TWG21: Assessment in mathematics education 3743

TWG22: Curricular resources and task design in mathematics education 3917

TWG24: Representations in mathematics teaching and learning 4205

TWG25: Inclusive Mathematics Education – challenges for students with special needs 4368

TWG26: Mathematics in the context of STEM education 4535

Preface: CERME 12 in virtual Bolzano

Carl Winsløw

ERME President

University of Copenhagen, Denmark; winslow@ind.ku.dk

The Conferences of ERME (European society for Research in Mathematics Education) have been held roughly biannually since 1998. The core of the conference is the *thematic working groups* (TWG) in which new, related research studies are discussed, based on papers which participants read in advance. While this format has remained almost unchanged since 1998, the scale and scope of CERME have developed considerably over the years: from 120 participants and 7 TWG at CERME 1, to 915 participants and 27 TWG at CERME 12. Moreover, CERME has gone from being a mainly regional congress (with only a few participants from other continents) to being a truly global event in mathematics education research, known for fostering high quality scientific communication, cooperation and collaboration. At CERME12, no less than 48 nations were represented (Table 1).

At the same time, it is evident that CERME12 was a very special – and historically difficult – congress to organize. It was first scheduled for February 3-7, 2021. In May 2020, the ERME board announced its decision to postpone the congress by one year, due to the then roaring outbreak of the COVID-19 pandemic. Indeed, large parts of the world – and most of Europe – continued to experience lockdowns and restrictions that would have made the scheduled congress impossible. Instead, an online *Pre-CERME12 event* was organized in February 2021, hosted by the Institute of Education at University College London, and made possible by the tireless efforts of the team led by Jeremy Hodgen and Eirini Geraniou (also chair resp. co-chair of the IPC of CERME12). The Pre-CERME12 event allowed the 27 TWGs to meet and prepare for conference, now postponed to 2022.

The biannual General Assembly of ERME was also held during this event. We warmly thank Susanne Prediger for her service as President of ERME from 2017 to 2021! Her leadership also contributed crucially to the organisation of CERME12, and thus to the results presented in these proceedings.

During the summer and fall of 2021, we all continued to plan for CERME12 as an onsite event in Bolzano, Italy. The YESS summer school was held near Bolzano in August, with great success. More than 700 papers and posters were submitted for CERME12 in September. But in November 2021, new and unknown variants of the virus appeared. Their alarming spread forced us to reconsider the situation. Finally, the LOC, the IPC and the ERME board jointly decided that CERME12 would be held as an online congress, as announced in a mail sent to all members of ERME on December 1st:

> It is with great sadness that we must communicate a decision which is forced upon us by the current developments of the COVID epidemic in Europe, and which has been taken by the ERME board in full agreement with us: CERME12 will be organized by the Bolzano team as an online conference, on the same dates as originally foreseen. For a long time we hoped for the much desired possibility of having the first CERME in three years as a normal, face to face event. Organizing a virtual CERME – which we will strive to hold as much "CERME spirit" as possible – will be a very demanding task, both in terms of finding good technical solutions, and in terms of organizing the programme and preparing the many TWG teams in a good way.

Table 1: The success of CERME12 in numbers – 915 participants from 48 countries

Indeed, it took a unique *tour de force* for all organisers to prepare – in just two months – an online version of CERME, based as it is on group work and interaction, rather than on one-way presentations (which are relatively easy to transmit online). These effort was crowned by the best success the new conditions could possibly allow: an online congress with more participants than ever, with virtually no technical problems, and not least with a high level of participant satisfaction.

In the history of ERME, CERME12 will be remembered as a scientific highlight during the long and hard pandemic. First of all, that is due to the plenary speakers and panelists, and to the contributors of papers and posters. Your efforts shine through the quality of the scientific texts offered by these proceedings. ERME, as a society of scholars, was not stopped – hardly delayed – by the pandemic, thanks to your ingenuity and unfailing determination to do and share first class research.

The realization of CERME12 was made possible also by the many people who organised the congress, under the difficult conditions alluded to above, namely:

- The Local Organizing committee, led by Giorgio Bolondi and Federica Ferreti, and all of the Bolzano team, including also the technicians who made the online congress run smoothly;
- The International Programme committee, led by Jeremy Hodgen and Eirini Geraniou;
- The leader teams of all 27 Thematic Working Groups.

For all your tireless and unselfish work during the three years between CERME 11 and CERME 12, the community owes you immense and extraordinary gratitude.

And the story goes on: ERME invites all interested researchers to CERME 13 (Budapest , Hungary, July 2023), and after that, to CERME 14 to be held in *real* Bolzano in February 2025.

Introduction to the Proceedings of the Twelfth Congress of the European Society for Research in Mathematics Education (CERME12)

About CERME12

The Eleventh Congress of European Research in Mathematics Education (CERME 12) took place virtually, hosted by the Free University of Bozen-Bolzano, Italy, from 2nd to 6th of February 2022, after a year's delay due to the pandemic. Jeremy Hodgen (UK) and Eirini Geraniou (UK) were chair and co-chair of the International Programme Committee (IPC), which comprised Giorgio Bolondi (Italy), Jason Cooper (Israel), Ana Donevska-Todorova (Germany / North-Macedonia), Çiğdem Haser (Finland / Turkey), Uffe Thomas Jankvist (Denmark), Leander Kempen (Germany), Esther Levenson (Israel), Nuria Planas (Spain) and Michiel Veldhuis (The Netherlands). Giorgio Bolondi and Federica Ferreti were chair and co-chair, respectively, of the Local Organizing Committee (LOC).

CERME12 hosted 27 Thematic Working Groups, listed in the table below. The TWGs 11 and 27 were new TWGs, created following a call launched just after CERME11, and a selection process involving the CERME12 IPC and the ERME board. They have both been very successful. Nine of the TWGs received so many submissions that they had to be split in two – more precisely the TWGs 01, 03, 05, 09, 14, 16, 18, 19 and 20. In the end, CERME12 had 27 TWG leaders and 110 TWG co-leaders.

Thematic Working Group	Leader	Co-Leaders
TWG1: Argumentation and Proof	Andreas Moutsios-Rentzos (Greece)	Orly Buchbinder (USA); Jenny Christine Cramer (Germany); Nicolas Leon (YR) until Aug 2021; and from Sep 2021: Viviane Durand-Guerrier (France); David A. Reid (Norway); Mei Yang

		(British Indian Ocean Territory/UK) YR
TWG2: Arithmetic and Number Systems	Elisabeth Rathgeb-Schnierer (Germany)	Judy Sayers (UK); Beatrice Vargas Dorneles (Brazil) until Sep 2021; Pernille Bødtker Sunde (Denmark) from Sep 2021; Renata Carvalho (Portugal) YR
TWG3: Algebraic Thinking	Dave Hewitt (UK)	Maria Chimoni (Cyprus); Cecilia Kilhamn (Sweden); Luis Radford (Canada) from Sep 2021; Jorunn Reinhardtsen (Norway) YR
TWG4: Geometry Teaching and Learning	Michela Maschietto (Italy)	Alik Palatnik (Israel); Lina Brunheira (Portugal); Chrysi Papadaki (Germany) YR
TWG5: Probability and Statistics Education	Caterina Primi (Italy)	Sibel Kazak (Turkey); Aisling Leavy (Ireland); Orlando Rafael Gonzalez (Thailand); Daniel Frischemeier (Germany) YR
TWG6: Applications and Modelling	Berta Barquero (Spain)	Susana Carreira (Portugal); Jonas Bergman Ärlebäck (Sweden); Katrin Vorhölter (Germany); Gilbert Greefrath (Germany) from Sep 2021; Britta Eyrich Jessen (Denmark) YR
TWG7: Adult Mathematics Education	Kees Hoogland (The Netherlands)	Javíer Díez-Palomar (Spain); Fiona Faulkner (Ireland); Beth Kelly (UK) YR
TWG8: Affect and the Teaching and Learning of Mathematics	Stanislaw Schukajilow (Germany)	Inés Mª Gómez-Chacón (Spain); Çiğdem Haser (Finland); Peter Liljedahl (Canada); Chiara Andrà (Italy); Hanna Viitala (Sweden) YR
TWG9: Mathematics and Language	Jenni Ingram (UK)	Kirstin Erath (Germany); Aurélie Chesnais (France); Ingólfur Gíslason (Iceland) YR

TWG10: Diversity and Mathematics Education: Social, Cultural and Political Challenges	Laura Black (UK)	Anette Bagger (Sweden); Anna Chronaki (Greece); Nina Bohlmann (Germany); Sabrina Bobsin Salazar (Brazil) YR
TWG11: Algorithmics	Christof Weber (Switzerland)	Janka Medova (Slovakia); Ulrich Kortenkamp (Germany); Simon Modeste (France); Piers Saunders (UK) YR until Oct 2021; Maryna Rafalska (France) from Oct 2021
TWG12: History in Mathematics Education	Renaud Chorlay (France)	Antonio M. Oller-Marcén (Spain); Jenneke Krüger (The Netherlands); Tanja Hamann (Germany) YR
TWG13: Early Years Mathematics	Bożena Maj-Tatsis (Poland)	Marianna Tzekaki (Greece); Esther Levenson (Israel); Martin Carlsen (Norway); Andrea Maffia (Italy) YR
TWG14: University Mathematics Education	Alejandro González-Martín (Canada)	Ghislaine Gueudet (France); Olov Viirman (Sweden); Athina Thoma (UK) YR; and from Sep 2021: Irene Biza (United Kingdom); Chris Rasmussen (United States); Ignasi Florensa (Spain) YR
TWG15: Teaching Mathematics with Technology and Other Resources	Alison Clark-Wilson (UK)	Ornella Robutti (Italy); Melih Turgut (Norway); Daniel Thurm (Germany) from Sep 2021; Gülay Bozkurt (Turkey) YR
TWG16: Learning Mathematics with Technology and Other Resources	Paul Drijvers (The Netherlands)	Florian Schacht (Germany); Nathalie Sinclair (Canada); Osama Swidan (Israel); Eleonora Faggiano (Italy) from Sep 2021; Seçil Yemen Karpuzcu (Turkey) YR
TWG17: Theoretical Perspectives and Approaches in Mathematics Education Research	Angelika Bikner-Ahsbahs (Germany)	Heather Johnson (USA); Anna Shvarts (The Netherlands); Abdel Seidouvy (Togo/Sweden) YR

TWG18: Mathematics Teacher Education and Professional Development	Janne Fauskanger (Norway)	Libuse Samkova (Czech Republic); Andreas Ebbelind (Sweden); Marita Eva Friesen (Germany) YR; and from Sep 2021: Tracy Helliwell (UK); Macarena Larrain (YR)
TWG19: Mathematics Teaching and Teacher Practice(s)	Reidar Mosvold (Norway)	Mark Hoover (USA); Siún Nic Mhuiri (Ireland); Edyta Nowinska (Poland/Germany); Helena Grundén (Sweden) YR
TWG20: Mathematics Teacher Knowledge, Beliefs and Identity	Fatma Aslan-Tutak (Turkey)	Miguel Montes (Spain); Francesca Martignone (Italy); Miguel Ribeiro (Brazil); Veronika Hubeňáková (Slovakia) YR
TWG21: Assessment in Mathematics Education	Paola Iannone (UK)	Francesca Morselli (Italy); Michal Ayalon (Israel); Michiel Veldhuis (The Netherlands); Gözde Kaplan Can (Turkey) YR
TWG22: Curricular Resources and Task Design in Mathematics Education	Shai Olsher (Israel)	Sebastian Rezat (Germany); Annalisa Cusi (Italy); Nataly Essonnier (France) YR
TWG23: Implementation of Research Findings in Mathematics Education	Mario Sánchez Aguilar (Mexico)	Boris Koichu (Israel); Morten Misfeldt (Denmark); Rikke Maagaard Gregersen (Denmark) YR until Aug 2021; Linda Marie Ahl (Sweden) YR from Sep 2021
TWG24: Representations in Mathematics Teaching and Learning	Anna Baccaglini-Frank (Italy)	Carla Finesilver (UK); Michal Tabach (Israel); Kate O'Brien (USA/UK) YR
TWG25: Inclusive Mathematics Education – Challenges for Students with Special Needs	Petra Scherer (Germany)	Hana Moraova (Czech Republic); Michael Gaidoschik (Italy); Helena Roos (Sweden) YR
TWG26: Mathematics in the Context of STEM Education	Behiye Ubuz (Turkey)	Michele Stephan (USA); Clelia Cascella (Italy/UK); Nelleke Den Braber (The Netherlands) YR

TWG27: The Professional Practices, Preparation and Support of Mathematics Teacher Educators	Ronnie Karsenty (Israel)	Stefan Zehetmeier (Austria); Hilda Borko (USA); Alf Coles (UK); Bettina Rösken-Winter (Germany); Birte Friedrich-Pöhler (Germany) YR

Editorial information

These proceedings are available as a complete volume online on the ERME website and each individual text is also available on the HAL open archive, where it can be found through keywords, title or author name. This has been the practice since CERME9, to increase the visibility of the huge work done in CERME conferences.

This volume begins with texts corresponding to the three plenary activities of CERME12: the plenary lecture by Susanne Prediger (Germany) on “Enhancing language for developing conceptual understanding: A research journey connecting different research approaches”; the plenary lecture by Jeppe Skott (Sweden / Norway) on “Conceptualizing individual-context relationships in teaching: Developments in research on teachers’ knowledge, beliefs and identity”; and finally the panel discussion “Big Questions in Mathematics Education”. This panel discussion was led by Anna Baccaglini-Frank (Italy), Ingi Højsted (Faroe Islands) and Janka Medova (Slovakia), chaired by Michiel Veldhuis (The Netherlands) and moderated by Eirini Geraniou (UK/Greece). The two plenary speakers, Susanne Prediger and Jeppe Skott, each gave a response to the panel discussion.

After the plenaries, the reader will find 27 chapters corresponding to the work done in the TWGs of CERME12 (with combined introductions from all the split TWGs). These chapters follow a similar structure: they start with an introduction; then the long paper contributions (8-page papers) and the short poster contributions (2 pages) are presented – in alphabetical order by first author’s name.

There are two kinds of introductions to the TWGs, according to the team’s choice: short introductions (4 pages) presenting the contributions; or long introductions (8 pages), which propose, in addition, an analysis of the current research on the theme of the TWG, and perspectives for the future. TWGs 04, 06, 07, 09, 14, 15, 17, 18, 19, 22, 25 and 26 have chosen this form of long introduction.

The publication of these proceedings is the result of a collaborative work, involving the CERME12 IPC, the TWG leaders and co-leaders, the LOC chair and co-chair and the wider team at Bozen-Bolzano. Particular thanks are due to Katrin Lambacher. We warmly thank all these people for their involvement, and hope that this volume will contribute to the development of mathematics education research in Europe and beyond.

Enhancing language for developing conceptual understanding: A research journey connecting different research approaches

Susanne Prediger

IPN Leibniz Institute for Science and Mathematics Education, Berlin, Germany, and TU Dortmund University, Germany, prediger@math.tu-dortmund.de

Typical problems in mathematics education require the pursuit of several research goals: not only explaining the problem and its underlying mechanisms, but also designing and evaluating instructional approaches for overcoming them. When the problem is complex, various research approaches need to be combined. In this plenary paper, I will summarize several steps from a 13-year research journey to serve as an example of how different research approaches can be connected to gain deep insights into language-responsive mathematics instruction. On a meta-level, the paper reflects the affordances and challenges of connecting different research approaches and thereby advertises extension of the networking practices that have been well established in ERME research.

Keywords: Connecting research approaches, conceptual understanding, language-responsive instruction, epistemic role of language

Introduction

With respect to typical problems in mathematics education, researchers can choose to pursue different research goals (Mason & Waywood, 1996; Burkhardt & Schoenfeld, 2003):

- *describing* the problem
- *explaining* the problem and its underlying mechanisms
- *designing* instructional approaches for overcoming the problem
- *evaluating* instructional approaches with respect to their effectiveness
- *describing and explaining* challenges in implementing the instructional approaches
- *designing* teacher professional development (PD) and material support for teachers to overcome the challenges

For each of these potential research goals, the need for different research approaches and different background theories (including theories from outside mathematics education) often resulted in research projects in the early years of the academic discipline making a choice between alternative research goals. However, within the last decades, the academic discipline has successively moved towards connecting several research approaches so that the research goals can increasingly be combined in longer chains of projects. In my view, this trend is highly desirable, as it allows research to really make a difference in mathematics classroom practices (Burkhardt & Schoenfeld, 2003).

My message for this conference paper is that we should continue this *important trend of connecting research approaches* while always keeping our feet on the ground, namely, on sound epistemological analyses of the mathematical topic and the topic-specific learning processes in view. I will try to exemplify what this can mean by reporting from the 13-year research journey of our MuM research group in Dortmund (MuM is an abbreviation for “mathematics learning under conditions of language diversity"). While treating a particular problem in the example (in this case, challenges of language in school mathematics learning), the aim of the last section will be to draw some more general conclusions beyond the specific problem being treated.

What I present here is grounded in CERME work in two ways: Our research on language has profited enormously from the ideas exchanged in the CERME Thematic Working Group (TWG) on language throughout several years (Planas et al., 2018), and the meta-perspective from which I reflect on the research journey today is a continuation of ideas emerging from the CERME TWG on theories (Artigue et al., 2005; Kidron et al., 2018), valuing different research approaches and striving to network them (Bikner-Ahsbahs, Prediger, & Networking Theories Group, 2014), not only with respect to using different theoretical lenses on the same data, but with respect to combing through and shifting the research questions, research objects, and perspectives across several studies.

Overview of a 13-year research journey

Our research journey started with recognizing a serious problem occurring in many countries: failure to provide equitable access to mathematics for students with low language proficiency. To address this problem, a chain of research questions and design challenges were pursued:

- What exactly is the problem with language in mathematics? (describing and explaining)
- How can language be enhanced in mathematics classrooms? (designing)
- What language demands are crucial for concept development? (designing and explaining)
- Is language-responsive teaching effective for developing conceptual understanding? (providing evidence for effectiveness)
- Who profits from language-responsive instruction? (extending the target group)
- How does teachers' enactment affect the learning gains? (explaining and connecting to high-quality instruction)

In the following subsections, I try to sketch how these questions were iteratively treated from different perspectives in the 13-year research journey, without accounting for all technical or theoretical details. The section is not a typical research report: Its aim is to exemplify the needs that were identified and the decisions that led to identifying the necessity to connect several research approaches in longer research journeys.

What exactly is the problem with language in mathematics?
Describing and explaining by large-scale assessments

Usually, educational problems are ill-defined in the beginning (Silver & Herbst, 2007). This was also the case for our problem: Large-scale assessments have repeatedly shown that school systems in many countries fail to provide equitable access to mathematics for all students (Braswell, Dion, Daane, & Jin, 2005; Haag et al., 2013; OECD, 2007). Originally, this failure of school systems was often conceptualized as achievement gaps of students with low socioeconomic status, immigrant status, and/or multilingual background (OECD, 2007; Stanat et al., 2012). This led to problematic deficit-oriented policies and approaches for multilingual students (Gutiérrez, 2008; similarly for other challenges of low-attaining students, Hodgen et al., 2021).

The description of the problem, however, depends on the categories used: When not only immigrant status and multilingual background but also the students' *academic language proficiency* in the language of instruction are captured in the large-scale assessment, this background factor (to be further explained below) turns out to be most relevant for students' mathematics achievement (Prediger et al., 2018) and for students' mathematical learning gains throughout a year of schooling in German schools (Ufer & Bochnik, 2020).

From a sociolinguistic perspective, *academic language* is described as a language register between students' everyday language and the technical formal mathematical language (Schleppegrell, 2004; Snow & Uccelli, 2009) and is functionally characterized as the register "used by teachers and students for the purpose of acquiring new knowledge and skills…, imparting new information, describing abstract ideas, and developing students' conceptual understanding" (Chamot & O'Malley, 1994, p. 40). It is seen as important learning medium, both for classroom communication and as a thinking tool in an important epistemic function for mathematics learning (Schleppegrell, 2004). Although the construct of "register" has sometimes been reduced to lexical and grammatical features, Halliday's (1978) definition also entails language use in larger language units above the sentence level. We refer to interactional discourse analysis to capture these language units above sentence level as discourse practices. Discourse practices are conventionalized genres that are interactively co-constructed relying on patterns available in speech communities' knowledge (Heller & Morek, 2015). Academic discourse practices are those optimized for school purposes, in particular *reporting procedures*, *explaining meanings* to convey or construct knowledge, and *arguing* to negotiate divergent validity claims in classrooms.

From a socioeducational perspective, the critical feature of academic language is that it is an unequally distributed learning prerequisite to which some students get more access at home than others, depending on their family backgrounds (Snow & Uccelli, 2009), which is an example of how social background factors coincide with academic language proficiency.

For education practices, the sociolinguistic and socioeducational theoretical embedding of explanative statistical findings that academic language proficiency is a relevant background factor for mathematics achievement leads to changes in responsibilities: Whereas students' family background factors (immigrant status, socioeconomic status, and/or multilingual background) are considered static and cannot be changed by schools, schools can indeed take responsibility for enhancing students' academic language proficiency in order to reduce language-induced achievement gaps, including those occurring in mathematics (Thürmann, Vollmer, & Pieper, 2010).

Large-scale assessments can also support locating the language-induced achievement gaps within different types of mathematical knowledge: In our own study on a high-stakes test of 1,495 10th graders, we expected the language gaps to be largest for items with high reading demands, following the idea of language biases in the item texts (as found, e.g., by Abedi & Lord, 2001). But a differential item functioning analysis revealed that the language gaps were largest for items with high conceptual demands, even if reading demands were low (Prediger et al., 2018). This finding was strengthened by a recent longitudinal study throughout Grade 2 (Ufer & Bochnik, 2020) showing that students' language proficiency had much less impact on gains in procedural skills ($\beta = 0.16$) than gains in conceptual understanding ($\beta = 0.30$ for using concepts for solving word problems and $\beta = 0.29$ for representing operations and concepts in visualizations). In both studies, language gaps were largest for *developing conceptual understanding of mathematical concepts*. These quantitative findings resonate with the sociolinguistic characterization of academic language as learning medium.

As an educational consequence of the identified language-induced achievement gaps, enhancing students' academic language is now considered an important step in achieving more equitable access to higher-order thinking across all subjects (Thürmann, Vollmer, & Pieper, 2010; Chamot & O'Malley, 1994). In Germany, this call for enhancing academic language in all subjects has been integrated into educational policy directives and the syllabus, yet without much support for helping teachers to realize this goal (MSW, 1999).

Summing up, *large-scale assessments* detected an ill-defined problem (there are problems with equity) and helped to locate the problem more exactly, namely, in the relevant background factors (the disparities can be traced back to academic language proficiency) and the type of mathematical knowledge (language gaps are largest for items with conceptual understanding). External *theoretical perspectives* (here from sociolinguistics) helped to understand the findings (academic language proficiency has an important epistemic role for developing higher-order thinking, including conceptual understanding). However, neither large-scale assessment nor the external theoretical backgrounds alone can orient instructional approaches to how to overcome the problem (Sullivan, 2015).

How can language be enhanced in mathematics classrooms? First attempts to learn design principles from good practices

Given the missing support for teachers, it was no surprise that the educational policy directive calling for enhancing students' academic language (MSW, 1999) had only very limited impact in schools. Ten years later, the educational ministry reacted by including language enhancement into the curriculum of initial teacher education of all subject matter teachers. However, this reform risked failure because subject-specific instructional approaches and curriculum materials that could be used in teacher education programs were not available for subject matter teacher educators.

That is why, in 2009, the MuM research group in Dortmund started its work aimed at providing support for mathematics teachers and mathematics teacher educators to enhance students' academic language of school mathematics. The first search for good practices revealed a typical problem that had also been documented in other countries: Many mathematics teachers who start working on enhancing students' language concentrate on simple vocabulary work, mostly concentrated on formal technical mathematical language or grammar (e.g., DFEE, 2000; problematized, e.g., by Moschkovich, 2010), but without an explicit focus on the discourse practices in play. This restriction to vocabulary work was also documented by de Araujo and Smith (2022), who analyzed US algebra textbooks with respect to the hints and materials provided for working with language learners: Reduced cognitive demands and less ambitious learning goals are combined with isolated vocabulary work, but there was no support for engaging students in discourse practices.

Identifying this problem led us to go beyond our attempt to learn from good practices to performing a qualitative classroom video study of 73 mathematics lessons in five Grade 5 classrooms. We studied how teachers engaged their students in discourse practices and what kind of support was given for students with low academic language proficiency (Erath et al., 2018). By coordinating an epistemic perspective on students' participation in collective knowledge constitution processes with the socio-linguistic perspective of interactional discourse analysis (Quasthoff, 2011), we replicated well-known findings that students' mathematical learning opportunities tend to be very significantly shaped by their ability to participate in the discourse (with various theoretical approaches collected by Herbel-Eisenmann et al., 2011), and "content learning is inseparably bound up with language learning and vice versa" (Barwell, 2005, p. 207). In particular, we showed that students' participation in classroom interaction depends on their proficiency in actively engaging in discourse practices such as explaining and arguing, for which almost no learning opportunities were provided in the observed classroom interaction (Erath et al., 2018).

Summing up, the qualitative classroom video study allowed us to confirm the role of academic language proficiency as learning medium and as unequally distributed learning prerequisite, but we could identify hardly any good practices for enhancing students' discourse competences. Although this study substantially contributed to explaining the problem in the discursive dimension, it was again not able contribute to overcoming it.

How can language be enhanced in mathematics classrooms? Second attempt through using design principles imported from language education

As our descriptive, non-interventionist video study in regular mathematics classrooms provided hardly any empirical insight into how language can be enhanced in mathematics classrooms, we changed to an interventionist research approach, namely, to design research. Design research is the research approach that combines the research goals of developing instructional approaches with gaining deep empirical insights for explaining mechanisms of the teaching learning processes (Gravemeijer & Cobb, 2006). In our case, we first had to create the language-responsive teaching learning processes we intended to investigate.

A careful literature review in language education (including second-language education) allowed us to import design principles that have proven effective for providing learning opportunities for learning academic language. We imported three generic design principles for language learning in language lessons:

- *DP1 Pushed output.* Students learn academic language when consistently being pushed to talk and write (Swain, 1995; Walqui, 2006).
- *DP2 Use multiple representations*. Students can construct meanings for new language when moving between multiple representations and language registers (von Kügelgen, 1994).

- *DP3 Sequence language registers*. Students can acquire language when it is carefully sequenced in a language learning trajectory starting from the everyday language and moving through academic language to the technical language of the subject matter (Gibbons, 2002).

These principles gave us important first ideas and strengthened our confidence that good language-responsive classrooms can also be high-quality mathematics classrooms: DP2 has a long tradition for developing conceptual understanding, even before language registers were considered (Lesh, 1979), and DP3 resonates with a similar sequencing principle for mathematical learning opportunities, the level principle in realistic mathematics education (Gravemeijer, 1998). DP1, the emphasis on students' active talk, was advocated in mathematics education before language became an explicit focus (as traced by Austin & Howson, 1979; Pimm, 1987).

What academic language demands are crucial for developing conceptual understanding? Design research for overcoming the specification gap

Research approach

Even if the design principles provided first ideas for the design of an instructional approach that can enhance students' language in mathematics classrooms, we detected a crucial *specification gap*, as the generic design principles imported from other academic disciplines do not help to specify the demands of the learning content in detail (Bailey, 2007). What exactly are the academic language demands that are most crucial for developing conceptual understanding in mathematics?

In our topic-specific design research approach (Prediger & Zindel, 2017), specifying and structuring the learning content is a key working area for treating what-questions (what needs to be learned?) that is also informed empirically by design experiments (van den Heuvel-Panhuizen, 2005) as depicted in Figure 1.

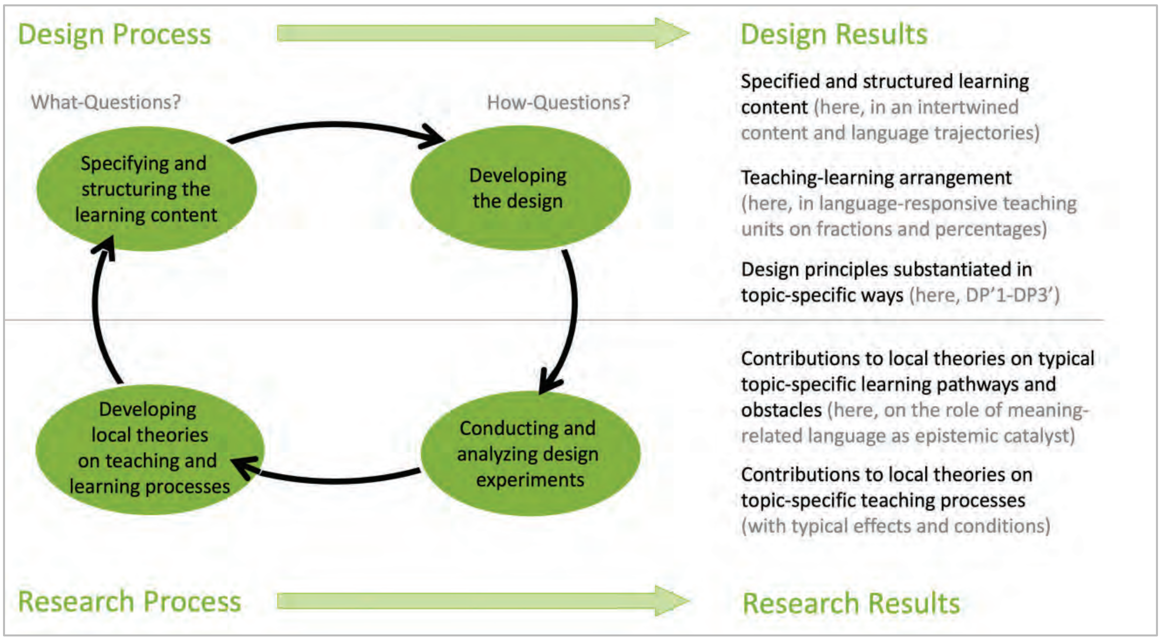

Figure 1. Working areas in topic-specific design research (adapted from Prediger & Zindel, 2017, p. 4168)

In the first design research study (Prediger & Wessel, 2013), we built upon fine-grained existing *specifications* of typical challenges (Behr et al., 1992) and knowledge elements needed for developing conceptual understanding of fractions and overcoming typical mathematical challenges (the part-whole relationship, ordering fractions, and finding equivalent fractions, preferably in a fraction bar model; see Cramer et al., 2009). The language learning content was only vaguely specified in the beginning of our design research study. Developing a first prototype *design of the teaching-learning arrangement* for this learning content is the second working area in the design research cycle (see Figure 1), for which we used the generic design principles DP1, DP2, and DP3.

In the third working area, *design experiments* with monolingual and multilingual seventh graders with low German academic language proficiency were conducted to determine what everyday language resources they bring in and what elements of academic language would support their participation in the process of meaning-making for the mathematical concepts in view.

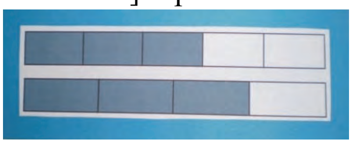
The *qualitative analysis of the design experiments* helped to explain the epistemic role of academic language in more depth. It informed the specification of the crucial academic language demands by acts of empirically grounded theorizing in the fourth working area.

Case study of Cavit and Ismet for specifying the needed academic language

The case of Cavit and Ismet (first analyzed in Prediger, 2013) can illustrate the third and fourth working area, in particular the empirical specification of crucial academic language demands. For this, I provide selected insights into the analysis of one design experiment, conducted in a pair setting with Cavit and Ismet, two sixth graders (12 years old) who were born in Germany and spoke fluent everyday German (and Turkish in their families) but only limited academic language at the beginning of the study. The boys were selected by their teacher as assignments showed incomplete understanding of fractions after their first encounter.

Following the design principle DP2 (using multiple representations), the teacher asks the boys to translate the given fraction bars into symbolic fractions, and they translate easily to 3/4 and 3/5 (see figure in the transcript). Following the design principle DP1 (pushed output) and being aware that students often assign other meanings to graphical representations than the conventional meaning in school arithmetic (Behr et al., 1992), the teacher presses the boys to explain the meaning of the fraction bar.

9 Teacher:	What in this graphical representation [*points to the fraction bars*] represents the fraction?
10 Cavit:	Eh, the... First, you need to count the fields, that is five, and then, the three colored fields, [*silently*] three fifths.
11 Teacher:	Exactly. And which of these two [*points to the fraction bars*] represents the three fifths, actually?
12 Cavit:	First, um, you have to count the fields [*hints at the fraction bars*], here it is one, two, three, four, five [*points at every field of the fraction bar*], and then three, colored [*looks at the teacher*].



The brief transcript (translated from the original German transcript published in Prediger, 2013) documents a particular variant of speechlessness on both sides, both teachers and students, who speak without any lexical or syntactical errors, but the conversation about the mathematical meanings gets stuck. When asked to explain how symbolic fractions and fraction bars are connected (Turn 9), Cavit limits his answer to the discourse practice of reporting the drawing procedure for the graphical fraction bar instead of explaining the meanings of the four fields, the three colored fields and the relationship between them (Turn 10). From his utterances (following a perhaps too implicit teacher question), it is unclear if he understands the part-whole relationship or not. When the teacher asks again, the teacher's speechlessness is indicated by posing nearly the same implicit question as before (Turn 11). Cavit understands the interactive demand for a further explication, but explicates his answer only by counting 1, 2, 3, 4, 5 (Turn 12). In this moment, neither the teacher nor the students seem to have the means to talk about the part-whole relationship, and it is still left unclear if the boys understand the relevant part-whole structure in the bar or not.

At this point in most German mathematics classrooms, the teacher would have given up, assuming in a strength-oriented view that the boys have the right idea even if they cannot communicate it explicitly. This teacher, however, continues to engage the students in making connections between the two representations (following DP2 and DP1) by engaging them in comparing the fractions graphically:

17 Teacher:	How can you see from this picture [*points to the fraction bars*] which fraction is bigger?
…	
24 Ismet:	Here is five [fields] though and there four; from this you see that this [*points to the fraction bar of 3/5*] is big and this is small [*points to the fraction bar of 3/4*].
25 Cavit:	I agree.

When the boys are asked to compare the fractions in the bars, idiosyncratic ideas about the meanings become evident that were not inferable from their earlier utterances. Ismet adopts a typical comparison strategy (Clarke & Roche, 2009) and argues that 3/5 is larger than 3/4 because its fraction bar has 5 instead of 4 fields (Turn 24), and Cavit agrees (Turn 25). It is only in this discourse practice of describing structures (which is more elaborate than reporting a drawing procedure from Turns 10-12) that their ideas about fractions become explicit and discussable. Rather than focusing on the part-whole relationship, they focus on the digits three and five separately without bundling them into one conceptual entity. By this, they are not able to unfold the meaning of fractions as shares appropriately. This observation resonates with a problem previously identified by Steinbring (2005): the "problem of potentially interpreting the given concrete objects and reference contexts for mathematical signs and symbols … as *relational structures*" (p. 5).

A thorough analysis of the boys' discourse practices and their lexical means to realize them exemplifies typical observations: To articulate procedural aspects in the symbolic representation, technical phrases such as nominator and denominator are sufficient. But in this technical language alone, they cannot express conceptual understanding (see Figure 2). The successful translation between graphical and symbolic representation gives a first indication of some conceptual understanding. However, even if the translation is successful, this does not necessarily mean that the connection between two representations involves a deep understanding.

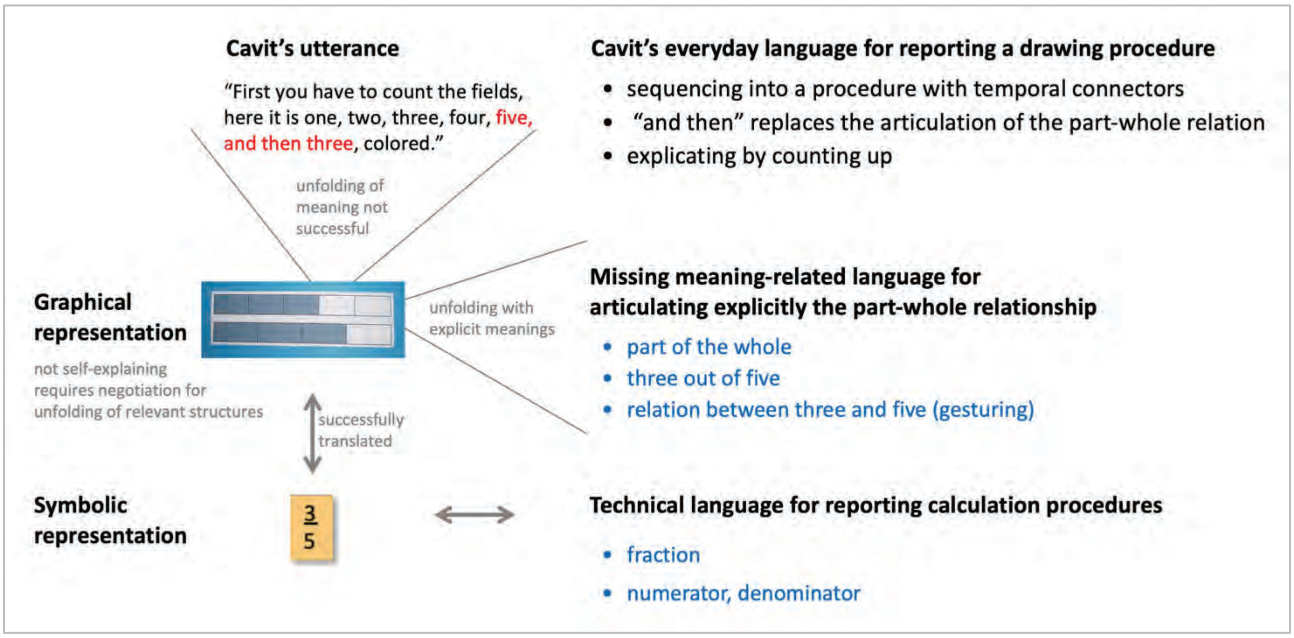


Figure 2. Analysis of involved language registers for the case of Cavit and Ismet

The surface nature of the understanding (sufficient for translating the representation) becomes apparent when the comparison of fractions is to be conducted within the graphical representation (Turn 24), as this requires the unfolding of the fraction concept as a conceptual entity describing the relationship between the whole and the part. From here, it is worth looking back at Turn 12 to analyze Cavit's utterance articulating the surface connection of representations. Rather than explaining the meaning of fractions, Cavit engages in a less demanding discourse practice, namely, reporting a drawing procedure. This proceduralization is an example of sequential reporting also being realized in conceptual contexts, yet without the meaning really being clarified.

Cavit addresses the digits three and five separately; the only connector used between them is "and then," a temporal connector that substitutes the articulation of the part-whole relationship (see Figure 2). The requested further unfolding only leads to counting to five. To articulate the part-whole relationship more explicitly, other meaning-related phrases would have been needed, such as "three out of five" or "part of the same whole." The transcript continues with the teacher offering these meaning-related phrases and filling them with the conventional meaning by heavily gesturing for the relation of five thereof three. By drawing upon gestures for the part-whole relation (indicating the whole, and therein the parts always related to the whole), the teacher attaches the new phrases to students' existing resources and equips them with the meaning-related phrases that enable them to engage in the more demanding discourse practices.

What exactly is the problem with the epistemic role of academic language while developing conceptual understanding? Theorizing by combining epistemic and discursive perspectives

Students' conceptual challenges with fractions as part-whole relationships and comparing fractions have been well documented in the literature (and the existing state of research on student thinking on fractions, e.g., Behr et al., 1992; Clarke & Roche, 2009). The case of Cavit and Ismet's struggle with *articulating* the part-whole relationship adds substantial explanative findings on the role of language in students' conceptual learning pathways to the existing state of research, as it shows typical phenomena we found in many design experiments, for fractions and other mathematical concepts. These phenomena formed the main object of theorizing in the fourth working area of the design research cycle (Figure 1, systematically reflected on in Prediger, 2019). In our research journey, the grounded theorizing based upon these empirically identified phenomena required the combination of epistemic and discursive perspectives.

From an *epistemic perspective*, mathematical concepts are hard to learn as they are usually abstract and relational in nature (Steinbring, 2005). They compact complex relationships (such as the part-whole relationship or functional relationships) into new conceptual entities (such as fractions or functions) that can then be integrated into higher-order networks and relationships. Technical mathematical language is optimized for addressing these abstract concepts in a highly concise and economic manner and allows experts to communicate and think with the language very efficiently. However, for learning the technical language in its compacted form, it must first be unfolded into its meanings (Prediger & Zindel, 2017).

Early work on language in mathematics assumed that all of the unfolding of the formal technical language can be conducted in students' everyday language (e.g., Gallin & Ruf, 1990). But the analyses of multiple design experiments revealed that there is a mediating language register between the everyday language and the technical language that needs to be equally concise and explicit in expressing relationships yet informal, without technical terms and symbolic representations. This is exactly the part of the academic language register that is most crucial for developing conceptual understanding, and we termed it meaning-related language (Pöhler & Prediger, 2015).

From a *discursive perspective*, meaning-related language can be characterized by the discourse practices of explaining meanings and describing mathematical relationships and structures. These discourse practices are typical for the academic language register (Heller & Morek, 2015), and discursively more demanding than narrating or reporting procedures (as already touched by Setati, 2005). In the lexical dimension, reporting procedures mainly requires the less complicated sequential connectors ("first," "and then," etc.), whereas explaining meanings and describing mathematical relationships requires more complex connectors and meaning-related phrases for articulating the key relationships (such as the examples in Figure 5 below). These phrases can also include grammar features in the syntactical dimension (as elaborated in Prediger & Hein, 2017; Prediger & Şahin-Gür, 2020).

For each mathematical topic, these meaning-related phrases need to be identified by epistemological analysis and ideally by empirical investigations of topic-specific learning processes, drawing, of course, upon the existing states of topic-specific research. Consequentially, the research was extended to percentages (Pöhler & Prediger, 2015), logical structures of proofs (Prediger & Hein, 2017), functions (Prediger & Zindel, 2017), qualitative calculus (Prediger & Şahin-Gür, 2020), and other topics. For each mathematical topic, meaning-related phrases for the rich discourse practices of explaining meanings and describing mathematical relationships were identified as crucial.

Summing up, the four practices of theorizing in the first design experiment cycles (fourth working area in Figure 1) led to building a theoretical foundation for specifying the language-learning content (first working area in Figure 1): focusing on the rich discourse practices of explaining meanings and describing mathematical relationships and structures, together with the meaning-related phrases used to realize these discourse practices in processes of developing conceptual understanding. Without the strong epistemological focus on conceptual understanding of mathematical concepts and the epistemic perspective on unfolding their highly compacted meanings, the meaning-related language and its importance as intermediate register would not have been identified.

How can meaning-related academic language be enhanced in mathematics classrooms? Substantiating the design principles with respect to specified learning content

Whereas "how-questions" (How can the learning be enhanced?) and "what-questions" (What has to be learned?) are often treated as independent (like in the beginning of our research journey), the research approach of topic-specific design research has the potential to integrate both questions in subsequent design experiment cycles (Prediger, 2019). The sketched theorizing on the role of the discourse practices of explaining meanings and describing mathematical relationships for unfolding the meaning of mathematical concepts also provided the empirical foundation for substantiating the three generic design principles in more mathematics-specific ways, as shown in Figure 3, so that they can be tailored to enhance those academic language demands that are crucial for developing conceptual understanding of mathematical concepts such as fractions, percentages, and functions.

