benjamin Rott[2]

[1]University of Cologne, Cologne, Germany; peter.gonscherowski@uni-koeln.de

[2]University of Cologne, Cologne, Germany; benjamin.rott@uni-koeln.de

Since the role and the availability of digital technology in society is growing, educators need to increasingly more often decide when and what digital technology to integrate into their teaching. Thus, those decision-making competencies need to be developed and measured especially for pre-service mathematics teachers. Therefore, we conducted an explorative interview study to understand the variety of argumentation and justification of pre- and in-service mathematics teachers on whether to use or not use digital technology in the teaching phases of Prediger et al. (2013), and what criteria they use in making those decisions. The analysis shows that (1) based on the arguments and justifications different level of decision-making competencies can be distinguished and (2) the recorded criteria on whether to use or not use digital technology are suitable for reflective practicing of such decisions.

Keywords: Digital competencies, Pre-service teachers, Student teacher evaluation, Technological advancement, Decision making skills.

Introduction

Given the growing role of technology in society and education, as well as the growing number of digital technologies available to teachers (Ally, 2019; Clark-Wilson et al., 2020), it is important that the technology-related competencies of educators constantly evolve and valid instruments to evaluate such competencies are necessary. Educators have to decide increasingly more often when and what technology to integrate into their teaching practice to be effective and meet the demands of society and their learners — not only because of curricular guidelines/standards — but also because the aim to prepare their students for a work environment in the future which will be even more digitalized and driven by technology. In summary, the skill and the knowledge of educators to make appropriate decisions on when and what digital technology to use in teaching is driven by the increased digitalization of society and an increasing number of digital technology available and thus of high importance to educators. Not surprisingly the skill and the knowledge of selecting suitable digital resources have been added to educator competency frameworks like ISTE Standards for Educators (International Society for Technology in Education, 2000) or the DigCompEdu (Redecker, 2017). Even though the DigCompEdu framework lacks references to the educator's orientation towards implementing technology in classrooms, it has been cited as one of the most compressive frameworks in its suitability of educators' need to integrate digital technology (Tabach & Trgalová, 2020) and therefore is used as a basis for our research. DigCompEdu entails twenty-two competencies and one of them is "Selecting digital resources," which is defined as "To identify, assess and select digital resources for teaching and learning. To consider the specific learning objective, context, pedagogical approach, and learner group, when selecting digital resources and planning their use." (Redecker, 2017, p. 20). It should be noted that although increasing the efficiency of an educator because of the use of digital technology is not included in the DigCompEdu definition, it has been cited as a significant factor in the selection process of educators (McCulloch et al. 2018). Given the importance of the competence "Selecting digital resources," it needs to be fostered as part of the educational program of pre-service teachers; to evaluate such processes, the competency needs measure instruments and items which reflect that importance. With that in mind, we aim to develop open-end items for an external assessment and conducted this interview study to better understand the decision processes of pre- and in-service teachers on the use or not use of digital technology in teaching. In the following sections, we first describe the theoretical models, we used in preparation for this interview study. Subsequently, we present the results of the study with pre-/in-service mathematics teachers in Germany.

Theory

In the planning of the interview study, it became apparent that (1) a clear definition of digital technology within education and (2) a model to describe the situational context of teaching settings is required. Thus, we briefly introduce the digital technology definitions given by Clark-Wilson et al. (2020) and the model of teaching phases of Prediger et al. (2013).

Definition of digital technology in education

Clark-Wilson et al. (2020, pp. 1225–1226) group digital technologies by function. The function of the technology inherently determines its use within a teaching situation and are termed as follows.

a) Organizing: "As a support for the organization of the teacher's work (producing worksheets, keeping grades)"

b) Representation: "As support for new ways of doing and representing mathematics"

c) Collaboration: "As a support for connecting, organizing in communities, communicating and sharing materials"

d) Independent: "…a commercial and industry driven function, which supports students' more independent work and focuses on practicing and assessing previously taught mathematical knowledge and skills in a range of online formats."

We use these technology categories since they align with the definition of the competency "Selecting digital resources" and with aspects of the competencies in the area of "Teaching and Learning" of the DigCompEdu framework.

Core teaching phases by Prediger et al. (2013)

Prediger et al. (2013) describe a model of teaching that can be used to design teaching arrangements and to make situational teaching decisions. In the model, four core phases are differentiated*: Connecting (C), Exploring (E), Systemizing (S), and Practicing (P)*. These core phases are defined by their didactic function, cognitive activity, and epistemological quality. Whereby the didactic function designates the perspective of the educator and the cognitive activity encompasses the perspective of the learner. The authors state, that other aspects of teaching e.g., creativity and collaborative exchange can be developed within each phase by providing those stimulations. This aligns with the digital technology categories of *Collaboration* and *Independent* as outlined in the previous section. In the context of this paper, we use the model of Prediger et al. (2013) to evaluate the decision-making processes regarding whether to use or not to use digital technology within each phase. Digital technology can be used in all four teaching phases to either support a didactic function, the cognitive activity or both. (Büchter et al., 2019; Hillmayr et al., 2020; Peschek & Schneider, 2002; Reinhold et al., 2020; Swanson, 2020). While some of the studies are directly attributed to a particular phase, others are applicable to all or multiple phases.