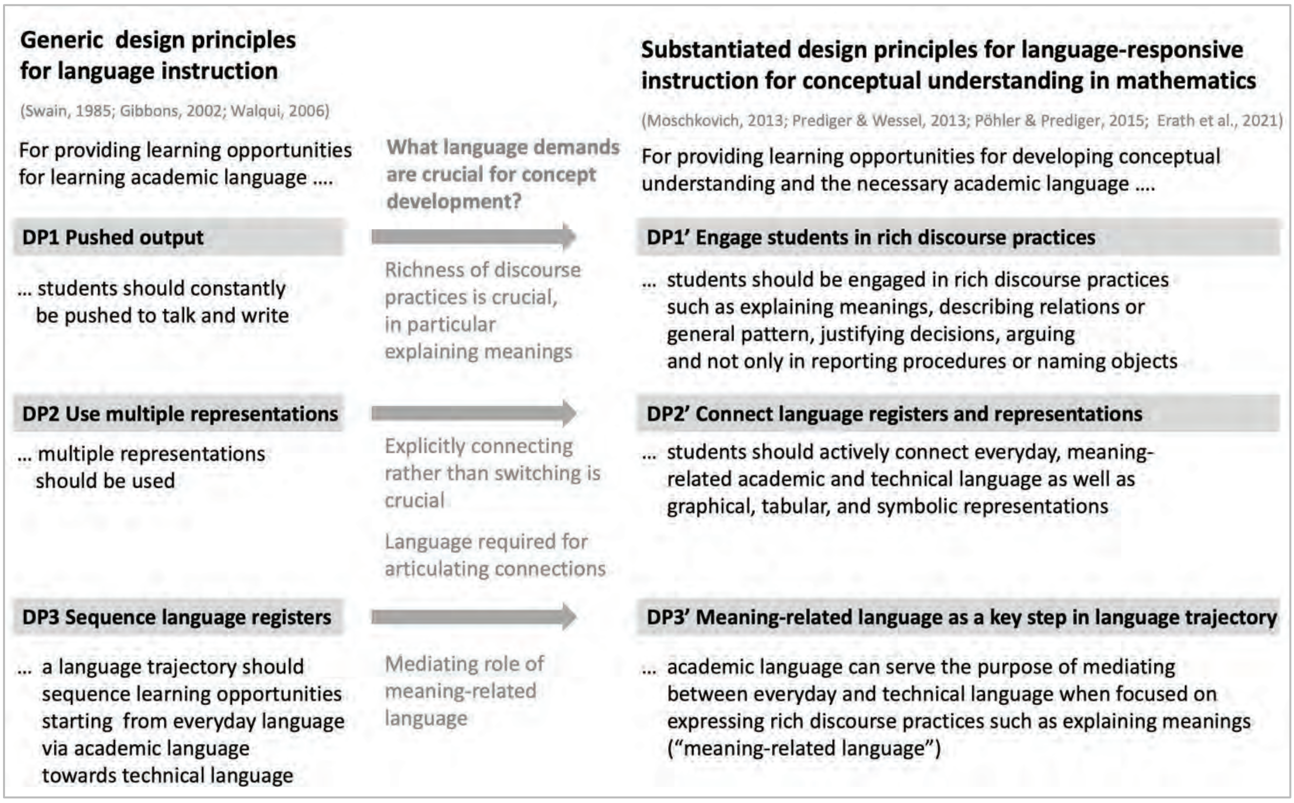

Figure 3. Adapting generic design principles into substantiated design principles for language-responsive instruction of conceptual understanding of mathematical concepts

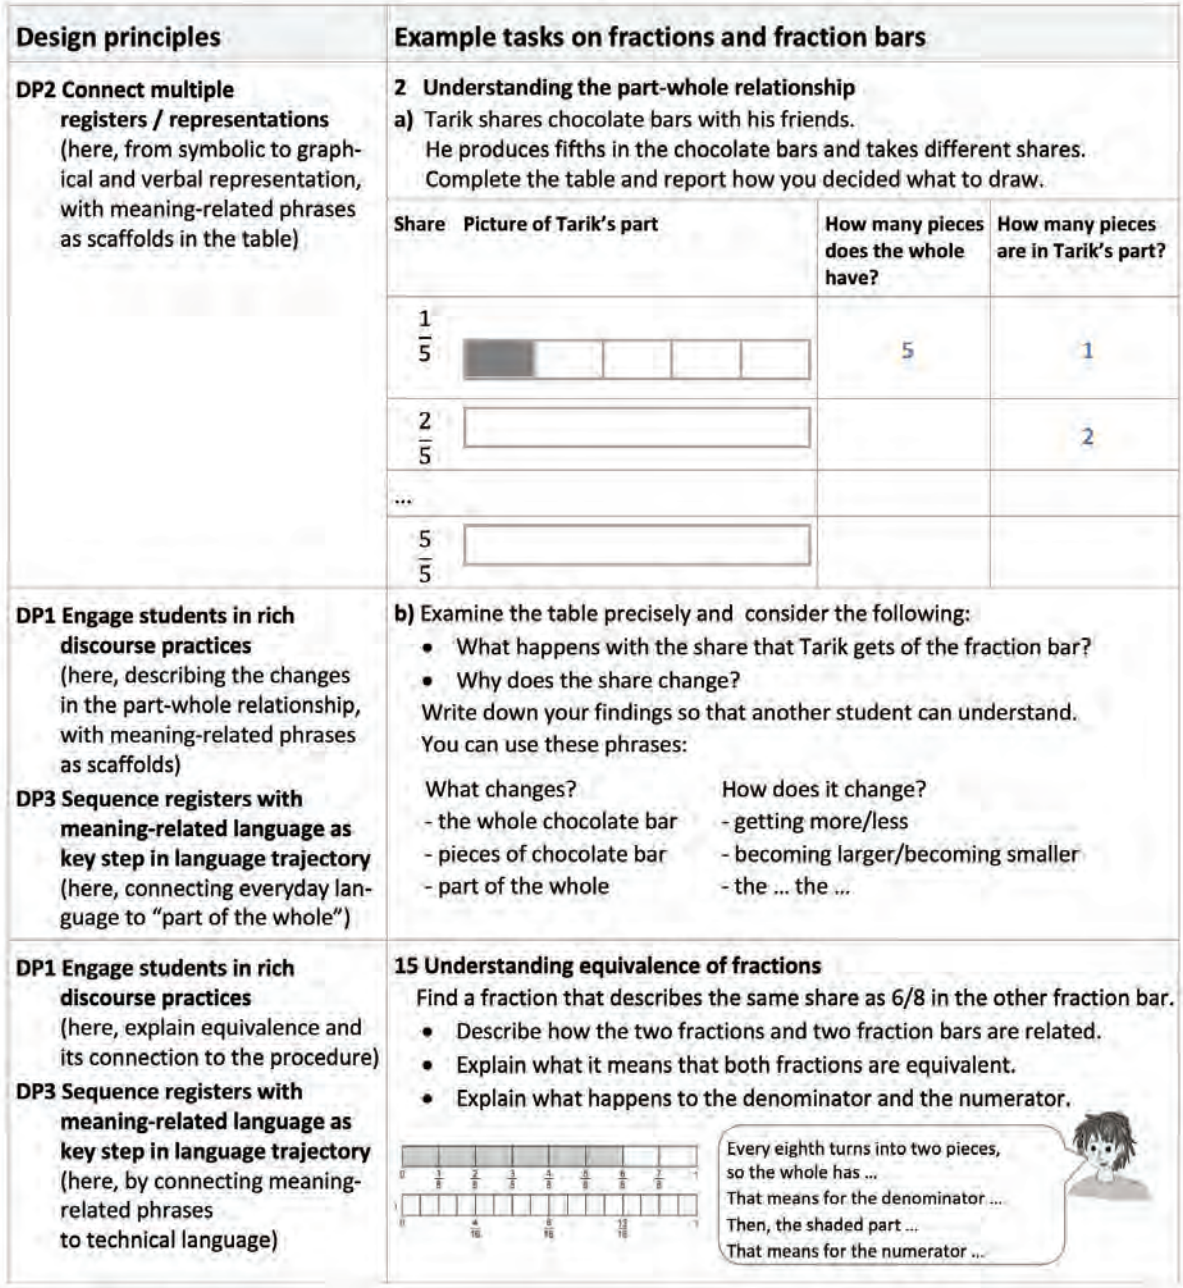
To refine design principle DP1 (pushed output), we take into account the required *richness* of discourse practices in which students are engaged: Because the discourse practices of explaining meanings or describing mathematical relationships are more relevant for developing conceptual understanding than narrating incidences or reporting procedures, DP1 was refined into "DP1 Engage students in rich discourse practices."



Design principles	Example tasks on fractions and fraction bars
DP2 Connect multiple registers / representations (here, from symbolic to graphical and verbal representation, with meaning-related phrases as scaffolds in the table)	**2 Understanding the part-whole relationship** **a)** Tarik shares chocolate bars with his friends. He produces fifths in the chocolate bars and takes different shares. Complete the table and report how you decided what to draw.
DP1 Engage students in rich discourse practices (here, describing the changes in the part-whole relationship, with meaning-related phrases as scaffolds) **DP3 Sequence registers with meaning-related language as key step in language trajectory** (here, connecting everyday language to "part of the whole")	**b)** Examine the table precisely and consider the following: • What happens with the share that Tarik gets of the fraction bar? • Why does the share change? Write down your findings so that another student can understand. You can use these phrases: What changes? - the whole chocolate bar - pieces of chocolate bar - part of the whole How does it change? - getting more/less - becoming larger/becoming smaller - the ... the ...
DP1 Engage students in rich discourse practices (here, explain equivalence and its connection to the procedure) **DP3 Sequence registers with meaning-related language as key step in language trajectory** (here, by connecting meaning-related phrases to technical language)	**15 Understanding equivalence of fractions** Find a fraction that describes the same share as 6/8 in the other fraction bar. • Describe how the two fractions and two fraction bars are related. • Explain what it means that both fractions are equivalent. • Explain what happens to the denominator and the numerator.

Share	Picture of Tarik's part	How many pieces does the whole have?	How many pieces are in Tarik's part?
$\frac{1}{5}$		5	1
$\frac{2}{5}$			2
...			
$\frac{5}{5}$			

Figure 4. Example tasks realizing the refined design principles DP1-3

For design principle DP2 (use multiple representations), the empirical analyses of many learning processes showed that switching between representations is not sufficient. Instead, explicit connections must be drawn and articulated (as for Cavit and Ismet, who switch successfully but cannot explain the connection). Because this applies not only for graphical, tabular, and symbolic representations, but also for everyday language, meaning-related academic language, and technical language, as their connections also contribute to the meaning-making processes (Gibbons, 2002), DP2 was substantiated into “DP2 Connect language registers and representations.”

For design principle DP3 (sequence language registers), the findings about the mediating role of meaning-related language as a particular part of academic language resulted in articulating “DP3 Emphasize the meaning-related language as a key step in the language trajectory,” because academic language can serve the purpose of mediating between everyday and technical language when focused on expressing rich discourse practices such as explaining meanings (“meaning-related language”). Whereas the refined design principles DP1 and DP2 are present in many instructional approaches (Moschkovich, 2013, and many others; see overview in Erath et al., 2021), the explicit input or elicitation and then consolidation of meaning-related language seems to be the major contribution of the Dortmund research to a vivid field of research and development.

Figure 4 sketches how the design principles were realized in the design of the teaching unit on fractions (Prediger & Wessel, 2013, here cited in the version from Prediger et al., in press). Whereas the tasks have multiple similarities to previous approaches (e.g., Cramer et al., 2003), the consequent demand on explaining meanings is substantially strengthened and supported.

Summing up, the refinement of generic design principles by mathematics-specific and even topic-specific considerations on the epistemic role of meaning-related language in the processes of conceptual understanding led to a substantiation of the design principles for enhancing language not as an end in itself but enhancing *language for mathematics learning*. As observation studies in regular classrooms did not help for this step, design research with its iterative combination of development and qualitative research and of what-questions and how-questions was the research approach of choice in this step.

Within the CERME thematic working group on language in mathematics education, the substantiated design principles found resonance with colleagues and their empirical findings from various countries. Building upon the impressive and complex descriptive and explanative findings on language in mathematics education that have been summarized for the occasion of the ERME birthday book (Planas et al., 2018), the thematic working group has now increasingly also turned to design challenges and their treatment. This extension of common research goals has been expressed in the jointly compiled *ZDM* special issue 53(2) on design principles and teaching practices that enhance students’ language for learning mathematics. The review paper introducing the special issue elaborates six design principles, among them the three from Figure 3 (Erath et al., 2021). The other three are “establish various mathematics language routines,” “include students’ multilingual resources,” and “compare language pieces (form, function, etc.) to raise students’ language awareness,” which are not foregrounded in this paper but have enriched our approach on other occasions. Many working group members have started to combine some of the design principles flexibly, and there is still research to be done on their interdependence.

Is language-responsive teaching effective for developing conceptual understanding? Controlled trials for overcoming the quantitative evidence gap for different target groups

The research review on designs and teaching practices for enhancing language for mathematics learning by Erath et al. (2021) summarizes 26 *qualitative* studies (from many ERME members and beyond) that have provided highly interesting, deep insights into the functioning of some of the language-responsive design principles and conditions of success that need to be considered for their application (and many more studies would have been available for this summary of an impressive body of qualitative research). So far, however, very few studies have provided quantitative evidence for the hypothesized effectiveness of these design principles on students' measurable learning gains. Given the increasing importance of quantitative evidence for policy decisions and research-based professional development, reducing *this quantitative evidence gap* can contribute to two aspects of orienting policies and convincing mathematics teachers and teacher educators: (a) Does it work? (b) For whom does it work? (Cai et al., 2021).

(a) According to methodological standards, quantitative evidence of effectiveness can be gained in controlled trials in pre-post-control-group designs showing that certain instructional approaches result in significantly larger measurable learning gains than mathematics instruction not following these approaches (Styles & Torgerson, 2018). In the MuM research group, we conducted several quasi-experimental and randomized controlled trials to confirm the hypothesis that language-responsive instruction combining the design principles DP1-DP3 can indeed enhance students' conceptual understanding significantly better than in business-as-usual control groups with comparable abilities and teacher backgrounds, first for fractions (Prediger & Wessel, 2013; Prediger et al., in press) then for percentages (Prediger & Neugebauer, 2021).

(b) Beyond confirming hypotheses on effectiveness, controlled trials can also help to deconstruct simplistic ideas about the target group. In the beginning, language-responsive mathematics instruction was mainly planned and offered to a particular target group with a combination of three disadvantaging factors: multilingual background, low academic language proficiency in the language of instruction, and limited school success (see research overview in de Araujo et al., 2018). But from a sociopolitical perspective, the exclusive focus on this particular target group is critical, as it can nurture deficit views on multilingual students, either by the misunderstanding that the three factors always coincide, or by suggesting particularistic approaches rather than inclusive access to good teaching (Barwell, 2005; Moschkovich, 2010). In contrast, the effects of language-responsive instruction on successful multilingual students, on multilingual students with high academic language proficiency, or on monolingual students with diverse language proficiency or school success were hardly investigated, so we decided to conduct three extensions (see Figure 5):

- A first extension of the target group included monolingual students with low academic language proficiency in the language of instruction (measured by standardized cloze tests). They were shown to profit as much as the original target group from language-responsive mathematics instruction (Prediger & Wessel, 2018; Smit & van Eerde, 2013).

- A second extension of the target group involved students with high academic language proficiency: Prediger and Neugebauer (2021) showed in a quasi-experimental field study that monolingual and multilingual students with diverse academic language proficiencies profited equally from a language-responsive intervention on percentages.
- Language-responsive mathematics instruction was, however, still mainly being provided to students with mathematical difficulties at risk of being left behind by the school system. As long as empirical findings about language-responsive teaching concentrate on struggling students, principles of language-responsive mathematics instruction might be misunderstood as being relevant only to overcoming problems. To avoid deficit-oriented policy discourses and practice discourses about language as a problem, it is crucial to provide empirical evidence that not only students with mathematical difficulties profit from language-responsive mathematics instruction, but also successful students. In our recent *JRME* paper, we reported from a randomized controlled trial that confirms exactly this third extension of the target group: Not only students at risk but also successful students in higher tracks can profit significantly more from language-responsive mathematics instruction than from business-as-usual control groups (Prediger et al., in press). Within the language-responsive instruction, low academic language proficiency is less predictive for weaker learning than in the control groups.

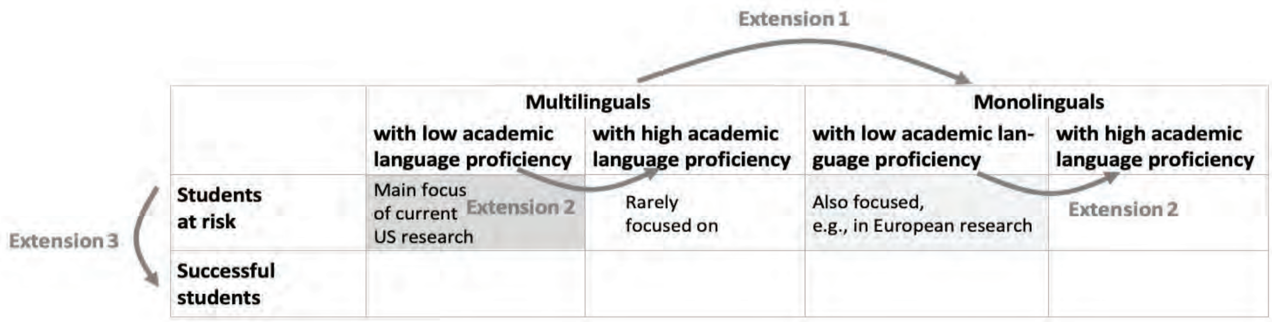


Figure 5. Research base for inclusive language-responsive instruction needs extensions of the target group from multilinguals at risk with low language proficiency to all students (Prediger et al., in press)

Summing up, the quantitative evidence gap can be reduced by findings of a chain of controlled trials showing that students of all backgrounds (monolingual and multilingual backgrounds, students with all degrees of academic language proficiency, and students with the whole range of school success) can profit mathematically from language-responsive mathematics instruction. These indications for effectiveness can strengthen the research base for language-responsive mathematics instruction as being *inclusive for all students* when realized with the strong focus on the design principles from Figure 3. They confirm that enhancing meaning-related language can serve as an epistemic catalyst for developing the conceptual understanding of all students.

This example also shows that every research has a sociopolitical component: As long as our methodological choices (in this case, the choice of our samples) perpetuate deficit orientations or particularistic approaches (in this case, by focusing on a too-specific target group accumulating different challenges or claiming too-specific needs), instructional approaches meeting the needs of particular students' risk continuing to be positioned in a deficit context outside mainstream classrooms. It is our responsibility as researchers to make wise choices in the research questions, methods, and samples we consider so that they can enter mainstream classrooms. Of course, this emphasis on inclusive use of language-responsive teaching for all students does not question the need to allocate more learning time for students at risk who are slower learners. However, it makes it clear that these students do not necessarily need other kinds of instruction.

At least in Germany, the particularistic character of language-responsive mathematics instruction is also fueled by the separateness of different research approaches: Language-responsive instruction is often investigated completely separately from the general academic discourse on high-quality mathematics instruction, which was something we wanted to overcome, as called for by Cai et al. (2020). This challenge guided decisions for the next step in the research journey.

How does the quality of teachers' enactment affect learning gains?
Video quality study for explaining and connecting the approaches to high-quality instruction

Although the overall effectiveness of our instructional approaches was shown in several controlled trials, we could also identify large differences between classes. In the implementation study for the language-responsive teaching unit on percentages, an intraclass correlation coefficient of 0.32 in the 70 intervention classes indicates that 32% of the variance is explained by which class the students were in. As the class compositions were comparable, we assumed this variance could be traced back to different instructional practices the involved teachers used in enacting the language-responsive approach, even though all worked with the same shared language-responsive curriculum materials (presented in Prediger & Pöhler, 2015) and all participated in the same professional development addressing the design principles and the ideas underlying the approach (four sessions of 3 hours each).

Many qualitative case studies have shown how teachers' enactment of instructional practices can promote or hinder the mathematical and language-related learning of the students (e.g., Barwell, 2020). In two research reviews (Walshaw & Anthony, 2008; Erath et al., 2021), a large number of qualitative case studies were summarized that identified typical teaching practices and established classroom norms and hypothesized whether they were productive or unproductive. However, except for one insightful study (Ing et al., 2015), little quantitative evidence has been provided for validating these qualitatively generated hypotheses on the potential effects of these teaching practices.

Within the research logic of controlled trials, the instruction itself is often treated as black box, so researchers have increasingly called for opening the black box and studying the teaching learning processes that occur during the interventions (Styles & Torgerson, 2018). For our research context, the existing qualitative findings suggested strongly that this trend should be followed. Hence, we decided that we need to change the research approach again and open the black box for a video study in a first approach on the following research question: How does the quality of teachers' enactment affect learning gains?

In our research journey, the research question was pursued by analyzing the video-recorded teaching practices from 18 of our heterogeneous intervention classes in a quantitative video-based approach—

a selection that was presumably positive as these 18 teachers volunteered to be videorecorded. Rather than only capturing the realization of the language-responsive design principles, we decided to take into account the large body of research on instructional quality in mathematics (Charalambous & Praetorius, 2018) in order to overcome the separate treatment of instructional quality in general and language-responsive mathematics instruction in particular. We chose (and adapted slightly) Schoenfeld's (2013) Teaching for Robust Understanding (TRU) framework to capture instructional quality in mathematics classrooms, as this framework shares the same ideas of quality with an emphasis on conceptual focus and was optimized in contexts of equity and underprivileged students. The TRU framework has five interconnected dimensions:

- *Mathematical Richness:* To what extent is the mathematics discussed clear, correct, and well justified (tied to conceptual underpinnings)?
- *Cognitive Demand:* To what extent do classroom interactions create and maintain an environment of intellectual challenge?
- *Equitable Access:* To what extent do activity structures invite and support active engagement from the diverse range of students?
- *Agency:* To what extent do students have opportunities to conjecture, explain, and argue, thus to developing agency and authority?
- *Use of Contributions:* To what extent is student reasoning elicited, challenged, and refined?

With respect to language-responsive instruction, we have slightly adapted the dimensions and added two further dimensions (Prediger & Neugebauer, 2021):

- *Discursive Demand:* To what extent do students engage in rich discourse practices? (aligned to our DP1 from Figure 3)
- *Connecting Registers:* To what extent are language registers and representations systematically and explicitly connected? (aligned to DP 2 and DP3)

Our rating of video-recorded lessons revealed that the assessed instructional quality in 18 intervention classes was on the highest level for 79-92% of the time in four dimensions, namely *Mathematical Richness*, *Cognitive Demand*, *Agency*, and *Connecting Registers*. This can be interpreted as a modest indication that the professional development and language-responsive curriculum material (presented in Prediger & Pöhler, 2015) supported the teachers in enacting an impressive instructional quality. In particular, it shows that the refined design principles DP1-DP3 (see Figure 3) are suitable for increasing the *Mathematical Richness* and *Cognitive Demand*, which are the two most content-related quality dimensions. In contrast, for the quality dimensions *Discursive Demand*, *Equitable Access*, and *Use of Contributions*, the 18 teachers showed a high variance in their enactment. These dimensions therefore seem to be less supported by the curriculum material per se and depended more on teachers' moves and strategies in directing classroom discussions (Ing et al., 2015), as has been indicated by a large body of qualitative research (Walshaw & Anthony, 2008).

To validate the hypothesis that these quality dimensions matter for students' learning, we conducted a multi-level analysis to find out how the seven quality dimensions predicted students' measurable learning gains (while controlling for individual background factors). And, indeed, the three dimensions that varied most with teachers' enactment—*Discursive Demand*, *Equitable Access*, and *Use of Contributions*—had an additional significant impact on students' learning gains, but so did *Agency*, in spite of its high-quality realization (Neugebauer & Prediger, submitted). Although the sample of 18 classes is not yet very large, these findings provide promising (and significant) indications for confirming the hypotheses on productive teaching practices by revealing multilevel quantitative evidence for their impact on measurable learning gains.

Summing up, this video quality study shows that language-responsive mathematics instruction can be realized in ways that achieve high instructional quality for *Mathematical Richness* and *Cognitive Demand.* This again can be interpreted as further evidence that enhancing language is an epistemic catalyst in mathematical classrooms if supported by topic-specific curriculum material. At the same time, teaching practices in the classroom interaction can still heavily vary with respect to *Discursive Demand*, *Equitable Access*, and *Use of Contributions*, and their enactment on a high-quality level has additional impact on students' mathematical learning gains. This means that the more the teacher achieves (in engaging all students in rich discourse practices [DP1] and in building upon students' informal ideas and emerging language for the further learning trajectory [DP3] by connecting these elements [DP2] in their moderation of the classroom discussions), the more the students have developed their conceptual understanding on the mathematical topic in view, in this case, percentages. These findings call for integrating more professional learning opportunities for productive teaching practices to raise and maintain discursive demands, provide equitable access, and make use of students' contributions in the discussion about future professional development offers (as, e.g., Kazemi et al., 2021). We might also assume that teachers need some more time to implement these quality dimensions into their practices than we gave them, but this is only one of the several challenges in implementing promising instructional approaches.

Again, this example shows the strength of combining different research approaches, in this case with the aim of including the insights from qualitative research into quantitative designs and validating the generated hypotheses (Creswell, 2015).

Looking back from a meta-level: What does connecting research approaches mean?

In most ERME research, connecting research approaches has been mainly interpreted in two modes:

- connecting methods for a well-articulated research goal (e.g., in the long and rich tradition of mixed methods approaches; see Creswell, 2015) and
- networking theoretical approaches (most often used for analyzing given data from two theoretical perspectives; see Bikner-Ahsbahs, Prediger, & Networking Theories Group, 2014).

Both modes also occur in our research journey: With respect to combining methods, the chain of our projects is characterized by sequential explanatory and exploratory mixed-methods designs. Explanatory mixed-methods designs are used when quantitative findings on statistical connections are investigated deeper in qualitative methods in order to explain the quantitative findings (as in our case, explaining the epistemic role of academic language in more depth after large-scale assessments showed that language gaps are largest for conceptual understanding). Exploratory mixed methods designs explore the generalizability of qualitatively identified phenomena (in our case, generalizing conditions of success in applying the design principles identified in case studies to a larger number of classes and measurable learning gains).

With respect to theoretical approaches, two characteristics make the coordination and integration of theoretical approaches absolutely necessary for the presented chain of (overlapping and interacting) projects:

- Research on language in mathematics learning always requires both an epistemic perspective and a language-related (here, mainly discursive) perspective and an integration of both for explaining how language learning and mathematics learning are related (Barwell, 2005; Moschkovich, 2010). As these networking practices have not been made explicit in this current paper, I refer to three papers from our work that best document different kinds of networking practices (Erath et al., 2018; Prediger & Şahin-Gür, 2020; Prediger & Hein, 2017).
- Design research is always the bricolage of theoretical elements (Alberto, Bakker, et al., 2019; Prediger, 2019). In our case, the integration of the what-questions into the how-questions led to substantiating design principles based on instructional and epistemological foundations (see Figure 3). As in many other cases, topic-specific design research often requires the integration of instructional theories (underlying the design principles) with epistemological theories (underlying the structuring of the content; see, e.g., Alberto et al., 2019).

Beyond these two most discussed modes of connecting research approaches, the summary of our research journey in Table 1 exemplifies that the connection of research approaches in such a chain of overlapping and interacting projects is substantially fueled by *deriving new research questions* from answers to former research questions, and these new research questions become most productive when involving *shifts in the research objects*.

These shifts in research objects are worth reflecting on more systematically, because the choice and the constitution of the research object can have a substantial impact on what can be achieved as a research goal and how research can provide the foundation for design practices (diSessa & Cobb, 2004). For example, as long as only student achievement gaps are the research object, the research hardly contributes to overcoming the problem (Gutiérrez, 2008; Hodgen et al., 2021), and as long as only students with accumulated challenges are investigated, deficit views might be perpetuated without exploring the commonalities to other target groups. Overcoming the problem requires turning to teaching practices and design principles as major research objects (Sullivan, 2015). Additionally, focused mathematical instruction also requires detailed epistemological and empirical insights into the students' learning pathways of particular mathematical topics: This combination of design principles and topic-specific pathways is typical for didactical design research (Gravemeijer & Cobb, 2006; Prediger, 2019). Beyond these, the teaching practices enacted by teachers while realizing a design approach are important research objects for understanding the challenges in implementation processes (Burkhardt & Schoenfeld, 2003), which is also far beyond what we started to understand modestly in our projects.

Table 1. Summary of the research journey in its several steps: shifts in research questions and objects

Method	Research goal	Research question	Research object
Large-scale assessments	Describing and explaining language gaps	What exactly is the problem with language in mathematics?	Student achievement gap Students' background factors Knowledge types in items
Qualitative video study	Identifying good practices	How can language be enhanced in mathematics classrooms?	Teaching practices in regular class-rooms
Import from other disci-pline	Transferring generic design principles	How can language be enhanced in language classrooms?	Design principles for language instruc-tion Tasks and pedagogies
Design research	Explaining learning path-ways and typical obstacles	What is the problem with the epistemic role of academic lan-guage while developing concep-tual understanding?	Students' learning pathways towards conceptual understanding in a mathe-matical topic
Design research	Specifying the mathemati-cally relevant language-learning content	What academic language de-mands are crucial for develop-ing conceptual understanding?	Relevant language in students' mathe-matical learning pathways towards conceptual understanding
Design research	Substantiating language-responsive design princi-ples for math instruction	How can meaning-related aca-demic language be enhanced in mathematics classrooms?	Design principles for enhancing language for developing understanding of mathematical concepts
Controlled trials	Validating effectiveness of approach for different target groups	For whom is language-respon-sive instruction effective for developing understanding?	Effects of language-responsive instruc-tion for learning gains of students with different background factors
Quantitative video study	Disentangling conditions of effective language-responsive teaching	How does the quality of teachers' enactment affect the learning gains?	Teaching practices in language-responsive classrooms and their effects on learning gains

Finally, with every shift in research object, new theoretical perspectives also enter the scene (from epistemological backgrounds of the topic, theories of learning, theories of language and learning, theories of instruction, etc.). In the long run, an integrated theory rather than a chain of unconnected research objects should be the overall research aim. However, this aim will require two more decades and the joint communication, cooperation, and collaboration of various researchers from other European and non-European sites to integrate the different empirically grounded theory elements into a coherent theory on enhancing language as epistemic catalyst for developing mathematical understanding.

It is a particular strength of the ERME community not to be afraid of complex connections of theories and research approaches (Artigue et al., 2005; Bikner-Ahsbahs, Prediger, & Networking Theories Group, 2014): This was established as a meta-theoretical position in the TWG on theoretical approaches and has spread widely to other TWGs in ERME. In the same way that the idea of networking theories was spread among the whole ERME community within the last decade (as documented by Artigue et al., 2018), I hope that this paper can fuel the idea that big problems require complex chains of projects within one research group and more complex networks of projects of several research groups to treat them. This is presumably not only true for language as an epistemic catalyst for mathematics learning, but also for other exciting areas in mathematics education research.

Acknowledgment

This paper was developed in the MuM research group (which focuses on mathematics learning under conditions of language diversity) in Dortmund, financially supported by the German Ministry for Education and Research (BMBF) and the Deutsche Telekom Foundation. I thank my whole research group for their wonderful and inspiring cooperation. For the writing of this paper, I was greatly supported by valuable comments of Núria Planas and Jeremy Hodgen on an earlier draft.

Conceptualizing individual-context relationships in teaching: Developments in research on teachers' knowledge, beliefs and identity

Jeppe Skott

Linnaeus University, Sweden, & University of Agder, Norway;
jeppe.skott@lnu.se & jeppe.skott@uia.no

Abstract: Research on teachers' knowledge, beliefs and identity have contributed with significant new understandings of their respective fields. In this paper I track developments in each of them over the last few decades and address the question of how individual-context relationships have been conceptualized. Part of the answer is that the two first fields have primarily drawn on the constructivist inspiration that initially gave rise to them, while identity research has been based on more fundamentally social understandings of human functioning. Another part of the answer is that none of the three fields has to any great extent drawn on interactionist approaches. I suggest that doing so may be a fruitful way ahead, if we want to understand the role of the teacher for group life as it emerges in schools and classrooms.

Keywords: Teachers knowledge, teachers' beliefs, teacher identity, the social turn, interactionism.

Research on teachers and teaching

Studies of teachers and teaching have been a prominent part of mathematics education research for decades (Sfard, 2005). This is so not least at CERME conferences, where the research interest seems to have grown consistently over the last 20 years (Skott et al., 2018). Large parts of this research have focused on teachers' knowledge, beliefs and identity, which have often been treated as separate teacher characteristics and dealt with by use of different theoretical frameworks.

Inspired by constructivism, research on teachers' knowledge and beliefs has traditionally considered their respective key constructs mental entities residing within the individual and been premised on the expectation that they have considerable impact on teaching quality and student learning (Cross Francis et al., 2015; Skott, 2015b; Sowder, 2007). In this sense, teachers' knowledge and beliefs have been treated as almost independent variables and semi-causal determinants of classroom practice.

Over the last 10-20 years, this approach to research on and with teachers has been challenged and modified, and perspectives with a stronger social and contextual emphasis have been adopted. This is so in two ways. First, studies of teachers' knowledge and beliefs tend to be less inclined than before to expect that these mental constructs may serve as explanatory principles for practice and to a greater extent adopt – or at least call for – dynamic perspectives on the relationships between knowledge and beliefs on the one hand and classroom practices on the other (Ball, 2018; Skott, 2015c). Second, the field of teachers' professional identities has grown into prominence, generally using more fundamentally social frameworks when studying teaching-learning processes (e.g. Darragh, 2016; Skott, 2013). In general, then, individual-context relationships are viewed differently now than a few decades ago. However, this is so in different ways within and across the three sub-fields.

One aim of the present paper is to outline significant aspects of these developments and elaborate on the theoretical differences involved. This means that rather than discussing specific results on, for instance, teachers' knowledge, beliefs, and identities as they relate to particular mathematical contents (e.g. algebra or problem solving) or particular educational settings (e.g. special categories of schools or teachers), I describe developments from a somewhat different vantage point. Doing so, I am inspired by what Lerman calls "the social turn" in mathematics education research (Lerman, 2000, 2006). The questions I ask are how and to what extent aspects of "the social" have been taken into account in studies of teachers' knowledge, beliefs, and identity, in particular how the individual-context interface is dealt with. It is part of the answer to the latter of these questions that interactionism has played next to no role. It is another aim of the paper to invite considerations of the potential of interactionism, if intentions of research on and with teachers include understanding the meaning teachers make of their professional lives and the role of teachers for the practices that evolve in their classrooms.

I begin the paper with accounts of the developments and main emphases in research on teachers' knowledge, beliefs, and identities over the last few decades. It is beyond the scope of the paper to present a comprehensive review of research in all three fields, and my presentation of the literature is necessarily selective. I seek to present a critical overview that does justice to significant developments within each of them, including their similarities and differences. One of the differences is the extent to which the literature is self-reflective and discusses its own key constructs (i.e. knowledge, beliefs and identity) and the methodological problems involved in researching them. The notions *beliefs* and *identity*, for instance, are recurrent objects of attention, while this is less so with *knowledge*. Another difference is that there are a few established frameworks that dominate research on teachers' knowledge, all of which draw on Shulman's work from the 1980s, while a similar canon of frameworks does not exist in the two other fields. These differences are necessarily reflected in the structure of my presentation.

Following from that, I relate this account to "the social turn", that is, "the emergence into the mathematics education research community of theories that see meaning, thinking and reasoning as products of social activity" (Lerman, 2000, p. 23). I do so by discussing three aspects of research on teachers' professional identities, those of agency, situatedness and structure. Using this triad, I argue that the individual-context relationship is conceived of differently across and to some extent within the three fields. However, I also suggest that interactionist perspectives are conspicuously absent in all of them and that an interactionist complement to current approaches may be useful when seeking to understand the dynamic character of the teacher's role for the emergence of group life in schools and classrooms. In particular, I refer to a framework called *Patterns of Participation* (PoP), a result of networking social practice theory (e.g. Holland et al., 1998; Lave, 2019; Wenger, 1998) with symbolic interactionism (e.g. Blumer, 1969; Prus, 1996) as one possible interactionist approach.

Research on teachers' knowledge

Background and rationale of research on teachers' knowledge

Teachers' knowledge of the subjects they teach has been discussed for decades, including its relation to knowledge of and proficiency with other aspects of the profession (Hill et al., 2007). Some of these studies seek to find positive correlations between teachers' academic proficiency with mathematics and their students' performance. The studies by Begle (1972) and Eisenberg (1977) are classic examples of this. Conducted at the height of the *New Maths* era, Begle's study tested highly qualified teachers' understanding of "modern algebra" (groups, rings and fields) and the real number system and found that any correlation with student learning was so small "as to be educationally insignificant" (p. 13). Eisenberg (1977) did a similar study with a more representative group of teachers, but also found that "teacher knowledge of subject matter had little effect on student performance" (p. 222).

Summing up the results from these and similar studies, *Adding it up*, a report from the National Research Council in USA, argues much later that "proposals to improve mathematics instruction by simply increasing the number of mathematics courses required of teachers are not likely to be successful" (National Research Council, 2001, p. 375). Based on such results, the rationale behind later research on mathematics teachers' knowledge has been to come to grips with what mathematics teachers need to know and how. The results suggest that this knowledge needs to be closely linked to the work of teaching, if it is to improve instruction (e.g. Hoover et al., 2016). The most dominant frameworks that make such links draw on Shulman's work from the 1980s (Shulman, 1986, 1987).

Shulman's knowledge base for teaching

In the 1970s and 1980s, behaviourist process-product studies played a significant role in research on teachers (e.g. Medley, 1977). Shulman challenged this approach and bemoaned its lack of attention to teachers' thinking and to the contents of instruction, which he called a blind spot and a missing paradigm in the field (Shulman, 1986, 2015). In response, he built on a study of novice, secondary teachers of English, biology, social studies, and mathematics to develop a description of teachers' knowledge with seven categories, three of which were immediately related to the contents of instruction: curriculum knowledge, content knowledge, and pedagogical content knowledge (Shulman, 1986, 1987). Especially the last two of these have been discussed extensively in mathematics education and in other educational scholarship.

In relation to *content knowledge*, Shulman says that teachers are members of scholarly communities and "must understand the structures of subject matter, [that is] the principles of conceptual organization, and the principles of inquiry" (Shulman, 1987, p. 9). In essence, this does not differ from the knowledge of others, who know the subject. In contrast, *pedagogical content knowledge* (PCK), the most frequently cited category in Shulman's framework, is specialised to teaching. It is that blend of content and pedagogy that forms "an understanding of how particular topics, problems, or issues are organized, represented, and adapted to the diverse interests and abilities of learners, and presented for instruction" (Shulman, 1987, p. 8). In a continental European tradition this resembles methodological or technical aspects of *didaktik* and in the US it was part of the testing of teachers, also before Shulman coined the term of PCK (Hill et al., 2007).

Frameworks on mathematics teachers' knowledge that build on Shulman

A long list of studies have drawn on Shulman's knowledge base for teaching, both in mathematics and in other subjects. Generally, they shift the emphasis from analyses of the subjects themselves to how they are used in teaching. It is a joint outcome that it is not only PCK that is special to the profession, so are aspects of the contents itself. Four of the most prominent of these frameworks in mathematics are Ma's *Profound Understanding of Fundamental Mathematics*; *Teachers' Specialized Knowledge of Mathematics* developed by Carrillo and his colleagues; Rowland et al.'s *Knowledge Quartet*; and Ball et al.'s *Mathematical Knowledge for Teaching*.

Ma (1999) studied the mathematical knowledge of Chinese and U.S. primary teachers. At the time of the study, Chinese teachers were educated in normal schools that recruited grade-9 students for a 2-3 year programme (Li, 2012). Novice teachers, then, were 18-19 years old and had no post-secondary education. In contrast, all American teachers had at least a college degree. In spite of that, the American teachers were outperformed by their Chinese colleagues on tasks from the primary school curriculum, for instance $1\frac{3}{4} \div \frac{1}{2}$, and when asked to suggest educationally relevant situations to represent the meaning of such tasks. Ma concludes that there were significant differences between "the mathematical substance" of the knowledge of the two groups of teachers (p. 92). The Chinese participants were closer to having *Profound Understanding of Fundamental Mathematics* as they focussed on the relationships among the four operations and on longitudinal coherence, while the American teachers had a fragmented understanding of school mathematics that missed important interconnections among different parts of it.

Carrillo and colleagues introduced a framework called *Mathematics Teachers' Specialized Knowledge* (MTSK) (e.g. Carrillo-Yañez et al., 2018; Carrillo, 2021). MTSK, which has been used extensively in recent CERMEs, draws on long-term cooperation between researchers and teachers working at different educational levels. MTSK structures knowledge in terms of *mathematical knowledge* and *pedagogical content knowledge*, which are supplemented with a category of beliefs. Mathematical knowledge is divided in the three sub-categories on topics, practices and structure of the subject and PCK consists of knowledge of teaching, of learning and of standards for learning mathematics. MTSK focuses "exclusively on the knowledge specific to the mathematics teacher" (Carrillo-Yañez et al., 2018, p. 237) and considers neither professional knowledge that may be shared with teachers of other subjects, nor whether parts of the knowledge in the model is shared with other professions. As Carrillo (2021) says, it "is the model in its entirety that is specialized" (p. 90).

Rowland et al. worked with prospective teachers and developed the *Knowledge Quartet* (KQ) as a perspective on the knowledge they need and on the situations in which they need it (Rowland et al., 2005; Rowland, 2008). The four parts of the KQ – foundation, transformation, connections and contingency – describe how the participants' content-related knowledge "contribute to their teaching during the […] the school-based placements" (Rowland et al., 2005, p. 256). In Rowland et al.'s terminology, *foundations* consist of knowledge and beliefs "possessed" and concern "knowledge, understanding and ready recourse to [teachers'] learning *in the academy* […] irrespective of whether it is being put to purposeful use" (Rowland et al., 2005, p. 260, emphasis in original). Transformation and connections are categories of "knowledge in action". *Transformations* describe how "knowledge possessed" needs to be transformed to be educationally powerful, and *connections* concern the coherence of mathematics, that is, how concepts and procedures may be linked and sequenced in education. The last element of the KQ, *contingency*, is "knowledge in interaction" and concerns teachers' capacity to deal with unexpected, content-related issues, for instance when students ask unexpected questions or make unforeseen conjectures. Contingency, then, includes being able to respond to students' ideas as they come up and the willingness and capacity to deviate from the original plan if necessary.

The most referenced perspective on mathematics teachers' knowledge is *Mathematical Knowledge for Teaching* (MKT), developed by Ball and her colleagues (e.g. Ball & Bass, 2000; Ball et al., 2008). Like the frameworks mentioned previously, MKT is an answer to the questions of what knowledge teachers need in instruction and whether and how they need to know it differently from others, who are also proficient with the subject. As mentioned before, Ball et al. build on Shulman, and one contribution of MKT is an elaboration of what may be entailed in PCK in mathematics. Another contribution is a distinction between common content knowledge, that is, knowledge of the contents that teachers share with others who know the subject, and a form of specialised knowledge of the contents itself, "mathematical knowledge that equip [teachers] to navigate […] complex mathematical transactions flexibly and sensitively with diverse students in different lessons" (Ball & Bass, 2000, p. 94). One aspect of specialised content knowledge (SCK) is to be able to "unpack" mathematics, that is, pulling apart compressed concepts and procedures in order to help students understand inherent meanings. SCK is required also if teachers are to deal with tasks such as "responding to students' 'why' questions", "linking representations to underlying ideas and to other representations", and "giving or evaluating mathematical explanations" (Ball et al., 2008, p. 400; the authors list 16 such mathematical tasks of teaching). It is an important aspect of the early work on MKT that SCK be understood in relative isolation from educational issues. It is "a kind of *mathematical* understanding that is pedagogically useful and ready, [but] not bundled in advance with other considerations of students or learning or pedagogy" (p. 88, emphasis added).

Over the last few years, Ball has focused increasingly on the work of teaching itself, rather than on a knowledge base on which it is expected to rest. She deplores that "[s]cholars were [previously] studying classrooms and analysing discourse, tasks, and interactions, but were not unpacking what is involved for the teacher in doing those things" (Ball, 2018, p. 14). This perspective challenges the connotation of knowledge stability, which is apparent in Ball's earlier work, and it is reflected also in a change of terminology, as Ball (like others) shifts her wording from knowledge to knowing and from teacher to teaching. The more dynamic understanding of the teacher-context relationship reflects the recognition that "teaching is co-constructed in classrooms through a dynamic interplay of relationships, situated in broad socio-political, historical, economic, cultural, community, and family environments" (p. 15). The shift of emphasis invites interpretations of teaching and teacher proficiency that align more closely with the social turn. They also seem to question the previous claim that mathematical knowledge is not "bundled" with considerations of students and pedagogy.

Looking across the frameworks on mathematics teachers' knowledge: professional emphases and constructivist inspiration

The frameworks presented above have contributed significantly to shifting our understandings of what teachers need to know by emphasising the professional and specialised aspects of teachers' knowledge. They differ in their empirical grounding as well as with regard to their interpretation of what *specialised* may mean; to the categories of knowledge they use; to whether beliefs are included or not; and to their relative emphasis on knowledge itself relative to the situations in which the categories become professionally relevant.

The frameworks, however, all build on Shulman's work from the 1980s, which, as mentioned earlier, may be seen as a response to process-product studies of teachers and teaching. There are two related aspects to this. First, process-product research had no interest in the contents of instruction. In line with Shulman, the four frameworks refocus attention to the contents. They also take Shulman's emphasis on professionalism a step further by suggesting that it is not only PCK, but also parts of teachers' knowledge of the subject matter itself that is special to teaching. Content knowledge is, then, not merely a matter of knowing mathematics, but a matter knowing what and how mathematics is used in teaching. As Ball and Bass (2002) say the knowledge teachers need "has features that are rooted in the mathematical demands of teaching itself" (p. 4). In this sense, there is a contextual element to the understandings of teachers' knowledge in all of them: knowledge of the contents is at least to some extent contextualised to the profession.

Second, Shulman's knowledge base for teaching was a response to the behaviourist stance of process-product studies. In contrast, he and his team focused on "teacher thinking, teacher knowledge, teacher planning, teacher decision-making, and teachers' conceptions of their subject matter and how that related to how they performed" (Shulman, 2015, p. 6). There is a cognitive emphasis and a focus on individual meaning-making in this (cf. Shulman & Shulman, 2004) that aligns with attempts in mathematics education at the time to initiate "a constructivist revolution […] to countermand the stranglehold that behaviorism had on the field" (Steffe, 2007, p. 281). This "revolution" brought with it new perspectives on students' learning and knowing, by arguing that knowledge and meaning are acquired and possessed individually, although possibly supported or constrained by the social situation. A similar interpretation seems to have guided the frameworks on mathematics teachers' knowledge, at least until fairly recently. Although they are different, the frameworks all originally carried connotations that knowledge is possessed by and resides in the individual, although enactment may be contextually framed. Until recently, they did not draw on other understandings of what it may mean to know.

Research on teachers' beliefs

Background and rationale of belief research

Research on teachers' beliefs also gained momentum in the 1980s, both in mathematics education and in other educational scholarship (Ashton, 2015; Skott, 2015c). There were two aspects to the background for the growing interest (Skott, 2015b). First, some researchers sought to understand classroom processes from the teachers' perspectives (e.g. Nespor, 1987). Elbaz (1983), for instance, explained her own intention of doing so by distancing herself from the general field of research on teachers:

> Too frequently the emphasis was on diagnosing teacher failings and on prescribing improvements, whereas I was interested in seeing and understanding the situation from the teacher's own perspective. (Elbaz, 1983, p. 4)

Second, there was an interest in solving "problems of implementation". The constructivist revolution coincided with a shift of emphasis from subject matter products to processes, in mathematics for instance from algorithms, definitions and proofs to problem solving and later to for instance reasoning and communication. The (sometimes implicit) question in belief research was – and still is – how one may expect this reform to materialise, if its priorities are not shared by the teachers. Therefore, much research has focused on (1) what teachers' believe about mathematics and its teaching and learning, sometimes focussed on particular mathematical topics (e.g. problem solving, probability, algebra) and supplemented with their beliefs about themselves as learners, teachers and doers of mathematics; (2) how beliefs may change; and (3) what the relationships are between beliefs and classroom practice.

Thompson (1984) was one of the first in mathematics to point to belief research as a possible challenge to the behaviourist underpinnings of most research on teachers and teaching at the time. She used the term *conceptions* about a union of teachers' "beliefs, views, and preferences" and argued that "[f]ailure to recognize the role that the teachers' conceptions might play in shaping their behavior is likely to result in misguided efforts to improve the quality of mathematics instruction" (p. 106). Based on a multiple case study of three American junior high school teachers, she addressed the questions of (1) whether there were "incongruities between the teachers' characteristic instructional behavior and their professed conceptions"; (2) how such incongruities may be explained; and (3) whether differences among the teachers may be accounted for with reference to their conceptions (p. 107).

Thompson's second research question suggests that she considered teachers' conceptions the default explanation for classroom practice, as any discrepancy between the two was in need of an explanation. Based on a similar premise, a tremendous amount of research has been conducted on teachers' beliefs ever since, both in mathematics education and beyond (e.g. Clark & Peterson, 1986; Conner & Singletary, 2021; Grossman et al., 1989; Hoffman & Seidel, 2015; Pajares, 1993; Richardsen, 2003; Thompson, 1992; Wilson & Cooney, 2002; Yurekli et al., 2020). In fact, the expectation of belief impact on practice has been the main raison d'être of the field, even to the extent that it has at times been turned into one of direct causality (e.g. Ernest, 1991; Schoenfeld, 1992).

However, belief research has turned out to be a complicated endeavour. Belief change, often seen as an affective counterpart to conceptual change, is difficult to accomplish (Gill & Hardin, 2015); beliefs are not readily observable, and it has proven difficult methodologically to elicit, infer or attribute beliefs, to teachers, based on more readily observable indicators (Abd-el-Khalick & Lederman, 2000; Philipp, 2007); and the congruity thesis has been challenged as much as confirmed in empirical studies (Fives & Buehl, 2012). This last difficulty has led to modifications of the initial emphasis on impact. Before discussing this issue further, I introduce one other challenge, the conceptual problems with the key construct of beliefs.

The concept of beliefs

As mentioned above, Thompson used the term of conceptions about a combination of beliefs, views and preferences. She did so without specifying differences between the three elements or relationships between the higher-level concept of conceptions and each of them. This is not uncommon in the field. As Pajares (1992) said, the construct of beliefs is "messy" and travels under alias. Mason (2004) made a list of related terms, indeed, one or more beginning with every letter of the alphabet – *a*ffect, *b*eliefs, *c*onceptions, …, *z*eal – and commented at the end: "No wonder it is hard to make sense of it all!" (p. 347). This terminological multiplicity goes hand in hand with conceptual confusion and there is little consensus about how *beliefs* – or many of the other terms on offer – may be defined and relate for instance to knowledge (Gill & Fives, 2015; Kagan, 1992; Philipp, 2007; Russ et al., 2016).

Beyond discussions of the concept of beliefs itself, considerable effort has gone into considerations of how beliefs are held and how they function (e.g. Cooney et al., 1998; Pajares, 1992). It is argued, for instance, that they may be unconscious and implicit (e.g. Buehl & Beck, 2015; Kagan, 1992; Rokeach, 1969). Green (1971) suggests that beliefs may have a mutual quasi-logical relationship, as they may be primary or derivative in relation to one another. Further, they may be central or peripheral in terms of psychological significance, and they are held in clusters that are internally coherent, but may be somewhat mutually isolated. As an example, one may consider possible quasi-logical relationships for a teacher among different beliefs about mathematics, students, learning, and about herself in relation to mathematics. One may also wonder what the relative significance is of these beliefs, whether and how they are clustered with each other or other professionally relevant beliefs, and what it matters for belief impact how they are held.

It has also been argued that different beliefs serve different functions. Based on a comprehensive literature review, Fives & Buehl (2012) argue that beliefs may filter information and be important for what a teacher pays attention to for instance in professional development (PD). Beliefs may also structure interpretations of situations and problems, for instance a problematic classroom situation. Finally, they may guide action, for instance when self-efficacy beliefs play a role in the teacher's perseverance in a classroom interaction.

In spite of the confusion about the concept, there does seem to be some consensus about how the term of beliefs is used. A core of the beliefs construct – as used in the literature – may be summed up in four features, namely that beliefs are (1) subjectively true and (2) affectively laden and that they (3) build on substantial prior experiences and (4) have some explanatory power in relation to action and meaning-making (Skott, 2015b). These four characteristics of how the term is used suggest, respectively, that the term is associated with significant degrees of conviction, commitment, stability and impact. The last two of these indicate that the notion of beliefs is an example of what Sfard (2008) calls objectifications, that is, reifications of processes and actions that take on a life of their own as they are interpreted as self-sustained entities with predictive power (Skott, 2015c).

Returning to the quandary of belief impact

As indicated earlier, one finding in belief research is that the impact of teachers' beliefs on classroom practice may not be as direct as initially expected. For the larger part of the field, however, beliefs are still considered the default explanation for classroom practice and as for Thompson (1984) an apparent lack of congruity calls for explanations. Sometimes explanations for lack of documented belief impact refer to methodological problems with accessing these elusive constructs or to the conceptual issues outlined above. Fives & Buehl (2012) argue that if different beliefs may serve different functions (filtering information, framing observations, and guiding action), it is hardly surprising that beliefs inferred from a teacher's response to a questionnaire differ from those accessed when observing how she acts in a possibly conflictual classroom situation. Others have argued that apparent lack of compatibility between espoused and enacted beliefs may reveal that the beliefs are held differently, for instance that beliefs enacted may be unconscious, but more centrally held than those espoused in a research interview (e.g. Cross Francis, 2015). Still others suggest that the problem is caused by methodological difficulties and may be solved by using more specific self-report items or more fine-grained methods of analysis (e.g. Speer, 2008; Yurekli et al., 2020). Finally, Leatham (2006) suggests viewing beliefs as "sensible systems", which – in a situation with apparent inconsistencies – requires the researcher to "look deeper, for we must have either misunderstood the implications of that belief, or some other belief took precedence in that particular situation" (p. 95). Leatham suggests an interpretive stance in which inconsistency is an observer's perspective that does not do justice to the complexities of teaching.

The approaches above come to the rescue of the premise of belief impact by referring to the conceptual or methodological problems of the research process itself. Others have pointed to more substantive issues by suggesting more dynamic interpretations of belief-practice relationships (cf. Skott, 2015b). Schoenfeld (2011) modifies his previous deterministic description of belief impact somewhat and suggests that classroom dynamics may require the teacher to reconsider his/her approach. However, subsuming beliefs under the broader heading of orientations, he maintains that the teacher's "routine and non-routine decision making can be fully characterized as a function of his [mathematics–related] resources, goals and orientations" (p. 13). Sztajn (2003) and Skott (2001) suggest that the significance of mathematics-related beliefs may be challenged and overruled by other educational concerns in a teaching-learning situation, and Lerman (2001) and Hoyles (1992) argue that beliefs are situated and that differences between for instance those espoused in a research interview and observed in a classroom interaction are different by virtue of those situations. The last two sets of approaches do away, respectively, with the premise that *mathematics*-related beliefs impact practice and the expectation of belief stability across contexts. However, they both use beliefs about objectified mental entities, although the significant beliefs in a particular situation may not relate to mathematics and may not be temporally and contextually stable.

One may regret the lack of an agreed-upon definition of beliefs and the methodological difficulties involved in researching them. These problems may be seen as an impediment to growth in the field and to the accumulation of research results. However, developments in belief research indicate that the conceptual core of the term as outlined previously suffices for it to function as what Blumer (1969) calls a sensitizing concept, that is, a concept that does not "provide descriptions of what to see, […] [but] merely suggest directions along which to look" (p. 148)[1]. In combination with the multiplicity of methodological approaches used in the field, this has led to more nuanced and multi-faceted understandings of affective aspects of teaching, including modifications to the field's own initial rationale, the expectation of semi-causal relationships between stable, mathematics-related beliefs and practice. There has, then, been a move from beliefs to dynamic affect systems (cf. Pepin & Roesken-Winther, 2015), a move that has also been apparent at CERMEs (Skott et al., 2018). As suggested above, however, these modifications do not seem to change what is meant by the term *beliefs*. The larger part of the field draws on the original constructivist underpinnings, and even when these are challenged by notions of situatedness (Hoyles, 1992; Lerman, 2001), the perspective on beliefs as objectified mental entities may persist.

Research on teachers' professional identities

Background and rationale of research on professional identities

Since the turn of the century, teacher identity has become a significant field in mathematics education, even though it has only played a minor role at CERMEs (Skott et al., 2018). As with studies of teachers' beliefs, there seem to be two mutually related and often combined aspects to the research interest: One is to understand the lives of prospective or practising teachers in view of cultural and social demands and affordances (e.g. Arslan et al., 2021; Beauchamp & Thomas, 2011; Brown & McNamara, 2011; Cochran-Smith et al., 2012; Hong, 2010; Lutovac, 2020; Skott, 2019); the other is to consider the character and development of identities as they relate to teachers' participation in teacher education or PD programmes (e.g. Bobis et al. 2020; Darragh and Radovic, 2019; Gresalfi & Cobb, 2011; Heyd-Metzuyanim, 2019; Hodgen & Askew, 2007; Horn et al., 2008; Jong, 2016; Ntow and Adler, 2019). Irrespective of which of these interests dominate a particular study, identity research moves beyond cognitive configurations such as knowledge and beliefs when seeking to understand teaching and teacher development. Hodgen and Askew's (2007) wording that their case study of a primary teacher in the UK is based on the premise that professional change "involves at least in part becoming a 'different' teacher and a 'different' person" (p. 474) seems indicative of much research on professional identity. Part of the background to the interest in identity, then, is to challenge

[1] I reluctantly refer to Blumer here. As we shall see later, his theoretical stance is at odds with those adopted in belief research and he argues explicitly against the significance attached to constructs like beliefs. In spite of that, I find the notion of sensitizing concepts useful as a metaphorical description how the term of beliefs has functioned in belief research.

purely cognitive or epistemic approaches and move towards more comprehensive understandings of teachers and teaching, including social and cultural perspectives on identity and identity development. This is reflected in discussions about the concept itself.

The concept of identity

Teacher identity has become a productive line of research, but there is no agreement about a theoretical stance in the field, let alone about a definition of the concept itself (e.g. Beijard et al., 2004; Darragh, 2016; Day et al., 2006; Lutovac & Kaasila, 2018). In fact, the concept of professional identity seems as “messy” as the one of beliefs (cf. the section on beliefs).

Based on her review of the literature, Darragh (2016) lists five different categories of frameworks used in identity research in mathematics education: participative (based on social practice theory), discursive, narrative, psychoanalytic, and performative (based on positioning theory). All of these have also been used in the subset of identity studies on teachers’ identities and sometimes combined in different ways (e.g. Brown & McNamara, 2011; Losano et al., 2018; Mosvold & Bjuland, 2016). However, the participative approach seems to dominate research on mathematics teachers’ professional identities (Lutovac & Kaasila, 2018).

One main difference between the frameworks on offer is the emphasis on local contexts relative to broader structural issues for the character and development of identities. In the first case, the main concern is with whether and how teachers negotiate and identify with normative identities in the locally social, for instance when engaged in PD. In the second case, structures and power relations beyond the current situation are from the beginning part of the conceptual framework.

Across the most frequently used approaches, however, professional identities are considered socially constituted, in either a local or more structural sense, and consequently considered multiple, dynamic and contextually dependent, rather than somewhat stable personality traits. This profound role of “the social” in identity research is evident also in the most frequently used theoretical imports used in the field. Wenger (1998), for instance, talks about identities as negotiated ways of being a person in a context. Looking back on her own work on situated learning, Lave (2019) says that one goal was “to parse a community’s day-today practice with respect to producing ‘old-timers’ from ‘newcomers’” (p. 138), and that the concept of identity was introduced “to insist that knowledgeable skill is only a small part” of that process (p. 137). Holland et al. (1998) say that identities “must be conceptualized as they develop in social practice” (p. 5). And Gee (2000-2001) uses identity about “being recognized as a certain kind of person in a given context” (p. 99). The recurrent references to contexts and practices in these wordings suggest that identities deal with the sense people make of themselves and each other at a particular time and place. They are conceived as individualities that are multiple and contextually dependent.

Aspects of the core of identity

There seem to be three common aspects to and perspectives on lived identities in the definitions above, those of agency, situatedness, and structure (Skott, 2019). In combination with the concern for lived individualities, this identity triad may be seen as the core of the identity concept (figure 1). Like the core of the beliefs construct, it functions as a sensitizing concept that does not determine what to look at, but suggests directions along which to look.

Agency is an individual or communal willingness and capacity to act within social worlds, to influence how they unfold (e.g. Holland et al., 1998). It does not carry connotations of an independent and autonomous actor; rather the premise is that

> [b]oth the immediate and broader social contexts orient teachers' actions, but do so in open-ended ways, leaving space for professional decision-making and agency. Experiences of this agentic space and of the outcomes of manoeuvring within it are aspects of identity. (Skott, 2019, p. 470)

Agency functions both when engaging actively in social practices and when being reluctant to do so. As an example of the latter situation, consider a teacher, who distances herself from the activities in the mathematics department at her school, because she experiences her colleagues as in opposition to the notion of quality instruction promoted by practices at her recent teacher education programme, which still functions an affectively-laden inspiration for her. Both her dissociation from the department and her affective and active affiliation with the teacher education programme are aspects of agency that may affect her professional experiences of herself at the school, that is, her professional identities.

The second core aspect of professional identity is that of situatedness. It acknowledges the local negotiation of the meanings of a practice, including the significance and use of artefacts, reifications and relationships. Such negotiation relates to identity as it both establishes and unfolds by means of mutually acknowledged positions that influence professional experiences. In the example above, the positions of the teacher in the department and at the school more generally are continually renegotiated, for instance positions of being an outsider, being elitist, or being a good mathematician. This negotiation may take place in department meetings, when having lunch in the staff room, and when establishing other – and possibly more productive – collaboration with colleagues beyond the department or with the leadership.

Finally, there is a structural aspect to identity. The way I use the term, *structure* concerns issues stemming from beyond the immediate situation and therefore subject to little agentic control, even if their meaning is negotiated locally. People, reifications, artefacts as well as networks of relationships among them may be subject to such structural influence. A dominant political discourse on teachers and teaching is in this sense structural. Schooling, as constituted globally and locally, is structural with its organisation within and between institutions, formal power relations and divisions of labour, and with the related formal qualification procedures and requirements, timetables, and assessment systems. These structural aspects position teachers and significantly influence lived experience in the profession. Consider again the example above. If a government decision is issued on the subject matter competence of teachers (e.g. all teachers need a Master's degree) or on the introduction of new mathematical contents (e.g. computational thinking) the teacher may be positioned differently at the school, leading to different experiences of herself as (not) valued, as (in-)competent, and possibly as redundant.

As we shall see later, the relative emphasis on and understandings of the relationships among the nodes of the identity triad differ between studies. But to some extent, most identity studies include all three, indicating a more fundamentally social understanding of the individual-context relationship than in research on teachers' knowledge and beliefs.

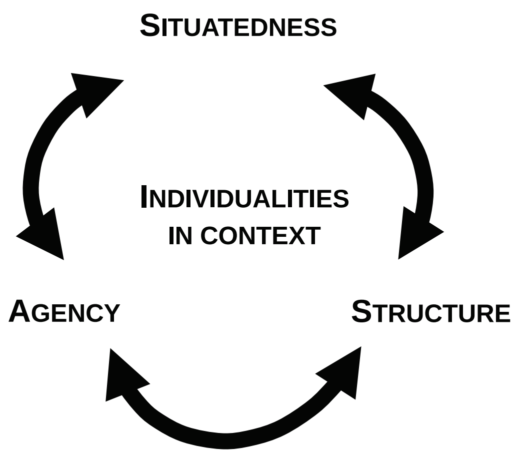

Figure 1: The identity triad: aspects of and perspectives on individualities in context

Summary – so far

It is time to sum up the discussion in order to address the questions of how research on teachers' knowledge, beliefs and identity have developed over the last few decades, in particular how individual-context relationships are conceived and whether and how developments align with "the social turn". I use the answers to set the stage for the following section.

The phrase of the social turn refers to a set of developments in mathematics education research beginning in the second half of the 1980s. This was at the peak of the constructivist revolution, but it was also the period in which the first references were made to theories and frameworks that challenged the exclusive emphasis on individual cognition and conceptualised learning and human functioning in more fundamentally social terms. Ever since, increasing numbers of studies have drawn on theoretical imports to mathematics education such as generations of cultural-historical activity theory (Engeström, 2001; Vygotsky, 1978, 1986; Wertsch, 1985), social practice theory (Holland & Lave, 2001; Holland et al., 1998; Lave, 1988, 2019; Lave & Wenger, 1991; Wenger, 1998, 2010), discourse analysis (Gee, 2000-2001, 2005), and positioning theory (Harré & Van Langenhove, 1999), as well as on Sfard's theory of commognition (Sfard, 2008). They have all fuelled "the strong version" of the social turn, as they describe "learning as development within socio-cultural historical practices and […] see meaning, thinking and reasoning as products of social activity" (Lerman, 2006, p. 172).

My argument so far is that research on teachers' knowledge and teachers' beliefs that developed in the wake of the constructivist revolution were decidedly cognitive in their approach. In both fields, the respective key constructs were considered teacher characteristics that functioned almost as independent variables in relation to instruction and classroom practice. These constructivist underpinnings still seem to inform these lines of research. However, contextuality has gradually been taken into account in both fields, also at CERMEs (Skott et al., 2018). The frameworks developed have explicitly phrased their understandings of teachers' knowledge with reference to the profession, and both fields increasingly consider social challenges to how knowledge and beliefs are enacted, that is, adopt a dynamic acquisitionist stance. This means that to some extent the initial expectation of a semi-causal relationship between context-independent knowledge and beliefs on the one hand and classroom practice on the other has been modified, and that context is considered a possible support to or limitation on the enactment of individuals' knowledge and beliefs. Recently, steps have been taken in research on "knowledge" to adopt more fundamentally social perspectives on human functioning, reflected for instance in the use of the gerund *knowing*. In belief research, the more dynamic understandings do not encompass a reformulation of what it means to believe, for instance if reflected in a similar shift from *beliefs* to *believing* or *affectively relating*. Beliefs are still considered relatively stable mental entities that are acquired and possessed by individuals. In general, then, these fields have not turned social.

The situation is different in research on professional identities. This field took off after references to sociology, anthropology, and cultural psychology had become commonplace in mathematics education research. The emphasis on situatedness and structure and the understandings of agency in identity research indicate that it differs from most research on teachers' knowledge and beliefs with regard to its stance on "the social". In identity research, "the social" is generally not considered merely a set of external constraints on the otherwise autonomous functioning of the individual. Rather, "the social", in the local as well as in the structural sense, significantly influences, and in some interpretations constitute professional identities.

The identity triad – a tool for characterising approaches to identity research

Different understandings of the relationships among the three aspects of the identity triad may serve to characterise approaches to identity research (Losano & Skott, submitted). Darragh and Radovic (2019), for instance, study the effects of long-term PD participation for a group of primary teachers in Chile. They explicitly distance themselves from approaches that do not sufficiently take "the wider social, cultural and political context" into consideration (p. 519). As they use the term, identities are discursive entities existing in a cultural realm beyond the individual and the local situation. Teachers select among and attach themselves to these cultural identities. With the terminology of the present paper, this is a highly structural perspective, and agency is a matter of selecting among predefined identities on offer in cultural worlds (cf. Losano & Skott, submitted).

A different perspective is offered by Westaway (2019). She emphasises agency when focusing on how the experienced teacher in her South African case study enacts her professionalism. This is done in ways that are supported and constrained by local and structural conditions. Not least in South Africa, structures and cultural mechanisms in the form of conflicting systemic roles stemming from the apartheid and post-apartheid eras "condition the way teachers express their […] teacher identities" (p. 484). However, Westaway distances herself from "systemic accounts" of identity, and in her study "the agency of the teacher is re-inserted into understanding why teachers continue to reproduce the old systemic roles of a teacher" (p. 490).

Finally, some research focuses on situatedness. This is often so in studies of whether and how a teacher education or PD programme supports teachers in moving from peripheral to more comprehensive participation in the reform (cf. Lave & Wenger, 1991). In this case,

> reform-oriented practices become the centre of attention [and] the trend is to prioritise a particular set of practices, those related to the PD or teacher education programme, and a related figured world, the reform. (Skott, 2018, p. 608)

Often, tensions between practices promoted by the PD in question and the ones that dominate teachers' school life are acknowledged. Gresalfi and Cobb (2011), for instance, argue that there are normative identities for teaching in both a school context and in a PD, and the question is whether and how participants identify with others' expectations in these contexts, that is, develop personal identities that align with the normative ones.

An interactionist complement to identity research

I suggest that there is a need for a complement to the three approaches to identity research mentioned above, notwithstanding the potentials of each of them. There are two reasons for this, one that relates to studies with significant emphases on agency or structure, and one that refers to studies that emphasise structure or situatedness. My arguments, then, refer less to the nodes of the identity triad, than to approaches located near two of the three axes between them. I refer to these approaches as variable oriented and community/society oriented, respectively. My argument is that in the first case there is a risk of not acknowledging the significance of the locally social that emerges for instance in a classroom or among colleagues at a school. In the second case, the risk is that, somewhat ironically, identity research may lose sight of the individual, as it focuses on pre-established social practices or structures. I suggest that what may be missing in both cases is an interactionist complement that focuses on the emergence of group life, and I argue that Patterns of Participation is one possible framework for doing so. In this section I introduce PoP before returning to possible limitations of the approaches located near the two axes mentioned above.

PoP revitalises symbolic interactionism (SI) when researching learning and lives in schools and classrooms and combines SI with social practice theory (e.g. Skott, 2013). SI seeks to understand the emergence of group life and focuses on how meaning evolves in the locally social when people interact with one another. Interaction, then, is not merely a term for people taking turns in a communicative setting; it is the process through which "people come to fit their activities to one another and to form their own individual conduct" (Blumer, 1969, p. 10). In this process, they instantaneously see themselves and the objects attended to from the perspectives of individual or generalised others and adjust their own contributions accordingly. A teacher may, for instance, see herself and the task or contents attended to in a particular situation through the eyes of the students and anticipate and interpret their verbal and physical reactions to her own conduct, for instance their tone of voice or their lifted eyebrows. She may also – to use a symbolic interactionist phrase – take the attitude to herself of generalised others in the form of practices and figured worlds beyond the current situation such as collaborative settings with colleagues, the discussion at a recent parent meeting, the reform as promoted in a

PD, or a different set of pedagogical concerns that may be unrelated to the contents of instruction (Skott, 2019).

The PoP perspective that I use, define teacher identities as the fluctuating experiences of being, becoming and belonging that evolve as teachers engage with their students, their colleagues, the leadership or others in relation to the profession. Such experiences may include being a good mathematician (or not), becoming recognised as an important adult by the students (or not), and belonging at the school or in the wider professional community (or not). In what follows, I use the identity triad to show how this perspective differs from the approaches to professional identity mentioned previously.

The agency-structure axis: Variable oriented approaches and an interactionist response

Studies that attach primary importance to agency or to structure do not necessarily disregard the role of situatedness for teacher identity. Indeed, Darragh and Radovic (2019) are explicit that teachers select a specific identity “in a particular context and for a particular audience” (p. 518). In spite of that, there is little attention to the role of the locally social and no concern for the possibility that unfolding, local events co-constitute identities, or for what makes the teacher select a particular identity “in a particular context and for a particular audience”. Similarly, but at the other end of the axis, an over-emphasis on agency may overlook aspects of identity that emerge in the locally social. In this sense, neither approach is particularly concerned with the negotiation of identities as teachers engage in local practices.

Studies that highlight agency and structure differ in their perspectives on identity, but in both there is, then, a risk of disregarding the significance of the locally social (see figure 2). If this is the case, they become examples of what Prus (1996) refers to as “variable oriented social science”, that is, approaches that “reduce the study of the human condition to ‘individual properties’ or ‘social structures’” (p. xviii). In contrast and in line with SI, Prus suggests that social science is to understand group life as it unfolds, and

> acknowledge and attend to the ongoing accomplishment of everyday life in the ‘here and now’ (while mindful of the evershifting present within people’s experiences with the past and their anticipations of the future). (Prus, 1996, p. xviii)

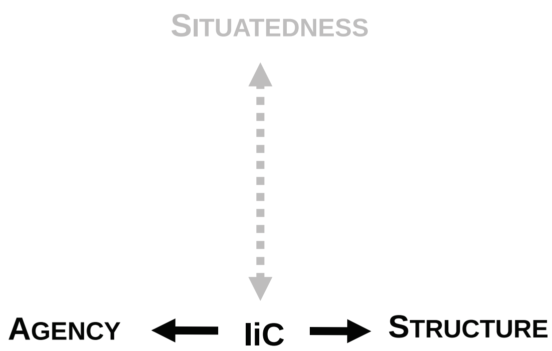

Figure 2: Variable-oriented approaches: *Individualities in Context* (IiC) near the agency-structure axis; little attention to situatedness

The interactionist perspective, then, takes the dynamic view of identities beyond merely being a matter of enacting identities (although possibly constrained by local or structural conditions) or selecting among a number of pre-given ones in some situation. It suggests that identity is itself an emergent phenomenon, "a moving target", one that may be in flux, for instance as classroom processes unfold (Losano & Skott, submitted). It invites a focus on processual identifyings, rather than identities, to avoid the objectifying connotations of the latter term. The criticism of variable-oriented approaches, then, is that they do not sufficiently pay attention to situatedness, that is, life as it emerges locally.

The structure-situatedness axis: Community/society oriented approaches and an interactionist response

Studies that highlight structure or focus on situatedness share their concern for the social constitution of identity and for pre-defined social structures or practices. They focus on what the situated-normative or structural identities on offer are in a particular situation. For ease of communication, I refer to these as community/society oriented.

Lutovac and Kaasila (2018) argue that such approaches may not do justice to key aspects of identity, as they lose sight of the individual. Similarly, I have argued that there is a need to re-centre the individual, rather than a particular practice, if the intention is to understand teacher identities as they evolve in interaction (Skott, 2018). From this perspective, community/society oriented approaches pay limited attention to agency, which is reduced to a matter of selecting among predefined identities on offer or choosing (or not) to identify with and move from peripheral to more comprehensive participation in a pre-established practice (figure 3).

This is at odds with the interactionist approach. As Blumer (1969) says, people act towards the meaning situations have for them, rather than towards structures, and meaning emerges in and from social interaction as an outcome of people taking (each) others' attitude to the situation at hand. As an example, Leticia Losano and I have argued in our study of an experienced, Brazilian primary teacher, that agency is located squarely in the locally social as an aspect of a person-practice interface (Losano & Skott, submitted). Agency is a matter of how the teacher combines and capitalises on the different attitudes she may take to herself in interaction, including how she actively renegotiates the meaning and significance of previous and anticipated future practices and figured worlds in view of interactions as they unfold at the instant. From this perspective, professional identities are not viewed as determined by pre-given structures or practices, but as dynamic experiences of being, becoming and belonging that evolve as teachers participate in group life.

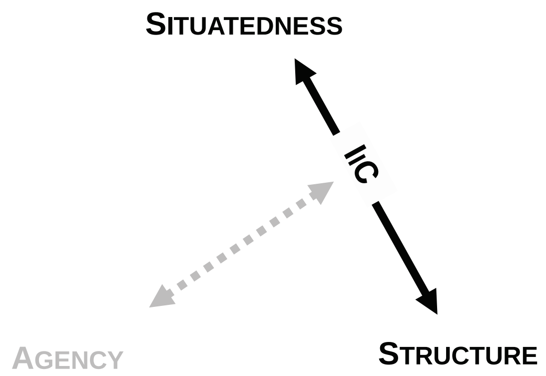

Figure 3: Community/society-oriented approaches: *Individualities in Context* (IiC) near the structure-situatedness axis; possibly with limited attention to agency

The agency-situatedness axis: The location of the interactionist approach

The suggested interactionist complement to other approaches to identity is located along the agency-situatedness axis, that is, an axis oriented towards emerging individualities in the locally social. Neither the variable oriented, nor the community/society oriented approach disregard the aspect of identity located outside their main axes, although these aspects play a minor role. In a somewhat similar sense, approaches located on the locally-social axis, including the interactionist approach, do not disregard structural issues. However, it is not an a priori decision that these issues play a role, but empirical questions whether, how and why this is so. The PoP framework, with its interactionist complement to the other approaches, is based on networking social practice theory and symbolic interactionism (e.g. Skott, 2013, 2018, 2019). The intentions with PoP include developing dynamic and contextual understandings of teachers and teaching, including their professional identities. The attempt is, then, to re-centre the individual, while maintaining the participatory stance of most studies of identity and as part of that to shift the emphasis from identity to fluctuating identifyings (figure 4).

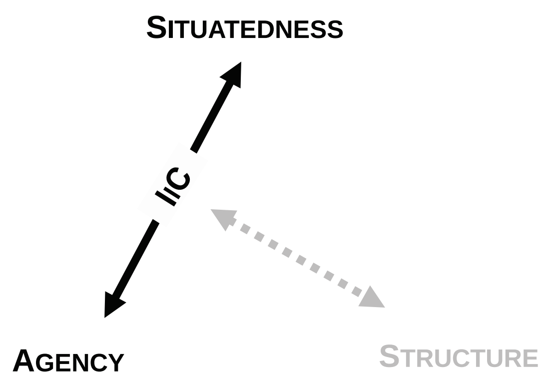

Figure 4: Locally-social approaches: *Individualities in Context* (IiC) near the situatedness-agency axis; acknowledge structure if empirically justified

Extending the participatory stance to studies of teachers' 'knowledge' and 'beliefs'

It was a main point in my discussion of research on teachers' knowledge and beliefs that these fields have "turned social" to a lesser extent than research on professional identity, and, indeed, to a lesser extent than most mathematics education research. Recently, suggestions have been made to do away with the acquisitionist underpinnings of research on teachers' knowledge, but the field does not seem to have moved far in that direction (yet?). To the extent that beliefs and knowledge are still considered objectifications, that is, reified mental entities residing within the individual with substantial impact on practice, agency is a matter of enacting such objectifications, and structure and situatedness are merely considered external constraints. Interpreted in the terms of the identity triad, research on teachers' knowledge and beliefs are located close to the agency node, and there is little in these fields that corresponds to the move from identities to fluctuating identifyings in identity research.

This invites the question of whether it is helpful for understandings how teachers contribute to classroom practice and student learning to shift the emphasis from *Mathematical Knowledge for Teaching* to *Mathematical Knowings When Teaching* and from *Beliefs about mathematics and its teaching and learning* to *Affectively relating to mathematics and students in classrooms* (cf. the section 'Summary – so far'). I suggest that the answer is in the affirmative and that the PoP framework is one possible way of doing so. PoP was initially developed as a participatory challenge to mainstream belief research, and I have argued elsewhere that it is a useful alternative (Skott, 2013, 2015a). It differs significantly from the cognitive underpinnings of belief research and sheds light on the emergent character of how teachers relate affectively to mathematics, to their students' learning of mathematics and to the acts of teaching as classroom processes unfold.

So far little has been done with PoP in relation to teachers' knowings when teaching. My recent study with Despina Potari and Chara Papakanderaki suggests that it may also have some potential in that field, that is, for understanding how teachers' ways of knowing relate to interactions as they unfold for instance in a classroom (Skott et al., submitted). This study brings to the fore relationships between agency, situatedness and structure in the case of an experienced and highly qualified Greek teacher, Elena. In the course of the study, Elena moves from a somewhat traditional secondary school in Athens to an "experimental and model school" that is well known for developing innovative approaches to teaching. The data are from two teaching-learning sequences on functions in grade 10, one from each school. Although they are on the same contents and both taught by Elena, the two sequences are very different. The students' ways of participating differ and so do the mathematical objects of attention, even the object of function. Also, Elena's experiences of belonging differ, and so do the ways of knowing required of her, in particular how she deals with relations between informal and different aspects of formal mathematics. The point in the present context, then, is that it is not only aspects of Elena's professional identifyings that change in and through the interactions; so do her ways of knowing the contents.

Summary and conclusion

Research on and with mathematics teachers has over the last 40 years taken the professional tasks of teaching still more seriously and acknowledged that teaching is relational work conducted in local situations and conditioned by broader structural contexts. After having challenged the behaviourist approach in process-product studies as well as the emphasis on academic mathematics in early mathematics education scholarship, our field changed the emphasis towards (1) understanding teachers' thinking and meaning making as they relate to the profession, with special emphasis on mathematical knowledge for teaching (not necessarily in the MKT sense) and (2) the beliefs teachers hold about the subject and about its teaching and learning. To some extent this takes the social situation of schools and classrooms into account. After the turn of the century, more fundamentally social approaches have been used in the study of teachers' professional identities.

The outline above suggests that research on and with mathematics teachers in general turned social later than other fields of mathematics education, and it may be argued that research on teachers' knowledge and beliefs still has not done so to any great extent. The question I have addressed in the present paper, however, is not merely whether or not specific subfields have turned social, but what it may mean to do so.

To address this last question, I used the identity triad to locate different approaches to research on and with mathematics teachers, and argued that neither research on teachers' knowledge, teachers' beliefs nor teacher identity has adopted an interactionist approach to understanding the emergence of group life. I suggest that this may be needed, if the ambitions of research on and with teachers include understanding the contextual meanings they make of learning and lives in schools and classrooms.

Big Questions in Mathematics Education: A Panel Discussion

Eirini Geraniou[1] and Michiel Veldhuis[2]

[1]IOE, UCL’s Faculty of Education and Society, University College London, London, UK; e.geraniou@ucl.ac.uk

[2] IPABO University of Applied Sciences Amsterdam & Utrecht University, Netherlands, m.veldhuis@ipabo.nl

Three researchers, Anna Baccaglini-Frank, Ingi Højsted and Janka Medová, were invited to present and discuss their proposals for a research agenda for mathematics education over the next 20 years in a panel discussion chaired by Michiel Veldhuis and moderated by Eirini Geraniou.

In this paper, Anna Baccaglini-Frank summarizes the perspective that she presented, as leader of TWG24 "Representations in Mathematics Teaching and Learning", bringing attention to a shift in how groups of researchers in Mathematics Education think and talk about mathematical objects and their representations. She argues that such a shift has theoretical and practical implications that should be taken into account in future research, especially when addressing some "Big Questions in Mathematics Education".

In this paper Ingi Højsted outlines central points from his presentation at the plenary panel "Big Questions in Mathematics Education" of CERME12. He begins by briefly recounting the historical struggles with implementation of digital tools in mathematics education, and refers to the importance of how digital tools are utilized. To provide an example of the nuances and complexity of the research involved on digital technology in mathematics education, he focuses on the specific digital tool of dynamic geometry environments and describes pertinent dimensions of research foci in relation to this software: student learning, task design, the teacher. He considers some of the major challenges with regards to the implementation of dynamic geometry environments as well as other digital resources in mathematics education. Finally, he reiterates the three broad questions posed for the plenary panel debate.

This paper summarizes Janka Medová’s contribution to the plenary panel discussion Big Questions in Mathematics Education and focuses on the role of algorithms in mathematics education. Mathematics and computer science are interrelated from their substance. They share several common concepts including the algorithms, but the way they work with them differ among the two disciplines. Algorithms provide an additional dimension to mathematical knowledge, the deep procedural knowledge. Involvement of coding and work with algorithms in mathematics instruction seems to be a promising activity bridging the two disciplinary approaches. The questions: (i) how the work with algorithms contributes to students’ learning and (ii) how to prepare teachers for this kind of activities should be investigated.

Big Questions in Mathematics Education: A “Representations in Mathematics Teaching and Learning” Perspective

Anna Baccaglini-Frank

Department of Mathematics, University of Pisa, Italy; anna.baccaglinifrank@unipi.it

I summarize the perspective that I presented, as leader of TWG24 “Representations in Mathematics Teaching and Learning”, bringing attention to a shift in how groups of researchers in Mathematics Education think and talk about mathematical objects and their representations. I argue that such a shift has theoretical and practical implications that should be taken into account in future research, especially when addressing some “Big Questions in Mathematics Education”.

Keywords: Digital extension, mathematical objects, representations.

A shift in how we think about mathematical objects and their representations

In a recent paper (Baccaglini-Frank et al., 2022), we discussed what we see as a shift away from a Platonic conception of mathematical objects and their representations, characterizing various current lines of research in Mathematics Education. Such a shift opens new venues to how we think and talk about representations, which, in turn, influences how we use (and study) them in the teaching and learning of mathematics. In Plato’s allegory of the cave, representations of mathematical objects are seen as reflections of natural things; such reflections inspire artificial objects, of which we only get to see shadows; such shadows are the imperfect forms that allow indirect access to the “real” perfect objects behind them. An implication is that whoever seeks mathematical knowledge should strive to obtain *mental representations* as close as possible to the ideal (non-physical) forms. The Platonic philosophical stance is at the basis of much research on mathematical representations. Many theories on learning mathematics claim the importance of understanding mathematical objects by somehow tapping on their “true” meanings that can be constructed by abstracting from their representations. However, researchers in Mathematics education, including members of the CERME12 community, have also started exploring different theoretical perspectives on the meanings and representations of mathematical objects (e.g., Miragliotta & Lisarelli, 2022; Palatnik & Abrahamson, 2022).

A very important shift away from the Platonic perspective has been initiated by Anna Sfard in her Commognitive Framework (2008). Taking a Vygotskian socio-constructivist perspective, and following Wittgenstein, Sfard sees mathematical objects as no longer residing in some hyper-reality, but in discourse itself, being part of an autopoietic system, a system that defines its own objects. Hence, their meanings stem from the ways in which realizations of a mathematical object are used discursively. An implication of such a shift is that the term “representation” is inappropriate: Sfard rejects the Platonic view of mathematical objects existing “out there” and being re-presented in discourse; rather, for her, mathematical objects “come to life” as part of a discourse of certain human communities.

Another perspective, supported by cumulative data from various fields (neurobiology, robotics, kinesiology) is casting doubt on the Platonic view, and in particular on its implication that bodily experiences are separate from the ideal “mental representations” discussed above. Indeed, the “embodied” turn in cognitive science rejects the hierarchical mind–body separation and stresses that perception and action are formatively constitutive of our thinking. In the Mathematics Education field, the embodied paradigm has been taken to suggest that learning new concepts begins with discovering new ways to act in the environment, using new instruments to perform tasks on discovered affordances (e.g., Abrahamson & Bakker, 2016). Working with the things themselves, students develop a capacity to act efficiently; they learn to describe the world mathematically to coordinate collaborative actions; they iteratively encounter more complex problems; and ultimately they modify the environments to solve emergent problems (Abrahamson & Abdu, 2021).

A specific interest of mine concerns learning mathematics with or through digital tools. Turning away from the Platonic perspective, these can be conceived as "extensions" of our mind-and-body selves, and we can explore new ways of thinking, talking and using representations of mathematical objects. This is a line opened by posthuman discourse that describes the blending of human and technology as a "triumphant overcoming" the "natural" limitations of the human body, leading to the fascinating notion of "digital extension" (see the discussion on Merleau-Ponty in Dolezal, 2020).

My three questions

Based on the shift discussed above, on discussions in TWG24 over past meetings, and on my personal research interests, I am particularly interested in thinking about the three following questions.

Question 1: ***How can we (and will we) produce and share representations/realizations of mathematical objects to make teaching-learning processes truly inclusive?*** Indeed, producing and sharing representations/realizations of mathematical objects are fundamental processes to consider and study in the context of inclusive mathematics education. Research in this domain has highlighted the importance of using multi-modal channels of communication, perhaps also supported by Artificial Intelligence artifacts (e.g., Lew & Baccaglini-Frank, 2021). Given the new perspectives on what representations/realizations of mathematical objects might be, we should explore ways to share and appropriate others' thoughts and personal experiences with such representations.