Research questions/evaluating educators' competency of "Selecting digital resources"

To understand the selection and decision process on whether to use or not to use digital technology in teaching lessons of (prospective) teachers, we conducted exploratory interviews with in-service and pre-service teachers to answer two research questions (RQ).

> RQ1: How do pre-service and in-service teacher reason for or against the use of digital technology in the context of a specific learning subject, learner age group, and teaching phase?

Regarding this question, we let the interviewees choose their preferred content and learning group to reason on familiar grounds. All four phases of the model of Prediger et al. (2013) are addressed by the respondents.

> RQ2: What criteria do pre- and in-service teachers use when deciding on the use of digital technology in teaching?

With this question, we specifically inquired what role the age group of the learner and the learning content have in the decision process and on the learner/educator perspective.

Methodology

We have used semi-structured interviews in the explorative study. Next to some demographic questions, the respondents were first asked to explain along with the four phases of teaching on a specific mathematics subject and student group whether to use or not use digital technology. In the second part of the interview, we enquired about the use of digital technology in teaching—not restricted to a particular subject and student group. This two-prong approach was taken to gain an understanding of how participants would reason within a specific setting as well as in more general terms of teaching with digital technology. We interviewed five pre- and five in-service mathematics teachers in Germany. Regarding the former, two interviewees were at the beginning (1st and 2nd semester) and three at the end of their studies (6th, 8th, and 10th semester); they studied with an emphasis on special or on lower secondary education. Regarding the latter, teaching experiences varied between four and thirty years in lower and upper secondary education. The broad diversity of participants was chosen to get insight into the maximum variability of answers and reasoning. All interviews were conducted in German and transcripts were coded using qualitative content analysis (Mayring, 2000).

Qualitative analysis of the interview study

In the following, the results of the coding are presented. Citations are abbreviated and designated as either pre-/in-service teacher indicated by the prefix "Pre-T-"/ "In-T-" followed by a number indicating the semesters of study or the years of teaching as well as the point in time in the interview. Only the English translations of the interview coding by the authors are presented to save space.

Results regarding research question 1

Two different approaches within the first section of the interview were taken by the participants. One participant, a pre-service teacher in the sixth semester, stated that the selection of digital technology cannot be made by the teaching phases and that the decision is rather based on the type of technology. For the analysis, this interview was excluded as although the approach is valid it does not answer the research question at hand. The responses of the remaining participants were used as the basis for answering the imminent research question using a two-layered approach. In the first layer, we differentiated the type of arguments and justifications and in the second layer, we reviewed the types of digital technology groups used within each phase.

For the first layer of analysis, we differentiated argumentations with (i) no argument, (ii) arguments(s) which were not substantiated or overly generalized, and (iii) argument(s) substantiated by either a didactic function, cognitive activity, or own application. First, we provide some examples of the applied coding system and later a summary of the types of argumentations clustered by participant groups. The following response is an example of "no argument," indicating to not use digital technology in the *Connecting* phase because of no knowledge of technology to be useful in this phase.

[06:17] – Pre-T-2: *Connecting. Well. I would say no…At the moment I cannot think of a use for software to capture one's previous experience. I would do that I think rather in a conversation ...*

An instance of a response with an overly generalized argument and justification reads like this.

[09:38] – Pre-T-2: *So first of all, I think in general it makes sense to use it [digital technology], because I just think that it totally focuses the attention of students.*

In addition of being an overly generalizing argument, it could be debated if this line of argumentation is correct, as studies suggest that prolong use of digital technology or media can have adverse effects on learners' cognitive ability and attention span (Lodge & Harrison, 2019). A response with an argument substantiated by a didactic and cognitive function is the following explaining the use of a quiz app [Biparcours] versus paper & pen worksheets in the *Connecting* and *Exploring* phase.

[11:16] – In-T-10: *So now I use a digital tool [Biparcours], which is not explicitly mentioned in the curriculum... I found this methodologically useful here for motivation and to promote self-directed learning. The [students] can work through the questions in the [Bipar] course at their own pace and receive automated feedback and continue…*

The app is used to reactivate the learner's prior knowledge of a related subject and letting them explore the new content. The decision is explicitly supported by the didactic goal in those phases and fostering self-learning. Also the motivational aspect of technology on the cognitive activities of the learners has been mentioned in the reasoning. The response also implies the aspect of automated feedback and leveraging aggregate instead of individual results to assess the outcomes of the phases. This speaks for the aspect of educators' efficiency because of technology. A response using in the argumentation a cognitive perspective is given next.