Question 2: ***How does (and will) learning occur (a) through making representations/realizations of mathematical objects or (b) through making artifacts that make these?*** A very interesting (to me) direction of research has been opened by research on "learning as making", in a constructionist perspective, where, for example, shapes in space are constructed using a 3D pen or a 3D printer (e.g., Ng & Sinclair, 2018; Ng & Tsang, 2021), or sketches of figures are produced on the plane by drawing robots that can be programmed by young children using a graphical block coding language (e.g., Baccaglini-Frank et al., 2020; Baccaglini-Frank & Mariotti, 2022).

Question 3: Finally, since learning experiences can be very different and involve many different factors, I ask***: How can we capture and study students' experiences with representations/realizations more holistically?*** I ask this because in most of the research studies I am familiar with, we attend to only a small part of the "whole picture", focusing, for example, either on cognitive aspects or affective ones, or on a certain small "bit", of a student's larger and more complex interaction with an artifact. However, I believe that it would be beneficial to have analytical tools that allow us to see more of the bigger picture. Perhaps we could work harder on trying to integrate results from studies that each looked at a small bit, but that together can provide new insights into students' learning processes.

Big Questions for Research on Digital Technology in Mathematics Education

Ingi Heinesen Højsted

University of the Faroe Islands, Faculty of Education, Tórshavn, Faroe Islands; ingih@setur.fo

This paper outlines central points from my presentation at the plenary panel "Big Questions in Mathematics Education" of CERME12. I begin by briefly recounting the historical struggles with implementation of digital tools in mathematics education, and refer to the importance of how digital tools are utilized. To provide an example of the nuances and complexity of the research involved on digital technology in mathematics education, I focus on the specific digital tool of dynamic geometry environments and describe pertinent dimensions of research foci in relation to this software: student learning, task design, the teacher. I consider some of the major challenges with regards to the implementation of dynamic geometry environments as well as other digital resources in mathematics education. Finally, I reiterate the three broad questions posed for the plenary panel debate.

Keywords: Digital technology, implementation, DGE, the teacher dimension.

Looking back

Since the introduction of digital technology in mathematics education, extensive research has been conducted in relation to the implementation of different types of digital tools. In fact, already in the mid-eighties, the very first ICMI study (Churchhouse et al., 1986) considered the consequences computers and informatics might have on mathematics and mathematics education, and at that time, researchers were optimistic. However, two decades later, in the 17th ICMI study, Michelle Artigue looked back and reported that "The situation is not so brilliant and no one would claim that the expectations expressed at the time of the first study have been fulfilled" (Artigue, 2009, p. 464). During his CERME11 plenary speech, Paul Drijvers reflected on the low effect of integration of digital technology in mathematics education, acknowledging that "the mathematics education community is still struggling with the integration of digital technology in teaching and learning." (Drijvers, 2019, p. 8), while suggesting that the quality and exploitation of the digital tools are essential ingredients for effective integration. The manner in which digital technologies are utilized seems to be essential (Drijvers, 2019; Højsted & Mariotti, 2021; Jankvist & Misfeldt, 2015). In fact, Niss (2016) proposes that "the very same piece of digital technology can give rise to 'marvels' as well as to 'disasters' in mathematics education. This means that no ICT system, hard or soft, is, in and of itself, good or bad for mathematics education." (p. 247).

Of course, there are many different types of software, and many different software of the same type. If we take the paradigmatic example of dynamic geometry environments (DGE), which has received a lot of research attention, more than 40 DGE had been developed by 2012 (Hollebrands & Lee, 2012). Initially, much of the DGE research focused on students learning with DGEs, for example, Arzarello and colleagues' (2002) seminal work that categorized seven spontaneous ways in which students drag objects in DGE. Another example is Mariotti's (2015) elaboration of the semiotic potential of the dragging tool to introduce conditional statements.

More recently, research attention has shifted towards task design, with authors describing DGE task design principles for specific mathematical aims, for example non-constructability tasks and dependency tasks in relation to conjecture generation and reasoning (Baccaglini-Frank et al., 2017; Højsted & Mariotti, 2021), or developing frameworks to assess task quality (e.g. Trocki & Hollebrands, 2018).

Less research has been conducted in relation to the role of the teacher in facilitating the implementation of DGE (Komatsu & Jones, 2018). The same applies to other digital tools, as described by Traglová and colleagues (2018), who reviewed the research output on digital technology in mathematics education coming from CERME conferences since 1999, "the awareness of the importance of the teacher dimension in research on technology in mathematics education [...] emerged slowly" (p. 154). Although there are several salient contributions on the role of the teacher (e.g., Bartolini-Bussi & Mariotti, 2008; Drijvers et al. 2010) it is my impression, that this dimension still needs the most research attention. Suggesting the same in her PME plenary, Ana Sacristán proposed that teachers are the key players for the successful implementation of digital technologies, calling for "more teacher involvement in both professional development, and as co-constructors and collaborators in the design of technological implementations and resources" (Sacristan, 2017, p. 90).

Indeed, any designed digital mathematical resource may be adopted by their users (teachers and students) to suit their perceived needs in a particular classroom context (e.g., Trgalová & Rousson, 2017). The appropriation process may lead to a use of the resource that is not coherent with the educational intentions of the designer.

In a recent study (Højsted & Mariotti, in press), we found that collaborating with teachers about theoretical aspects of technology implementation can be a complex affair. This intricate issue requires reflecting on how to interface with teachers effectively to accomplish specific educational goals, while taking into account the variety of possible pedagogical paradigms that different teachers may adopt – paradigms that may well be implicit.

Looking forward

Even if much has been accomplished in research on digital technology in mathematics education, it is evident that successful integration of digital technology into teaching and learning mathematics remains a difficult and complex issue – akin to a gordian knot. Therefore, looking forward, I suggest that we reflect on these broad questions in the plenary debate:

1. How can we ensure that in another two decades, we are not still disappointed?
2. Which are the main issues hindering successful implementation of digital technologies in mathematics education and what are the solutions? (The teacher dimension? Design of resources?)
3. How can solid research findings on digital technologies in mathematics education find its way into praxis?

Algorithms in mathematics education

Janka Medová[1]

[1]Constantine the Philosopher University in Nitra, Faculty of Natural Sciences and Informatics, Department of Mathematics, Nitra, Slovakia; jmedova@ukf.sk

This paper summarizes my contribution to the plenary panel discussion Big Questions in Mathematics Education and focuses on the role of algorithms in mathematics education. Mathematics and computer science are interrelated from their substance. They share several common concepts including the algorithms, but the way they work with them differ among the two disciplines. Algorithms provide an additional dimension to mathematical knowledge, the deep procedural knowledge. Involvement of coding and work with algorithms in mathematics instruction seems to be a promising activity bridging the two disciplinary approaches. The questions: (i) how the work with algorithms contributes to students' learning and (ii) how to prepare teachers for this kind of activities should be investigated.

Keywords: Algorithms; mathematics education.

Mathematics and computer science are interrelated since the inchoative stages. Various fields of mathematics, including Boolean algebra, algebraic structures, discrete mathematics and probability provided the theoretical base for the emerging field of computer science. Some years later, in 1976, computer science started to pay off its debt by solving the problem of four colors using the thousands of hours of computing time (Appel and Haken, 1978). The nature of mathematics and natural sciences as they are practiced in the professional world is developing towards computational thinking (Weintrop et al., 2016). Nowadays mathematicians perceive computing as an inherent part of doing mathematics (Lockwood et al., 2019). The use of computers allows processing the calculations in mathematical statistics, even the work with big data.

Algorithms lie on the border between mathematics and computer science. Each discipline looks at algorithms from a different point of view. Computer scientists (e.g., Wirth, 1985) define algorithms as finite, general, deterministic, resultative and elementary which has only limited use in mathematical proofs. Mathematicians investigate the existence and correctness of algorithms, whereas computer scientists look at the algorithms in a more utilitarian way, looking for the real-time instantiations, preferring obtaining the result to its preciseness. Therefore, heuristics were developed for solving problems with high complexity.

Algorithms occur in curricula of both mathematics and computer science. Algorithms for basic mathematical operations were the traditional part of mathematics education. In recent years the algorithms have started to disappear from mathematics curricula as conceptual understanding was in main focus of mathematics educators and procedures were often perceived as the 'rote learning'. On the other hand, Star (2007) sees the particular value in the procedural knowledge itself. Star foregrounds the deep procedural knowledge where the procedure is "known deeply, flexibly, and with critical judgment" (p. 133). Deep knowledge of algorithms, its principles and correctness might be seen as an amalgam between conceptual understanding and procedural fluency, so-called precept (Gray & Tall, 1994). Some studies (Lockwood & De Chenne, 2021) demonstrated the added value involving coding in students' mathematical problem solving. Furthermore, using coding for solving mathematical problems may strengthen the computational thinking of the learners. The questions about how knowledge about algorithms contributes to students' learning of particular mathematical concepts and procedures and how can students profit from generalization of the mathematical procedures in an algorithmic way remain open.

If we want to approach algorithms from both sides, mathematics and computer science, we should decide who should teach about algorithms. There are countries, e.g. Slovakia, where algorithms and programming have had a strong position in curricula since the 1980s, as a part of computer science education. In other countries, e.g., France, algorithms are part of mathematical curricula. Both possibilities have their strengths and weaknesses. Teachers, specialists in mathematics or computer science focus on different characteristics of algorithms, in accordance with the disciplinary practices. Kortenkamp (this proceedings) describe several types of activities usual for work with algorithms in computer science: (i) design of algorithms, (ii) describing the algorithm in a (formal) language; (iii) carrying out algorithms, (iv) proving the correctness of algorithms, and (v) comparing algorithms with respect to complexity, elegance, or simplicity. These activities can be seen also in mathematics lessons and may serve as a bridge between the two disciplinary practices.

The teachers are the agents of any educational change (Kieran et al., 2013) and their work is shaped by their resources, orientations and goals (Schoenfeld, 2010). How the mathematics teachers' predispositions influence their practice regarding the algorithms, what is the knowledge needed to teach algorithms as deep procedural knowledge and whether mathematics teachers see any value in algorithmic approaches to mathematical objects should be examined in further studies.

Introduction

Argumentation and proof continue to attract the growing and wide interest of the mathematics education research community, which was also evident in CERME 12. In Thematic Working Group 1 (TWG01; “Argumentation and proof”), 39 participants from 15 different countries from 5 continents actively engaged in the discussion of the 30 papers and 3 posters. CERME 12 was the first to be organized online; a challenge and an opportunity to investigate ways of practicing and promoting communication, cooperation, and collaboration. For this purpose, the work of TWG01 was organized in both parallel split-group sessions and whole-group sessions, aimed to maximize active participation and to ensure the coherence and unity of the TWG01 identity in the subgroups. Moreover, the online format of the conference proved to be a great opportunity to organize a joint session with Thematic Working Group 9 (TWG09; “Mathematics and Language”). The session allowed the discussion of topics of the common interest of both TWGs, allowing for our practicing the ERME’s spirit of communicating, cooperating and collaborating beyond the conceptual boundaries of our TWG.

The papers of TWG01 were organized in seven themes, which were presented and discussed in split-group or whole group sessions: 1) Theoretical and epistemological perspectives about argumentation and proof, 2) National and international perspectives about argumentation and proof, 3) Argumentation and proof in primary mathematics education, 4) Argumentation and proof in school and university mathematics, 5) Argumentation and proof in teacher education, 6) Argumentation and proof beyond mathematics text and context, and 7) Argumentation, Language and Proof (this was the theme of the joint session with TWG09).

In this introduction chapter, the papers are presented and discussed in three broader topics, in line with the main themes elicited in the discussions of our group: a) Argumentation and proof in school and university, b) Theoretical, epistemological and sociocultural perspectives about argumentation and proof, and c) Argumentation and proof in different texts and contexts.

Discussion of Papers

Argumentation and proof in school and university

In the TWG01 Introduction section of the CERME 11 proceedings, it was noted that one of the areas that the TWG01 participants "would like, and hope, to see more research in future CERMEs was: *The teaching of proof and argumentation* in both school and university settings, including in teacher education with particular emphasis on argumentation and proof at the elementary school level." In CERME 12, the topic of several papers appeared to address this, with a particular focus on primary education. The presented papers investigated diverse aspects of the primary school students' argumentation and proof, including the students' conceptions and understandings about proof (as presented in the papers of Sigrid Iversen and of Merve Dilberoğlu, Erdinç Çakıroğlu and Çiğdem Haser), designs to support the students' proving skills and in highlighting the empirical-deductive gap (as discussed in the papers of Melanie Platz, of Jo Knox and Igor' Kontorovich). Moreover, we had the opportunity to discuss different aspects of reasoning that occur at these educational levels: data-based argumentation as investigated in the paper of Jens Krummenauer and Sebastian Kuntze, and Simone Jablonski's paper about mathematical reasoning outside of the classroom. Furthermore, we discussed topics specific to higher educational levels, including a paper about proofs without words at the secondary education level by Nadav Marco, Alik Palatnik and Baruch Schwarz, as well as Katharina Kirsten's paper about the proving strategies employed by first year university students.

Considering teacher education, a central issue concerned the importance of working with future and in-service teachers to explore ways of efficiently incorporating research findings about argumentation and proving in teacher training and professional development programs. Such efforts were evident in the papers of Orly Buchbinder and Sharon McCrone and of Gabriel Chun-Yeung Lee. At the same time, the papers of Thomas Bauer and Eva Müller-Hill and of Fiene Bredow and Christine Knipping allowed us to gain deeper insight on the teachers' practices through the lenses of different theoretical perspectives. Moreover, Lakatosian ideas were at the crux of three papers concentrating on teachers (the papers of Mei Yang, Andreas Stylianides and Mateja Jamnik, and of Dimitrios Deslis, Andreas Stylianides and Mateja Jamnik) and on teacher educators (as discussed in the paper of Magdalini Lada and Tore Alexander Forbregd).

Overall, the presented papers offered the opportunity for rich discussions about the commonalities and specificities of teaching and learning argumentation and proving at the different educational levels (with a special focus on primary education), as well as about the appropriateness of the respective research approaches. At the same time, the discussion about the implementation of Lakatosian ideas in teacher education raised fruitful deliberations about the way that ideas that have been developed in a specific sociocultural context may (or may not) be applied to educational research, which leads to the second broader topic of the papers discussed in TWG01.

Theoretical, epistemological and sociocultural perspectives about argumentation and proof

The meaning(s) of proof, its relationships with the validity of mathematical knowledge and with the notion of truth, are important epistemological issues that are constantly being re-visited in the TWG01 meetings; question certainties helps to enrich, broaden and alter perspectives. Along these lines, Viviane Durand-Guerrier discussed the dialectical relationships between truth and proof, while the discussion was enriched by Vergnauds' ideas as employed in Nadia Azrou's paper and by Habermas' rationality in the paper of Paolo Boero. Moreover, the role of logic and deductive reasoning is at the crux of argumentation and proof and, hence, in this CERME, logic was again a central theme of our discussions in TWG01. Miglena Asenova's paper, challenged the traditional perspective of classical logic and set-theoretical assumptions, while we had the opportunity to consider the role of unitizing predicates as presented in the paper of Paul Christian Dawkins and Kyeong Hah Roh, as well as the role of deductive reasoning in word problems as investigated in the paper of Rimas Norvaiša.

Considering the complexity of the argumentation and proof phenomena, the discussions about epistemological and theoretical perspectives were explicitly linked with the role of the sociocultural aspects in the teaching and learning of argumentation and proof. For this purpose, we focused on the diverse perspectives and realizations of assessment in different countries (for example, Chile, Hungary, Norway), drawing upon the papers of Kinga Szűcs and of Manuel Goizueta, Constanza Ledermann and Helena Montenegro. Furthermore, the paper of David Reid broadened the discussion to include 'reasoning' in the national curricula and standards in several countries. Moreover, the paper of Karolína Mottlová and Jana Slezáková offered an insight of implementing ideas of the curriculum of one country to another (respectively, from Singapore to Czech Republic), focusing on word problems. At the same time, language appears to be a crucial factor in mastering the logical structure of proofs, as discussed by Kerstin Hein. The latter issues about language are also explicitly linked to the third broad topic of the papers discussed in TWG01.

Argumentation and proof in different texts and contexts

Argumentation and proof have been traditionally linked with language and verbal communication, but in CERME 12 the participants draw the attention to broader conceptualizations of text, including non-verbal and multimodal aspects. Within this context, we discussed the explanation norms expanded to include explanation videos and the explanation norms, as presented in the paper of Jessica Kunsteller. Moreover, in the last CERME, the participants' discussions involved various aspects of the issues of language in argumentation and proof, while it was noted that it might be sensible to address this complexity in collaboration with colleagues of TWG09 and linguists. In this CERME, we addressed this issue by having a joint session with TWG09, where we had the opportunity to discuss language, argumentation and proof. For this purpose, we initiated the inter-TWG collaboration by critically focusing on Toulmin's scheme, which has been a staple tool for analyzing argumentation. The various implementations and extensions to the Toulmin's model were synthesized in the paper of Jenny Cramer and Leander Kempen, while the paper of Andreas Moutsios-Rentzos explicitly acknowledged multimodality in the discussion about argumentation and text. Two papers of colleagues of TWG09 (of Christoph Körner and Michael Meyer, and of Jorge Toro and Walter Castro, which may be found in the TWG09 part of the CERME 12 proceedings) allowed us to reflect upon the commonalities and differences of the two groups with respect to language issues in argumentation and proof.

Furthermore, mathematics is at the crux of the modern scientific, non-mathematical texts, such as physics. The participants of TWG01 investigated aspects of argumentation and proof in historical and physics texts, as presented in the paper of Laura Branchetti, Alessia Cattabriga, Olivia Levrini and Sara Satanassi.

Conclusions and Future Directions for TWG01

We argue that CERME12, the first to be conducted online, offered the participants the opportunity to be engaged in rich, broad and deep discussions about a variety of issues and perspectives. Importantly, we noted a valuable mix of a continuity of topics from previous CERMEs with novel ideas. A series of questions were posed that paint potential paths of future research projects.

Considering the *teaching of argumentation and proof*, we noted the tensions amongst research, intentions and actuality in everyday teaching and the importance of findings ways to bridge the potential divides. Furthermore, we ponder how can we make the teaching of argumentation and proof feasible for the different grades, curricular, educational and sociocultural settings? Should it be incorporated in everyday teaching practices across mathematical contents or should there also be a dedicated section to specific argumentation and proof practices (for example, about logic)?

Moreover, drawing upon the fact that in the modern curricula mathematics is present in non-mathematical courses, we identified a need for investigating *interdisciplinary perspectives about argumentation and proving* in texts, textbooks, and teaching practices.

The rapid technological advances appear to crucially affect the established communication norms and modalities, as they become part of the everyday teaching. Within this context, conceptualizing and investigating *language issues related to argumentation and proof* seems to need to be re-visited, and broadened to include non-verbal (multimodal, embodied, affective etc) and/or implicit aspects.

The *sociocultural aspects of argumentation and proof* seem to be another area of interest that transcends various perspectives, including the implementation of specific theoretical and/or epistemological perspectives in different context (to the one that the perspective originated), as they may entail both cultural and cognitive dimensions.

All these areas of interest intersect in complex ways and derive from this TWG01 meetings and should not be interpreted as prioritizing specific lines of research over others. We are aware that proof and argumentation are approached from different perspectives (and in other TWGs groups) and in TWG01 we are committed to voicing and exploring this diversity.

Questioning the Exclusivity of Classical Logic and Set-Theoretic Assumptions in Analysis of Classroom Argumentation and Proof

Miglena Asenova

Free University of Bolzano, Italy; masenova@unibz.it

The paper highlights the necessity to question the exclusivity of classical logic, or of approaches that are reducible to it, in the analysis of classroom proof and argumentation processes, as well as the role of the set-theoretic language as intrinsically linked to classical logic. Two examples drawn from mathematics classroom are analysed, recurring to the Ancient Indian empiricist Nyaya logic and to Peirce's non-standard quantification, associating the last to a "free logic", not axiomatizable within an axiomatic system where the specification axiom applies.

Keywords: Logic, Non-standard quantification, Nyaya, Free logic, Set-theoretic language.

Introduction.

The kind of logic students spontaneously resort to when they conjecture, argue or proof in mathematics classroom is often difficult to capture with the formal instruments of propositional logic (Barrier et al., 2009). Some scholars propose natural deduction for First Order Logic (FOL) as useful to reduce the distance between non deductive argumentation schemes and mathematical proof because of the possibility it offers to work on objects rather than on properties (Durand-Guerrier, 2005). To capture reasoning in Mathematics Education (ME) also Hintikka's dialogical logic, in reference to game theoretic semantic, is studied (e.g., Arzarello & Soldano, 2019; Blossier et al., 2009). What is common to these approaches is that they all are classical[1] or are reducible to the classical one.[2] Now, as Lindström's theorems shows, classical logic is intrinsically connected to set-theoretic language (Zalamea, 2021). In classical FOL the variables the quantifiers refer to, range on sets that represent the domains of the predicates. One of the fundamental axioms of set theory[3] is the axiom of specification: given a set A and a formula φ(x), there exists a subset B={a ∈ A: φ(a)}. This axiom is based on Frege's symmetry principle according to which one obtains "an equivalence […] (locally, within the restricted universe A) between φ(a) (intensionality) and a ∈ B (extensionality)" (Zalamea, 2009/2012, p. 324). If this axiom fails, both the law of the excluded middle (thus classical logic) and the standard use of quantifiers fail, because it is not guaranteed that a property univocally determines a set. From the other hand, the domain of reference of the statements during a learning process evolves over time and to grasp this evolution, sets should become "variable" (Lawvere & Rosebgough, 2003). Such sets can be captured by topoi in intuitionistic logic, considering an

[1] Classical logic is the logic where the law of the excluded middle ($A \vee \neg A$) and the law of non-contradiction ($\neg(A \wedge \neg A)$ hold, while non-classical logics are logics where at least one of these two characteristic properties does not hold. Examples of non-classical logics are the paraconsistent logic (the principle of non-contradiction holds only locally but not globally) and the intuitionistic logic (the law of the excluded middle does not hold and consequently also the double negation does not mean in general an assertion: $\neg\neg A \nvdash A$).

[2] The concept of truth in the game-theoretic semantic is different from the classical one (it is based on the logical existence of a choice function that guarantees the existence of a winning strategy for one of the players, called the verifier), but it can be shown that this truth concept is equivalent to the Tarskian one (Arzarello & Soldano, 2019) and thus to the truth conception in classical bivalent logic that follows the Aristotelian tradition.

[3] I refer to the Zermelo-Fraenkel axiomatic system with the axiom of choice (ZFC), as it is the standard axiomatic set–theoretic system within which mathematics usually is developed.

evolution over time, but not by classical sets. Classical sets, and thus classical logic, could be considered as special cases where time collapses into a moment and sets become fix.

Summing up, since classical FOL is exactly tailored to capture classical set theory, restriction to set-theoretical language may not allow different kinds of rationalities, that need to give up some of the constrains of set-theory, to be recognised, and thus it prevents also the investigation of possible shifts between "non-standard" and classical rationalities. Indeed, such "epistemic" rationalities require to consider indeterminacy about the properties that hold or do not hold for an object. I argue, recurring to examples, that non-classical approaches to logic and quantification, which don't require set-theoretic assumptions, could be able to put into evidence these aspects in the analysis of reasoning in mathematics classroom. In this way, (at least) novices' reasoning in ME, even if it does not match to classical logic, could be recognized as *knowledge* within a suitable rationality frame (Boero, 2017), rather than as a lack of rationality.

Theoretical framework.

Nyaya and empiric rationality. In the Western mathematical tradition, the Aristotelian syllogism represents the basis of logical reasoning and for mathematical proofs only the deductive syllogistic inferences are accepted. On the other hand, D'Amore (2005) shows that when dealing with proof, novice students might spontaneously resort to a type of logic very different from the Aristotelian one– the Indian Nyaya logic, a pragmatic and empiricist logic, linked to perception. In the Nyaya induction and deduction are closely interconnected within its "syllogism". Furthermore, the use of examples is not only permitted but is expected by the argumentative model itself and the "formal" and "material" aspects are closely intertwined in it (Sharma, 1962, p. 186), for the inferential model itself is conceived as a proof process of truth. According to D'Amore (2005), the Indian Nyaya philosophical school (1st century BC) recognizes a pre-eminent importance to four *means of knowledge*: testimony, analogy, perception and inference. The inference is what can be considered the Nyaya "syllogism" and has the following structure: (1) the Assertion (what one wants to prove); (2) the Reason; (3) the Thesis (a general proposition followed by an example); (4) the Application; (5) the Conclusion. Finally, one of the fallacies of the "right reasoning" in Nyaya is reasoning on non-existent objects.

Peirce's non-standard quantification. In ME also non-standard quantification, that cannot be framed within classical FOL, is epistemologically accounted (Blossier et al, 2009), with the aim to explain difficulties in managing quantification in classical sense at tertiary level or in the shift from secondary to tertiary level. These authors show that expert students (at tertiary level) spontaneously use different kinds of quantification that often involves temporal aspects and a kind of variation of the variables that often do not fit with the $\exists\forall$-variation as it is known after the introduction of the axiom of choice. They mention within the non-standard approaches to quantification Bolzano's (link between constant and variable quantities) and Cauchy's (link between variable quantity and fixed limit) ones, but they also account for the Peircean one, putting into evidence that it does not rest on logical distinctions but is "inner to the individuum" (Blossier et al., p. 84). I will deepen this last non-standard approach.

According to Peirce, quantification can be general, vague, or precise. Peirce calls generality, vagueness, and determination "the three affections of terms, [which] form a group dividing a category of what Kant calls 'functions of judgment'" (Peirce, CP, 5.450)[4]. *Generality* means absence of distinction of individuals rather than validity for every individual, as it is the case for the classical

[4] Peirce's Collected Papers (CP) are quoted in the usual way: (Peirce, CP, volume number.paragrph number).

universal quantifier that quantifies over sets of individuals; it can be expressed by words like *any*, *whatever*, etc. *Vagueness* means a certain type of existence that does not break the absence of distinction of individuals, but states that there are suitable generic individuals that satisfy a certain property; it can be expressed by words like *some*, *certain*, etc. It is similar to the classical existential quantifier but while the genericity of the latter rests on the proof of independence from the choice of a specific individual, the former rests on the *knowledge of the possibility* to choose individuals that remain indistinct, without a real actualization. *Precision* means effective actualization of possibility; the precise individual represents a rupture of the relationality that distinguishes the vagueness. As Hintikka's logic also the Peircean one is a dialogic logic with a game-theoretic semantic (Pietarinen, 2019), but Peirce's logic is epistemic in a different manner as Hintikka's one. Indeed, as Zalamea (2021) shows, Peirce's logic can be captured by sheaf-logic and sheaf-logic is intuitionistic. Thus, quantification in Peirce's logic does not require the axiom of specification and the symmetry of Frege's abstraction principle fails in general. Furthermore, according to Hintikka (2001) intuitionistic logic is truly epistemic because the crucial notion in it: "is not *knowing that*, but *knowing what* (*which, who, where, …*), in brief, *knowing* + an indirect question, that is, knowledge of objects rather than knowledge of truth" (p. 10) and this *knowing-what*-logic "cannot be analysed in terms of *knowing that* plus the apparatus of received first order logic" (p. 11).

The Nyaya logic is an example of an empiricist logic where reasoning applies on single objects, considered as "existent" by the subject; Peirce's logic with its non-standard quantification can be considered as an example of *free logic,* where the domain the quantifiers range over is not necessarily a closed set but "the class of existing things" (Nolt, 2021). In this sense, these two approaches are compatible and can be combined, at least at the basic level considered in this context.

Methodology of research.

A hermeneutical approach to the text analysis (Palmer, 1969; Bagni, 2009) is adopted. In this approach, the procedure consists in a dialectical back and forth between the meaning of the single parts of a text (oral, written etc.) and its global sense, in a meaning-increasing dialectical interpretation. The begin of the interpretation is always based on the interpreter's presuppositions about the original context of the analysed text (cultural, historical, etc.). The concept of *personal space* (Brown, 1996) of the protagonists (students and teacher) is used to frame the researcher's presuppositions in entering the analysis of the classroom excerpts and in searching for a global meaning, going from the part (examples) to the whole (discussions and conclusions) and vice versa. According to Brown, the *personal space* is the (virtual) space where "an individual sees him or her self acting" (p. 120); it is made by all the aspects, interests, constraints and means that inform the subject's acting in a context and is a source for meaning because "the individual acts in the world he or she imagines to exist" (p. 121). Here it mirrors the students' and teacher's background, inferred by the cultural context they are merged in while making mathematical statements or orchestrating mathematical classroom activities.

Data analysis and discussion.

Example 1: Empiric rationality, Nyaya, and non-standard quantification.

In this section an argumentative text produced by a 15-year-old high school student is discussed. S/he should answer the question: Is it true that *Each number that ends with the digit 1 is a prime number (that means without divisors different from 1 and the number itself) or it is divisible by 3*? The teacher's approach is Aristotelian and her and the student's personal spaces are inferred from information provided by the researcher that collected the data[5]. They are framed by the personal backgrounds (professional and formative), as well as by the classroom context.

In the analysis (Figure 1) classical Aristotelian and Nyaya-lenses are adopted: student's words are marked in **black bold**; the classification based on the Nyaya-scheme in green; the interpretation based on the Nyaya rationality frame in orange and the one within the Aristotelian frame in blue[6].

Assertion. **It is true,**

Statement whose truth is intended to be proven, as well as the expression of an intuition / Expression of an intuition.

Reason. **in fact, if we consider 11, 21, 31, 41, 51, 61, 71, etc. we see that they are all prime numbers or numbers divisible by 3.**

Reason why the statement is true. / Examples.

-------- **On the other hand, it is possible to reason also in general terms.**

Introduction of the general statement / Introduction of the generalization.

Thesis 1. **If a number is prime and greater than 2, it ends with an odd digit**

Shows the existence of the object he is talking about.

Thesis 2. **As for 3, among its multiples there are 21, 51, 81, 111, 141, etc.,**

Shows the existence of the object by showing generic examples.

Reverses thesis and hypothesis.

Application 1. **(and 1 is just an odd digit).**

Application 2. **all numbers ending on the right with the number 1.**

It is shown that the conditions of the Reason are fulfilled. / Wrong reasoning due to the inversion between thesis and hypothesis; tries to prove the inverse statement.

Conclusion. **The thesis has been proven.**

It has been "proven" that given any number that ends with 1, it is either prime or is divisible by 3. / He "proved" the hypothesis.

Figure 1: Interpretation of student's argumentation resorting to the Nyaya approach and to the classical Aristotelian approach

Discussion of example 1.

The student's *personal space* is characterized here by: (1) the experience of the concept of proof in Euclidean geometry; (2) some first explicit information about how a proof is made (thesis, hypothesis, general reasoning, no use of examples); (3) some elements of set-theoretic language in reference to number sets, without deepening of quantification; (4) the interest in showing the own ability (the student was firmly convinced that her/his proof is a good one and s/he wants to prove the truth of the Assertion); (5) the constraint that the text is addressed to the teacher. The teacher's *personal space* is framed at least by the following elements: (I) a valid proof starts from the hypothesis and ends with the thesis; (II) proof is deductive and the use of examples means induction; (III) her spontaneous, implicit, or explicit, use of set-theoretic language as object *language* in mathematical contexts, due

[5] The analysed text was produced with research purposes completely different from the present one; thanks to prof. Paolo Boero from the University of Genoa for having authorized its use for this alternative analysis and for helping to detect the information that was needed to reconstruct the teacher's and the student's personal spaces. We know that the teacher graduated in the mid-1990s at the University of Genoa by a five-years graduation program in Mathematics. In this context, proof is based on classical Aristotelian approach and the object language is always set-theoretic.

[6] The Thesis and the Application of the Nyaya scheme are divided in two parts and the examples are missing.

to her mathematical *forma mentis*. Both *personal spaces* are framed by the assumption that one "uses language in much the same way as everyone else" (Schulz, as quoted by Brown, 1996, p. 121).

The fact that the student has not recognized that the statement is false does not matter; the focus is on her/his reasoning. From the teacher's "classical" point of view, the basis of the student's reasoning could be summed up as follows: The student tries to show that there is a partition of the set of numbers ending with 1 in two subsets: the set A, containing the prime numbers greater than 2 ending with 1, and the set B, containing the multiples of 3 ending with 1. However, s/he does nothing but show that the set of prime numbers ending with 1 is a subset of the set of numbers ending with an odd digit and that there are multiples of 3 ending with 1. Of course, in this way s/he has not proved the existence of the supposed partition, but only the fact that there are two non-empty subsets of the sets A and B, reversing so thesis and hypothesis. Let us now eliminate references to sets in the mathematical sense, that do not belong to everyday reasoning: thinking of the number 3 does not necessarily mean thinking of it as a natural or as a rational number, but as an "object" in itself, in the same way as one thinks of a cup not as an element of the set of all cups, but as an object that falls under the senses.

We see that the student lists some numbers ending with 1, followed by ellipsis, as if this list were to continue. The mathematically shaped thought might interpret this list as the representation of an infinite set. But this list is not necessarily an infinite set in actual sense; it represents probably indeterminacy or vagueness in Peirce's sense or, at most, potential infinity. Indeed, if the student reasons in terms of numerical sets s/he should now try to prove the existence of the supposed partition and s/he does not. But if s/he *does not* reason in terms of numerical sets, what could s/he try to prove? Maybe that given *any* number that ends with 1, *that* number is prime or is a multiple of 3. This reasoning is based on an interpretation of "each" (the universal quantifier) in the sense of "any", that has no meaning in classical FOL but means *generality* in Peirce's sense. The student considers the first numbers listed as *random* cases (any) and finds that they have the required characteristics. This is a not valid generalization both in classical and in Peirce's sense. What the student has shown is that there exist *some* numbers that satisfy the property and so s/he would be able only to quantify recurring to a *vague* existence. This reasoning produces a sort of "fake" generalization by induction. The student knows that the generalization by induction on single cases is not allowed and that s/he must produce a reasoning with general validity (the text is addressed to the teacher). What could *mean* in the student's *personal space* "reasoning that applies in general"? S/he seems simply to produce an *existence* proof, s/he shows that the object being discussed *actually exists* in the sense of the Nyaya logic, and that it is *precise* in Peirce's sense: there are primes (greater than 2) ending with 1 and there are multiples of 3 ending with 1. But the proof is different in the two cases. In the first case s/he shows that the numbers whose existence she wants to prove are a special case of other numbers, "defining" them by next genus (numbers ending with an odd digit) and specific difference (which end with 1). In the second case the proof of existence is made by bringing *examples*. However, s/he does not simply bring examples in the common sense because s/he does not reason on *particular* multiples of 3, but on *some multiples chosen by chance* (they are *vague* in Peirce's sense). To sum up, there seems to be a lack of distinction of vagueness (seen as randomness) and generality (seen as indeterminacy) in Peircean sense. To bridge the gap between every-day-rationality within an empiricist logic (Nyaya) and mathematical rationality, the awareness of this distinction seems to be a necessary condition. Furthermore, the truth concept in the empiricist logic that fits to student's reasoning, seems to be closer to the idea of existence (precise or vague), rather than to the one of generality.

Example 2: Quantification within “blurred” domains.

The second example refers to a classroom argumentation led by the same teacher in another classroom. A worksheet with the argumentation discussed in example 1 is used to show that the proof is not valid. First, the teacher asks to tell if the proof is valid, but the students’ attention is captured by the semantical aspects: they detect two counterexamples (121 and 91) and state that it is false. The teacher brings the attention back to validity by asking what the reasoning on the worksheet is.[7]

9	Student 5:	The reasoning is that the multiples of 3 and the prime numbers end with 1.
10	Student 4:	No, that SOME multiple of 3 and SOME prime numbers end with 1. […]
17	Student 8:	Maybe you want to say that … that for CERTAIN prime numbers or multiples of 3 things are going well because they end with 1, but this doesn’t mean … […]
19	Student 3:	Yes, the reasoning says only that SOME prime numbers or multiples of 3 end with 1.
20	Student 9:	Even, although if ALL prime numbers or multiples of 3 should end with 1, there could be numbers that end with 1 and ARE NOT prime numbers or multiples of 3.
21	Student 6:	It is as if there is a reversal!
22	Teacher:	S6 said something important: “it is as if there is a reversal”. It is an important idea!
23	Student 1:	The hypothesis and the thesis?
24	Student 6:	It seems to me to be of a different matter!
25	Student 4:	To me too, it is a matter … of numbers. Of sets of different numbers. […]
29	Student 9:	I will try to say it again, I don’t know if it is OK: the multiples of 3 and the prime numbers are POSSIBLE numbers that end with 1, but these POSSIBLE numbers do not mean that they are ALL the numbers that end with 1.
30	Teacher:	I would say that’s it.

Discussion of example 2.

In this example the argumentation is carried out by a group of students. Nevertheless, one can state that the elements (1), (2), (3) and (5) of the student’s personal space in example 1 are also elements of the personal spaces of these students because the cultural and formative backgrounds are the same. The element (4) of the student’s personal space in the example 1 is substituted by the following one: (4’) uncertainty about what validity means in a proof and how it can be accessed, beside by bringing of counter examples. This topic is addressed for the first time in this lesson. The teacher’s personal space is the same described in example 1 with the following addition: (IV) intention to focus the discussion on the lack of validity due to a reversal of thesis and hypothesis.[8]

Most of the punctuated words in the transcript are related to quantification but apart from the line 9, the statements show students’ struggle with the determination of the domain of validity of the reasoning expressed on the worksheet and of its relation to the domain of the inverse statement which would be a valid one. The non-standard quantification used by the students express the indeterminacy of that domain: SOME, CERTAIN, NOT ALL, POSSIBLE numbers. For instance, as Student 4 (line 10) sums up the reasoning on the worksheet, s/he uses the term *some* as vague existential quantifier in Peirce’s sense because s/he knows that there are such numbers (the argumentation on the worksheet tells it) but their multitude is indeterminate; s/he is not able to “close” epistemically a set with this property. In line 22 the teacher supports Student 6’s intuition (line 21) that there is a reversal, meaning that the thesis and the hypothesis are reversed, as suggested by Student 1 (line 23). But the students’

[7] In the excerpt we use CAPITAL LETTERS for punctuated words and “…” for pauses longer than 5 seconds.

[8] The points (4’) and (IV) are based on a communication made by the researcher that collected the data.

intuition is not a matter of hypothesis and thesis, it is a matter of "numbers", of "sets of different numbers" (lines 24 and 25): There are numbers that satisfy thesis and hypothesis but also numbers that satisfy only the thesis but not the hypothesis. Thus, the inverse statement of the statement to be proved is not a valid inference. This is quite more than what the teacher wanted to put into evidence (reversal of thesis and hypothesis) although it is logically equivalent to it. As in example 1, students' quantification is suitably captured by the Peircean approach that expresses the epistemic uncertainty as vagueness related to variable sets, but unlike in the example 1, the argumentation produces an insight compatible with the teacher's one, related to classical logic. Thus, an investigation about shifts between different logical frames would be useful to better frame the logical analysis.

Conclusions.

According to the hermeneutical approach, the interpretation of the students' behaviour in the examples is meaningful within the global analysis (discussion) and vice versa. Going on in the interpretation, the analysis shows that students spontaneously resort to non-standard logics and non-standard quantification in Peirce's style and that these kinds of quantification and logic allow to formulate an argumentation that explains in a *reliable way* the lack of validity of a proof resorting to blurred domains, not considered within set-theoretic language. In this sense, further research should examine the shifts between different logical frames and the role of the relation between metalanguage and mathematical object-language not only in mathematics (Asenova, 2019), but also in ME. Furthermore, one can state that: (i) The novice's concept of truth might be related to the concept of *existence* of the objects involved in the statement and not to a predicate that it might satisfy: A statement is true if the objects involved in it actually exist; this kind of existence could be "proven" on different levels: by showing one or more "exemplars" with the required characteristics; by referring to single objects as to randomly chosen examples, in a sort of genericity; by referring to a characterisation of the object by a definition by comparison and contrast; (ii) The concept of "reasoning that applies in general" might be related for the student to the *production of a procedure* of a proof of existence, rather than to reasoning that applies to all cases and therefore to no one in particular. All these aspects join some of the students' most recurrent difficulties concerning proof (Stylianides & Stylianides, 2017) and emerged thanks to the non-standard approaches in the analysis.

Framing students' difficulties with the concept of proof, with reference to Vergnaud's Conceptual Fields Theory

Nadia Azrou

University Yahia Fares, Medea, Algeria; nadiazrou@gmail.com

By considering proof as a concept, according to Vergnaud's Conceptual Fields Theory, I would like to show how this framing of proof allows describing and interpreting some students' difficulties with proof at the meta-mathematical level. After motivating the choice of the framework and presenting it, I have considered examples of students' proofs, which showed difficulties regarding the mastery of operational invariants, of situations of reference and of the different representations of the concept of proof.

Keywords: Meta-knowledge of proof, conceptual fields, students' difficulties with proof.

Introduction

Researchers have identified several types of students' difficulties with proof and proving; in particular difficulties related to: mathematical logic (Selden & Selden, 1995); language (Boero, Douek, & Ferrari, 2008); writing the proof text (Selden & Selden, 2007; Azrou & Khelladi, 2019); understanding of concepts (Dreyfus, 1999); theorems and definitions (Moore, 1994); strategies of proving (Weber, 2001); argumentation (Balacheff, 1988) and conceptions of proof and related proof schemes (Harel & Sowder, 1998). Also many other researchers dealt with some of the above issues.

I am interested in investigating a type of students' difficulties, which intertwines with some of the above categories (in particular, those related to: conceptions of proof, writing the final proof text, theorems and definitions). My interest concerns students' knowledge of the proof at the meta-level (the logical features of proof, the role of the hypotheses, the requirements for proof texts, etc.). This type of difficulties is related to one of the main differences between students' and mathematicians' proving. Mathematicians would use some aspects of that meta-knowledge when they explain a proof to another mathematician or when they write a proof on the blackboard for students, however most of it remains implicit and it is not the object of any teaching in many university courses of mathematics. In fact, meta-knowledge of proof is so obvious to mathematicians that they are not aware that it might be unseen by students when proofs are written on the blackboard or when students read proofs in mathematics textbooks.

In the literature, the shift to the meta-mathematical level in order to interpret some students' difficulties with proving is proposed by several authors. In particular, Antonini and Mariotti (2008) provided a model to study the proof by contradiction and stated that 'some of the difficulties highlighted in the literature (…) can be described and interpreted in terms of the complexity that the move from the theoretical level to the meta-theoretical level requires' (p. 7).

Turiano and Boero (2019) considered a proof task in Euclidean geometry submitted to 10^{th} grade students, for which an easy proof by absurd (more precisely, by contradiction: see Antonini & Mariotti, 2008) is possible. Students showed difficulties on two points: the fact that the figure (representing the negation of the thesis) was impossible (to see and to imagine) and the managing of the proof by contradiction at the meta-level. Usually, when mathematicians choose the proof by absurd as a way to prove a theorem, they follow *in a rather automatic way* the rule of the game: starting by negating the thesis, in spite of the fact that they are convinced that it is true! Expert mathematicians work like a high school student does, when she applies the distributive property in arithmetic. Vergnaud's notion of "theorem-in-action" in his Theory of Conceptual Fields accounts for this kind of mastery of the distributive property, as a property used many times without necessary reflecting on its origin or interpretation, or on its truth in other situations. These considerations brought me to consider this research problem: Is it possible to move from the level of ordinary concepts (like those of the conceptual fields of additive structures and of the multiplicative structures, considered in Vergnaud, 1990), to the meta-mathematical level by considering proof, theorem, definition as concepts (according to Vergnaud's theory) and, in particular, by trying to describe and interpret some students' difficulties with proving in terms of lack (or misuse) of theorems-in-action for the concept of proof? Moreover: might some students' difficulties be described and interpreted in terms of lack of reference situations for the concept of proof, or lack of mastery of some operational invariants for it (like the negation of a statement), or poor linguistic representation of proof – as results from the analysis of university students' difficulties with proof-text writing in Azrou and Khelladi (2019)? This paper presents a first, partial attempt in this direction.

The idea of considering proof as a concept (according to Vergnaud's Conceptual Fields Theory) has been suggested to me by the elaboration of Durand-Guerrier, Boero, Douek, Epp and Tanguay (2012) on the roots of the mastery of proof, where they considered the use of theorems-in-action[1] in order to promote students' conceptualization of logical principles. Then, I have thought of theorems-in-action for the concept of proof, and I have hypothesized that in order to be competent in proving, students should not only master the definitions and properties related to the mathematical concepts involved in it, but they should also master the meta-knowledge of proof, by mastering proof as a "concept" (according to the Conceptual Fields Theory). The aim of this paper is to show how the extension of Vergnaud's framework to the concept of proof (even if rather limited in this moment) allows to interpret and to classify some student's difficulties.

Theoretical framework

Vergnaud (1990) considers a concept as a triplet of three sets: C= (S, I, $\mathcal{S}$), where:

S: the set of the different situations, which give sense to the concept (the reference).

I: the set of the operational invariants, which are the basis of any operation related to the concept (the meaning).

$\mathcal{S}$: the set of linguistic and non linguistic representations of the concept.

[1] A theorem-in-action is a mathematical property that a person may not be consciously aware of but may use in certain situations, such as to find an answer to a mathematical question. However, because the property may not apply to all the situations in which the person might try to use it, it could lead to an invalid deduction (Durand-Guerrier et al., 2012, p. 377).

For the concept of proof, I have defined its related three sets, respectively, as:

S: the set of the reference situations of the proof (situations of proof in geometry, in Algebra, in arithmetic, etc, different types of proof).

I: the set of the operational invariants (related to the logical structure of proof).

$\mathcal{S}$: the set of the different representations (linguistic; symbolic; geometrical, etc).

As concerns the operational invariants, Vergnaud (1990) considers three types:

- Invariants of propositional type (e.g. a theorem-in-action), which might be true or false, like the fact of considering that if a number of objects is multiplied by 2, 3, …then their price is also multiplied by 2, 3, … (which, is expressed by the theorem-in-action f (nx) = nf (x)). A theorem-in- action may be true or false, depending on the assumptions (e.g. the axioms) and the situation: as an example, many high school students think that every continuous function is derivable, according to the functions usually dealt with by them, and sometimes they even use it without making it explicit;

- Invariants of propositional function type: they are not susceptible to be true or false, they are concepts in action, like the two-arguments propositional function R (x,y) "… is on the right of …"), reported in Vergnaud (1990, p. 143), and the three arguments propositional function "Triangle A'B'C' is symmetrical to triangle ABC in relation to line d" (with reference to the corresponding drawing), reported in Vergnaud (2009, p. 91);

- Invariants of argument type: they are obtained, for instance, by the instantiation of the variables x and y in a propositional functions R (x,y); or in the case: "to be greater than" is an anti-symmetrical relation (Vergnaud, 1990, p.144); or in the case: Symmetry conserves lengths and angles (Vergnaud, 2009, p. 91).

The following examples account for a partial solution of the problem to move from concepts at the mathematical level, to concepts at the meta-mathematical level. I give examples for the three types of invariants for the concept of proof, which result from analogy with the three types of invariants considered by Vergnaud (1990; 2009).

- Examples of invariants of propositional type: a counter example for a general statement is sufficient to prove that the statement is false; to prove that A⇒B it is sufficient to prove that not B⇒not A.

- Examples of invariants of propositional function type: the implication $A \Rightarrow B$, the equivalence $A \Leftrightarrow B$, the negation of A.

- Examples of invariants of argument type: "n is an odd number" is the negation of "n is an even number".

And here is an example of a theorem-in-action about the concept of proof that is false in general but may be true in some situations: if A⇒B then not A ⇒ not B.

I consider that mastering meta-knowledge of proof is mastering it as a concept (with its components, according to Vergnaud' theory). The aim of this paper is to show, in particular and with relatively easy cases, how the partial framing of meta-knowledge of proof, which I have developed till now, works when we would like to analyze students' proof texts and how:

- It is suitable to interpret some students' difficulties with proof in term of the three components of the concept of proof (reference situations, operational invariants and linguistic representations).

- It may be used to distinguish between the sources of two kinds of difficulties put into evidence in the literature: difficulties deriving from the didactic contract (particularly those related to the lack of, or to inappropriate, reference situations); and difficulties inherent in the lack of knowledge of basic notions related to the logical aspects of proof (related to the lack of operational invariants).

The course and the participants

The following examples have been taken from written productions of fourth year students from an Italian university, who attended a 24-hour compulsory course on argumentation and related teaching and learning issues. In the next year, students would take their master's degree, which is necessary to become primary school teachers in Italy. In high school, all students have met mathematical proof in geometry, where "met" means they have been taught several proofs and have been required to learn them and to expose some of them at the blackboard. Usually, they have also met some proofs in arithmetic (e.g., the classical proof of the irrationality of $\sqrt{2}$, or the Euclid's proof of the infinity of natural numbers). Students have never met proofs in previous mathematics and mathematics education courses at the university (only some justifications of the "why" of some arithmetic rules). In the course on argumentation that I am considering here, lectures engage students in filling (during the lecture, and sometimes at home) individual worksheets that concern the topics presented by the teacher. In these worksheets, students are also invited to write down the possible difficulties met by them. Students usually try to do their best in filling the worksheets. Then, some students' productions are chosen by the teacher, for comparison and classroom discussion. The final evaluation is based on the student's detailed self-reflection on, and revision of, her own worksheets, taking what has been discussed in the classroom into account.

The following examples are taken from the worksheets filled by the students in the last part of the course, devoted to argumentation to validate elementary arithmetic statements and to check the validity of proofs produced by other students. In some cases, also audio recordings or field notes of the discussions concerning those worksheets are available. Proof of the truth of general elementary statements in arithmetic is presented as an argumentation with a statement that concerns a specific set of elements (e.g., natural numbers, or couples of consecutive odd numbers), and a reasoning that guarantees the truth of the claim for all the elements of the given set. The reasoning may be a verbal reasoning, or reasoning based on the use of algebraic language. Students already know from high school that checking with a finite number of cases the validity of a statement that concerns an infinite set of elements does not guarantee the truth of that statement, while a single example (counterexample) is sufficient to prove that a general statement is false. Students are invited to reason as mathematics would require them to do; they know that possible educational implications will be discussed later in the classroom.

A-priori analysis of the task

Task 1

Prove that 1 is the only common divisor of two consecutive numbers.

Students have the necessary knowledge about the mathematical concepts involved in the task (divisor, consecutive numbers); they know what "the only" means.

A possible proof is: let n and n' be consecutive numbers (n<n'). Assume that d≠1 is a common divisor of n and n'. Given that n is a multiple of d, the successive multiples of d are n+d, n+2d, n+3d, and so on. Thus n' must be one of those numbers. Thus n' cannot be the consecutive number of n. Thus, it is true that the only common divisor of n and n' is 1.

Theorem in action (for the concept of proof): to prove that A implies B it is sufficient to prove that 'not B' implies 'not A'.

Another possible proof is: let n and n' be consecutive numbers (n<n'). Assume that d≠1 is a common divisor of n and n'. Then d divides n, thus the remainder of the division n:d is 0, and d divides n', thus the remainder of the division n':d is 0. But as n'=n+1, the rest of the division n':d is 1, which results in a contradiction with the previous result (0≠1).

Theorem in action (for the concept of proof): to prove that A implies B it is sufficient to prove that a contradiction may be derived (given A) from 'not B'.

Examples of students' proofs for task 1

Among their productions, we have the following ones:

Example 1

> Any two consecutive numbers have only 1 as common divisor, because if any two consecutive numbers would have common divisors different from 1, then also 1 and 2 would have common divisors different from 1: this is false because they have only 1 as common divisor.

In this case, we find a situation of a rather common lack of mastery of the *theorem- in- action: to negate "P is true for every x" it is sufficient to find one case of x for which P is false.* This student, during her effort to build a proof by absurd, negated "P is true for every x" by assuming "P is false for every x"; then she proved that this assumption is in contradiction with the case of 1 and 2.

Example 2

> Any two consecutive numbers have only 1 as common divisor, because if by absurd one divisor d≠1 of n would be also a divisor of n+1, then n+1 would be a multiple of d, which is false because n and n+1 do not have common divisors greater than 1.

In this case, there is a problem with the mastery of the *theorem-in-action concerning the proof by absurd*: in order to prove that B (d=1) is true under the hypothesis A (if d is a common divisor of n and n+1), the student assumes that B is false (d≠1), then he gets the conclusion that B is true by showing that if B is false it brings to A, which brings to B.

Also, the mastery of *the operational invariant of propositional type "implication"* looks weak for this student, which resulted in the confusion between the hypothesis and the thesis.

Example 3

> Any two consecutive numbers have only 1 as common divisor:
>
> d=1 d\n d\n+1 n+1-n=1
>
> (n+1):d =q+r =1≠ 0 if d≠1. d=1

According to the student-author's intervention in the discussion, his intention was to prove that $d=1$ by considering a divisor d of n and $n+1$. Since $n+1 - n = 1$, if $d\neq 1$ the division of $n+1$ by d has a remainder $r=1$ (and not 0, corresponding to divisibility of $n+1$ by d). Hence $d=1$.

This example is a case of *poor linguistic representation* of a valid reasoning: the sequence of symbols and words (only one word, *if*) does not allow to distinguish between what must be proved ($d=1$ is the only divisor) and what is assumed to build the proof (d as a divisor), and to understand some steps of the proof. In particular, (n+1):d=$q+r=1\neq 0$ *if* $d\neq 1$ is the short writing of a piece of reasoning, where even the algebraic meaning of the '=' sign is twice lost! Similar cases have been considered by Azrou and Khelladi (2019).

Task 2

After the activity on the common divisors of two consecutive numbers, students are requested to prove that the only common divisors of two consecutive even numbers are 1 and 2.

Students have at their disposal, in their worksheet, two kinds of valid verbal proofs concerning the common divisor of two consecutive numbers (these proofs have been produced by two students and then discussed in the classroom):

I) A proof by multiples, based on the consideration of the distance greater than 1 between two consecutive multiples of every number greater than 1 (like the first proof of the a-priori analysis).

II) A proof by remainders (of the division of the second number by the divisors of the first number), like the second proof of the a-priori analysis.

The aim of this task was to engage students in the reflection of what was in common with the first task (the logical structure of reasoning) and what was different (the different hypotheses).

Examples of one student's text for task 2

> I have tried to write a general argumentation starting by the definition I (the proof by multiples) but I was unable to understand the rule that allows getting the proof for two even numbers. I was able to understand the general rule but only in single examples, but when I try to write the argumentation, I am unable to find the right words. I think that the reasoning is based on a formula I need more time to understand, and in this moment, I do not know it.

Firstly, note how the student uses the word "definition" for a "proof" (we might interpret it as a sign of a possible weak mastery of the operational invariants which concern the *meaning* of definition and proof). During the discussion on her production, this student makes a long intervention on her difficulties: according to her, she was not able to make a connection between the proof required in this case, and the proof met in high school (Euclid's theorems in geometry, the proof of the irrationality of $\sqrt{2}$). Even the transition from the proofs discussed in the classroom for the case of consecutive numbers to this new proof situation had been hard for her.

> I was very confused. I had in my mind the proofs in geometry, where clear hypotheses are given and then we must move to the thesis step-by-step. Also, the proof of the irrationality of $\sqrt{2}$ was clear to me: the assumption that $\sqrt{2}$ is rational must bring to an absurd conclusion through formulas. The proofs in the case of consecutive numbers, … I do not see the hypothesis, yes, they look like proofs by absurd, but also the thesis… and the negation of the thesis… Also, not clear for me the use of algebra in one of the proofs that we have seen: I do not see how we must use algebra, the formula that we must use.

This example looks very interesting: the student engaged a lot in previous mathematics and mathematics education courses, with enough good results as concerns the discussion of teaching and learning problems. She looks very committed with this task. Her words reveal a possible lack of *well-interiorized and valid reference situations* of proof. This lack results in a misleading approach to proving in general: "we *must* move to the thesis", "the assumption (…) *must* bring to an absurd". "I do not see how we *must* use algebra". These sentences correspond to what the student wrote in her worksheet: "I was unable to understand the rule that allows to get the proof", "I think that the reasoning is based on a formula (…) that in this moment, I do not know*".*

Like in the case of ordinary concepts, in the case of the concept of proof it is not sufficient to have met some instances of proof and to have learnt some proofs in order to get reference situations for the concept, which are suitable to support problem solving in new proving situations. Moreover, this example helps to focus on what do reference situations mean for the concept of proof: how reference situations for proof are related to the construction of a new proof?

Discussion

As we have seen in the above examples, considering proof as a concept according to Vergnaud's Conceptual Fields Theory is a promising tool to identify and analyze students' difficulties related to the mastery of proof at the meta-level. However, a lot of work is still to be done. Here are three possible directions:

- By deepening the analysis of the components of the concept of proof (particularly as concerns the identification of the operational invariants of the three types), and their role for the development of students' proving competencies and in the interpretation of their difficulties. I think that special attention should be paid for the inferences (among the operational invariants of the concept of proof), since they are a way of considering at the meta-mathematical level what happens at the mathematical level, for instance, when a student writes: "d>1, hence the consecutive of n does not belong to the set n+d, n+2d, n+3d, …" (see task 1).

- By clarifying what the mastery of "reference situations" means in the case of the concept of proof, in terms of how it intervenes in proving (see the last example).

- By identifying the conceptual field, to which the concept of proof belongs, particularly as concerns its three components.

How preservice teachers enact mathematical argumentation and proof in class – an activity-theoretical perspective

Thomas Bauer[1], Eva Müller-Hill[2]

[1]Philipps-Universität Marburg, Germany; tbauer@mathematik.uni-marburg.de

[2]University of Rostock, Germany; eva.mueller-hill@uni-rostock.de

Argumentation and proof as core activities in mathematics should be staged continuously and meaningfully in mathematics lessons. But to what extent are preservice teachers at the end of their studies able to adequately introduce mathematical argumentation and proof as activities into their classroom planning and staging? Activity theory makes a valuable contribution to answering this question by emphasizing the importance of prospective teachers' development of motives and goals, corresponding modes of action, subjective constructions of meaning and the ability to identify appropriate objects for argumentation and proving activities in the classroom. In this work-in-progress paper, we outline an activity-theoretical framework and present empirical research tools based on it for analyzing prospective teachers' classroom enactments. We apply these to case studies from an exploratory, qualitative study with preservice teachers in their final year of study. We present first results and draw conclusions towards future work.

Keywords: Argumentation, proof, activity theory, preservice teacher education, second discontinuity.

Introduction

In preservice teacher education, one way to address the *issue of developing preservice teachers' ability to adequately introduce mathematical argumentation and proof as activities into their classroom planning and staging* is to foster students' own argumentation competence, e.g., via proving tasks, and to get them acquainted with didactical models and theories on developing argumentation competence in class. However, it is unclear whether this kind of study suffices, within the bounds of possibility, to prepare preservice teachers well for teaching mathematical argumentation. One source of such doubt is the so-called phenomenon of double discontinuity (Klein, 1908), which concerns two difficult transitions: first, the secondary-tertiary transition, when students enter university (see Gueudet, 2008); second, the transition from university to teaching at school. For the latter transition, the crucial question is to what extent teachers are able to make effective use of academic knowledge in their teaching. There is evidence in practice that teachers do not make full use of their content knowledge and pedagogical content knowledge when designing lessons. An activity-theoretical approach can help to theoretically ground such practical impressions regarding the second discontinuity and to substantiate and qualify them through empirical research. It goes beyond the consideration of the role of affect and beliefs for teaching argumentation and proof, but can also function as an interface to it. It offers starting points for the development of suitable formats for preservice teacher training courses in order to effectively address this issue.

Activity-theoretical framework

Activity-theoretic perspectives have already proven helpful in the teaching and learning of mathematical argumentation and proof in connection with the role of tools and cultural artifacts (e.g.

Cerulli, Pedemonte, & Robotti, 2005). In our work we shift the focus to the role of motives, goals, and constructions of meaning in the teaching of mathematical argumentation. We use the conceptual framework of Leontjew (1982), as developed further by Lompscher and Giest (see Bruder & Schmitt, 2016). From the perspective of activity theory, the constitutive elements of human activities are a superordinate *motive*, the *objects* of activity, and *ways or means of action* to act on and with the objects. The motive drives actions directed towards an object of activity, dependent on the repertoire of ways of action and available means. Concrete *goals* of such actions realize the motive in various ways. In individual activity, superordinate motives usually are unconsciously or subconsciously behind consciously set goals for actions. In the process leading from the superordinate motive to the concrete goals of action, *individual constructions of meaning* emerge.

The activity-theoretical framework enables us to analyze differences and commonalities between mathematical practices at university vs. school – they manifest themselves in all components of the activity-theoretical framework: a) While one of the central motives of university practice lies in the argumentative justification and explanation of the deductive derivability of a statement within the framework of a mathematical theory, a related motive in school mathematics would focus on truth or general validity of a statement rather than its derivability. b) While at university the objects of activity are explicitly stated (as in propositions, conjectures or proofs), the objects in school mathematics are often more implicit, "hidden" opportunities for argumentation (such as the comparison of different solutions or the justification of calculation rules). c) At university, the ways and means of action consist (in the context of justification) in valid reasoning within the framework of globally ordered mathematical theories. In school mathematics, we rather find plausible and example-based as well as heuristic and generic argumentation, and (more informal) deductions in locally ordered propositional systems. Prominent goals realizing the motives of argumentation activity in both practices are the well-known "proof functions" according to Villiers (1990).

Research question for the exploratory study

From the perspective of activity-theory just presented, we can now formulate an initial hypothesis with regard to issue raised at the beginning. *We hypothesize that preservice teachers often do not adequately develop suitable motives and corresponding constructions of meaning in their studies, as well as develop an inadequate repertoire of actions and dismiss possible objects for argumentation and proof in mathematics lessons. Consequently, they are often not able to give space and shape to argumentation and proof in their own school teaching in a way that in principle accommodates the profound and multifaceted meaning of these activities for relevant mathematical practices.* The hypothesis is motivated by the observation from university teaching practice that preservice teachers develop a highly reduced image of mathematical argumentation and proof during the mathematics lessons that they experienced at school, which is only put into perspective in de facto little mediated ways at university. Moreover, constructions of meaning for argumentation and proof, developed in university and school mathematics practice, are primarily shaped by actual experience: "Meaning is educated" (Leontjew, 1982). These experiences can be quite one-sided in both of the respective practices. For example, preservice teachers at university increasingly experience that the meaning of proving is systematization, whereas in the school practice they experience it may at best mean verification. Possible objects of argumentation and proof as well as appropriate ways of acting are often not perceived very much. At school, for example, objects of proof appear only singularly, objects of argumentation rather covertly, and generic argumentations are often not (fully) recognized as argumentations. Furthermore, the respective practices are partly experienced under other, more dominant overriding motives, for example as “learning practices” under the motive of solving set tasks according to certain standards. In school, for instance, an emphasis on application, when experienced as dominant, may overshadow meaningful motives of argumentation and proof. We consider such discontinuity experiences of naturally existing differences between mathematical practices on the part of preservice teachers as an additional cause of the circumstances claimed in our hypothesis, and pose the following, *open research question* for our explorative study:

> *In which sense do preservice teachers lack effective motives and corresponding constructions of meaning, appropriate ways of acting or access to suitable objects, in order to stage argumentation and proof activities in a meaningful way in the mathematics lessons they plan and conduct?*

Methodology of the exploratory study

Using the activity-theoretical perspective described above, we deductively developed an observation and analysis framework for teaching productions by preservice teachers. In our study, we applied this instrument in the context of a course in the final year of study, in which six pairs of preservice teachers each plan one classroom session on a mathematical subject of their choice, carry it out as a teaching experiment with their fellow students as peer experts, and receive professional and peer feedback. Hence, we observed and analyzed a total of six different classroom sessions. The chosen topics for the sessions were: *area of triangles* (1), *power functions* (2), *half-life* (3), *zeros* (4), *binomial formulas* (5), *scalar product* (6). The two authors worked independently of each other with a semi-structured observation sheet and compared their observations in follow-up discussions. Descriptions of observed, argumentative or argumentation-related actions of the teacher, of requests for such actions to the learners, as well as related formulations of goals, motives or object designations made by the teacher were noted in the sheet. The time and phase of the lesson or the phase transition were also recorded, as well as optional comments by the observers, both descriptive and interpretive in nature, for example on the actual actions of the learners. In addition to the completed, semi-structured observation sheets, the written plans, the classroom materials and the preservice teachers’ written post-lesson reflections form the data basis of our study.

As a first step of evaluation of the observational data and the planning and reflection documents, we describe stably occurring phenomena and patterns and propose an activity-theoretical analysis and explanation. The framework categories of *motive*, *object*, (*way of) action*, *goal*, and *construction of meaning* we use are obtained deductively from activity-theory. We supplement these inductively with intended or actual motives, goals and ways of action that can be recognized in the data.

Results

In a first review of the observational data, we were able to identify three overarching phenomena and associated stable patterns as specific manifestations of the phenomena in the teaching productions of the preservice teachers, which contribute to further differentiate our initial hypothesis with regard to our research question. In the following, we describe each phenomenon and its patterns, give concrete examples of the patterns and propose an activity-theoretical explanation for the phenomenon.

Phenomenon 1: Missing out on opportunities for argumentation

Results and answers of the learners are not questioned further in class, sometimes not even checked. In addition to "how did you arrive at this result?", questions like "why does it work that way?" and "what is good about this way?" are missing, i.e., questions that are fundamental for mathematical argumentation as an activity.

Phenomenon 1 occurs in three different patterns and shows up both on the situational-spontaneous level of action and on the level of reflexive planning action. As we illustrate in the following, these observations can be understood from an activity theoretical perspective as an indication that the availability or accessibility of *objects of argumentation* has an impact on two essential professional competence areas of teachers: "reflective competence" and "action-related competence", which are defined and measured through the corresponding action (Lindmeier, 2011).

We first describe the patterns and concretize them through examples from the staging observations. Then we add suitable excerpts from the planning observations.

Pattern 1.1: Receiving results and moving on. *Learners' answers are received and rated, but they are not questioned further or confronted with each other.*

Answers and results are not used as potential objects of argumentation activities. This applies both to planning ("symptoms": discussion phases are planned far too briefly, possible variants for solutions are not considered in advance) and to situational ad hoc action in lessons.

Pattern 1.2: Leaving questions from students behind. *Unexpected questions from learners are acknowledged as an element of classroom interaction, but they are left behind as objects of argumentation.*

This pattern primarily concerns situational ad hoc action in class.

Pattern 1.3: Leaving opportunities unused in task construction. *The argumentative potential is not exploited in task construction, the staging does not focus on argumentation.*

This pattern primarily concerns the planning process, when during task construction possible objects of argumentation are not realized and hence do not become effective in staging.

We choose examples for the patterns from session 6 ("scalar product") because all three patterns occur in this session. An overview of the patterns that were recognized in agreement by both observers (regarding all phenomena and sessions) is provided in Table 1. The learning content of session 6 are four basic mental models for the scalar product, relating it to *projection*, *orthogonality*, *product,* and *angle*. Small groups of learners go through four learning stations, each assigned to one of the basic mental models. Patterns 1.1-1.3 can be recognized in the staging observations in the following places:

> [1.1: Receiving results and moving on] At station 1 (*projection*) the learners spend much time with calculations, which are then only looked at. Later in plenary, a pure checking of results is done.
>
> [1.2: Leaving questions from students behind] In plenary after the station work, a learner reports purely procedurally, which the teacher acknowledges with "OK". The question of whether the

scalar product can be negative is raised by a learner and answered by the teacher, but only with the brief mention of an inappropriate technical term. It was obviously not foreseen in the planning.

[1.3: Leaving opportunities unused in task construction] At station 2 (*orthogonality*) the teacher asks about “commonalities” among the given cases of vector pairs. In return to the answer “are perpendicular”, the teacher asks “why”. This could be a good attempt to go into depth argumentatively. Unfortunately, the teacher’s question remains unanswered and is then not pursued further. The conceptual aspect of relative coordinates, which would have been part of such an argumentation, remains excluded throughout the whole session.

Table 1: Phenomena and patterns (X = pattern recognized in class or found in planning documents)

Phenomena	*Patterns*	*Sessions*					
		1	2	3	4	5	6
(1) Missing out on opportunities for argumentation	1.1: Receiving results and moving on	X	X	X	X	X	X
	1.2: Leaving questions from students behind		X			X	X
	1.3: Leaving opportunities unused in task construction	X		X	X		X
(2) Missing focus on content and conceptual core	2.1: Strong emphasis on methodological side of teaching	X		X		X	
	2.2: Missing the conceptual core		X	X	X		X
(3) General structure and discursive character of argumentation not exemplified.	3.1: Teaching by preparing written tasks or task sequences without a (local or global) argumentation-oriented dramaturgy	X	X	X	X	X	X

The additional planning observations can be used on the one hand to support that the occurrence of the three patterns in class is consistent with the planning: The planning statement “The educational content of the lesson is the recognition of a new operation and the application of the arithmetic operation with vectors” is consistent with extended phases of mechanical calculations as described, in contrast with short phases for in-depth comparison of results (Pattern 1.1). The planning statements “The pupils are able to *experience* the scalar product in its various forms and effects in group work” and “In addition, it can have a motivating function to *show* the practical benefits of the new operation” (our emphasis) indicate Pattern 1.3 inasmuch as they focus on the phenomenological rather than on the argumentative aspect. On the other hand, both the staging observations and the planning observations reported so far appear to be in contrast with goals that the preservice teachers set, partly with explicit reference to German core standards K1-6 and levels of cognitive complexity AB1-3:

> “The learning objectives are as follows. [...] The pupils *explain the effect* of the scalar product […] and *explain the connection* between the scalar product and the cosine (K1, K6, AB3). [...] [They] realize that the angle between the vectors plays a *crucial role*. [T]hey *discuss why* zero comes out for the orthogonal vectors and not for the other vectors.” (our emphasis)

We explain phenomenon 1 from an activity-theoretical perspective in a more general way on the level of *objects*: Our findings suggest that, even though goals were set that are appropriate for argumentation activities, in task construction preservice teachers do not succeed in connecting these goals to suitable objects of activity. In our example, they do not recognize the basic mental models of the scalar product as objects of argumentation activity, but rather as phenomena to be experienced.

Phenomenon 2: Missing focus on content and on the conceptual core

A lack of focus on content and on the conceptual core within the planning manifests itself in a conspicuous accumulation of learning activities that are not properly related to the learning content of the session. Accordingly, there is no focused content-related activation of the learners; in particular, activities that can be beneficial to argumentation (e.g. observation) lose the content focus.

Phenomenon 2 occurs in two patterns that fit a distinction developed in Renkl & Atkinson (2007) from the viewpoint of educational psychology: active responding, active processing, and focused processing. *Active responding* merely refers to a visible engagement of the learner with the learning environment. *Active processing* refers to actual processing of the content, beyond overt action and interactivity. Finally, the stance of *focused processing* emphasizes that it may be crucial that learners activities are focused on the central concepts and principles to be learned.

Pattern 2.1: Strong emphasis on the methodological side of teaching. *The staging is methodically (and sometimes technically) overloaded with actions that are not related to the mathematical learning content. As a result, learners' engagement contributes little to their understanding of the content.*

The occurrence of this pattern only leads to active responding of the learners in the sense of Renkl & Atkinson (2007). Pattern 1.1 particularly concerns the level of reflective planning actions.

Pattern 2.2: Missing the conceptual core. *The staging contains mathematical actions related to the mathematical learning content, but these do not reach its mathematical core. As a result, learners' engagement is not focused on the content core. In particular, argumentation-related activities appear not to be "conceived from an explanatory warrant" with a view to foster learners' deeper mathematical understanding.*

In Pattern 2.2 active processing of the learners can be observed, but their mathematical engagement does not constitute focused processing. The pattern concerns planning as well as staging.

The staging in session 3 ("half-life") exemplifies both patterns (see Table 1). The learning content is the half-life in the context of exponential functions, which is concretized regarding the real-life phenomena of beer foam decay and dice throwing. The individual patterns can be recognized in the staging observations in the following places:

> [3.1: Strong emphasis on the methodological side of teaching] The foam measuring activities or the implementation of the dice throwing experiment dominate the staging of the group phases.
>
> [3.2: Missing the conceptual core] In working with the experimental data, learners are asked to plug in and calculate in the first place. Modelling work including discussions about the exponential behavior (as core of the matter) is neither visible during the group phases nor addressed in the follow-up plenary. In both phases we observe active processing, but no focused processing.

The planning documents reveal a certain tension: on the one hand, the aim of the session appears to be the *application* of existing knowledge about exponential processes and half-life to self-conducted, real-life experiments, presupposing that it is *already known* that the core processes involved are exponential. However, the planning of the concrete implementation is geared towards *argumentation* – but it is unclear from which premises and to which conclusion the argument leads:

> “Pupils use the example of an everyday phenomenon to apply their already learned knowledge and skills about half-lives. They determine experimentally the half-life of dice throwing and beer foam decay by conducting experiments.”

> “In the case of the dice experiment, arguments can be made mathematically or with the help of exponential correlations. In the case of beer foam, […] the learners should argue that the half-life does not change. Here, they could, for example, argue with prior knowledge from the previous lesson or the exponential equation. [...]”

All in all, the planning fluctuates between a focus on argumentation about exponential behavior on the one hand and experimentation and application on the other. In the implementation, we saw no argumentation-related activities, but a number of unfocused technical or instrumental activities like measuring, plugging-in, and calculating instead. We explain phenomenon 2 on the level of *motives*: Regarding Pattern 2.1, one possible explanation of our findings could be that “active” learning (in a naive interpretation of “being active” as “doing”) and application to the real world are effective as superordinate motives that override specific motives for mathematical argumentation activities. Regarding Pattern 2.2, the preservice teachers could be guided by rather nonspecific motives like “doing mathematics” (not specifying the content focus) or “doing argumentation” (unaware of concrete assignments of functional roles within the arguments).

Phenomenon 3: General structure and discursive character of argumentation are not exemplified

There is a lack of exemplification of mathematical argumentation by the teacher as a “living model” and as a knowledgeable navigator in argumentative classroom discourse. Such discourse hardly takes place, and if at all, the structural elements of argumentation remain hidden.

We observed one stable pattern which occurred in all six sessions (see Table 1):

Pattern 3.1: Teaching by preparing written tasks or task sequences without a (local or global) argumentation-oriented dramaturgy. *The teacher prepares pre-formulated work assignments for individual or group work, and then largely fades into the background in the production. Neither the work assignments nor the classroom discussion of the results guide argumentation activities in a structural or discursive sense and clarify the argumentative dramaturgy.*

This pattern concerns planning activities in the first place, but can also be instantiated, e.g. in the form of an ad hoc decision of the teacher to withdraw from an active role in a class discussion. Due to limited space, we have to dismiss more detailed example illustrations. We explain phenomenon 3 on the level of *sense constructions*: The planning documents show that the preservice teachers are somehow aware of the general motives of mathematical argumentation activity and also concretize these in part in suitable goals, such as exploration, conjecture and systematization. However, the chosen ways of action are often either not appropriate for pursuing the selected goals or they are not implemented as part of an effective argumentative dramaturgy. A reason for this could be that the preservice teachers lack the corresponding meaningful experience that could serve as a source of meaning constructions. Hence, they lack a basis to link goals and suitable ways of acting in a meaningful way and to concretize the motives of argumentation activity in the lesson.

Summary and Outlook

We showed how an activity-theoretical framework can be used to analyze prospective teachers' classroom enactments. Our analysis of preservice teachers' lesson planning and staging exhibits phenomena and stable patterns that can be explained in terms of motives, objects, goals, ways of action, and meaning construction. Due to the exploratory nature of our study, we obviously cannot draw general conclusions. Regarding specific limitations, we point out that the lessons were conducted in a university seminar (in digital format) with peers as learners. While one could argue that the participants might act differently in a real-life setting, we conjecture that core elements of analysis (i.e., motives and objects) are not affected substantially by the setting. Our observations differentiate the hypothesis formulated at the beginning and illuminate it as a general issue in teacher education from a new perspective. Our activity-theoretical analysis of the three phenomena interprets them as specific variants of the overarching phenomenon of the 'second discontinuity': Developing preservice teachers' own argumentation competence and didactical knowledge alone might not be sufficient for them to successfully enact mathematical argumentation in class. From a developmental perspective, an important objective for future work is the design and exploration of appropriate formats for teacher training that sustainably address the observed discontinuity phenomena. Of particular interest might be in how far the phenomena identified in our observational data can be developed into explicit guiding principles for teaching mathematical reasoning and proof (e.g., Buchbinder & McCrone, 2022) and be incorporated into preservice teacher courses.

Developing students' rationality by constructing and exercising rational mathematical templates: The case of counter-examples

Paolo Boero

Università di Genova, DISFOR, Italia; boero@dima.unige.it

The aim of this paper is to put into evidence two aspects of the production of counter-examples during students' approach to it and its development: the epistemic and the teleological (strategic) components of the specific process that brings to the production of a counter-example. By considering two 8th grade classroom discussions (the first one, on counter-examples in arithmetic and the other, in geometry) I will discuss how those aspects are of general interest for the development of students' conscious dealing with the truth of statements and the effectiveness of strategies (i.e. with the development of students' rationality, according to Habermas). Also some affective aspects will be considered, as concerns their effects on the productivity of the discussion.

Keywords: Habermas' rationality, rational mathematical templates, counter-examples.

Introduction

In the perspective of developing rational behavior in mathematics (according to Habermas' elaboration on rationality), a need emerged in our research, suggested by what Habermas (1998) presents as the ideal situation of exercise of communicative rationality:

> Communicative rationality is expressed in the unifying force of speech oriented towards understanding, which secures for the participating speakers an intersubjectively shared lifeworld, thereby securing at the same time the horizon within which everyone can refer to one and the same objective world. (Habermas, 1998, p. 315)

What are the components of "an intersubjectively shared lifeworld"? The definition of rational mathematical template (RMT) (Boero & Turiano, 2020) as *the couple consisting of a mathematical entity (*e.g., the definition*) and a rational process that is purposefully oriented to produce an instance of that mathematical entity* was an attempt to identify and frame (in particular, for mathematics – but the same may be done for other disciplines) some crucial disciplinary components of rational behavior, whose mastery is needed for the interpersonal (and intra-personal too) productive and enjoyable discursive exchange described by Habermas. In Boero & Turiano (2020) we have shown how the RMT construct may work as a tool to analyze the gradual access of students (under the guide of their teacher) to the mastery of the RMT of definition and to productive classroom discussions on definitions. Some open research and educational problems have been briefly presented at the end of that paper. In particular we have considered the need of further investigating the affective dimension of the classroom activities concerning the approach to, and the exercise of, RMTs. That dimension is inherent in the fact that the mastery of RMTs looks as one of the most important conditions for students' and teacher's wellbeing in the mutual exchanges among them and with the Other (the culture). We have also considered the need of identifying didactical choices that are suitable to promote the development of RMTs in the classroom.

In this paper the analysis of two discussions in the same classroom concerning the RMT of counter-example will allow to say more about the development of the RMTs in the classroom: to identify some aspects of the mastery of RMTs on the epistemic and teleological sides, which are relevant for the development of students' rationality, and to provide further evidences concerning the relevance of the affective dimension of classroom interactions for the productive exercise of the RMTs.

Habermas' elaboration on rationality, and rational mathematical templates

Basic notions concerning Habermas' elaboration on rationality are resumed here. Habermas (1998) proposed the construct of rationality (and that of rational behavior) to deal with discursive practices that are characterized by *awareness* when checking the truth of statements and the validity of reasoning according to shared criteria (*epistemic rationality*), evaluating strategies to attain the aim of the activity (*teleological rationality*), and choosing suitable communication tools to reach others in a given social context (*communicative rationality*), the three components being strictly interconnected.

In past years, researchers both in our group and outside it have attempted to adapt Habermas' construct to mathematics teacher education and to plan teaching aimed at developing and analyzing students' rational behaviors (see Boero & Planas, 2014, for a general account about it and a presentation of five studies).

As concerns RMTs, when we have chosen the provisional expression "Rational Mathematical Template" to name (see above) *the couple consisting of a mathematical entity (in our case, the definition) and a rational process (...),* we had in our mind that the rational behavior in the case of the production of a definition (or a mathematical model, or a mathematical proof, etc.) is *specific* for that entity as concerns the three sides of rationality, and also for the whole organization of the process. In particular in Boero & Turiano (2020) we have tried to shed light on how the RMT of definition developed in strict relation to the development of mathematical rationality in the domain of theoretical mathematics: in the second episode, the students took care of criteria that characterize a mathematical definition and that allowed them to decide whether a formulation satisfies them (*epistemic rationality*); they engaged in a goal-oriented process (*teleological rationality)*; during the discussion, the students were concerned with the formulation of the definition and engaged in mutual corrections about it (*communicative rationality*). Still in Boero & Turiano (2020) we have discussed the relationships of our construct in mathematics education with other constructs, in particular with the "process-oriented routines" and the "product-oriented routines" of Lavie, Steiner and Sfard (2019).

Counter-examples in the perspective of rationality

The following ICMI-11 Abstract (Antonini, 2008) well represents the perspective in which a great deal of research work (including Antonini's contributions) has been performed on the generation of examples (including counter-examples) in Mathematics.

> Generating examples of mathematical objects can be very difficult for students and it can be considered a problem solving activity. In literature, some potentialities of such activity are suggested, from different points of view and for different reasons. Our investigation aims to better identify the characteristics and the potentialities of the processes of constructing examples. The analysis, carried out by observing students' processes in Real Analysis, reveals a high complexity of examples generation tasks.(…) The study on these processes highlights the potentialities of

generating examples activity as a tool for researchers in investigating many aspects of students' thinking and for teachers in promoting students' understanding and conceptualization.

In spite of sharing Antonini's point of view on the relevance, difficulty and complexity of dealing with students' production of examples (including counter-examples) as a didactic and a research challenge, the perspective of the research development presented in this paper is different. We want to investigate the classroom production of counter-examples as an instance of the development of students' rationality.

Two discussions in the same classroom

The source of the data

Covid-19 pandemic prevented the teachers who collaborate with me from experimenting classroom situations suitable to construct and exercise RMTs, and by this way to get new elements to corroborate previous hypotheses and answer research questions. However, we have at our disposal, in our group, a lot of transcripts from discussions in primary and lower secondary classes of the past. About 20 years ago we had already elaborated (without any explicit connection with rationality) a germ of idea of "mathematical template" to be developed in the classroom in order to ensure understanding of texts and productive discussions on some mathematical subjects. I have found (under the counter-example label) two transcripts of discussions, with teacher's field notes, which are of interest for the present development of the research. They come from the same 8th grade class of 22 students, in April. Students were 13 and 14 years old; most of them were from middle class. The teacher was Marina Molinari; she was a member of our research team since the eighties.

Underlined words (in the original transcripts) mean that the tune of the voice changed towards putting into evidence what was said; … means: long pauses.

The first discussion: making explicit the notion of counter-example

As we will see later, students had already met some rather easy situations of production of counter-examples (in mathematics, grammar, sciences), without naming them counter-examples.

T: Today we will consider something new (or better: something that we have done several times, but more complex this time – we will see it later!). Let us consider natural numbers that end by 1. Let us explore them, their properties.
S1: like 1, 11, 21, 31?
T: yes! 41, 51, and so on. Let us think for some minutes alone. Silence, please. Try to find some properties of the people of this tribe.
(laughs)
(after about 4 minutes)
T: What have you discovered?
S2: they look …
S3: most of them are prime numbers: 1, 11, 31, 41.
S4: and the others are divisible by 3.
T: thus we may write (she goes to the blackboard, and writes):
"P: all natural numbers that end by 1 are divisible by 3, or prime numbers".
Is it OK for you? Or do you find some exceptions?
S5: not, 21 is also divisible by 7.
T: (writes on the blackboard: 21 is also divisible by 7).
Is 21 an exception for what is written above? (she points at the statement P). It is not an easy answer… Let us try together!

Some voices: Yes… Not…

T: Yes or not? Let us try to know the different positions.

S6: Not, P says that all numbers … all natural numbers that end by 1 are divisible by 3, or prime numbers, while 21 is also divisible by 7.

S4: but it is divisible by 3, thus it is not an exception.

S5: all the students in this school are boys or girls, it is true without any exception. None of us makes an exception (a few hidden laughs in the class). While in the case of P… 21 is an exception.

S7: but P does not exclude the divisibility by 7. Like 81: it is divisible by 3, by 9,… (Other examples are made)

S5: in the case of the students of this school, there are only boys and girls, in the case of P it is like if there is also some special boys who are also another thing (laughs in the classroom). Like 21 or 81, which are divisible by 3, but non only by 3.

S8: it is true that each student in this school is a boy or a girl, but a boy may have blue eyes, this property does not make an exception.

T: perhaps you, S8, have seen the point… May you come back from boys and girls to numbers?

S8: yes, but I do not find the words… I try: 21 is divisible by 3, but it has also other properties… It is divisible also by 7, it is bigger that 20, these properties do not disturb the fact that it is a number ending by 1, not a prime number, but a number divisible by 3. Thus it agrees with P!

S9: and every number that ends by 1 is also divisible by itself… This does not disturb the truth of the statement!

S4: P is true if all numbers that end by 1 are prime or divisible by 3. To be prime or divisible by 3 is sufficient for the truth of P.

S7: if we ascertain it for all numbers.

S5: I start to understand. Yes, P does not say that all numbers are prime or divisible by 3 only! Being divisible by 7 is another property – like for a girl with black hair, like for Samantha, who is a girl with other properties.
(some laughs… Samantha is a very pretty girl! And she looks happy of the reference to her, and smiles)

S6: me too… P does not say “only by 3”, divisibility by 7 is another property, no problem!

T: OK, you have solved together a difficult problem! But the original problem remains: is P true?

S4: uh, 121… it ends by 1 and is neither prime, nor divisible by 3. 121 is equal to 11 by 11.

S9: here we have a true exception!

S8: yes, 121 is equal to 11 by 11, it is not a prime number.

S10: and it is not divisible by 3! Thus P is not true!

T: very well, we have discovered what we call a “counter-example” in mathematics: an example, which shows that the property that we are discussing is not true, in our case: not true for all numbers ending with 1! Your task for the next lecture is to write a letter for a student of another class, to explain what we have discussed today and what we have discovered. We have still some time for us… I ask you: do you remember cases in which we have met some kinds of counter-examples?

S4: yes, in grammar… It is not true that all names of Italian people, which end by a, are female. Andrea is the name of a male!

Other examples follow of situations met in the past: odd numbers that are not prime numbers; dolphins that are mammals which do not live on the ground.

Second discussion: exercising RMT of counter-example in elementary geometry

Two weeks later students are making conjectures on the geometry of triangle. They have already discovered (by exploration in different situations: acute triangles, obtuse-angled triangles, etc.) some general properties, like: in every triangle, each side is shorter than the sum of the other two sides; and: each height of a triangle is no longer that the adjacent sides (i.e. the sides from the same vertex). Students have also discovered that some properties that are true in some situations are not true in other situations (e.g. that one median is not always shorter than the adjacent sides).