[07:45] – In-T-4: *I think that when you're exploring and discovering new mathematical facts, the effort is very high... and if you can relieve this high cognitive hurdle that's involved in the discovery, in some form by having the technology take away certain repetitive sequences of actions, like the construction, which is done identically over and over again, we can outsource that…*

Following the outlined coding the responses of the participants were categorized by (1) the four teaching phases, (2) the type of argumentation and substantiation of the arguments and (3) the types of participants. We differentiated three groups, Pre-T-2, Pre-T-8/10, and In-T-x.

The analysis yielded the following results: First, the arguments and the level of justification progresses from "Pre-T-2" who provide only arguments in the *Exploring* phase which were substantiated by either their own experience in using digital technology or by providing examples of the use of digital technology, to Pre-T-8/10 who provided arguments supported by cognitive perspective for the *Connecting* phase and arguments supported by cognitive as well as didactic perspective for the *Exploring* phase. And then to the in-service teachers who provided arguments for all four phases supported by didactic, cognitive aspects or own application of technology and are most comprehensive. Second, regardless of the participant group a justification is given by the respondents for the *Exploring* phase. Thirdly, only the in-service teachers provided substantiated arguments for the *Practice* phase. In summary, based on the coded argumentation and justification pre- and in-service teachers can clearly be distinguished.

The second layer of the coding reviews the technology groups *Organizing*, *Representing*, *Collaboration*, and *Independent* in the context of the teaching phases. The results by the three participants groups Pre-T-2, Pre-T-8/10, and In-T-x are shown in Table 1. Pre-T-2 named only technologies in the *Representation* group (and here also only GeoGebra) but were able to argue for their use in the *Exploring* phase like Pre-T-8/10 and In-T-x. The latter however did not only provide a more comprehensive list of technologies in the group (e.g., GeoGebra, Excel, CAS) they also were able to identify and argue for the use of digital technologies regarding the *Independent* and *Organizing* group in this phase. The * in the table denotes phases in which participants argued not to use digital technology or did not see the value of it. Their level of argumentation was assessed in the first layer of the coding.

Table 1: Digital technology groups by phase and participants group

	Pre-T-2	Pre-T-8/10	In-T-x
Connecting	None*	None*	Independent, Organizing
Exploring	Representation	Representation	Representation, Independent, Organizing
Systemizing	None	Collaboration	Collaboration
Practice	None	None	None*

Peculiar is that the In-T-x see the value of the technology grouping *Independent* in the *Connecting* phase, but do not see the same benefit in the *Practice* phase, in particular they do not see the aspect of using digital technology for assessments. A possible explanation is that the use of digital technology for assessments is not widespread and not necessarily the main didactic objective of the phase. It also becomes apparent in this layer of coding, that the decision of using digital technology in a particular teaching phase is a decision on how a digital technology supports the didactic function and a cognitive activity. Since the didactic function and the cognitive activity in the four phases are discriminative, different technology groups are highlighted for a phase. The aspect of "independent working" supported by the technologies in that grouping, although potentially applicable to all four phases, is more relevant in the *Connecting*, *Exploring* and *Practice* and to a lesser extend relevant in the *Systemizing* phase. The same applies to technology in the *Representation* grouping, which enables to present content in multiple and new forms and thus is more relevant in the *Exploring* phase and not or to a lesser extend relevant in the other phases. *Collaboration* technology, which enables the sharing of information -- educator to learner and learner to learner – was assessed to be more relevant in the *Systemizing* phase, where the didactic goal is to link the learning of the individual to the group. Inductive the hypotheses can be made that the *Representation* technology used in the *Exploring* phase is more dependent on the teaching domain and that the technology in the grouping *Independent, Organizing* and *Collaboration* are neutral to the teaching domain. Based on the two layers of analysis we can summarize (1) the competency, meaning the argumentation and reasoning skills as well as the knowledge about digital technology in education distinctly differs and progresses from Pre-T-2 to In-T-x. (2) The technology groups differ regarding the teaching phase and distinct technology groups can be assigned to a single phase respectively.

Results regarding research question 2

In second part of the interviews, we investigated the selection criteria the participants use in their decision processes. The cumulative view of the results is organized by (i) learner age and abilities, (ii) learning content, and (iii) educator perspective. The criteria are formulated either as continuum statements (younger to older learners, less to more) or dichotomous yes/no statements. Criteria which are limited in their scope because of the context they were provided in or the participating teaching group being either special-, lower- or higher education are marked accordingly.

Learner age and abilities (In-T-x)

- The younger the learners, the lower the cognitive demand of the technology can be and the lesser own personal devices are available. Also the younger the learners, the more oversight is required to ensure the digital technology is used responsibly and in the intended didactic manner.
- Motoric abilities (Pre-T-2, Pre-T-8/10)
    - No: Do not use technology, if it is likely that it gets damaged.
    - Yes: If it enables the inclusion of learners [overcomes impairments of learners].

Learning Content (In-T-x)

-Yes: If the curriculum demands the use of a particular technology.
-Yes: If the content can only be taught using a particular technology.
-Digital technology should enable or support dynamic and different forms of representations and the ability to outsource repetitive activities which are not the focus of the didactic goal.

Educator perspective (In-T-x)

- Technology by commercial providers generally puts a higher burden on the user either because of financial costs, login and registration requirements or the data collection by the provider.

From the list it becomes apparent that the participants use no hard rules at what learner age to start with using digital technology. It should also be noted that some of the participants stated that they weigh in their decision and selection of technology different criteria and are making tradeoffs when deciding. Otherwise the list of criteria has been deduced from the participants responses and should be seen as an accumulation of the teaching practice of the in-service teacher in combination with the arguments and reasoning given in the previous section.

Discussion and outlook

In the interview study, we were first able to show that by the argumentation and justification of whether to use or not use digital technology that we can differentiate between three groups (pre-service teachers at the beginning and pre-service teachers at the end of their studies as well as in-service teachers) within all four phases of the model by Prediger et al. (2013). In the *Exploring* phase, the differences are seen regarding the justification, whereas in the other phases, the differences are seen regarding argument and justification. Additionally, whereas the in-service teachers provided multiple digital technologies for each technology group by Clark-Wilson et al. (2020), the pre-service teachers especially at the beginning of their studies were only able to provide a few examples in the *Representation* group. Either because they are not aware of digital technologies and/or they did not bring them in context with the teaching phases, which needs to be considered in the development and measurement of the digital competency "Selecting digital resources." To verify the reliability of the findings a quantitative study should be conducted.

Secondly, there are indications that the role of the technology groups, as described by Clark-Wilson et al. (2020), differs regarding the teaching phase and that the technology groups can be assigned to a teaching phase in the model by Prediger et al. (2013) respectively. As such, the decision process on the use of digital technology in a teaching phase can be seen as a decision regarding digital technology and not necessarily regarding a specific teaching phase.

Thirdly, although the technology grouping of Clark-Wilson et al. (2020) and the model of the core phases of teaching of Prediger et al. (2013) were created within the context of mathematics education, the findings of the interview study suggest that they are transferable to other teaching subjects/domains. Digital-technology grouped as *Independent, Collaboration and Organizing* potentially is common across teaching subjects and the technology in the group *Representation* is teaching-subject specific. In order to validate these findings, we are planning a quantitative pre/post survey with participants outside of mathematical contexts using the offered approach in this interview study.

The study is limited to pre-service teachers at one university and in-service teachers of one region in Germany, all in context of teaching mathematics. Nevertheless, we were able to provide insights into the decision-making process on the use of digital technology. The accumulated list of technology decision criteria will require further review with regard to its application in the development process of pre-service teachers. Especially the scope of the decisions they will have to make in their future teaching practice needs to be considered versus the decisions they are subjected to by others namely the school leadership or curricular guidelines.

This research explores the relationships that future mathematics teachers establish between modelling, mathematical content and technology when designing tasks for teaching mathematics. By means of a qualitative analysis, aspects were revealed in the design of tasks that provide evidence for the transversality of mathematical and extra-mathematical content. In the design process characteristics related to the modelling process were identified. Also observed was how the use of Dynamic Geometry Software (DGS), associated with the construction of static and dynamic simulations, can expand and transform the mathematical work initially planned in a task. The findings of this work show the potential of the design of modelling tasks to the development of knowledge for training future teachers.

Keywords: Modelling, Dynamic Geometry Software, tasks, pre-service teacher

Introduction and conceptual framework

The role of the teacher in selecting, designing or modifying tasks has been discussed in different environments, where two elements that frequently stand out are the intended task and the enacted task. This research explores the work that future mathematics teachers carry out during the process of designing the intended task. In particular, in keeping with the work of Sullivan and collaborators, we study the “interactions among aspects of task design: design elements of tasks, the nature of the mathematics that is the focus of the tasks, and the task design processes” (Sullivan, Knott & Yang, 2015, pp. 84). Tasks for learning mathematics can be classified in different ways, depending on the activities they promote. In this work, a modelling task is defined as one that encourages the modelling activity, where modelling is understood as a transition between reality and mathematics in order to address a problem that occurs in real life.