The teacher decides to suggest the exploration of the angle between the height and the median of a triangle, which originate from the same vertex. In a few minutes a student (S1) hypothesizes that such angle is smaller than the angle between the adjacent sides. The teacher writes such statement (as statement P) on the blackboard:

P: For every height of a triangle, the angle with the median from the same vertex is smaller than the angle between the adjacent sides.

and invites students to explore if it is true. After a few minutes, the discussion starts

S1: I have proposed that P is true by considering a normal situation: the median and the height inside the angle between the concurrent sides in the same vertex.
S2: yes, it is obvious that in that case P is true, the angle between the median and the height is inside the other angle formed by the sides!
S1: I agree that is obvious that P is true in that case, but I have made two other drawings, with a right-angled triangle and the height that was a cathetus, and an obtuse triangle with the height that was outside the triangle… and I have seen that P was still true!
T: S1, come at the blackboard and show those two cases!
(S1 goes to the blackboard and draws the two situations, with the chalk, the ruler and the square – see Figure 1)

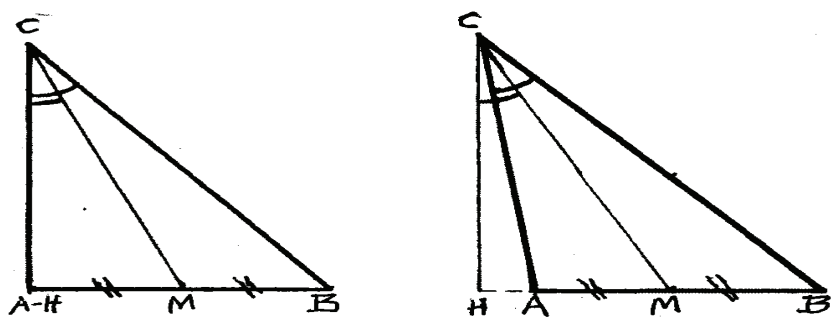

Figure 1: S1's figures

S3: it is clear that P is true also in the case of the right-angled triangle.
S4: because the angle between the height and the median is still inside the other angle…But in another case…
S1: (takes a sheet of paper and by folding it according to the smaller angle she shows that also in the second case P is true).
S4: yes, it is a good example for P also in the case of the height outside the triangle, but…
S5: we need to find if there is a counter-example.
S1: but the property might be true, like in the case of the sum of two sides of a triangle!
S6: (she hints at the blackboard) look at the second drawing… the horizontal side … If I move it rightward…
S7: I see it… the segment walks
S8: or moves like a worm.

S9: not, the worm increases and shortens the length…

S5: or if I shorten it… around the median… the median must remain the same… the angle between the adjacent sides becomes smaller and smaller, …
(S5 makes some drawings corresponding to the shortening of the horizontal side)

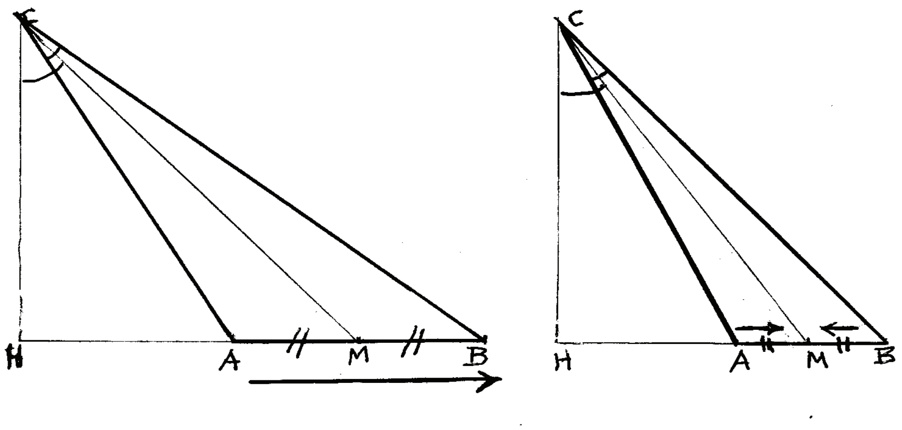

Figure 2: S6's and S5's ways of generating counter-examples

S6: beautiful! The angle between the two sides becomes smaller and smaller, up to zero, while the angle between the median and the height is still the same!

S5: an infinity of counter-examples!

S1: now I realize why I was not able to find the counter-examples: I was stuck to three cases only.

T: which cases?

S1: the height inside the triangle, the height that was one side of the triangle, and one case only of height outside the triangle.

S8: you were not lucky… if you had drawn another figure,…

S11: is it a problem of being lucky or not?

S8: we need a method to find counter-examples!

S5: I see here: the method is to move the figure; but in the case of the numbers ending with 1 the method looks very different!

S6: I am confused with the idea of one method, it is not like to calculate a division!

S1: following previous examples of search of counter-examples, I had a method… which did not work in this case!
(a long silence in the classroom)

T: Let us stop here. I am very satisfied with your work: with the contribution of different people we were able to get a solution for the problem posed by S1 with his … (many voices: conjecture) and to ask ourselves how to produce counter-examples.

Like in the first episode, the teacher asks students to write down a report on the above discussion.

Discussion: Theoretical and educational implications

Now we will consider some aspects of the above discussions. They concern the teleological and the epistemic sides of students' rational behavior, which are specifically inherent in the production of counter-examples, with an eye to educational and theoretical implications related to those sides. We will also consider some affective aspects of the discussions and their relationships with the productivity of the classroom work.

We may identify in the two discussions two different kinds of search for counter-examples: the exploration of individual examples (in the case of the arithmetic statement) and the continuous exploration of the figure (in the case of the geometric statement). What is it better to do, in order to develop students' mastery of the RMT of counter-examples? A solution might be to put into evidence the strategies that have allowed to solve the problems, in the perspective of students' "learning" of them. However Habermas' elaboration on rationality suggests that the a-posteriori analysis of the strategies that result in a failure (or in a success), and of the reasons for that success or failure, is important in order to perform better in future situations. Thus, in an educational perspective, Habermas' position suggests that what counts is not to learn the specific, effective strategies for the different kinds of situations, but to develop the capacity of analyzing them. We find in Habermas (1998), as requirements for teleological rationality in the case of a successful actor:

> he knows why he was successful (or why he could have realized the set goal in normal circumstances); and: this knowledge motivates the actor (at least in part) in such a way that he carries out his action for reasons that at the same time explain its possible success (Habermas, 1998, pp. 313-314)

In the Habermas' rationality perspective, what is relevant is to guide the students to analyze the relationship between the constraints and the opportunities of each experienced situation, on one side, and the goal to achieve, on the other, in the perspective of a-priori making the same kind of analysis in future situations. This remark does not concern only the case of the RMT of counter- example: when students learn to analyze a situation of production of counter-examples they learn to develop a rational behavior (on the teleological side) of more general interest for their rationality.

As concerns the epistemic side of the RMTs, we may observe that in both discussions the full mastery of knowledge inherent in the two problem situations (e.g.: the notions of consecutive numbers, of divisibility, and of prime number, in the first case; and of median and height of a triangle, and the different, possible shapes of triangles, in the second case) was fundamental for the productive development of the discussions. The activation and the productive exercise of a RMT requires a competence which underlies the RMT and that must be specified as a component of epistemic rationality, only implicit in Habermas' elaboration, if we want to adapt the rationality construct to mathematics education needs: the identification and choice of suitable knowledge related to the content of the statements. It includes also the logic-linguistic aspects of the situation at stake, as it is evident in the first discussion (the requirement "divisible by 3, or prime number" does not exclude divisibility by another number). These aspects are relevant in the case of the RMTs related to activities like conjecturing, proving, defining (for the RMT of definition, see Boero&Turiano, 2020).

As concerns affective aspects, we know that the productivity of the discussions (not only for the solution to be achieved, but also for the development of the students' competencies) strongly depends both on long term and on specific educational choices of the teacher. The productive search of counter-examples looks not only as a consequence of the already developed collaborative style of work in the classroom, but also as a promoter of the maintaining and developing of that style of work, of fundamental importance for the development of students' rationality (cf: "an intersubjectively shared lifeworld").

In the reported discussions we have seen how students intervene on their mates' interventions in a very collaborative way – both in the case of an opposition, and in the case of a collaboration to develop their mates' thought, or to make it more precise. Many times the utterance of a student is continued by another student. It is like if the development of ideas is a collective enterprise (which does not contrast the defense of personal ideas). Note also that in the first discussion students S5 and S6 are free to express how they have overcome some wrong ideas: a strong support for those students who (possibly) shared the same ideas but did not express them. Moreover (coming back to the problem of how to develop students' teleological rationality) what S5 and S6 do is precisely what is requested in general in that direction, according to Habermas. And it is also of general interest for the development of students' rationality the shift to the meta-level at the end of the second discussion, a strong contribution to develop students' awareness about their choices and actions (a crucial requirement for rationality).

The work in the classroom is apparently un-stressful: students' minds may move freely from technical mathematical issues to thoughts very far from mathematics, with jokes and double-sense interpretations. Note that this freedom helps (in the first discussion) to understand that some additional properties do not "disturb" the properties to be checked; and (in the second discussion) it allows to get a second infinity of examples through the image of the worm whose length changes. The productive (and friendly) climate in the classroom results from the conscious choices of the teacher since grade 6 (in Italy, the teacher teaches her students from grade 6 to grade 8), within the context of our research team.

Continuity and rupture between argumentation and proof in historical texts and physics textbooks on parabolic motion

Laura Branchetti[1], Alessia Cattabriga[2], Olivia Levrini[2], Sara Satanassi[2]

[1]University of Milan, Italy; laura.branchetti@unimi.it

[2]University of Bologna, Italy; alessia.cattabriga@unibo.it, olivia.levrini2@unibo.it, sara.satanassi3@unibo.it

In this paper, we analyze different presentations in a historical text by Galilei and a textbook for high school of the parabolic motion of a projectile with a lens developed within Mathematics education research on argumentation and proof (cognitive unity; Mariotti et al., 1997; Pedemonte, 2005). The analysis highlights possibilities and problematic issues, with particular attention to the aspects related to continuity and rupture between argumentation and proof in textbooks and the different interdisciplinary relationships between mathematics and physics mirrored by historical sources and textbooks. We discuss how a comparison between them can be exploited to develop a discourse about interdisciplinary that can enlarge the view of the relationship between the two disciplines and didactical implications that can be inferred from this comparison.

Keywords: Interdisciplinary approach, epistemology, proof, cognitive unity, textbook evaluation.

Introduction

To introduce the topic of our contribution, we start from three different representations of the trajectory of a projectile:

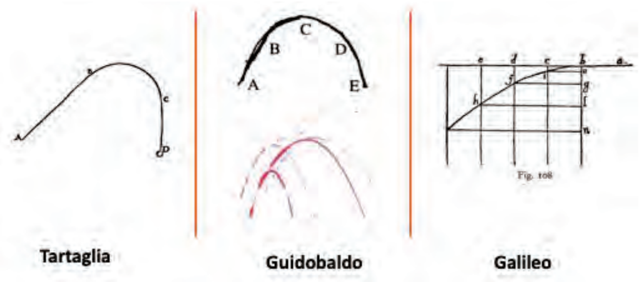

Figure 1: Three different representations of trajectory of projectile in historical texts

In Tartaglia's representation, the trajectory of a projectile consists of three parts: a straight part, followed by an arc of a circle and then ending in a straight vertical line. As stressed in Renn et al. (2000, p. 316): "in the Aristotelian tradition, projectile motion was conceived of as resulting from the contrariety of natural and violent motion, the latter according to medieval tradition acting through an impetus impressed by the mover into the moving body. According to this understanding of projectile motion, the trajectory cannot be symmetrical because the motion of the projectile is determined at the beginning and at the end by quite different causes. At the beginning it is dominated by the impetus impressed into the projectile, at the end by its natural motion towards the center of the earth.". Principles elaborated to interpret motion on the Earth were "embodied" in the form of trajectory, pursuing the aim to provide an axiomatic foundation to the analysis of projectile motion. Guidobaldo's sketch comes from an experiment. The paradigm was slowly changing in science and his transition work was crucial to challenge the medieval perception of motion. As we can see in his representation, the “symmetry” that he had experimentally found in the trajectory (it the ball will take the same path in falling as in rising, and the shape is that which, when inverted under the horizon) led him to corroborate the idea that not necessarily the different kinds of motions are consecutive. This opened the path to new hypotheses compatible with the possibility that motions can compose each other; in this frame, the trajectory could resemble a catenary or hyperbola or parabola. Galilei (1638), as we will show, in *Discourses and Mathematical Demonstration Relating to Two New Science*, completed the process of proving that the trajectory is parabolic, setting up an axiomatic system and grounding reasoning on rigorous proofs inspired to Euclidean ones. These steps were crucial in the birth of Physics and clearly show that the structure of reasonings developed mainly in Geometry, like axiomatics and deductive proofs, from the very beginning played a key role in the development of Physics (Renn et al., 2000). Udhen et al. (2012) stressed that: “the relationship between physics and mathematics has many facets, from the possibility to discover new physics within the mathematical structure to the mathematical nature of basic physical concepts. […] students should not only recognize that mathematics is a valuable tool for physics, but also that it can provide the underlying structure of a physical theory” (p. 493). These historical cases clarify why mathematics is said to play a structural role in physics.

Institutional context and differences between historical texts and textbooks

To promote students’ awareness of the interdisciplinary relationships between mathematics physics and philosophy, in a historical perspective, is a goal of secondary school in the Italian Licei (Mathematics curriculum). In particular teachers are asked to pay attention to these aspects with respect to the XVII century and the birth of modern science. The books by Galilei are the primary sources to consider in order to analyse the topic from the historical-epistemological point of view. In this book the conceptions of disciplines and their relationship differs from today since it is a foundative book, one of pillars of modern scientific method, and an example of rich scientific text that intertwines explicitly many dimensions of knowledge that nowadays are codified in disciplines (mathematics, physics, engineering, philosophy). Physics textbooks for secondary school present a disciplinary didactical transposition that is consistent with the (implicit or explicit) didactical goals of the authors. The topic is not addressed in the same way as Galilei: parabolic motion is presented as a particular case of two-dimensional motion and introduced deserving a lot of space to algebraic passages and formulas, also in the proof. The main differences can be due to the targets (scientific community vs students), the goals (proposing a new theory vs teaching), the development of disciplines and their epistemologies (Euclidean geometry and study of motion vs M&P curriculum at school), interdisciplinarity (scientific discourse intertwining different dimensions vs combination of elements of knowledge taught with a disciplinary perspective).

Literature review and research questions

In this paper, we focus on a specific aspect, epistemologically relevant from the disciplinary and interdisciplinary point of view, that is the way argumentation and proof (A&P) are presented in two texts about parabolic motion: Galilei (1638) and the chapter Two-Dimensional Kinematics in the physics textbook by Walker (2017; high school edition, translated also in Italian). Among the different textbooks used in Italy, we chose that one because it is quite rich from the epistemological point of view (Bagaglini et al., 2021). A first reading of the books showed that in both cases they deal with proving/demonstrating that the trajectory of a projectile is an arc of parabola, but the meanings of the term "proving" seemed to change, as well as the way proof were presented and intertwined with other aspects of the scientific argumentation. We consider A&P key concepts to analyse the structural role of mathematical thinking in physics learning in an interdisciplinary perspective. On one hand awareness about the relationship between mathematical proofs and physical argumentation contribute to developing an authentic picture of the role of mathematics in physics. On the other hand, to trigger a reflection about the meaning of A&P in mathematics and physics (M&P) is an opportunity to investigate the epistemology of such disciplines. With respect to the literature review in mathematics education, our research aims at contributing to address some open questions proposed in the handbook by Durand-Guerrier et al. (2012) about A&P in mathematics and empirical sciences: To what extent should mathematical proofs in the empirical sciences, such as physics, figure as a theme in mathematics teaching so as to provide students with an adequate and authentic picture of the role of mathematics in the world? Could a stronger emphasis on the process of establishing hypotheses (in the empirical sciences) help students better understand the structure of a proof that proceeds from assumptions to consequences and thus the meaning of axiomatics in general? We consider the way the bridge built between mathematical and physical aspects of A&P is presented crucial to address the nature of such a relationship from the didactical point of view. The type of presentation of a proof is already under investigation in mathematics education; open questions we are interested in are: To what extent and how is the presentation of a proof (verbal, visual, formal etc.) (in)dependent on the nature of the proof? Do students perceive different types of proofs as more or less explanatory or convincing?" (Durand-Guerrier et al., 2012). We hypothesized that connecting the notions of A&P in M&P makes this aspect even more important, since the verbal, the visual and the formal aspects of proof might play a different role in explaining and convincing students when "mathematizing" observation and reasonings about empirical phenomena or experiments, and in mirroring the nature of such a kind of proof, whose complexity is evident also in the historical cases briefly resumed in the introduction.

In this paper we analyse the way knowledge belonging to M&P (objects, reasonings, assumptions, epistemological issues) is used in argumentative steps and proof in different texts. We consider the analysis of A&P in texts and the comparison with historical texts a key step to move from the historical-epistemological and cognitive analyses to the classroom practices, in particular considering teacher-students education. This issue has been investigated by papers presented in CERME10 (Stylianides et al., 2018); among the themes discussed, we contribute to highlight the role of language in teaching and writing proofs and to search for analytical frameworks for argumentation and proof in textbook expositions.

Research framework

The didactic value of inserting proof into an argumentative process that involves students in the formulation of conjectures has been highlighted by many studies as a way to move from a reproductive approach to demonstration to a productive one and to focus on proof as a process more than on proof as a product. The construct of cognitive unity has been introduced by Mariotti et al.

(1997) to encode this idea and to stress the need for didactical situations in which the construction of a proof naturally follows from the exploration of a problematic situation by students. In particular we refer to this key aspect: "some aspect of continuity, concerning the production, during the construction of the conjecture, of the elements ("arguments") that are used later during the construction of the proof" (p. 1). This way some elements that characterize the proof (the choice of a statement to refer to, or of the semiotic representation register) are not artificially and suddenly introduced but arise naturally from the exploration, as it happens when statements are proved in research. Otherwise there is a cognitive rupture (Pedemonte, 2005). Proving that the trajectory of a projectile motion is parabolic can be considered a conjecture-proving problem, according to the characterization of Mariotti et al. (1997).

We assume that continuity should be pursued also in physics teaching to guarantee a productive approach of students to proving in this field, in particular when mathematics appears in the statements and semiotic representations of physical entities, since students need to activate resources related to their conception and experience of mathematical processes. What happens to the flow of observation and conjectures about physical phenomena when mathematics enters the discourse? If teachers have to guide a classroom discussion to help the students to include these aspects, is continuity between A&P pursued or do their interventions cause cognitive rupture? As we showed, the issue is critical from the epistemological point of view, so we think teacher-students need examples and meta reflection to guide the students properly in such classroom discussions. The cognitive unity has been developed, and is mainly used, to analyse students' reasonings. We consider texts targeted to non-expert readers as examples of forms of presentation of reasonings, as they were teachers' speeches when they guide students who made observations and conjectures to gradually organize their reasonings. These can be prototypes of different ways the teachers scaffold students' approach to interdisciplinary A&P in the classroom, with possible different impacts on students' learning. We consider thus it useful to carry out analyses with the same lens used with students of the ways the texts guide the readers to move from exploration to A&P.

Methods

The books were analysed at two scales: a global analysis of the organization of the books with epistemological and linguistic lenses (Bagaglini et al., 2021), and zooming in on some excerpts where we could find relevant aspects to analyse in order to identify continuity and rupture between A&P in the texts. In this paper we focus on the second aspect. From the methodological point of view, we referred to the analysis of cognitive unity and rupture proposed by Pedemonte (2005):

– *structural analysis*: refers to the link between the structures of statements used in argumentations and in proofs. There is structural cognitive unity when statements used in the argumentation are also used in the proof. Otherwise, there is structural cognitive rupture.

– *referential analysis*: refers to the systems of reference used in argumentations and in proofs, that is, the systems of signs (drawings, calculations, algebraic expressions, etc.) and systems of knowledge (definitions, theorems, etc.) used. There is referential cognitive unity when some systems of signs or knowledge are used both in the argumentation and the proof. Otherwise, there is referential cognitive rupture. We enlarged it according to our goal (interdisciplinary analysis of prototypes of A&P

connections). We carried out a structural and referential analysis of relevant excerpts from the third and fourth day, concerning the study of local motions in Galilei (1638) and Walker (2017). We identified statements in A&P related to parabolic motion and then systems of representation and knowledge belonging to both mathematics and physics (considered as disciplines taught at school in grades 9-10 in Italy in the textbook's analysis and as historical disciplines analyzing Galilei's excerpts). We organized them on tables reporting on the left the excerpt (statements), on the right the referential analysis. By comparing the A&P steps, thanks to the structural and referential analysis, we detected unity or rupture in both texts. Because of space constraints, we report only a few excerpts to show the analysis of the proof of the statement "the trajectory of a projectile is parabolic" and the previous choices made in the argumentative part.

Main results of the analysis of unity or rupture in Galilei's and Walker's texts

By steady or uniform motion [1], I mean one in which the distances traversed by the moving particle [2] during any equal intervals of time [3], are themselves equal. [D1].	Definition of uniform motion using proportions (equal space in equal time)
A motion is said to be uniformly accelerated [4], when starting from rest, it acquires, during equal time-intervals [3], equal increments of speed.[...] the distances traversed [2] are proportional [D1] to the squares [5] of the times.	Definition of accelerated motion using proportions (equal increments of speed in equal time, space proportional to the square of time)
Imagine any particle projected along a horizontal plane without friction; if the plane is limited and elevated [6] the resulting motion which I call projection [7], is compounded of one which is uniform and horizontal [1] and of another which is vertical and naturally accelerated [4].	Definition of projectile, that incorporates the assumption of composition of motions
Theorem 1 – Proposition 1: A projectile [7] which is carried by a uniform horizontal motion [1] compounded with a naturally accelerated [4] vertical motion describes a path which is a semi-parabola [8].	Theorem formulated using previous definitions
The section of this cone [..] which is called a parabola [8] [..] the square [5] of bd is to the square [5] of fe in the same ratio [9] as the axis ad is to the portion ae.	Definition of parabola
Let us imagine an elevated [6] horizontal line or plane ab along which a body moves with uniform [1] speed from a to b. Suppose this plane to end abruptly at b [6] [..]. Draw the line be along the plane ba to represent the flow, or measure, of time; divide this line into a number of segments, bc, cd, de, representing equal intervals of time [3] [..] in proportion [D1] to the squares [5] of cb, db, eb, or, [..] in the squared ratio [9] of these same lines. [...]the distance traversed [2] by a freely falling body varies as the square [5] of the time; in like manner the space eh traversed [2] during the time be will be nine times [D1] ci; thus it is evident that the distances eh, df, ci will be to one	Proof is presented, where: - the same terms introduced before are used, as well as the same spatial representation (segments/intervals of time) - it is stressed the use of proportional reasoning, that was used to define the kinds of motions that are combined - G. recalls the assumptions about the composition of motions

another as the squares [5] of the lines be, bd, bc. The square [5] of hl is to that of fg as the line lb is to bg [D1]; and the square [5] of fg is to that of io as gb is to bo; therefore the points i, f, h, lie on one and the same parabola [8]. 	- G. recalls the setting associated to the definition of projectile with the same words - G. intertwines the definition of parabola and the characterization of accelerated motion in order to exploit the linguistic analogies to stress that the points must lie on a parabola.

Table 1: Analysis of Galilei's excerpts

Big Idea 1 Two-dimensional motion is a combination of horizontal and vertical motions. The key concept behind two-dimensional motion is that the horizontal and vertical motions are completely independent of one another; each can be considered separately as one-dimensional motion.	The combination and independence of horizontal and vertical motions are initially introduced in a lateral box as Big Idea. The status of the statement in terms of elements of A&P (axiom, theorem) is not expressed.
Projectile Motion: Basic Equations We now apply the independence of horizontal and vertical motions to projectiles. Just what do we mean by a projectile? Well, a projectile is an object that is thrown, kicked, batted, or otherwise launched into motion and then allowed to follow a path determined solely by the influence of gravity.	The Big Idea is applied to projectile motion to obtain its equations and a phenomenological description of the projectile is presented.
Demonstrating Independence of Motion: A simple demonstration illustrates the independence of horizontal and vertical motions in projectile motion. [..] Notice that the ball goes straight down, lands near your feet, and returns almost to the level of your hand in about a second. [...] To you, its motion looks the same as before. The fact that you were moving in the horizontal direction the whole time had no effect on the ball's vertical motion — the motions are independent. 	A figure represents a moving person with a roller skate and a falling ball; the two combined motions are represented with a reference to real life. The motion is seen also by an external observer and the trajectory is linear and vertical in the system of person and curved in the external system, that is represented through cartesian axes put onto the real life figure. The relativity of motion in different systems is used to demonstrate independence of motions.
To an observer who sees you walking by, the ball follows a curved path, as shown. The precise shape of this curved path—a parabola—is verified in the next section.  (a)	A picture (photo with a camera to a real world phenomenon) is proposed. In the description of the figure, it is mentioned the visualization of concepts and presented as one among other"examples of principle" of independence of motions.

FIGURE 4-4 Visualizing Concepts - Independence of Motion (a) An athlete jumps upward from a moving skateboard.	It is anticipated that the shape is a parabola and that this will be verified later.
 FIGURE 4-5 Trajectory of a projectile launched horizontally In this plot, the projectile was launched from a height of 9.5 m with an initial speed of 5.0 m/s. The positions shown in the plot correspond to the times t = 0.20 s, 0.40 s, 0.60 s, ... Notice the uniform motion in the x direction, and the accelerated motion in the y direction. and $y_0 = h$ This is illustrated in Figure 4-3. The initial velocity is horizontal in this case, corresponding to $\theta = 0$ in FIGURE 4-5. As a result, the x component of the initial velocity is simply the initial speed: $v_{0x} = v_0 \cos 0° = v_0$ The y component of the initial velocity is zero: $v_{0y} = v_0 \sin 0° = 0$ Substituting these specific values into our fundamental equations for projectile motion (Equations 4-6) gives the following simplified results for zero launch angle ($\theta = 0$): $x = v_0 t \quad v_x = v_0 = \text{constant} \quad v_x^2 = v_0^2 = \text{constant}$ $y = h - \frac{1}{2}gt^2 \quad v_y = -gt \quad v_y^2 = -2g\Delta y$ 4-7 Snapshots of this motion at equal time intervals are shown in FIGURE 4-6. PROBLEM-SOLVING NOTE Identify Initial Conditions The launch point of a projectile determines x_0 and y_0. The initial velocity of a projectile determines v_{0x} and v_{0y}.	A graph, resembling the one by Galilei but the use of x,y and units on the axes, is in a lateral box. The horizontal uniform motion is presented using proportions (equal space in equal time) without mentioning the nature of this description as definition. The same happens to vertical accelerated motion. Symbolic expressions are used for the generic case and the Galilei case is obtained substituting a value into equations for projectile motion.
 Parabolic Path RWP Just what is the shape of the curved path followed by a projectile launched horizontally? This can be found by combining $x = v_0 t$ and $y = h - \frac{1}{2}gt^2$, which allows us to express y in terms of x. First, solve for time using the x equation. This gives $t = \frac{x}{v_0}$ Next, substitute this result into the y equation to eliminate t: $y = h - \frac{1}{2}g\left(\frac{x}{v_0}\right)^2 = h - \left(\frac{g}{2v_0^2}\right)x^2$ 4-8 It follows that y has the form $y = a + bx^2$	An algebraic version of the proof is presented (never named proof), with: - reference to a curved path: - the term “found” instead of verify - use of symbolic expression of the two motions combined, as well as the parabolic generic equation - no reference to assumptions about the combination of motions - the use of terms “substitution” and “eliminate” - no mention of the previous graph and the exemplification of principles of independence.

Table 2: Analysis of Walker’s excerpts

Discussion and conclusions

The first analysis shows that Galilei’s text is characterized by structural and referential unity: he mathematized the relationship between space and time with magnitudes and proportions and used always the same objects and properties to merge the observation of phenomena, empirical laws and geometrical properties of conic sections. The mathematization of the experimental setting allowed him to prove, deductively, that the trajectory is a semi-parabola, under the hypothesis that the motion of a projectile results from a composition of independent uniform and accelerated motion. The theory of magnitudes bridges the concrete action of measuring and the theoretical comparison between geometrical magnitudes. The graphic representation plays a crucial role, since the action itself to trace a line/curve with a motion of a point is a sort of ideal machine that draws a trajectory, hybridizing the notion ofs trajectory and geometrical curve to treat the trajectory geometrically. In this case the structural role of mathematics clearly emerges: “importing” the structure of Euclidean proof in the investigation of motion allows to refine and strengthen argumentation.

In Walker's chapter, it is visible the effort to consider the dimension of A&P: there are physical assumptions, a definition of projectile, examples that ground the assumptions about the composition of independent motions on empirical facts, stressing that they are realistic. Some referential choices are consistent: the motion of a projectile is a particular case of a more general motion, equations of evolution are used to derive new equations treating time and space as algebraic variables. However, many elements of rupture are present. both in terms of structural and referential analysis of the relationship between argumentation and proof. Indeed, the presentation of the argument concerning physical principles and entities and the proof are presented with figures and pictures related to real life, while in the derivation of the equation they switch suddenly to algebraic language and analytical reasoning (substituting variables in functions). Moreover definitions, principle, inference, proof are never mentioned. The link between empirical aspects and mathematical knowledge is hard to establish for a reader, because of the strong discontinuity in terms of use of signs and semiotic registers for the expression of the statements.

Our analysis highlighted issues that we consider crucial from the didactical point of view since they connect relevant issues of mathematics education to interdisciplinarity M&P. In particular, from such a comparison prospective teachers can gain awareness about the ruptures that can be found in textbooks and thus adapt their teaching practices to pursue cognitive unity by reflecting on the aspects we stressed with their students and compensating for the weakness of textbooks.

How teachers address process-product dualities in mathematical argumentation processes

Fiene Bredow[1] and Christine Knipping[2]

[1]University of Bremen, Germany; bredow@uni-bremen.de

[2]University of Bremen, Germany; knipping@uni-bremen.de

Teachers play an important role in creating environments for mathematical argumentation processes in classrooms. In the transition from arithmetic to algebra for example, students depend on how teachers address the process-product duality of mathematical argumentation and the duality of mathematical objects. Two empirical examples illustrate that eight-grade students (13-14 years old) struggle with these dualities in mathematical argumentation processes and that they need support of their teachers when creating generally valid arguments in class. This study examines how teachers' actions guide students in handling the process-product dualities and how teachers thus influence and shape the construction of mathematical arguments in classrooms.

Keywords: Process-product duality, mathematics teachers, mathematical argumentation, classroom research.

Introduction

Little research has been done on how teachers act while initiating mathematical argumentations in class discussions (e.g., Conner et al., 2014; Schwarz et al., 2006). It is still uncertain what influence teachers' specific actions have on the quality of the arguments that emerge in classrooms. In addition, there are two process-product dualities students must handle in class when it comes to mathematical argumentations. On the one hand, mathematical argumentations are processes in which participants aim to justify or refute a claim with the intent to formulate a mathematical argument – a product. On the other hand, mathematical arguments are always arguments about mathematical objects and these mathematical objects can be interpreted in a process-oriented or a product-oriented way (Sfard, 1991; Sfard & Linchevski, 1994). Whether the interpretation of the mathematical objects is more process-oriented or product-oriented becomes visible in the arguments produced by the students. How these interpretations of mathematical objects in mathematical arguments are shaped or influenced by teacher actions is still mostly unexplored and is a focus in our project. This paper presents examples of mathematical argumentations in the transition from arithmetic to algebra from two grade 8 classes. The following research questions guide our analysis: How is a process-oriented or a product-oriented interpretation of mathematical objects reflected in the mathematical argumentations and arguments? How does the teacher address these interpretation processes?

Theoretical Framework

Process-product dualities in mathematical argumentations

In school contexts mathematical argumentations in the transition from arithmetic to algebra include two process-product dualities: 1) In classrooms, mathematical argumentation processes are mostly oral and generally distinct from the argument (product) that emerges, which is commonly fixed in a written form (Boero, 1999). This is one duality of mathematical argumentation. 2) At the same time, the mathematical objects in the argumentations can be understood in a dual way: operationally, this means process-oriented, or structurally, which means in a product-oriented way (Sfard, 1991; Sfard & Linchevski, 1994). The algebraic symbolic language, which is itself initially a learning object, can also be interpreted in these two ways. A process-oriented interpretation of an algebraic term means to understand the term as a "sequence of instructions" (Sfard & Linchevski, 1994, p. 191). The term, which one can calculate, represents a computational process. At the same time the term can be interpreted in a product-oriented way as a "product of a computation" (Sfard & Linchevski, 1994, p. 191). In this case, the term is treated as an object itself and mathematical structures of the term are focused. Mathematical argumentations reflect this duality.

These interplays between process-product dualities are significant in our data. For example, if one considers the sum of an even and an odd number, students calculate numerical examples on an operational level and conjecture that the sum is always odd. A process-oriented interpretation of a numerical term here means to calculate a concrete number. At the same time, it is possible to look at these numerical examples from a structural perspective and formulate them as generic examples. When arguing with their mathematical structure, a generally valid mathematical argument arises. Seeing this mathematical structure, requires a change from a process-oriented to a product-oriented interpretation, which students and teachers are often not aware of. A process-oriented interpretation of a term is not sufficient to create a valid argument for a general claim, because a generalization is needed, and this requires arguing with mathematical structures and general characteristics of the mathematical objects. How teachers and their actions contribute to this change of view and support the emergence of valid arguments is of interest here.

Mathematical arguments and their representation

According to Toulmin (1958) an argument consists of different elements. A claim is a statement that participants try to justify or refute. In this study claims are marked with a C. Data (D) are accepted, undoubted facts or shared knowledge of a community, the starting point of an argument. With a warrant (W) the step from the data to the claim is legitimated. Some arguments also contain backings (B) that state why a warrant is generally applicable. To describe the certainty of an argumentation step, a modal qualifier (Q) can be integrated into the argument. Sometimes rebuttals (R) indicate "circumstances in which the general authority of the warrant would have to be set aside." (Toulmin, 1958, p. 101). In addition to these core elements established by Toulmin (1958), Knipping and Reid (2015) introduced refutations (X) as another element of arguments. When parts of an argument are not accepted by a community or are not shared knowledge, these parts can be refuted. But a refutation is not a rebuttal. Refutations refute complete parts of arguments, whereas rebuttals only restrict the conclusion to a locally limited extent (Knipping & Reid, 2015). Therefore, refutations can apply to any element of an argument. In our data, we found statements about the applicability of the warrant in an argumentation step. We call this kind of statements backings B*. These statements specify a characteristic of the datum and relate the warrant, the general rule, to the data. This legitimates the use of the warrant in the argumentation step. These kinds of statements aren't backings in Toulmin's sense because they don't support the authority of a warrant in general but support its applicability in the specific case. On the other hand, they have a different function than data. Toulmin (1958, p. 106) states that data must be explicit in an argument, but these statements are additional facts which characterise the datum and don't need to be made explicit in the argument. Mathematical argumentation processes in mathematics classrooms often include more than one argumentation step. When a conclusion of a previous step is already accepted, it is possible to use this conclusion as data for another step.

Mathematical arguments are represented in different ways in mathematics classrooms. Reid and Knipping (2010) distinguish several types of arguments according to their representation. In school, in the transition from arithmetic to algebra, numeric generic, pictorial generic, narrative, and symbolic arguments are particularly important. Numeric generic arguments use concrete numbers and their inherent structures to justify a general claim. In contrast, pictorial generic arguments, also called visual proofs (Reid & Knipping, 2010, p. 136), practice transformations on visual objects to emphasize the mathematical structures and argue with them. Mathematical arguments which contain only words are called narrative arguments. Symbolic arguments are based on the algebraic symbol language. All these arguments can potentially be read and interpreted in a process- or product-oriented way (although this is already inherent in written narrative arguments). Each interpretation effects the validity of the proposed mathematical argument. Teachers are often only partly aware of these different interpretations when they guide their students in creating generally valid arguments.

Role of the teacher in mathematical argumentations in the transition from arithmetic to algebra

Developing generally valid mathematical arguments in classroom discussions is challenging for students and teachers, especially in the transition from arithmetic to algebra. Teachers have a decisive influence on whether and how mathematical arguments emerge (Schwarz et al., 2006; Conner et al., 2014). In the transition from arithmetic to algebra, mathematical structures are increasingly emphasised, and mathematical properties and relations are used for generally valid arguments. Empirical research documents that symbolic arguments often dominate in mathematic classes (Brunner, 2014). These types of arguments focus mostly on process-oriented transformations of symbols. In this case, the algebraic symbol language often remains misunderstood, and learners demonstrate difficulties in grasping the underlying mathematical structures of the algebraic symbol language used (Kieran, 2020; Pedemonte, 2008). For example, students show difficulties in the interpretation of the equal sign. The equal sign can be interpreted as a "do something signal" or as a "symbol for equivalence" (Kieran, 1981, p. 317). The first, process-oriented interpretation triggers students to calculate the term. The left side of the equation is seen as a task one needs to solve, while the right side is considered as the solution of the calculation. In a product-oriented interpretation, the equal sign can be seen as a symbol between two equivalent terms. In this way, the relation between the terms is focused. Grasping mathematical structures and relations is also crucial when creating valid mathematical arguments for general claims. A process-oriented calculation of a term is not sufficient to grasp inherent mathematical structures and to capture general characteristics of the term. Often a product-oriented interpretation of mathematical objects is required. For example, when arguing with the equation "$2\cdot x+2\cdot y=2\cdot(x+y)$" that the sum of two even numbers is always even, one needs to interpret the algebraic symbols and the equal sign in a product-oriented way. Without an interpretation of the equal sign as a relational symbol (product-oriented) between two terms, one cannot grasp the relation between the terms and cannot argue that the sum of two even number is always even. Students often struggle with these interpretations and need the support of teachers who are aware of these difficulties (Kieran, 2020).

Methods

For researching mathematical argumentation processes in the transition from arithmetic to algebra, a learning environment with 4-5 lessons (90 min each) was designed and implemented in three eight-grade classes (13-14 years old) in Bremen (Germany). The lessons were taught by their teachers, who had different school experiences. Teacher A had been a fully trained teacher for half a year only, teacher B had been a teacher for 10 years and teacher C had been teaching about 5 years. Teacher A and C worked at an "Oberschule" (a German type of comprehensive school), teacher B at a "Gymnasium" (a selective type of school). As a starting point, different representations of mathematical arguments (Reid & Knipping, 2010) were introduced to the learners to facilitate learners' various approaches to mathematical structures and to smooth the transition to algebra. Transcripts of the classroom discussions were made, which included drawings and descriptions of gestures and actions. Based on these transcripts the mathematical arguments that emerged in class were reconstructed with Toulmin's (1958) functional model of arguments, which is well established in mathematics education (Knipping & Reid, 2015).

As the goal was to reconstruct and analyse actual classroom argumentations, our reconstructions include statements and arguments that are not correct from a mathematical point of view. We keep the statements in the reconstructed arguments almost the same as the original utterances of the participants during the classroom discussions. So, it is possible to use the statements in the reconstructed arguments (diagrams) to analyse the participants' interpretations of the mathematical objects involved. For this analysis we use a distinction by Caspi and Sfard (2012), who differentiate between a processual, a granular and an objectified description of a term. A processual description of a term is a process-oriented description of the computational process. In an objectified, product-oriented description, the relationship between the objects is focused, and the actual computational process recedes into the background. Here verbs are nominalized to objects. The granular level is an intermediate step, which will not be focused in our analysis and this article. These analyses allow us to distinguish between a process-oriented and a product-oriented interpretation of mathematical objects in argumentations. For example, a student who describes the term "a+b" as "adding b to a" interprets the term in a process-oriented way, while "the sum of a and b" would be considered as a product-oriented interpretation.

This paper focuses on an argumentation task about "The sum of two even numbers". Students look at several numerical examples and generate a conjecture. Almost all students conjecture that the sum of two even numbers is always even. Afterwards, a reflection is requested if their conjecture is generally valid or if counterexamples exist. Finally, the students are asked to create a mathematical argument. In the following classroom discussion, students present their written arguments to the classroom community. While students' written solutions and arguments are projected on a wall, argumentative elaborations on these products are presented, which constitute further argumentation processes. Products and processes of argumentations are intertwined here. The results of our analyses of these discussions and argumentations are focused in the next section.

Results

In the following two examples, it becomes evident that students struggle with the process-product dualities mentioned above, when they attempt to construct a generally valid argument. The teacher shapes the students' handling of the process-product duality and thereby the creation of mathematical arguments. So, the crucial role of the teacher is apparent in these examples.

Example 1: Numeric generic argument in teacher A's classroom

In the first example, Tabea tries to support the claim that "The sum of two even numbers is always even" with a numeric generic example (figure 1). A projection of Tabea's notes is shown to the class: "14+20=(2·7)+(2·10)=14+20=34". Tabea's first attempt to justify the claim that "The sum of two even numbers is even" is based on a transformation of her numerical example "14+20". Her first transformation "14+20=(2·7)+(2·10)" can be seen as a step towards constructing a generic example. Tabea applies the property that even numbers are divisible by two and thus presents the numbers as a product with the factor two. In this representation a mathematical structure and a product-orientation become visible. In the second step however, Tabea switches to a calculation, "(2·7)+(2·10)=14+20", thus presents a process-oriented perspective. In this step, she doesn't use the represented mathematical structure for a general argument, but she comes back to her starting point. So, Tabea presents an argument that does not contain a generalisation and no connection to her general claim. Therefore, the teacher comments that Tabea "goes in a circle" and refutes Tabea's argument.

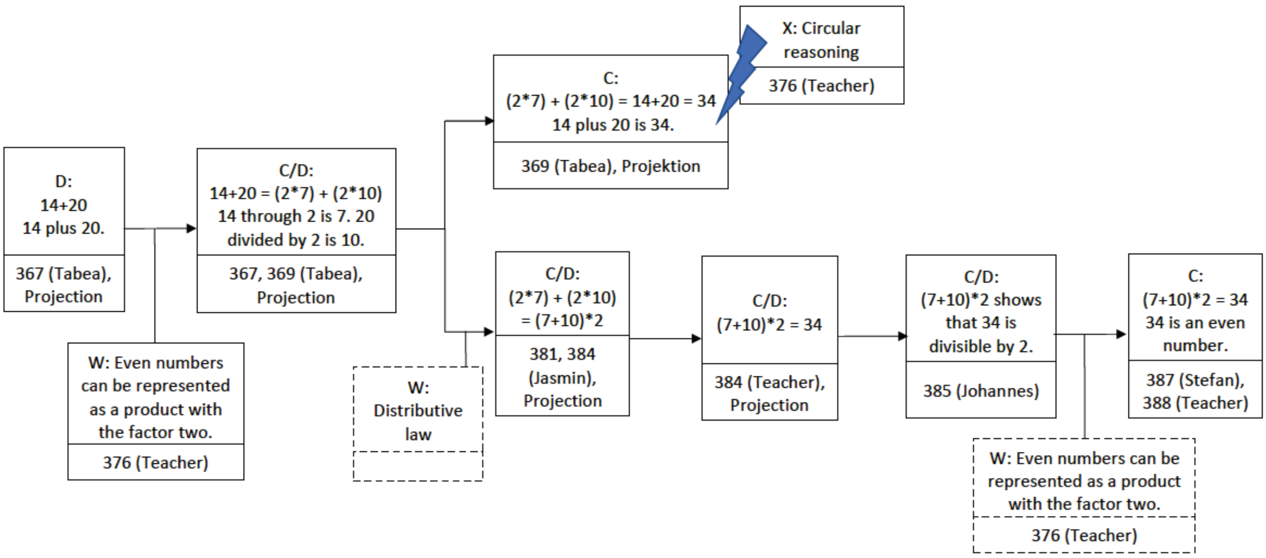

Figure 1: Reconstruction of the numeric generic argument with the Toulmin scheme (Example 1)

Later, the teacher repeats Tabea's first step and asks students to continue with "(2·7)+(2·10)": "What would be the next logical step now?". Jasmin extends Tabea's first step to "(2·7)+(2·10)= (7+10)·2" and uses the opportunity Tabea created. The inherent structure of the numerical example is used and represented explicitly. This requires a structural interpretation of the algebraic term and the equal sign. But now, the teacher pushes towards a calculation, saying that the product is 34. Here, the teacher switches back to a process-oriented interpretation. In the last two steps of the argument, the structure of the numerical example, inherent in the symbolic representation, is used for a conclusion by the students. Johannes finally states that the term "(7+10)·2" shows that 34 is divisible by two, and Stefan concludes that therefore, 34 is an even number. Both emphasise again a structural view. So, in these last two argumentation steps the structure of the generic example is used again. But like in Tabea's attempt, a generalisation is missing - there is no explicit connection to the claim that the sum of two even numbers is even, which the class tries to legitimate.