Various elements of teacher knowledge are brought to bear in the process of designing a task (Hill, Ball & Schilling, 2008). Moreover, when the design considers the use of technology and modeling, the range of knowledge required of the teacher is expanded. We have found results that indicate how participating in the design of modelling tasks in digital environments impacts the Technological Pedagogical Content Knowledge (TPACK) of future mathematics teachers (Guerrero-Ortiz, 2021). Different models have also been explored to describe the skills that a teacher should master to teach modelling, and ways have been suggested to operationalize development of these skills (Borromeo, 2018). The review of the literature reveals that designing tasks for learning is in itself a challenge for teachers and, by involving technology and modelling, the situation becomes even more complex as more knowledge is needed.

Based on the fact that the specific introduction of a type of tool promotes concrete changes in the activities that individuals perform (Jacinto & Carreira, 2017), the types of activities that emerge when modelling in digital environments reflect, to a certain extent, the potentials of the tool that individuals recognize, in our case, future mathematics teachers. By this way, we argue that in the modelling process, the actions of individuals reflect part of the mathematical thinking that is brought to bear when they explore ways of approaching the design of a modelling task. While technology itself does not have an objective, in this work we seek to answer the question: What are the characteristics of the modelling tasks designed by future mathematics teachers with the use of technology?

Methodology

By means of a qualitative analysis, we studied the design process and the modelling tasks for teaching mathematics developed by two groups of future mathematics teachers (G1 and G2). Each group consisted of three participants who had to design, implement and analyze a mathematics teaching task whose content and grade level were chosen by them. Before they designed the tasks, the participants had been introduced to problem solving and modelling in a Dynamic Geometric System (DGS) environment. The design of the task thus reflects in part their knowledge of modelling and their knowledge of teaching mathematics in digital environments. The work of these participants was chosen because it highlights the difficulties encountered by those who design modelling tasks, and it accounts of two modes of exploiting the DGS (Swidan & Faggiano, 2021) in teaching tasks. The information gathering instruments consisted of a document on which the participants reported the modelling process employed during the design of the task, and an electronic file containing the construction in GeoGebra. The written document was analyzed using the content analysis method, while the electronic file was analyzed using the “construction protocol” tool, which allows looking back and redoing every step of the geometrical configuration.

For data analysis, the task design process is first described, consisting of two major stages: the research and the pre-service teachers’ modelling process. Each of these stages in turn considers some of the actions shown in table 1. These stages highlight crucial aspects of the modelling process undertaken by the participants that have an impact on the task designed. Subsequently, based on how the participants exploited the technology, ways to expand or improve the task are explored.

Research		**Modelling**
- Choose the context - Explore mathematical and extra-mathematical knowledge -Focus on mathematical content	→	-Simplifying and idealizing - Construct models - Working with models - Obtaining mathematical results - Interpreting and validating

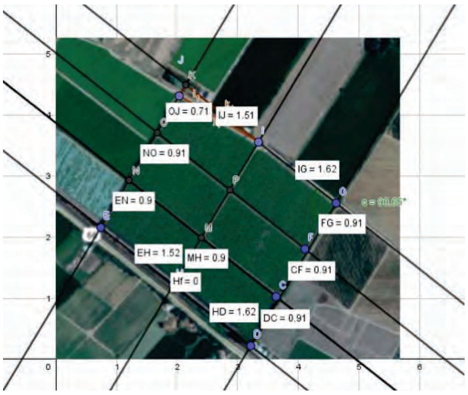
Table 1: Stages of the design process, compiled by authors

Data analysis

This section presents the analysis of the tasks designed by each of the groups. A general description is first shown according to the points listed in Figure 1, and the role of technology in each task is then analyzed, along with the ways in which the potential of DGS can be more fully exploited.

Analysis of design made by Group 1

Based on the school level of the course they were teaching during their professional training (12-13-year-olds), the participants in group G1 decided to address the *teaching of proportions and applications of areas*. Based on this choice of content, they studied the case of a crop farm. They began by exploring in Google Maps (Fig 1) the areas of some tomato, chard and potato farms, which are widely consumed in Chile, from where they obtained relevant data, such as the production yield per hectare, types of soils, climates, and recommended seasons for sowing (extra-mathematical knowledge).

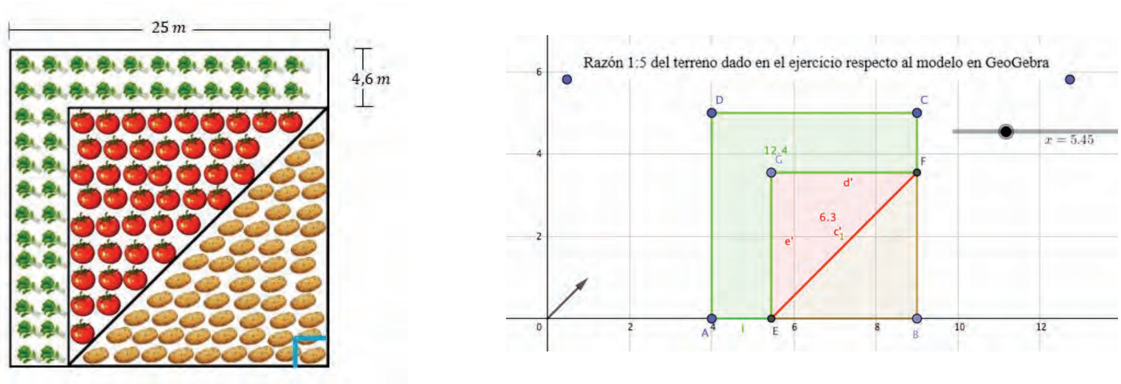


Product	Average yield per hectare	Distance between plants
Chard	16 294	0.4 to 0.5 m
Tomato	25 196	0.5 to 0.7 m
Potato	24 000	0.5 to 0.7 m

Figure 1. Initial exploration of the situation

After exploring the situation, an *idealization* process took place to determine the relevant information to be used in the teaching task, assuming a production yield per square meter. They also considered a square plot measuring 25 m x 25 m, with the condition that each field should have the same area (Fig 2). They also set the values by specifying the production yield per square meter: chard 15 kg/m^2, tomato 8kg/m^2 and potato 13kg/m^2. At this time, the study of the situation lost any semblance with reality, since when calculating the final production, they obtained quantities that differ considerably from the average values. This is explained by the *oversimplification* of the situation, which assumes that each plot of land produces the same amount of product and ignores the density of plants in a given area. This aspect is also related to the omission of the *validation* phase associated with modelling, so the initial approach to this task stands out for the participants' lack of control over their procedures and reflections. This is associated with a metacognitive ability for the development of the modelling process (Czocher, 2018).

In this case, the design of the task depends on the mathematical content for teaching (areas and proportions), an aspect that determined the study context selected and the restrictions in the exploration of a situation that should comprise a modelling task. Moreover, the questions that are finally posed to the students (Fig 2) denote that the activity could well be carried out by omitting the context. In other words, the context is not relevant to achieving the desired objective learning, nor is it a source of reflection. Regarding the DGS *exploitation mode*, since it was initially designed to have the students carry out the construction, it considers the use of tools, such as a polygon, a vector to define the diagonal that divides one of the plots of land, intersections and calculation of distances.



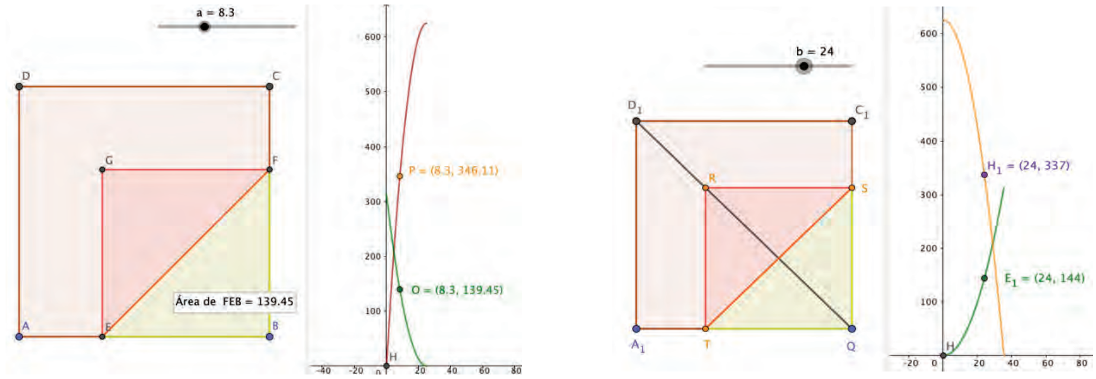
1. Calculate the area of each zone.
2. Calculate the length of the sides of each zone, since you will want to fence them in soon.
3. What is the approximate yield he can expect knowing that [...]
4. If he expands the plot with chard, knowing that the tomato and potato zones have to be the same, how will the proportion change […]

Figure 2. Task designed by a group of future teachers. This figure shows part of task 1 designed by G1 (the introduction has been omitted, which is of the type "Help Mr. Ramón to…").

The mathematical content present in the task, in coordination with the use of technology, can give rise to the exploration of mathematical concepts of another order, for example to introduce the image of simultaneous covariance of two quantities, an element that is essential to understanding the concept of function (Carlson, et al 2002). Based on the idea initially presented in the task, and in view of the fact that the context was irrelevant to the mathematical reflection, we next explore ways, from a purely *mathematical context*, in which the task could be exploited to encourage engagement by the students.