How does the teacher shape the argument? After Jasmin's transformation of the term, the teacher switches back to a process-oriented calculation of the result. The teacher guides the students with her statement to argue about the concrete number 34. She even asks what this term shows about 34: "What does this seven plus ten times two tell us now, what does it say about thirty-four?". This question invites students to focus on the concrete number, which makes it difficult for the students to conduct a generalisation. The students offer a product-oriented interpretation of the term, but stick to the specific example, instead of justifying the general claim. Therefore, a final conclusion like "The sum of two even numbers is even" is missing in the whole argument. A numeric argument emerges, but its generality is not discussed and addressed by the students and the teacher.

Example 2: Symbolic argument in teacher B's classroom

The second example illustrates the creation of a symbolic argument about the sum of two even numbers in a classroom discussion (figure 2). As a starting point, the teacher asks the students to express an even number with variables by referring to a previous symbolic argument, which also includes even numbers. Levke introduces "2·n" and "2·x" and the teacher writes the sum of them on the blackboard. In these summands, a characteristic of even numbers is visible; each summand is a product with the factor two. But the students' interpretation of the term is ambiguous. The situation allows either a process- or a product-oriented interpretation.

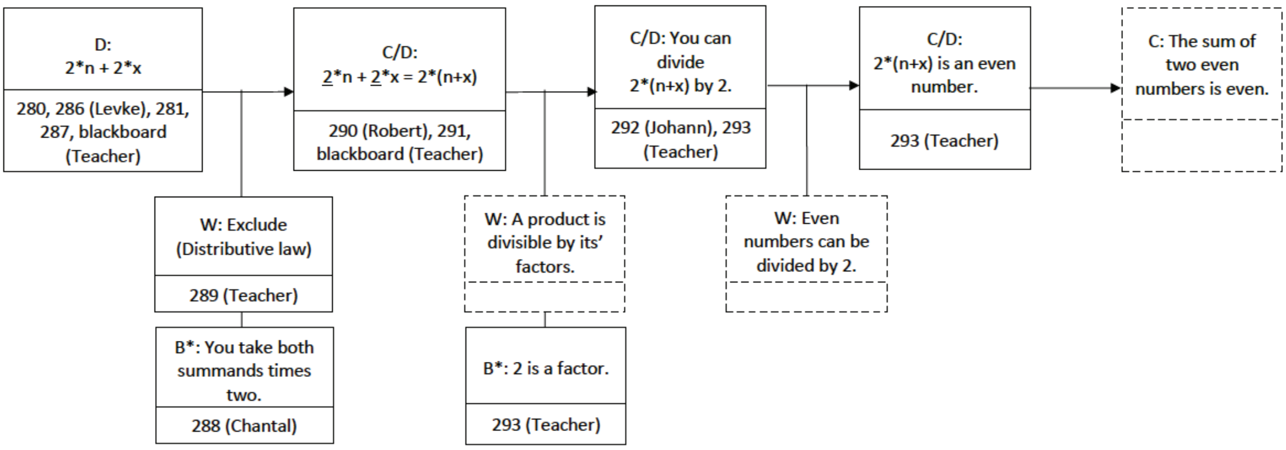

Figure 2: Reconstruction of the symbolic argument with the Toulmin scheme (Example 2)

The teacher asks what is common in both summands. Chantal points out that both are multiplied by two and thus indicates that the distributive law is applicable here. We reconstruct this as a specific kind of backing B*, which justifies not the warrant in general, but the applicability of the warrant in this argumentation step. Chantal's backing B* indicates her process-oriented interpretation of the term. The associated warrant, added by the teacher, is also expressed in a process-oriented way. Consequently, the term is operationally transformed into "2·n+2·x=2·(n+x)". Now "2·(n+x)" must be interpreted. Johann claims that one can divide this term by two. But he does not explicate a warrant and sticks to a process-oriented interpretation. The corresponding warrant “A product is divisible by its’ factors.” is left implicit. The teacher complements Johann’s argumentation step by “2 is a factor”, which is another example of a backing of type B*. This statement B* relates the general warrant to the specific case. “2 is a factor” now supports a product-oriented interpretation. Finally, the teacher concludes that “2·(n+x)” is an even number, and emphasises again a product-oriented interpretation, while the students’ interpretations of the term “2·(n+x)” might be different. If they create a generalisation and therefore connect the argument to the implicit final conclusion is ambiguous.

All in all, the whole argumentation process is strongly guided by questions from the teacher and the students are forced to answer these questions. Students mainly suggest process-oriented statements, while the teacher sometimes switches to a structural level and supplements elements for the argument. The students seem not to grasp the structural ideas proposed by the teacher, but they keep answering and arguing in a process-oriented way.

Summary and Conclusion

In the presented examples of two classrooms, both teachers try to address and shape the handling of the process-product dualities in students’ argumentations but in different ways. In both examples, a product-oriented interpretation is needed in the argumentation process to create a generalisation and produce a generally valid argument. In the first example, the teacher makes it difficult for the students to come up with such a generalisation, because she calculates the result of the generic example. The students use the structure of the created generic example for an argument, but they fail in generalising their claim; the students stick to their numeric example. The second classroom shows a teacher alternating between a process-oriented and a product-oriented interpretation, while students stick to a process-orientation. In two moments, students express a process-oriented statement and the teacher switches to a structural view. However, students do not reproduce this structural view in their contributions. In both classroom episodes a final general conclusion is implicit or even missing in the emerging argument.

All in all, the examples illustrate that a product-oriented interpretation of mathematical objects is often crucial for the creation of generally valid mathematical arguments in classrooms, while it is challenging for students and teachers. The first example also shows that a product-orientation is not sufficient. Especially for generic arguments, a generalisation is required for a complete and generally valid argument. A product-orientation does not produce a generalization by itself. In addition, students must handle the process-product duality of mathematical argumentation. The goal of these classroom discussions (example 1 and 2) is to formulate a written argument. In class, students and teachers switch back and forth between an interpretation of single steps in a written argument and the oral argumentation, where each step is justified and negotiated as reasonable.

It is evident that it matters for students how their teachers address the process-product duality of algebraic symbols. In both examples, it becomes obvious that the interplay between students’ and teachers’ process- or product-orientations is essential. Students need support in reflecting structures inherent in mathematical objects and making generalisations. The comparative analyses of the data in our project illustrate different challenges that teachers encounter in this context. More insights will be gained by further analysis in this project.

Guiding principles for teaching mathematics via reasoning and proving

Orly Buchbinder[1] and Sharon McCrone[1]

[1]University of New Hampshire, USA; orly.buchbinder@unh.edu; sharon.mccrone@unh.edu

Against the backdrop of policy documents and educational researchers' vision of proof as an essential component of teaching mathematics across content areas and grade levels, teaching of reasoning and proof in mathematics classrooms remains an elusive goal. Teachers and the type of teaching they enact in classrooms are crucial for achieving this goal. This theoretical paper builds on the concept of proof-based teaching and suggest a set of guiding principles for what we call teaching mathematics via reasoning and proving. *These principles were developed as a part of a multi-year design based project, and implemented in an undergraduate course* Mathematical Reasoning and Proving for Secondary Teachers. *We illustrate these principles using examples from proof-oriented lessons plan developed by prospective secondary teachers.*

Keywords: Reasoning and Proof, Classroom Instruction, Secondary Mathematics Teachers

The state of reasoning and proving in mathematics classrooms

Learning mathematics meaningfully entails more than following procedures and recalling facts; rather, it requires understanding, making sense of, and engaging in mathematical practices, such as identifying patterns, conjecturing, exploring with examples and counterexamples, and justifying and critiquing arguments. Collectively, these disciplinary practices are called *reasoning and proving* (Ellis et al., 2012; Stylianides, 2008). Proof serves many roles in mathematics, but in mathematics classrooms, reasoning and proving mainly serve to support students' sense-making by providing insights into *why* something is true, and not just *that* something is true. Importantly, the means for showing why should be through deductive reasoning rather than relying on authority of the teacher or a textbook (Hanna & deVillers, 2012). Student participation in reasoning and proving activities across grade levels and mathematical topics is widely recognized as essential for meaningful learning (NGA & CCSSO, 2010; NCTM, 2009), due to the focus on mathematical sense making. Reasoning and proving are also linked to knowledge retention, enhanced understanding and making mathematics intellectually satisfying for learners (Harel, 2013).

However, the uptake of reasoning and proving as an integral part of school mathematics has been slow and limited (Stylianides et al., 2017; Nardi & Knuth, 2017). Several potential explanations are offered for this phenomenon. Some researchers (e.g., Thompson et al., 2012) locate the problem with the dearth of examples in curricular materials for engaging students with reasoning and proving. Although there are some texts that aim to help teachers to integrate reasoning and proving in their teaching (e.g., Ellis et al., 2012; NCTM, 2009) they are often more appropriate for problem-based curricula rather than what can be considered a traditional secondary mathematics curriculum.

Another reason for the low occurrence of reasoning and proving in mathematics classrooms is that teachers and students tend to interpret it narrowly, as two-column exercises in high school geometry (Herbst, 2002). The didactic contract (Brousseau, 1997) that develops around this genre of exercises seem to be about reproduction of sometimes “obvious” mathematical results in a prescribed format. This leads both teachers and students to perceive proof as intellectually unexciting and a redundant activity (Harel, 2013). The powerful image of proof championed by mathematicians and championed by mathematics educators, does not seem to precipitate into mathematics classrooms. In addition, teachers’ own gaps in mathematical knowledge specific to proof and unproductive beliefs about teaching proof (for example, that only high-performing students can handle proofs) can sometimes pose barriers to classroom integration of reasoning and proving (Stylianides et al., 2017). But the issue runs deeper than that. Studies have shown that even teachers who seem to appreciate proof and acknowledge its importance in mathematics tend to prioritise development of procedural skills over proof-related activities in their own classrooms (e.g., Kotelawala, 2016).

Nardi and Knuth (2017) suggest that “Orchestrating a focus on proof appreciation requires a change in classroom culture with respect to proof and proving, a change that must start with the teacher”, but it would also require “changing classroom culture, curricula, and instruction” (pp. 268-269). As much as we agree with the authors about the need for change and the critical role of teachers in this process, we are doubtful whether such an overhaul approach to classroom teaching is viable. First, many teachers’ personal experiences with proof as learners and their mental image of what it means to engage students in proving may impede them from enacting reasoning and proving in their classrooms. Thus, the role of teacher preparation and professional development in spearheading changes in classroom instruction is critical. Some positive effects of teacher preparation and professional development programs on classroom teaching have been reported in the literature (see Stylianides et. al., for an extensive summary).

The second, and probably more substantial barrier for classroom integration of reasoning and proving, is found in factors external to individual teachers, but nonetheless critical, such as society, institutions and the culture of schooling (Chazan et al., 2016). Cultural environments dominated by standardized testing, pressure from parents, administrators and other stokeholds; a culture in which a teacher’s success is measured by the number of students passing tests, are less conducive change. In such environments, a teacher may find him/herself navigating a complex system of competing expectations and obligations; with the external pressure contributing to teachers’ reluctance to spend time on proof, instead of “covering” the curriculum.

Towards possible solutions

The problem and its plausible causes described above are not new, and several approaches to address it have been proposed over the years. One, already mentioned, is through teacher education and professional development initiatives aiming to enhance future and practicing teachers’ subject matter and pedagogical knowledge specific to proof, affecting their beliefs about proof, and providing ongoing classroom support for teachers enacting reasoning and proving in their classrooms (see Stylianides et al., 2017 for an overview). Such initiatives often rely on researcher-developed instructional materials that teachers try in their classrooms. These efforts are important as they help move the field towards developing theoretical and practical knowledge for making reasoning-and-proving a reality in mathematics classrooms. Towards addressing this knowledge gap, Stylianides et al., (2017) emphasized the need for theoretically sound and well-defined classroom interventions of short duration that support change of students' conceptions.

Another approach, proposed by Reid (2011), is Proof-Based Teaching (PfBT). As opposed to focusing on teaching proof, the PfBT is a way of teaching mathematics in which the teacher guides students through a carefully designed sequence of exploratory activities in which learners develop and prove mathematical results. The PfBT is akin to problem-solving teaching and inquiry-based learning (Ronis, 2008), but with the emphasis on students deductively proving the conjectures they develop during the exploratory activities. The PfBT approach seems to hold much promise for advancing change in teachers' classroom practices related to proof. Changing the discourse from teaching proof towards proof-based teaching, puts student learning of mathematics in focus, potentially helping to alleviate some of the tensions teachers might associate with proof. Far from being a simple change of rhetoric, the PfBT restores the place of proof and proving in mathematics (Hanna & deVillers, 2012), highlighting its role in production of mathematical knowledge.

The key element of PfBT, which guides the work of teaching, is the use of a *framing theory*. This theory outlines a sequence of definitions, statements, and conjectures that students are expected to discover and prove, to develop well-connected knowledge of particular mathematical content. For example, Reid and Vargas (2019) developed a framing theory for learning the operation on integers, called integer tiles theory (ITT), and enacted a PfBT teaching experiment in a 3rd grade classroom based on it. Although these results are encouraging, the PfBT model in its current form might not be easily extendable to secondary classrooms. The current state of educational research is such that many prominent topics in the secondary curriculum, e.g., quadratic functions, logarithms, trigonometry, analytic geometry, and others, do not have well-developed and well-established instructional theories. The lack of such theories may impede the broad application of PfBT. Thus, additional pathways are needed to promote instruction focused on reasoning and proof at the secondary level. In the next section, we outline Teaching Mathematics via Reasoning and Proof (TMvRP) model, which is close in spirit to PfBT, but does not rely heavily on the existence of established instructional theories.

Teaching Mathematics via Reasoning and Proving (TMvRP)

Our method

Guiding principles of the TMvRP model were gradually developed and formulated while engaging in the multi-year design-based research project in which we designed a special course *Mathematical Reasoning and Proving for Secondary Teachers*, and systematically studied its impact on prospective secondary teachers' (PSTs) knowledge, dispositions and practices specific to reasoning and proof. (Buchbinder & McCrone, 2020). In this course, the PSTs designed four proof-oriented lesson plans and taught them in local schools. The course discussions revolved constantly around the role of reasoning and proving in teaching and learning mathematics, and its usefulness and advantages for student learning. Having the PSTs design four proof-oriented lessons and enact these lessons in local schools aimed to convince the PSTs that (1) it is feasible to integrate reasoning and proving with *any* topic from the secondary mathematics curriculum, and (2) students are capable of learning complex concepts pertaining to deductive reasoning, such as conditional statements, indirect reasoning, and quantification. Through the iterative cycles of implementing and studying this course, the guiding principles of TMvRP models emerged.

The Guiding Principles of TMvRP

Guiding Principle 1: Teaching reasoning and proving must be fully embedded within the existing content of mathematics curriculum. When teachers perceive reasoning and proving as practical and not competing with their curriculum, then there is a chance, they will embrace it in their classrooms.

One of the key aspects that PfBT and TMvRP have in common is the emphasis on school mathematics, which we see as essential in order for teachers to get on board with the model. If teachers perceive reasoning and proving as taking time away from "curricular coverage", they will be reluctant to spend class time on it, sending an implicit message of irrelevancy to students. Thus, we integrated reasoning and proving within the regular mathematics curriculum.

Guiding Principle 2: Emphasis on deductive reasoning as a means to produce and validate mathematical knowledge. Proof-oriented tasks should focus on a small subset of deductive reasoning concepts, at the core of conventional mathematical knowledge.

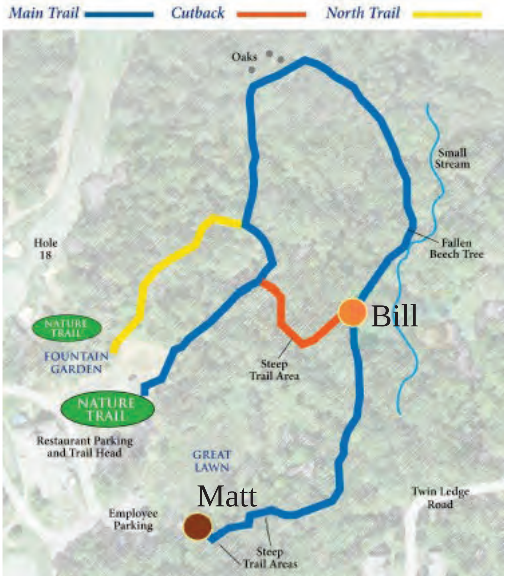
We wanted teachers and students to develop perceptions of reasoning and proving as central to mathematical thinking; processes that help to answer *why* something in mathematics is true (or false). At the same time, in mathematics there are special ways of responding to the question *why*, different from those used in everyday life, sciences, history or other fields. Mathematics requires deductive reasoning, which can be challenging to teach and learn. There TMvRP model allows to address some of the common and persistent proof-related misconceptions (Stylianides & Stylianides, 2017), such as students' overreliance on empirical evidence). Focusing on one such misconception at a time, or on one element of deductive proof can help to maintain the focus on deductive reasoning in the classroom discourse.

Guiding Principle 3: Use language, notation and representations within the conceptual reach of the students. This principle resonates with Stylianides' (2007) definition of proof in school as an argument that uses knowledge, language and representations that are within the conceptual reach of the classroom community. We operationalize this in our TMvRP model by encouraging teachers to *de-emphasize form of the proof* (e.g., two-column or algebra-only) and *avoid unnecessary "logical jargon"* (inverse, contrapositive). Instead, the model encourages multiple proof formats and representations, appropriate to the grade level, to communicate about deductive reasoning.

Illustration of the guiding principles of TMvRP in lesson planning

Following are excerpts of two lesson plans developed and taught by a PST Diane (a pseudonym) in a 9^{th} grade Algebra 1 class. We use these excerpts to illustrate the guiding principles of TMvRP. Lesson plan 1 integrated ideas pertaining the *role of examples in proving* with the mathematical topic of systems of linear equations through a context of the Hiking Exploration Problem (Fig. 1).

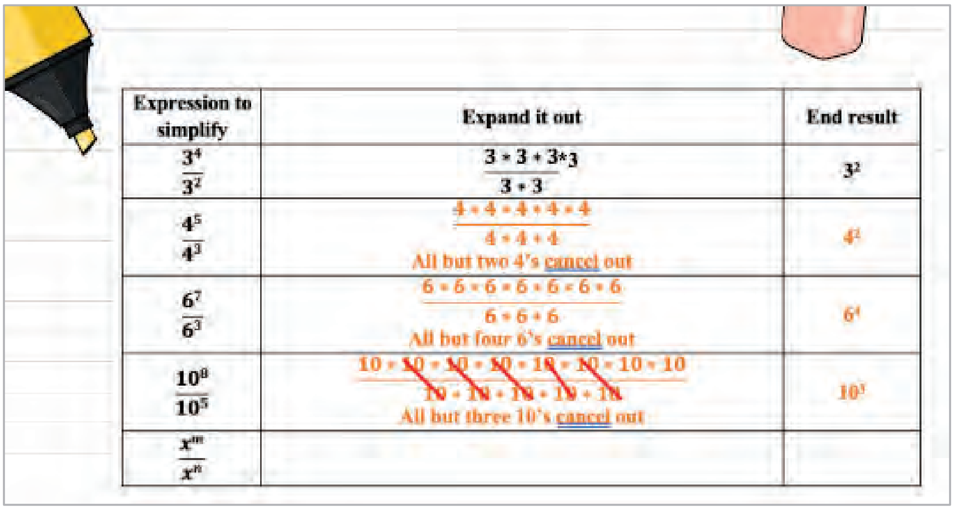
In Lesson 2, Diane integrated ideas about *direct (generic) proof and indirect proof* with the topic of quotient rule for exponents. Diane started by having the students explore patterns of simplifying numeric quotients by expanding the exponents (Fig. 2).



Given a map of a trail with the starting positions of two hikers. Matt starts at the trailhead and walks at a rate of 2 mph; Bill starts 3 miles up the trail and walks at a rate of 1 mile per hour.

1. Represent Matt and Bill's movement along the trail with equations.
2. Find evidence to support or disprove this claim: There exists a time on a 5-hour hike where Matt catches up to Bill.
3. What type of evidence and how much evidence do we need to prove or disprove this claim?
4. Solve the system of equations both graphically and algebraically. What does the solution mean in the context of the problem?
5. Find evidence to support or disprove this claim: Bill is always further ahead on the trail than Matt is.
6. What do we need to show to prove or disprove the claim in #5?
7. Put a point on a graph that represents a counterexample to the claim in #5. What x-value corresponds to it? Use our equations to show algebraically that this x-value is a counterexample.
8. What if the hike was only 2 hours long? Find evidence to support or disprove the claims: (a) There exists a time on the 2 hour hike where Matt catches up to Bill on the trail. (b) Bill is always further ahead on the trail than Matt is.

Figure 1: The Hiking Exploration Problem



Expression to simplify	Expand it out	End result
$\frac{3^4}{3^2}$	$\frac{3 \cdot 3 \cdot 3 \cdot 3}{3 \cdot 3}$	3^2

$\frac{6^7}{6^3}$	$\frac{6 \cdot 6 \cdot 6 \cdot 6 \cdot 6 \cdot 6 \cdot 6}{6 \cdot 6 \cdot 6}$ All but four 6's cancel out	6^4
$\frac{10^8}{10^5}$	$\frac{10 \cdot \cancel{10} \cdot \cancel{10} \cdot \cancel{10} \cdot \cancel{10} \cdot \cancel{10} \cdot 10 \cdot 10}{\cancel{10} \cdot \cancel{10} \cdot \cancel{10} \cdot \cancel{10} \cdot \cancel{10}}$ All but three 10's cancel out	10^3
$\frac{x^m}{x^n}$		

Figure 2: Developing the quotient rule of exponents

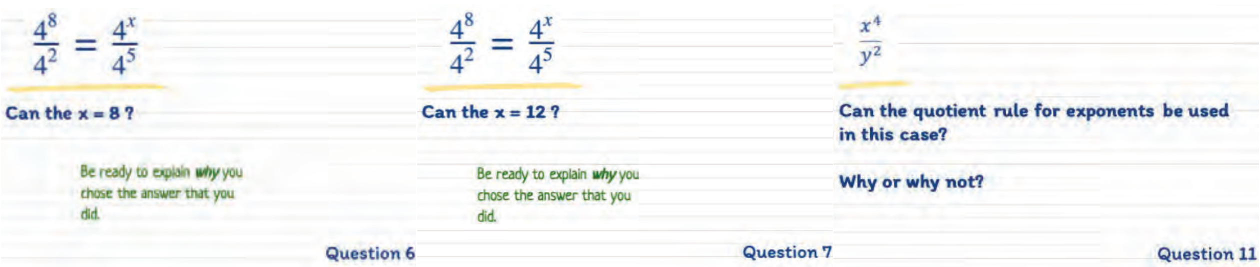

Figure 3: Questions intended for applying indirect reasoning

After students noticed and explained the pattern, Diane guided them through a generic proof (Mason & Pimm, 1984) of the rule. Next, she had students solve a set of tasks, which aimed to test the boundaries of use of the quotient rule (Fig. 3). When solving questions of the type shown in Fig. 3, Diane wanted students to assume that a given x-value is a solution, plug it in and obtain a false statement, which the students would interpret as a contradiction and conclude that the given x-value cannot be a solution. In the lesson plan, Diane wrote: "To summarize the indirect reasoning portion of the lesson, I want to make sure I emphasize that we are finding a contradiction to a statement, and that is why they are false." Note that in the context of this lesson, indirect reasoning has a form: "X cannot be Y, because otherwise we reach a contradiction Z". This does not constitute a proof by contradiction; nevertheless, being enculturated into explicit use of indirect reasoning can help students learn proof by contradiction at a later stage.

The two lessons clearly differ from each other. In the first lesson on the *role of examples in proving* students learned when it is appropriate to use examples to prove existential statements and counterexamples or disprove a universal statement in the context of solving a word problem. The second lesson on *indirect reasoning* did not rely on a real-world context, but it included exploring patterns, conjecturing, using direct generic proof of the quotient rule of exponents. The indirect reasoning came naturally, in the context of testing the boundaries of the quotient rule.

The outlines of these two lesson plans illustrate the guiding principles of TMvRP. First, reasoning and proving are fully integrated with the ongoing topic of the school curriculum. Proof concepts such as generic proof, indirect reasoning, role of examples in proving, and universal and existential statements support the learning of solving systems of equations and of exponent rules. Second, the mathematical topics provide a platform for the teacher to emphasize elements of deductive reasoning in ways that align naturally with the task. The teacher introduces students to the use of deductive reasoning in conventional mathematical ways, e.g., using supportive examples to prove existential statements and counterexamples to disprove universal statements. Third, while the teacher uses precise mathematical language throughout the lesson, she uses language within the students' conceptual reach and makes clear choices about what proof-related vocabulary is or is not critical for students in that lesson. For example, in lesson 1 Diane explained to students what a counterexample is and its role, but in lesson 2 she decided not to introduce the concept of indirect reasoning. In her lesson plan she wrote: "I don't think that using the words "indirect reasoning" is going to be particularly helpful to them [the students]." Regardless of whether we agree with Diane's choice, this example illustrates how a teacher makes instructional decisions regarding their own classroom and adjusts the language and representations to fit the students' perceived conceptual level, while introducing students to the deductive reasoning aligned with conventional mathematical practices.

Conclusions and Future Directions

In the extensive review of the research literature, Stylianides et al., 2017 observe a disproportionally larger number of studies describing difficulties related to teaching and learning of proof compared to studies seeking to address them. The line of research on research-based classroom interventions is gradually emerging, and with it some novel approaches to integrating reasoning and proving in classrooms, e.g. Reid's (2011), and Reid and Vargas' (2019) Proof-Based Teaching framework. In this theoretical paper, we discussed some of the barriers to such integration, some having to do with individual teachers and others reaching beyond to institutional, cultural and societal factors. The analysis of these factors motivated our design-based research project in which we worked to support and empower PSTs to enact reasoning and proving in mathematics teaching. Through this project, we developed the guiding principles for the Teaching Mathematics via Reasoning and Proof (TMvRP) approach: (1) Full curriculum integration, (2) Incremental and continuous emphasis on deductive reasoning, and (3) Adjustment of language, notation and representations to students' conceptual level.

We believe that instructional activities developed in accordance with these principles have a potential to position reasoning and proving as vehicles for learning mathematical content, making these processes appealing and manageable for both teachers and students. The PSTs in our course had four opportunities to apply the guiding principles of TMvRP to their lesson planning and teaching, as the examples of Diane's lesson plans show. Although some PSTs remained skeptical, the overwhelming majority of PSTs developed greater confidence in their ability to enact reasoning and proving in their classrooms. At the same time, we are mindful that the motivation for integrating proof in the lesson plans was external to PSTs as it was a course requirement. Thus, the question to what extent the TMvRP principles became part of their own teaching repertoire remains open. Hence, our new project focuses exactly on that: We follow the graduates of our mathematics education program into their supervised internship and the first two years of autonomous teaching to examine how (if at all) they continue integrating reasoning and proving into their teaching of mathematics. We hope that other researchers will be inspired to test TMvRP principles with prospective and/or practicing teachers to expand the research base behind this approach.

Toulmin and beyond: structuring and analyzing argumentation

Jenny Cramer[1] and Leander Kempen[2]

[1]University of Bremen, Bremen; j.cramer3@schule.bremen.de

[2]TU Dortmund University, Germany; leander.kempen@tu-dortmund.de

In recent years, the Toulmin model seems to have become a "silver bullet" when analyzing argumentation (and proof) in mathematics education. While the model and its adaptations are well-fitted especially to reveal the structure of arguments, it is not suitable to grasp all aspects of argumentation which are relevant to the mathematics classroom. In this paper, we outline both, possibilities and limitations of the Toulmin model and present some additional considerations concerning this model undertaken in the last decades. Furthermore, we present and discuss some alternative approaches to argumentation and highlight their additional benefits.

Keywords: Argumentation, Toulmin model, Rationality, Logic of inquiry, Walton's dialogue theory

Introduction

In this article, we would like to follow up on a question that arose in the context of the TWG Argumentation and Proof at CERME11: Which models can be used besides the Toulmin model to analyze (mathematical) argumentation? Indeed, the Toulmin model has proven and established itself for structuring and presenting argumentation processes in a mathematical context. However, the associated disadvantages and 'blind spots' of the model are often ignored or disregarded. Moreover, the model appears to be so widespread that young researchers in particular fail to identify alternatives that might be better suited to address their research questions.

Our first aim in this article is to show which possibilities the original Toulmin model offers for structuring mathematical argumentation processes, which advantages and disadvantages are associated with it, and which conceptual extensions of the model are discussed in mathematics education. Furthermore, we would like to discuss other perspectives on argumentation that go beyond structural analysis and present alternative approaches to investigating argumentation.

The Toulmin-Model

Toulmin (1958) proposed a model for structuring argumentation in general. Inglis et al. (2007, p. 4; emphasis in original) summarize this scheme as follows (see also Figure 1):

> Toulmin's (1985) scheme has six basic types of statement, each of which plays a different role in an argument. The *conclusion* (C) is the statement of which the arguer wishes to convince their audience. The *data* (D) is the foundations on which the argument is based, the relevant evidence for the claim. The *warrant* (W) justifies the connection between data and conclusion by, for example, appealing to a rule, a definition or by making an analogy. The warrant is supported by the *backing* (B) which presents further evidence. The *modal qualifier* (Q) qualifies the conclusion by expressing degrees of confidence; and the *rebuttal* (R) potentially refutes the conclusion by stating the conditions under which it would not hold.

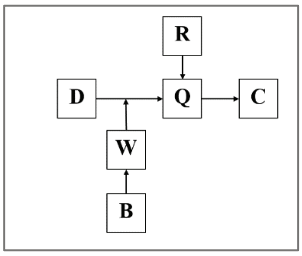

Figure 1: Toulmin's model of a general argument (similar to Inglis et al. (2007, p. 4))

As Nussbaum (2011, p. 86) points out, Toulmin did not originally intend to propose a model of argument. He originally wanted to counter formal logic with an alternative foundation for argument. Nevertheless, the model has been misinterpreted as normative. Toulmin was not concerned with the completeness of arguments, for example, to evaluate their quality. Especially in non-mathematical contexts, the warrants are often not made explicit. Nor was it Toulmin's concern to use the model to teach students how to propose an argument. It has been shown that the Toulmin model can be used to reveal argumentation structures in mathematical contexts (e.g., Inglis et al., 2007; Knipping, 2008). Here, the Toulmin model is often reduced to the somehow core aspects of Data, Warrant, and Claim. However, as stressed by Inglis et al. (2007) and Jahnke (2008), the whole model should be preferred to cover essential aspects of argumentations such as the backing, which specifies the warrant, or likewise the modal qualifier that serves to qualify the conclusion.

Limits of the Toulmin model and opening a discussion

The Toulmin model has its benefits when trying to reveal an argument's structure. However, some limitations of the model have to be considered, too. On the structural level, Nussbaum (2011, p. 86) discusses that in some situations, a reliable distinction between warrant and backing is hard to undertake, and there are some arguments in real life (such as arguments with a number of separate reasons) that do not fit the components and structure of the model. Aberdein (2013) criticizes that the Toulmin model is weak for the representation of instructions which may be part of mathematical arguments in particular. Due to its structural-analytical orientation, the model is less suitable for highlighting how people argue and why, and there is no focus on the correctness of arguments or their acceptance by others. In a collective argumentation setting, the Toulmin model does not specify who produces (parts of) the argument, and the context is not taken into consideration.

The Toulmin model furthermore does not capture the way in which an argument is presented to an audience, although as Gabel and Dreyfus (2019) show with regard to Perelman's new rhetoric, the audience is a major factor in proof teaching. This holds true not only in situations in which a teacher guides the argumentation, but also in collective argumentation settings. Motives and reasons with which intention which person contributes which reasons with which rhetoric are not part of the Toulmin model's structural focus but they are of importance when looking at argumentation and proof in the mathematics classroom.

Extensions of the Toulmin model

Inglis et al. (2007, p. 9–16) distinguish several warrant-types as categories of warrants with similar properties. In an argumentation, the check of some concrete examples or an apparent absence of a counterexample for the statement in focus might reduce the uncertainty about the conclusion of an argument. Such warrants are considered the *inductive warrant type* and might typically lead to modal qualifiers like "it seems that" or "it is plausible that". The *structural-intuitive warrant-type* is about using some kind of observation (it might be of an intuitive type or not) that might persuade the individual to accept the validity of a conclusion. Again, corresponding modal qualifiers might be "it seems that" or "it is plausible that". Finally, the deductive warrant-type is concerned with those warrants used in a valid mathematical proof (axioms, statements, algebraic manipulations, etc.). For professional mathematics, using a *deductive warrant* should normally lead to a modal qualifier like "with necessity". However, it has been shown in the literature that this need not be the case for students (see Reid & Knipping 2010, p. 62 for an overview). Kempen (in press) analyzed high school graduates' proof construction and extended the discussion of the oberserved warrants by the aspect of epistemic value. "The epistemic value is the degree of certainty or conviction assigned to a proposition" (Duval, 1991, p. 254; authors' translation). Accordingly, it can take on values such as obviously, likely, absurd, necessary, etc., and it is closely connected to the individuals' understanding of the content (Duval, 2007, p. 138). This extension is based on the idea that a warrant is linked with an individual level of conviction and validity. Kempen showed that the epistemic values attributed to the warrants involved have an impact on the conclusion's modal qualifiers.

Besides focusing on a single argument leading from data to conclusion, it is also possible to consider longer chains of arguments. Here, a conclusion becomes new data for the application of further warrants. Such chains of arguments have been described as "argumentation stream" (Knipping & Reid, 2019), "Recyclage" (Duval, 1995), or "Sequential" (Aberdein, 2006).

The Toulmin model is not only used as a tool to explore the local structure of an argument, but also its global structure (the structure as a whole) as described by Knipping and Reid (2019) when discussing classroom argumentations. In their analysis of global argumentation structures which transcend individual arguments, these authors added an element called "refutation" and explain:

> A refutation completely negates some part of the argument. In a finished argumentation refuted conclusions would have no place, but as we are concerned with representing the entire argumentation that occurred, it is important for us to include refutations and the arguments they refute, as part of the context of the remainder of the argumentation, even if there is no direct link to be made between the refuted argument and other parts of the argumentation. (Knipping & Reid, 2019, p. 5)

When analyzing complex arguments, e.g., when different people contribute to an argument, it has been valuable to use a schematic representation that enables the description of argumentation at different levels of detail, like using different shades, colours, or forms (see Knipping, 2003). Knipping and Reid (2013) show how teacher actions can shape argumentation processes in the mathematics classroom by identifying different global argumentation structures. They distinguish differently structured discourses that become visible in the shape of the global argumentation structure and thereby show how the Toulmin model may add to a deeper understanding of classroom interaction.

Kopperschmidt (1989) also links the local and the global structure by analyzing the micro and macro structures. The micro structure contains the *functional* analysis (role and functions of the different parts involved in an argument with respect to the Toulmin model), the *material* analysis (linguistic interaction), and the *formal* analysis (structural patterns involved). At the macro level, a distinction is first made between single-step and multi-step argumentation. Here, a multi-step argumentation can be convergent (all elements involved fully support or refute a particular claim) or controversial (the elements involved only partially support or refute a particular claim).

Further models and ideas for considering argumentation

In the following, we will present and discuss other perspectives on argumentation that enable further aspects and views on the topic and thus open up new perspectives for corresponding analyses. A comprehensive overview on developments and different perspectives in argumentation theory in general may be found in Van Eemeren et al. (2014). In selecting the perspectives listed below, we have tried to choose those that have experienced a certain spread in mathematics education and exemplarily focus on various aspects of argumentation beyond structure considerations.

Considering the purpose of argumentation: communicative versus strategic action

Arzarello and Soldano (2019) criticize the jurisprudential nature of the Toulmin model. According to them, in the type of argument considered by Toulmin "the goal is to convince the adversary, not the search/explanation of the truth, which is instead the goal of scientific argument, in particular in mathematics." (Arzarello & Soldano, 2019, p. 227). We do not necessarily share this criticism of the Toulmin model as being too narrowly focused on jurisprudential arguments. However, Arzarello and Soldano's critique raises an important issue: it might be necessary to consider the purpose of an argumentation when looking at argumentation in a classroom context.

One way to distinguish between different purposes in which argumentation may play a role is described by Habermas (1981). He postulates a distinction between two different types of action: communicative action towards reaching agreement, and strategic action focused on securing consent.

> Moreover the action theoretical approaches [i.e. communicative vs. strategic action] differ in whether for coordinating actions they postulate *agreement* [german: „Einverständis"; authors' comment], that means *common* knowledge [german: „gemeinsames Wissen"; authors' comment], or just an external *influence* [german: „Einflussnahme"; authors' comment] on another. "Common" knowledge needs to satisfy challenging conditions. It is not enough if participants share some opinions; not even if they know that they share those opinions. *Common* knowledge is a knowledge that constitutes *agreement*, while agreement terminates in the intersubjective recognition of criticisable claims. Agreement means that participants accept knowledge as valid, i.e. intersubjectively binding. […] The external exertion of influence (in the sense of a causal effect) on the convictions of another participant in the interaction, on the other hand, keeps a one-sided character. (Habermas, 1981, p. 574–575; emphasis in original; authors' translation)

Mathematical argumentation should be a conjoint search for the truth and thus oriented towards reaching common knowledge. However, it is doubtful whether all classroom situations fulfil these noble goals. A study examining the prevalence of communicative and strategic behaviour in the classroom might provide interesting insights.

Within Habermas' framework of communicative action, Boero (2006) identified the construct of rationality as an especially useful tool for grasping the complexity of a classroom situation. Boero (2006, p. 189–190; emphasis in original) paraphrases Habermas' perspective on three types of rationality:

> The *epistemic rationality* is related to the fact that we know something only when we know why the statements about it are true or false (otherwise our knowledge remains at an intuitive or implicit-pragmatic level). […] The *teleologic rationality* is related to the intended character of the activity, and to the awareness in choosing suitable tools to perform the activity and orient it to the aim to be achieved. The *communicative rationality* is related to communication practices in a community whose members can establish communication amongst them.

This threefold view on classroom situations shows that there is more to argumentation than its mere structural components. An individual or a group of individuals producing a mathematical argument need an awareness of shared knowledge which they can presume, they need to choose their tools and strategies wisely, and they need to choose means of communication which can be understood by other participants in the argumentation. Thus, rational behaviour presupposes an orientation towards communicative action.

Boero et al. (2010) have shown how supplementing the structural analysis of argumentation with the Toulmin model with Habermas' perspective on rationality opens up the possibility to consider a speaker's intentions and consciousness within the argumentation. Whether an argument is accepted by a community or not is not simply defined by its logical soundness, its correctness, or its adherence to a certain structure. To put it in a different way: What counts as proof in a 5th year classroom may differ significantly from what is considered an acceptable proof at university level. This is captured well in a quote from Habermas highlighted by Boero and Planas (2014, p. 205): "The rationality of a judgment does not imply its truth but merely its justified acceptability in a given context". Looking at argumentation from an epistemic, a teleological and a communicative perspective simultaneously may help us understand more about how an argument becomes a foundation of newly established common knowledge.

"Logic of inquiry" to account for discoveries in argumentation

Arzarello and Soldano (2019) point out that a perspective on argumentation with a narrow focus on deductive reasoning cannot account well for surprising discoveries. They refer to an example from the story *Silver Blaze* by Sir Arthur Conan Doyle. In this story, the fictional detective Sherlock Holmes concludes that a missing horse had not been stolen as assumed, but had indeed been taken by the stable owner, because the watch dog had not barked in the night. To account for the arising of such new theories and conjectures, Arzarello and Soldano introduce Hintikka's "logic of inquiry", to which they ascribe three characteristics: (i) the dialectic between questions and answers; (ii) the deep link with game theory; (iii) the functional interpretation of connectives and quantifiers (Arzarello & Soldano, 2019, p. 230).

According to the logic of inquiry, deductions such as the one made by Sherlock Holmes in the story can be rewritten into a chain of questions and answers. The argumentation is guided by definitory rules framing the deductive steps on the one hand, and by strategic principles generating the inquiry steps on the other hand. This interplay of rules and strategies forms a connection to game theory. Arzarello and Soldano (2019) show how mathematical proving processes can be regarded as (semantic) games. They introduce an example from a mathematics classroom in which students fulfil roles as verifiers or falsifiers in their joint search for the truth. In this model, the existence of a proof is tantamount to the existence of a strategy with which the verifier will always win.

Teaching and evaluation of argumentation: Walton's Dialogue Theory and a Bayesian approach to argument evaluation

Nussbaum (2011, p. 85) points out that argumentation models may serve three different purposes: analytical (with a focus on revealing the structure of an argument), normative (for judging an argument's quality or to determining what an argument should look like), and descriptive (to identify how people actually argue). He points out that the Toulmin model is primarily analytical, even though its components are not always clearly identifiable. Besides, also the adaptations towards the representation of global argumentation structures by Knipping (2003) serve a descriptive purpose. However, normative aspects are not covered by the Toulmin approach. Nussbaum (2011) therefore suggests two alternative frameworks for looking at argumentation in educational contexts: Walton's Dialogue Theory and Bayesian models of everyday arguments. In this contribution, we only take the former into consideration. The Bayesian model works with probabilistic calculations to help determine posterior odds; it does not help in evaluating mathematical arguments whose premises are usually either correct or incorrect.

Walton's Dialogue Theory, according to Nussbaum (2011), is a complex argumentation framework consisting of several levels: types of argumentation dialogues, specific argument schemes and critical questions, degrees of plausibility, and criteria for moral and aesthetic argumentation. Due to the limited space in this contribution, we focus on two aspects which appear particularly promising to address the shortcomings of the Toulmin model laid out above: argumentation schemes and posing critical questions, which may be applied both to the instruction and evaluation of argumentation.

One way to improve students' argumentation skills could be direct instruction in how to use different argumentation schemes. This has been a strategy in mathematics education, e.g. when teaching students two-column proofs or methods for proving by induction. However, while students might benefit from a scheme on which they can rely, it has been criticized in the past that students tend to apply such schemes without a deeper understanding of why the proof they are creating is, in fact, a proof. Regardless of whether argumentation schemes are explicitly taught to students, they can also serve to evaluate argumentation quality.

A second possible application of Walton's Dialogue Theory, according to Nussbaum (2011), is to use direct instruction on critical questions and *stratagems* useful for argumentation. "A stratagem is a generic type of brief argument expressed in discourse [such as…] I think [POSITION] because [REASON]" (Nussbaum, 2011, p. 93). Both, critical questions and stratagems, serve to inform students of evaluative criteria, which may in turn serve to assess argumentation quality from a teacher or researcher perspective.

Besides schemes and critical questions, Nussbaum (2011, p. 94) also presents a list of criteria for the assessment of argument quality. However, several criteria on the list appear ill-fitted for the mathematics classroom, as they rely on an assessment of the depth of a discussion. The quality of a mathematical argument is not necessarily dependent on the number of arguments brought forth, or by how many of the arguments brought forth were defeated. A closer look at Walton's schemes may, however, be beneficial also for evaluating and assessing mathematical argumentation with regard to quality.