Figure 2 (right side) shows the construction made by the participants, where slider *a* controls the length of side AE, which is congruent to side FC, such that when it is moved, it changes the area of each figure in the geometric configuration. The triangles EFG and EFB are congruent. Graphing the area of one of the triangles and the area of figure AEGFCD yields the right graph in Figure 3a. This can be used to introduce the study of variation, with segment length AE as the independent variable and the area as the dependent variable. The point where the curves intersect represents the case in which all three areas are equal.

Another interesting case that allows us to explore the DGS is the construction where the independent variable is given by the values of segment QR, resulting in the graphical representation shown in Figure 3b. Of note in this case are the different growth rates.



(a) Graph of side AE vs area of triangle FEB and AEGFCD

(b) Graph of side QR vs area of triangle and $C_1D_1A_1TRS$

Figure 3. Exploring different ways to approach the task

These ways of approaching the task, shown in Figures 3 a and b, supported by the dynamism offered by the software, can be used to explore the covariance between the input value and the output value (area) in the same situation. The construction of the dynamic configuration and the use of the slider to control the independent variable are essential to determine the dependency between the variables. This paves the way to introducing the concept of rate of change, domain and range as a preliminary step to studying functions, aspects that had not been initially considered in the design of the task. And improving the context of the task can lead to the study of a crop yield optimization problem. Note that in the previous cases, the sides of the triangle vary similarly, at the same time, giving rise to quadratic behavior. If we vary only one leg of the triangle while keeping the other constant, this results in linear behavior, which introduces a modification to the task. The table 2 below summarizes the main characteristics of this task.

DGS exploitation modes	Predicted mathematical knowledge	Mathematical knowledge emerging from the construction	Technical knowledge
-Construction of a geometric configuration, considering equal areas and different shapes. - Exploration of changes in areas and perimeters, and changes in yield - Static simulation	- Direct and inverse proportions. - Graphic and tabular representation - Lines, perpendicular, parallel, bisector - Triangles, their dimensions - Midpoint of a segment - Congruence - Calculating areas	- Vector - polygon - variable - straight line (vector definition) - point and segment - intersection - symmetry - distance - ratio	- slider to control the characteristics of the configuration. - Point in - Straight line passing through - Vector - Segment - Intersection - Axial symmetry - Distance between points

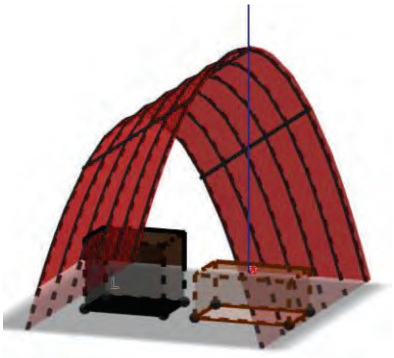
Table 2. Summary of the characteristics

Analysis of design made by Group 2

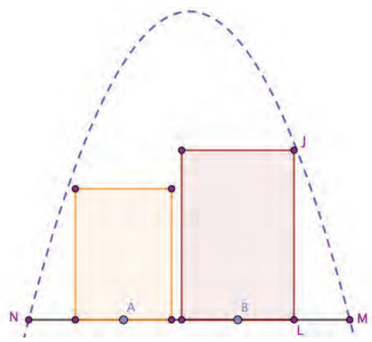
The design of task 2 is based on a study of the dimensions of vehicles that go through a tunnel. In this case, the participants looked for information online about the dimensions and shapes of tunnels, and about accidents where the vehicle impacts the structure due to exceeding the allowed dimensions. These aspects defined the *choice of context*. Based on the above, the situation was *simplified and idealized* assuming, primarily, that the vehicle moves in a straight line, and the shape of the tunnel was approximated by a parabolic arch with height and base width fixed (Figure 4a). From here, the participants determined the mathematical *learning objective* of the lesson (modelling situations using the quadratic equation, recognizing representations of the parabola and solving problems involving intersections) for high school students (16-17 years old). In this case, as in task 1, there was a certain disconnect with reality due to considering unrealistic data for the dimensions of the vehicles.

The simplification of the situation in this case leads to a study of different representations of the parabola in the context of DGS. On the one hand, by representing the shape of the tunnel with a parabola, the first element that emerges is its construction, which can be carried out in at least three different ways: *a conic given five points*, by means of its *algebraic expression*, and *using the parabola tool given the focus and directrix*. The participants chose the second option. The cars are then represented by means of rectangular prisms.

Task 2 asks, given the width, to determine the maximum height that vehicles can have that cross a tunnel shaped like a parabolic arch. This task requires broad mastery of DGS to construct the simulation that represents the situation in the 3D graphic view where the objects are moving (Fig 4a). The analysis is subsequently done in a 2D graphic view. The mathematical activity is then steered to determine the point where the height of the quadrilateral intersects the parabola (Figure 4b). This implies a mathematization process where the shape of the tunnel is represented with a parabola, with its axis on the y-axis, the maximum height of the tunnel (h meters) and its width at the bottom (*a* meters). These parameters are associated with the vertex of the parabola (0, *k*) and points (-*a/2*, 0) and (*a/2*, 0) respectively. This information is used to determine its equation $y = -\frac{x^2}{4p} + k$ and graph the parabola and quadrilaterals (Figure 4b).



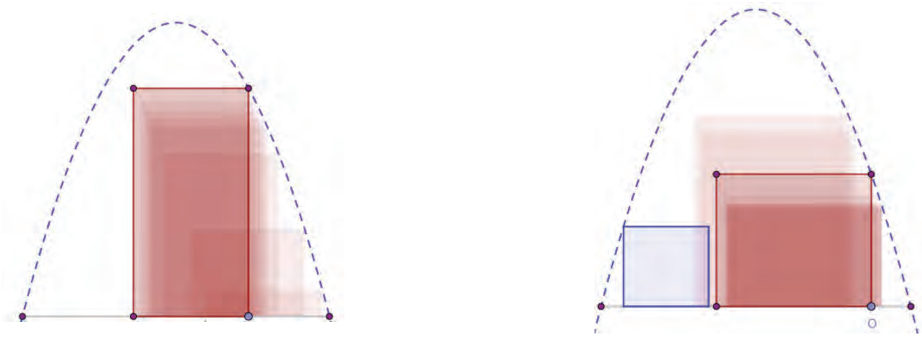
(a) Representation of the 3D situation



(b) Representation of the 2D situation

Figure 4. Students' representation of the situation

To explore the solution, if distance LM is fixed in figure 5b, the problem is reduced to determining the equation of the straight line that passes through points J and L, and solving the system of equations formed by the equation of this line and the equation of the parabola. But if this distance is not fixed, another DGS mode of *exploitation emerges* where the quadrilateral has horizontal movement, allowing for exploration to obtain different heights (Figure 5a).



(a) constant base, different heights **(b) allowed dimensions of two quadrilaterals**

Figure 5. Exploring the dimensions of the quadrilateral

Now, since there are two quadrilaterals, exploring the movement allows us to observe how the dimensions of one quadrilateral affect the dimensions of the other such that both can be inscribed in the area between the parabola and the line y = 0. Thus, another form to exploit DGS emerges when modifying the task to allow for exploration of the maximum dimensions that one or both quadrilaterals inscribed in the figure can have (Figure 5b). The characteristics of this task are summarized in Table 3.

DGS exploitation modes	**Predicted mathematical knowledge**	**Mathematical knowledge emerging from the construction**	**Technical knowledge**
-Exploration the intersections using DGS, considering the width and height of the quadrilaterals - Static simulation	- Midpoint - Elements of the parabola: concavity, vertex, endpoints, algebraic expression. - Intersections - Areas	- Line through two points - Segment, distances - Intersection. - Multivariate function with domain restrictions - Operations with functions - Parabola and its elements	- Slider to control the characteristics of the configuration. - Point in - Segment - Intersection - Distance between points - 3D graphic

Table 3. Summary of the characteristics of the task designed by group 2.

Discussion and Conclusions

In the above cases, we can differentiate between two elements associated with the design of the tasks. The first is the modelling process undertaken by the future teachers, which involves the following phases: selection of a real-life problem, simplification/idealization, recognition of the mathematical learning objective, and mathematization. When designing a modelling task, it was hoped that the participants would also model it; however, the analysis shows that their process does not span a complete modelling cycle, as defined in some of the commonly recognized modelling cycles (Doerr, Ärlebäck and Misfeldt, 2017). This is explained by the fact that the simplification was done with the goal of designing a task with a specific mathematical learning objective in mind, and not with the goal of teaching modelling.

The second element involves the potential of the software, as exploited by the participants. In both cases, they exhibit a general domain of DGS, their use of which is limited to fulfilling the objective of the tasks. Moreover, representing the situation or part of it in the DGS environment results in a mathematical exercise that, without adequate teacher intervention, could detract from the modelling objective. In the tasks analyzed, the software's role in mediating and enhancing the mathematical activity is evident in the mathematical work phase, a fact that should be taken into account in the pedagogical training of future teachers.

We also observed some tension between the choice of the mathematical learning objective and the choice of an interesting context for the students, in the sense that the choice of the mathematical objective precedes the exploration of a situation to model (task 1), or how the participants sought to determine the mathematical objects in a situation (task 2). This seems to give rise to a context dilemma, in which the solution to the task could either be found without involving a particular context, or the context may be irrelevant or be a source of difficulties in achieving the desired learning (Sullivan, Knott & Yang, 2015).