Conclusion: Widen the scope – there is more to arguments than structure

We started out from the question "Which models can be used beside the Toulmin model to analyze (mathematical) argumentation?". Our thorough consultation of alternative approaches to and perspectives on argumentation primarily shows the necessity of specifying the question further: *what exactly do we want to analyze? I.e., what is the focus and the purpose of our research?* The Toulmin model can be suitable or well-fitted to reveal the structure of an argument. This approach, however, makes the structure of an argument (in Toulmin's sense) visible; no more, no less.

As we have seen above, there are several attempts to extend the traditional Toulmin model to gain more information about the different parts involved in the model. Besides, also the connections between these parts have been (theoretically and empirically) analyzed further. It is, however, important to notice that an analysis of the different parts of an argumentation's structure does not imply any information about the soundness of the argumentation steps, the plausibility for the participants in the argumentation, or the generation of common knowledge.

In this paper, other aspects that might be focused on when discussing argumentation became visible that go beyond the (original) intention of the Toulmin model. These aspects can be described as considering the purpose of an argumentation (communicative versus strategic action), accounting for discoveries in the course of the argumentation, and the discussion and conceptualization of normative aspects and educational purposes.

From our point of view, we want to highlight the following conclusions. For structural analysis of the different parts of argumentation, we have not yet discovered a more suitable model than the Toulmin model with its extensions. However, a danger must also be pointed out here: If argumentation is theoretically defined according to the Toulmin model's structural components, the Toulmin model becomes the sole instrument of analysis. One should beware of this redundant relationship because it obscures the view of a field of research that, as we have shown here, is quite broad. Argumentation in the mathematics classroom is more than the sum of its (structural) parts. It involves awareness, validity, intentions, strategies, questions, rhetoric and rationality.

We have tried to broaden the view of the research field of argumentation in mathematics education. The examples we have chosen and brought up are well suited to point out horizons for further research on the topic.

The role of unitizing predicates in the construction of logic

Paul Christian Dawkins[1] and Kyeong Hah Roh[2]

[1]Texas State University, San Marcos, Texas, USA; pcd27@txstate.edu

[2]Arizona State University, Tempe, Arizona, USA; khroh@asu.edu

Based on data from a teaching experiment with two undergraduate students, we propose the unitizing of predicates *as a construct to describe how students render various mathematical conditions as predicates such that various theorems have the same logical structure. This may be a challenge when conditions are conjunctions, negative, involve auxiliary objects, or are quantified. We observe that unitizing predicates in theorems and proofs seemed necessary for students in our study to see various theorems as having the same structure. Once they had done so, they reiterated an argument for why contrapositive proofs proved their associated theorems, showing the emergence of logical structure.*

Keywords: Mathematical logic, Student reasoning, Undergraduate mathematics education.

Introduction

Theorem 1. "For every integer x, if x is a multiple of 6, then x is a multiple of 3."

Theorem 2. "For any integer x, if x is a multiple of 2 and a multiple of 7, then x is a multiple of 14."

Theorem 3. "For any quadrilateral $\blacksquare ABCD$, if $\blacksquare ABCD$ is a rhombus, then the diagonal $\overline{AC}$ forms two congruent, isosceles triangles ΔABC and ΔCDA."

Theorem 4. "Given any functions f, g that are continuous on the domain $[a, b]$, if $f(a) = g(b)$ and $f(b) = g(a)$, then there exists some c in $[a, b]$ such that $f(c) = g(c)$."

In what ways would we expect students to see these four statements as being "the same"? How would that sameness influence students' reasoning about these statements and related proofs? This is a contextual way of considering the role of logic in students' mathematical reasoning, since the primary analogy between these statements is their logical form: "For all $x \in S$, if $P(x)$, then $Q(x)$." In this study, we investigate how students build such analogies between statements and how it influences their judgments about contrapositive proofs. We propose *the unitizing of predicates* as a construct that describes how students conceptualize the various properties in the statements as entailing properties that each example either has or does not have. This affords a structural analogy between each statement and the corresponding set of objects, which can unify these statements across the mathematical contexts. We provide evidence for how unitizing predicates can be consequential for how students perceive logical structure within each context in the sense of truth conditions (when a statement is true or false) and related types of proof (i.e., direct or contrapositive).

While many studies show that students do not interpret common mathematical statements in a manner compatible with mathematical logic (Epp, 2003; Sellers, Roh, & Parr, 2021; Stylianides, Stylianides, & Phillipou, 2004), our approach to logic learning is to help students construct mathematical logic as they read meaningful mathematical statements. We do not try to use abstract symbols to replace the meaning of statements, which bypasses students' reasoning about the concepts in the statements. Rather, we conducted constructivist teaching experiments (Steffe & Thompson, 2000) to investigate an alternative approach in which students structure their interpretation of each statement (and their proofs) in a manner that affords structural analogies and repeated reasoning. In their survey of research on the teaching and learning of logic, Durand-Guerrier, Boero, Douek, Epp, and Tanguay (2012) argued that "it is important to view logic as dealing with both the syntactic and semantic aspects of the organization of mathematical discourse" (p. 385). To attend to both, logic must capture how Theorems 1-4 refer to mathematical objects, rather than merely how to remove meaning from the statements to render them "the same." The present study contributes to answering the following research question central to our overall agenda of research: How can students abstract logical structure and relationships in a manner that stems from and integrates with their reasoning about various mathematical topics? We propose that *unitizing predicates* provides a construct that characterizes how students can abstract the semantic structure of their mathematical reasoning about particular statements to afford the construction of logical structure that generalizes across contexts.

We focus in this report on a student constructing the principle of *Contrapositive Equivalence*: Contrapositive proofs, which begin "Let not $Q(x)$" and end "Thus, not $P(x)$", prove the given theorem. To understand how students attended to this form of proof and its invariant relationship to the theorems, we designed the theorems they read (which included Theorems 1-4) to vary the relationship between objects and properties in each statement. If we conceptualize a predicate as a truth-function that maps each object to a truth value ("T" if the object has the property or "F" if the object does not), then we can see how the predicates in the statements vary. Both properties in Theorem 1 are somewhat familiar and direct such that the predicate corresponds to a single category of numbers. The antecedent in Theorem 2 is a conjunction, meaning students must somehow combine the properties to yield a single predicate. The consequent in Theorem 3 involves auxiliary objects (triangles), which we may think of as rendering the predicate as a composition of functions (or mental actions). Finally, Theorem 4 is the most complex in that the input consists of pairs of functions, the antecedent is a conjunction, and the consequent is existentially quantified.

Literature on student understanding of conditionals and proof thereof

The mathematical use of conditional statements differs from the everyday meaning. One of the best-supported models for everyday interpretation is the suppositional account that posits people affirm a conditional based on the conditional probability of Q given P (Evans & Over, 2004). This means that people affirm some conditionals in the presence of counterexamples and explicitly think such statements are only about cases where P is true. Inglis (2006) found that mathematicians used a similar criterion, though they sought to know whether Q was certain given P, meaning no counterexamples were allowed. Two important corollaries of this are that the meaning of a conditional is strongly rooted in the meaning of the statement and the semantic links between P and Q. As a result, semantic links are hard to generalize across the statements above since they are context-specific, so to construct logic, students must attend to something more about the conditionals.

There are few studies on how students understand contrapositive equivalence. Stylianides et al. (2004) found that students directly taught the rule often gave answers in conflict with it, especially in mathematical contexts. Yopp (2017) provides one of the only accounts for how students should understand why contrapositives are equivalent. He argues that students should interpret conditionals by *eliminating counterexamples* (cases where P is true and Q is false), similar to how Inglis noted mathematicians reasoning. This supports both an explanation for why direct proofs prove and why contrapositive proofs prove, since a counterexample of the contrapositive statement is equivalent to a counterexample to the original. Hub and Dawkins (2018) observed a student providing a different justification rooted in the subset meaning, which states that a conditional is true whenever the truth set of P is a subset of the truth set of Q. Their student argued for contrapositive equivalence by noting that non-Q cases have no overlap with P cases, which they called the *empty intersection meaning*.

Theoretical framing

Consistent with our interest in how students construct logic as a shared structure across various mathematical statements, we conducted our study using the Radical Constructivist (von Glasersfeld, 1995) notions of assimilation and accommodation. Assimilation occurs when someone interprets a new experience as an instance of something known. Assimilation occurs in the context of goal-oriented activity, and assimilating to a scheme induces some action with an expectation to meet the reasoner's goal. When the goal is not met or something unexpected occurs, the reasoner may experience perturbation and thus engage in accommodation to assimilate the experience to a new scheme or modify the scheme to fit the new experience. This is often the opportunity for learning. Accommodation is often prompted by interlocutors (i.e., teachers) who introduce goals and prompt reflection on previous activities. In particular, we frequently asked the two students in our teaching experiment to compare their reasoning across various theorems and proofs and invited them to repeat their reasoning if possible. Such questions invited them to accommodate so as to construct a shared structure between the theorems and proofs, so as to promote reflexive abstraction by which they could project their images of their own activity onto a higher level where they could re-present the shared structure across the statements and proofs, which would for us constitute logical understandings.

Our notion of *unitizing predicates* is inspired by the work of Steffe (1983) and his colleagues in modeling students' construction of number concepts. They use *unitizing* to describe how children operate on quantities (counting or partitioning) to create new quantities (10 or 1/5) that are simultaneously a new unit and in fixed relation to the original unit (1). We can think of this as closure of numeric units under certain transformations. We use unitizing predicates to describe how students interpret the conjunction of predicates (Theorem 2), the composition of predicates (Theorem 3), and quantified predicates (Theorem 4) as new predicates with the same structure as simple predicates (Theorem 1). We call this unitizing predicates, since it is a form of closure under mental operations.

Methods

The teaching experiment reported here is part of an ongoing sequence of experiments focusing on how students can construct logic by reflecting on their mathematical activity. The participants, whom we call April and Moria, were recruited from a Calculus 3 (multi-variable and vector calculus) course at a public university in the United States. We recruited such students since we anticipated their mathematical understandings would be sufficiently strong, they would not have learned logic before, and they might go on from this course into a proof-based course (depending on their degree program). To further affirm these criteria, we asked them whether they had learned logic and had them complete a logic assessment (Roh & Lee, 2018). April and Moria were computer science majors at the time of participation. We met with them once per week outside of class time for 1-1.5 hours and paid them modestly for their time. We met with April and Moria for six sessions during which they read eight theorems, each paired with 2–4 proofs. Their task in each case was to determine whether each proof proved the statement and, if not, what statement it proved.

Consistent with teaching experiment methodology (Steffe & Thompson, 2000), the first author served as the teacher/researcher and the second author as an outside observer. All sessions were video recorded for iterative and retrospective analysis. During each session, we sought to build second-order models of their reasoning and test those models through questioning. This occurred at multiple levels such as meaning for concepts, construal of proofs, attention to logical structure, etc. Once Moria introduced Euler diagrams to represent the sets of objects referred to in each theorem/proof, we consistently invited the students to produce such diagrams. We hoped such activity would support relating the structure of different statements and re-presenting the logic of conditionals.

For this paper, our analysis focused on the students' construction of analogies between the statements and proofs. We attended to cases when they compared or contrasted theorems/proofs and for the opportunities to assimilate different theorem/proofs that shared the same logical structure (according to mathematical logic). This allowed us to attend carefully to their assimilation and accommodation activity and the particular means by which they connected theorems and proofs across contexts.

Results

We focus in this paper on April and Moria's reasoning about three proofs by contraposition, which proved Theorems 1, 3, and 4 stated above. April and Moria read these proofs during the first, fourth, and sixth sessions, respectively. For brevity, we provide only two of the proofs below in Figure 1 and omit the definitions students saw. "Proof 1.3" denoted the third proof associated with Theorem 1.

Proof 1.3

Regarding Proof 1.3, April produced her first argument for why a contrapositive proof did prove, to which we hoped she might assimilate later such proofs. Based on April's reading of Proofs 1.1 and 1.2, it was clear that she understood that all multiples of 6 are multiples of 3, but that some multiples of 3 were not multiples of 6. Upon reading Proof 1.3, April responded, "I think this is proving the theorem because it's saying if it's not a multiple of 3, then it can't be a multiple of 6." She elaborated in the context that "Because I already know that you have to have 3 times 2 times something to be a multiple of 6… Without being a multiple of 3, it's never going to equal a multiple of 6." She elaborated this argument relative to the proof saying, "Everything that you throw into it is going to give a remainder, how it's set up… you've already eliminated the fact that there's ever going to be a 3 in this, so it just doesn't formulate. It's like making a cake without the flour or the sugar."

We see a few important aspects of April's reasoning that are worth describing in some detail. First, her meaning for "multiple of d" was to factor out a d in an algebraic expression. Hence, she recognized that being a multiple of 6 entailed being "3 times 2 times something." Her meaning for multiple of 6 entailed her meaning for multiple of 3, inducing a sense of necessity between them.

Second, she gave a meaning to the negation of "multiple of 3" in terms of "give a remainder" which she could connect to the various equations in Proof 1.3. We have found that students often want to substitute a positive description for a negative predicate, which greatly facilitates their reasoning. April unitized the negation by giving it a positive meaning.

Third, based on the suppositional account of everyday conditionals (Evans & Over, 2004), we may expect students to think Proof 1.3 is irrelevant to Theorem 1 because it is not about multiples of 6. April explained how not being a multiple of 3 justifies the theorem using the analogy to ingredients. Since the factored out 6 is composed of a 2 and 3, then to try to make a 6 without a 3 is "like making a cake without the flour or the sugar." This argument implicitly draws upon the *empty intersection meaning* in that it shows no number can both be a non-multiple of 3 and be a multiple of 6.

Theorem to be proven 1: For every integer x, if x is a multiple of 6, then x is a multiple of 3.

Proof 1.3: Let x be any integer that is not a multiple of 3.
That means when we divide x by 3, we get a remainder of 1 or 2.
Then there exists some integer k such that $x = k * 3 + 1$ or $x = k * 3 + 2$.
If k is even, then there exists some integer s such that $k = s * 2$.
Substituting into the equations for x, we see:

$$\begin{aligned} x &= (s * 2) * 3 + 1 \\ &= s * 6 + 1 \end{aligned}$$

or

$$\begin{aligned} x &= (s * 2) * 3 + 2 \\ &= s * 6 + 2. \end{aligned}$$

This means x is not a multiple of 6, because x is 1 or 2 greater than a multiple of 6.
If k is odd, then there exists some integer t such that $k = t * 2 + 1$.
Substituting into the equations for x, we see

$$\begin{aligned} x &= (t * 2 + 1) * 3 + 1 \\ &= t * 6 + 4 \end{aligned}$$

or

$$\begin{aligned} x &= (t * 2 + 1) * 3 + 2 \\ &= t * 6 + 5 \end{aligned}$$

This means x is not a multiple of 6, because it is 4 or 5 greater than a multiple of 6.

Theorem to be proven 3: For any quadrilateral $\blacksquare ABCD$, if $\blacksquare ABCD$ is a rhombus, then the diagonal $\overline{AC}$ forms two congruent, isosceles triangles ΔABC and ΔCDA.

Proof 3.3: Let $\blacksquare ABCD$ be a quadrilateral such that when we form the diagonal $\overline{AC}$, the triangles ΔABC and ΔCDA are not both isosceles and congruent.
This means either the triangles are not isosceles, not congruent, or both non-isosceles and non-congruent.
If the triangles are not isosceles, that means that none of their sides are congruent.
This means $AB \neq BC$, which means $\blacksquare ABCD$ is not a rhombus.
If the triangles are not congruent, that means at least one pair of corresponding sides are not congruent.
Clearly, $AC = CA$, so it must be the case that $AB \neq CD$ or $AB \neq DA$.
In both cases, $\blacksquare ABCD$ is not a rhombus.
Therefore, $\blacksquare ABCD$ is not a rhombus.

Figure 1: Theorems 1 and 3 and their contrapositive proofs.

Proof 3.3

Proof 3.3 was the second proof by contraposition that April and Moria read in a new mathematical context and with a more complex predicate in the conclusion. It provided our first opportunity to see whether April would assimilate this proof to her prior argument affirming proof by contraposition. She did not do so initially, but later accommodated once she had unitized predicates relevant to the theorem and developed a strong sense that being a rhombus entailed the theorem's conclusion.

By the time April and Moria read Theorem 3 and its proofs, they had introduced Euler diagrams and the interviewer asked them to produce such diagrams for each proof to portray the relationships between the sets of objects discussed. April and Moria recognized there were two relationships in the early theorems: one set was "nested" in another (proper subset) and one was "nested and exhaustive" in the other (equal sets). Both of these are compatible with the subset meaning for the truth of a conditional, which we intended for them to develop.

Theorem 3 was the first task we introduced with a highly unfamiliar property. After reading Proof 3.1 (Direct Proof), April summarized it saying, "It proves why a rhombus is an isosceles." April thus used the term "isosceles" to stand for the antecedent condition in the theorem. In discussing Proof 3.2 (Disproof of Converse), they used the phrases "quadrilateral" and "rest of the sentence" to refer to that condition. They represented this in an initial Euler diagram with three nested regions: the innermost "rhombus," the outermost "quads," and the middle unlabeled.

At this point, April was searching for an effective way to refer to the consequent condition. She asked if there was a name for this category. The interviewer invited Moria and April to name this middle set, for which April chose the name "fancy." Moria wondered how this category related to parallelograms, and concluded that they are "more conditional than what we are going for in this."

When they then read Proof 3.3 (Proof by Contrapositive), April used the diagram to interpret the proof. She explained, "We're in quadrilaterals [pointing to outer region] and we can't go into fancy quadrilaterals, and therefore we cannot go into rhombuses." However, neither student at this point judged that Proof 3.3 proved Theorem 3. When the interviewer asked them to explain what Proof 3.3 proved, neither one explicitly connected the first line of that proof to "not fancy," despite April's association of the hypothesis with the outer ring of their diagram. Indeed, they seemed to struggle to articulate the hypotheses for Proof 3.3. Moria explained how, if one of the two triangles was scalene, the unequal sides or the triangles having unequal area meant they did not have a rhombus. Thus, while they found multiple ways to conceptualize how Proof 3.3's hypothesis entailed not being a rhombus, they did not judge this as relevant to Theorem 3. They failed to assimilate this proof to the line of reasoning April exhibited for Proof 1.3, though we see their arguments as having the same structure.

Toward the end of the session, the interviewer wrote abbreviated forms of Theorem 3, its converse, its inverse, and its contrapositive on the board (using the phrase "not fancy" in the last two) with a reproduction of their diagram with three nested regions. He asked Moria and April to interpret all four statements using the diagram. They were very comfortable explaining that Theorem 3 corresponded to the subset relation between rhombi and fancy quadrilaterals and that the converse was false because the relationship was "not exhaustive" and "you are going to have some fancy quadrilaterals that are not rhombuses."

Both students agreed that the contrapositive statement (abbreviated as "If not fancy, then not a rhombus") must be true. April explained that non-fancy quadrilaterals were in the outer region (covering it with both hands) and you cannot find a rhombus anywhere except the inner circle (the *empty intersection meaning*). The interviewer then returned to the question of whether Proof 3.3 proved Theorem 3. April now shifted to claiming that it can prove the theorem, explaining "You need to have it so that it forms the isosceles and you need to have it that the sides are congruent. You need to have those properties to have a rhombus." Once again, she was able to use her sense that rhombus entailed fancy to argue why failing to have fancy is sufficient not to be a rhombus.

What allowed April to shift from denying that Proof 3.3 proved Theorem 3 to affirming that it did prove? First, she desired a way to conceptualize the “fancy” condition in Theorem 3 as a predicate of quadrilaterals. By naming the category “fancy” and exploring its relationship to more familiar properties such as parallelograms, she constituted it as a predicate of quadrilaterals.

Regarding Proof 3.3, despite other relevant connections April made, she did not assimilate the hypothesis condition as equivalent to “not fancy,” which we consider a failure to unitize the negation. Once the interviewer wrote down the contrapositive using the phrase “not fancy,” April and Moria were able to assimilate Proof 3.3 to that statement and relate it to their understanding that “rhombus” entailed “fancy.” April’s empty intersection argument (that there are no rhombi among the non-fancy quadrilaterals) closely matched her argument for Proof 1.3. In the same way, having a factor of 2 and 3 was necessary to have a factor of 6, forming isosceles, congruent triangles was necessary to be a rhombus. Thus, April’s abstraction of her argument to the new mathematical context depended upon her ability to unitize the predicate “fancy,” to unitize its negation in Proof 3.3, and to coordinate the entailments among the properties.

Proof 4.3

Due to space limitations, we cannot present the text of Proof 4.3, which proves Theorem 4 from the introduction by contraposition. We will simply note that April initially saw the proof as irrelevant to the statement. Still, as with Proof 3.3 was later able to affirm the proof once she had conceptualized and named the conditions in the theorem. She later paraphrased the theorem as saying that if the endpoints of the functions “swapped” then the functions intersected. She then paraphrased the proof by contraposition saying, “If there is no intersection, there is definitely no endpoint swapping.”

Discussion

We make three claims about April’s ability to assimilate the theorems and proofs to her argument by contraposition. First, she could not assimilate the more complex theorems to the subset meaning (“nested” conditions) until she had unitized each predicate. Regarding Theorem 3, this entailed both seeing the condition on the triangles as a property of the quadrilateral and naming it. Regarding Theorem 4, this entailed conceptualizing the complex conditions and giving them names. Second, she needed to construct a relationship of entailment between the antecedent and the consequent in each theorem. She understood how being a multiple of 3 required being a multiple of 6. She had to construct similar senses of necessity regarding rhombus /fancy and endpoints swapping/intersection. Third, in the latter two cases, we see how unitizing the predicates and constructing a sense of entailment induced a shift from denying that the contrapositive proof proved to affirming it. This suggests that reconstructing each theorem as a relationship between two predicates was necessary to assimilate each new proof by contraposition into her original empty intersection meaning argument.

Based on these claims, we argue that unitizing predicates stands as an essential cognitive precondition for being able to render all of these theorems as having the “same logical structure.” Students must be able to treat more complex conditions as entailing a truth-functional predicate on the relevant set of objects. Furthermore, we note that unitizing predicates is non-trivial. Moria consistently had trouble in the experiment treating conjunctions as single predicates. For her, claims like Theorem 4 were relationships between three sets of objects instead of two, which prevented her from assimilating these theorems to the subset structure of Theorem 1.

We see two primary points of significance to unitizing predicates. First, we hope future work will continue to explore the necessary cognitive work involved in constructing various statements and proofs as having the same logical structure. Second, we hope logic instruction will begin to attend to this critical learning process rather than beginning with logical syntax. We fear that this does not help students like April learn how to unitize predicates and construct relationships of entailment, which we see as central to meaningful learning of mathematical logic.

Justification framework: A tool to analyze reasoning strategies for doing a geometric proof

Anairis de la Cruz Benito[1] and **Seyda Uysal**[2]

[1]Florida State University, Tallahassee, United States; ad19cc@my.fsu.edu

[2]Florida State University, Tallahassee, United States; su17b@my.fsu.edu

Keywords: Congruence, Geometric proof, Reasoning

In 2000, the National Council of Teachers of Mathematics highlighted proof as one of the most important components of mathematical thinking in justifying a mathematical idea in a fluent and formal way. One of the expectations is that students should be able to understand and construct mathematical proofs by the end of secondary school. The purpose of our study was to analyze and classify the justification strategies used by an honors high school student while producing a geometric proof. In this study, we adopted the justification framework (Marrades & Gutiérrez, 2000) to analyze a student's process of doing a congruency of triangles proof task. Data were collected through a cognitive interview and a written task on pencil and paper. The results showed that the student used deductive-formal, deductive-formal-structural, and deductive-failed types of justifications during her proof process.

Theoretical Framework

We used the justification framework developed and elaborated by Marrades and Gutiérrez (2000). The authors established the justification framework by expanding on previous approaches in academic literature. The framework provides an analytical tool to classify and analyze students' strategies in the process of constructing justifications in problem-solving. The authors adopted the concept of justification as "any reason given to convince people of the truth of a statement" (Marrades & Gutierrez, 2000, p. 89). Also, they referred to *proof* as a justification that satisfies the agreed-upon abstraction criteria by expert mathematicians as valid in an axiomatic system. The framework identifies two principal classifications which are empirical and deductive justifications. Within these classifications, there categories and subcategories. The empirical justification has four categories: failed, naïve empiricism (perceptual and inductive), crucial experiment, and generic example (example-based, constructive, analytical, intellectual). The deductive justification has three categories: failed, though experiment (transformative and structural), and formal (transformative and structural).

Method and Data Collection

We used purposive sampling method and the participation was voluntary based. The participant, Nina, was an 11th grade, honors, and a female high school student. Nina took an introductory geometry course previously where she received formal instruction on proofs. This was a crucial aspect of consideration for our study as we were interested in investigating the type of justification strategies the student will use in constructing a proof task. Some criteria we considered were that Nina was in the secondary school level, a level in which congruency of triangles is studied. In a pencil and paper environment and guided by a cognitive interview for 25 minutes, Nina worked on the congruency of triangles proof task.

Research Results

In Table 1, we present Nina´s justifications strategies. By applying the theoretical framework, we determined that the student used diverse strategies in engaging in the geometric proof task of congruency of triangle.

Table 1: Nina’ s justification strategies

Statement	Reason	Justification level	Description
<S ≅ <R	Given	Deductive → Formal	Because the problem gives me this information
XT bisects <SXR	Given	Deductive → Formal	I am given this
<SXT ≅ <RXT	Nina’ s thinking	Deductive →Formal → Structural	The definition of bisector (Congruency of angles)
<STX ≅ <RTX	Nina’ s thinking	Deductive → Failed	XT is a bisector
ST ≅ RT	Nina’ s thinking	Deductive →Failed	XT bisects the side SR in two equal parts
SXT ≅ RXT	Nina’ s demonstration	Deductive →Failed	The congruence theorem ASA

Nina’ s justification process was classified into the deductive main type of justification as she did not make use of any specific examples to do the proof justification, but instead used generic aspects of the problem, mental operations, and logical deductions. Nina´s first two arguments are deductive formal because she used only generic given aspects of the problem. After that, she employed a deductive formal structural argument by applying the definition of bisector to support her justification. Her next justification steps were categorized into the deductive failed strategy as she elaborated correct conjectures but failed in providing the correct justification for them. To summarize, Nina derived part of her justification by using an accepted definition and logical inferences from it. Later, she used an incorrect justification which consequently caused her next steps to be incorrect. Nina made an explicit effort to use rigorous symbolic language to express her thinking in written form while constructing sequences of logical deductions. Nevertheless, at the end she failed to succeed in elaborating the proof.

Limitations, and Future Directions

Because of the limited sample size and the participant’s status as an honors student, our findings cannot be generalized. A future direction of this study would be experimenting with more high school students from different backgrounds by including diverse geometry proof task types.

Two Primary School Teachers' Mathematical Knowledge of Content, Students, and Teaching Practices relevant to Lakatos-style Investigation of Proof Tasks

Dimitrios Deslis[1], Andreas J. Stylianides[2] and Mateja Jamnik[3]

University of Cambridge, UK

[1] dd544@cam.ac.uk; [2] as899@cam.ac.uk; [3] mj201@cam.ac.uk

Despite recognition of the importance of Lakatos-style proving activity in the mathematics classroom, we know little about whether teachers' relevant mathematical knowledge is conducive to supporting it in their classrooms. We take a step towards addressing this research gap by reporting the results of an exploration of two primary teachers' mathematical knowledge of content, students, and teaching practices relevant to Lakatos-style investigation of proof tasks. Through vignettes-based, semi-structured interviews, we presented the participants with 19 illustrated classroom episodes covering a range of Lakatosian techniques and a range of student ways of engaging with supportive examples and counterexamples to formulate, validate, refute, and refine conjectures of different types. Participants' responses revealed both productive and counterproductive understandings highlighting that although Lakatos-style proof lies within teachers' reach, supporting their preparation is crucial.

Keywords: Primary school mathematics, Mathematical knowledge for teaching Lakatos-style proof, Conjectures, Supportive examples, Counterexamples.

Introduction

In his book "Proofs and Refutations", Lakatos (1976) reconstructed prominent mathematicians' discussions on Euler's theorem to highlight the key role example use can play in proving and refuting conjectures. As a result of the increasing research interest about the incorporation of proof construction into mathematics classrooms (e.g., Stylianides, 2016), some studies (e.g., Balacheff, 1991; Komatsu et al., 2018) have investigated students' ability to comprehend and employ Lakatosian techniques to solve proof tasks and reported encouraging findings. However, few studies have centred upon primary school level (e.g., Komatsu, 2010; Reid, 2002) and none has had an explicit focus on teachers. Addressing these research gaps, our study sought to answer this research question: In what ways are two primary school teachers' knowledge of content, students, and teaching practices relevant to Lakatos-style investigation of proof tasks similar and different regarding the extent to which they may be able to support potentially their students' engagement with this style of proving?

Theoretical Frameworks

Phases of Lakatos-style Investigation of Proof Tasks

Drawing on Lakatos' (1976) original work and others' account of Lakatos-style proving activity in the mathematics classroom (e.g., Komatsu, 2010; Reid, 2002) we define Lakatos-style proving activity as an iterative and reflective process consisting of four interrelated phases (Deslis, 2020): in *Phase 1* students identify a conjecture which they wish to examine, based on a pattern, an educated guess, or simply following their teacher's suggestion. Then they start examining cases to investigate its validity. The discovery of supportive examples in *Phase 2* may indicate that the conjecture is likely to be true. However, in *Phase 3* counterexamples may also emerge from the examination of cases suggesting that the conjecture is false. In *Phase 4* students reflect on the previously discovered examples to appropriately modify the false conjecture. The domains of the original conjecture can either be restricted or expanded, to exclude the discovered counterexamples, or to transform them into supportive examples, respectively. Once the conjecture has been altered, a new investigation cycle begins aiming to the further refinement of the conjecture. It is important to note that, although our framework is based on Lakatos' work, it focuses on certain aspects of Lakatos-style reasoning and does not purport to reflect the whole complexity of his philosophy. For example, our framework does not focus on the interplay between defining and proving, which is crucial in Lakatos' work.

Conjecture Types

According to the classification of statements proposed by Tsamir et al. (2009), we identify three conjecture types: *Always-True* and *Never-True* conjectures are the two extremes, since only supportive examples and counterexamples emerge during their examination, respectively; in contrast, both example types emerge during the examination of *Sometimes-True* conjectures (see Figure 1).

Justification Schemes (JS) and Refutation Schemes (RS) for Student Understandings

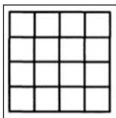
Justification and *Refutation* Schemes are two separate but interrelated three-level classifications describing a rather comprehensive range of student understandings about the interplay between examples and proving. According to Framework JS, which is based on Harel and Sowder's (1998) classification and its adaptation by Stylianides and Stylianides (2009), students at the least advanced level accept generalisations based on supportive evidence coming from a few easy-to-check cases. At the intermediate level they believe that only example-based evidence coming from the examination of representative cases can produce valid generalisations, whereas at the advanced level students are aware of the insufficiency of all types of example-based arguments. By analogy to JS, Framework RS, which we developed based on previous research on students' views around counterexamples (e.g., Balacheff, 1991; Lee, 2016), students at the advanced level consider the discovery a counterexample sufficient to refute a conjecture, while students at the intermediate level question the sufficiency of a single counterexample to refute a conjecture and demand the discovery of more counterexamples, preferably resulting from strategically selected cases. At the least advanced level students treat counterexamples as exceptions, resisting to the idea that the existence of counterexamples can affect the truth of a convincing conjecture. Students who hold the advanced schemes in relation to both example types can potentially also reach a meta-level that is key in the implementation of Phase 4 (Lakatos-style conjecture refinement). On top of the understanding that comes with the acquisition of the two advanced levels, students at this meta-level, which we call "*refinement scheme*", are able to reflect on the previously discovered supportive examples and counterexamples to get insights into how the refuted conjecture can be appropriately modified.

MaKTeLaP: Mathematical Knowledge for Teaching Lakatos-style Proof

Building on previous research on the knowledge needed to teach mathematics (Ball et al., 2008), or specifically proof (Buchbinder & McCrone, 2020), we describe the mathematical knowledge relevant to bringing Lakatos-style activity into the classroom (Deslis et al., 2021). We identify three knowledge components: (1) *CoLaP* which refers to the *Co*ntent knowledge about what constitutes appropriate use of examples in *La*katos-style *P*roof tasks; (2) *StuLaP* which refers to the knowledge of *Stu*dents' typical understandings around the example use in *La*katos-style *P*roving; and (3) *TeLaP* which refers to the knowledge of *Te*aching practices that can appropriately promote students' efforts to productively engage with *La*katos-style *P*roof. Since all Lakatosian phases revolve around two example types, namely supportive examples (SEs) and counterexamples (CEs), we can identify two subcomponents within each component, each focusing on the knowledge around one example type. For example, CoLaP splits into CoLaP [SE] and CoLaP [CE].

Methods

We collected our data through semi-structured interviews based on vignettes (Skilling & Stylianides, 2019), which are contextualised descriptions of classroom situations (Deslis et al., 2021). 10 in-service primary school teachers were presented with 19 classroom episodes with comic-style student characters discussing and exchanging arguments with their peers as they engaged in the phases of Lakatos-style investigation. Three student groups worked on the "Count the Squares" task (Zack, 1997) and each explored a conjecture of a different type (see Figure 1). The student dialogues we used were adapted versions of classroom episodes from fifth grade reported in Zack (1997) and Reid (2002) and covered the whole range of investigation phases and student understandings, as described by our theoretical frameworks. After each episode participants were asked to comment on the validity of arguments, evaluate students' understandings, and discuss how they would respond to each student contribution. We analysed responses for themes and ranked the various teacher understandings relevant to the different MaKTeLaP components and example types according to their level of sophistication (Deslis et al., 2021). In this paper we focus on two teacher participants, identify similarities and differences in their responses, and discuss the degree to which their understandings put them in a good position to support the incorporation of Lakatos-style proving activity into their classrooms. The characteristics of the two teachers were reasonably similar. Alcyone and Nephele (nicknames) were both female, 29 and 27 years old, respectively. At the time of the study, they had 18 and 45 months of teaching experience, respectively, and both held a Bachelor's and a Master's degree in Education. Both participants taught middle-sized (21 and 23 students) fifth-grade classes (ages 10-11) in similar and neighbouring schools in Athens, Greece, with most of their students coming from middle-income households.



How many squares are there in this 4-by-4 grid? Examine other similar grids of your choice. How many squares are there in each of them? Find a general rule that applies to grids of all sizes and prove your answer.

Group 1- Always True Conjecture:	Group 2- Sometimes True Conjecture:	Group 3- Never True Conjecture:
"The number of squares in an n-by-n grid is $1^2+2^2+\ldots+(n-1)^2+n^2$."	"The number of squares in an n-by-n grid is a multiple of five."	"If an n-by-n grid has N squares and an m-by-m grid has M squares, then the m×n-by-m×n grid has M×N squares."

Note. The phrasing of the conjectures has been altered; the student characters in the vignettes presented and discussed these conjectures using language that reflects the mathematical knowledge of students of their age.

Figure 1: The proof task and the conjectures that were investigated by the three student groups

Findings and Discussion

CoLaP: Knowledge of Content

Participants were asked to evaluate the arguments presented in the scenarios regarding their validity. The responses indicate that the two teachers' understandings about the role of examples in the investigation of conjectures had both similarities and differences (see Table 1). Commenting on whether it is appropriate to conclude that a conjecture is true based on the discovery of some supportive examples, Nephele preferred to judge on a case-by-case basis, while Alcyone's responses suggested a blanket rejection of this idea. For example, when the second group (Sometimes-True conjecture) found a few examples that supported their conjecture, the two teachers agreed that this does not allow us to conclude that the conjecture will work for any grid:

Alcyone: The absence of counterexamples so far is not evidence that they do not exist. The examples so far are supportive, but a counterexample can emerge any time.
Nephele: The generalisation is not permissible, because it is only based on two examples.

Alcyone maintained this opinion when commenting on a similar moment during the first group's investigation (Always-True conjecture). Yet, Nephele was convinced that it will work for all grids, although this generalisation would be based on the same number of examples as in the previous case:

Nephele: All the examples so far have confirmed the conjecture, so we can safely conclude that it is correct and works for all grids.

Their comments on arguments against the idea that any example-based argument can lead to safe generalisations of conjectures also highlighted the divergence of views:

Nephele: This is not necessarily true; sometimes even a few examples can provide undeniable evidence and thus enable us to conclude that the conjecture is true for all cases.
Alcyone: The examples may show that there is a possibility for the conjecture to be true, but we cannot be sure about that if the only evidence we have comes from examples.

Overall, Alcyone showed concrete and stable appreciation of the usability and limitations of supportive examples. She valued their role in the investigation of conjectures while being aware that we cannot prove a general statement merely based on examples. In contrast, Nephele's responses varied from one episode to another, indicating weaker understanding which is highlighted by her erroneous belief that in some circumstances examples can be used to prove general statements.

In contrast to the previous example type, the two teachers were found to hold comparable views about the appropriate use of counterexamples in refuting conjectures. Specifically, both participants' responses showed awareness that a single counterexample can sufficiently refute a general statement:

Nephele: Now that we have found a counterexample, we know that the conjecture is false.
Alcyone: The number of supportive examples we have found is irrelevant; one counterexample is enough to show us that the conjecture does not hold.

Table 1: Summary of Alcyone and Nephele's understandings relevant to CoLaP

CoLaP [SE]	*A:* Supportive examples can be used to investigate general statements, but they cannot prove them.	*N:* Supportive examples can be used both to investigate and to prove general statements.
CoLaP [CE]	*A & N:* A single counterexample can sufficiently refute a conjecture.	

STuLaP: Knowledge of Student Understandings

Turning to StuLaP, participants' judgements about the level of student understandings brought to the surface both similarities and differences in teachers' views (see Table 2). Alcyone not only recognised students' common belief that examples can be used to prove general statements is a misconception, but also was aware that the use of representative cases which have been strategically selected does not make the argument any more valid from a mathematical perspective.

> Alcyone: Any student who is happy to accept generalisations that are merely based on examples as proofs (no matter how many examples there are or the process through which they have been identified) has a significantly less advanced level of understanding than students who reject all kinds of example-based proofs.

Unlike Alcyone, Nephele was occasionally favourable towards the use of examples as a means to prove, since she tended to accept arguments that reflected the intermediate JS level as valid:

> Nephele: The student has not realised that the examples so far have covered the whole spectrum of possible grids and therefore proved that the rule is correct. His choice to reject example-based proofs in their entirety signifies weak understanding.

Unlike the case of supportive examples, the two participants had similar views about students' understandings around counterexamples. Specifically, both teachers spoke highly of students who believed that a single counterexample can sufficiently refute a conjecture:

> Nephele: Students who discard a conjecture immediately after the discovery of the first counterexample and consider further checks as unnecessary have a more advanced level of understanding than those who demand a substantial number of counterexamples to be discovered before they refute the statement.

Furthermore, both participants consistently criticised students who continuously treated counterexamples as exceptions and maintained their initial opinion ignoring the evidence against it:

> Alcyone: Students' refusal to reject a conjecture despite the existence of counterexamples and the treatment of counterexamples as exceptions indicates poor understanding.

Yet, Nephele also judged favourably students who were reluctant to reject conjectures after the discovery of one counterexample and instead demanded that a substantial number of counterexamples should be discovered, and characterised this practice as more productive than it actually is:

> Nephele: Students' reluctance to reject a conjecture immediately after the discovery of one counterexample and their need to find additional counterexamples shows a scepticism that is desirable in the classroom of mathematics.

Although Alcyone occasionally criticised this practice, in other episodes she also expressed views that were similar to those of Nephele:

> Alcyone: I like this student's critical attitude! It is always good to be reluctant and demand more evidence.

Overall, both teachers' responses showed a satisfactory degree of awareness about which student understandings about counterexamples signify an advanced level of understanding and which do not, mirroring, to an extent, their good content knowledge on counterexamples. Still, some of their reactions to students who resisted to conjecture refutation unless numerous counterexamples were discovered, were contradictory, thus showing knowledge fragility. The main differences lay in their understandings about student conceptions around supportive examples: unlike Alcyone, Nephele did not consider students' tendency to overrely on empirical arguments as a misconception.

Table 2: Summary of Alcyone and Nephele's understandings relevant to StuLaP

StuLaP [SE]	*A:* Students' belief that conjectures can be proved through supportive examples, even if these are coming from the examination of strategically selected cases, is counterproductive.	*N:* Students' belief that conjectures can be proved through supportive examples is counterproductive unless these are coming from the examination of strategically selected cases.
StuLaP [CE]	*A & N:* Students' belief that a conjecture must be refuted after the discovery of one counterexample is productive, as is students' desire to discover more counterexamples before they refute a statement.	

TeLaP: Knowledge of Teaching Practices

As for the third MaKTeLaP component (see Table 3), participants were asked how they would respond to students' contributions and how they would support students' efforts if they were their teachers. Teachers' responses showed that they promoted a slightly different usage of supportive examples in the exploration of proof tasks. To begin with the commonalities, both appreciated the importance of examining various examples in the beginning of the investigation:

Alcyone: The examination of several different cases is a reasonable thing to do after the formulation of a conjecture, since it can provide clues about how we can prove it.

Nephele's advice regarding which cases students should try first was even more specific:

Nephele: The examination of the easiest-to-check cases can be a convenient way to start.

However, Nephele also thought that it is appropriate to encourage students to terminate the investigation once much confirmatory example-based evidence has been found:

Nephele: The examples have shown that the rule works; now I'd advise students to stop, and I'd give them a new problem to solve.

Taking a different approach, Alcyone appreciated that despite the valuable contribution of supportive examples to the promotion of the investigation, it is inappropriate to conclude an investigation at the stage of the example examination even if several confirmatory cases have been discovered:

Alcyone: I'd tell the students that even if they have found several examples supporting their conjecture, it is prudent to remain cautious and continue the examination of cases in search of counterexamples, which can emerge anytime.

The two teachers' suggestions after the discovery of counterexamples were dissimilar, too. Nephele encouraged students to abandon the refuted conjecture and replace it with a new one:

Nephele: The conjecture clearly doesn't work. I'd encourage students to abandon this idea and try to formulate a new conjecture that is not related to the multiples of five.

Taking a step further, Alcyone not only advised students to replace the faulty conjectures, but also suggested that the new conjecture could be an improved version of the initial conjecture. She also added that reflecting on the characteristics of the previously discovered examples can provide clues for the appropriate modification of the refuted conjecture:

Alcyone: The students can review the examples they found to come up with a refined version of the conjecture. […] There might be a subset of grids for which the conjecture works; for example, for the n-by-n grids where n is a multiple of five.

All in all, both teachers' suggestions showed an appreciation of the important part example examination can play in the investigation of conjectures. However, Alcyone's suggestions in relation to both example types were clearly more sophisticated. Unlike Nephele, Alcyone was fully aware that supportive examples cannot prove general statements and judged the student arguments accordingly. Her suggestions to the students reflected an appreciation of the limitations of example use. A remarkable similarity between the two teachers' responses was that although both recognised that one counterexample can refute a conjecture, both also indulged in judging favourably students who attempted unnecessary checks to discover more. Yet, it was impressive that Alcyone encouraged the use of a technique that is surprisingly consistent with the spirit and the essence of Lakatos-style reasoning. Unlike Nephele who encouraged the replacement of a refuted conjecture with a new one, Alcyone said she would encourage students to use counterexamples not only to refute conjectures, but also to modify and refine them considering the characteristics of the previously examined examples. This practice lies at the heart of Lakatos-style activity and the fact that Alcyone reinvented it despite the lack of any prior relevant instruction in teacher education is encouraging.

Table 3: Summary of Alcyone and Nephele's understandings relevant to TeLaP

TeLaP [SE]	*A:* Use of supportive examples to initiate the conjecture exploration.	*N:* Use of supportive examples to initiate and terminate the conjecture exploration.
TeLaP [CE]	*A:* Use of counterexamples to refute the conjecture and reflection on their characteristics to refine it.	*N:* Use of counterexamples to refute the conjecture and then replace it with a new one.

Conclusion

Research on classrooms of expert teachers (e.g., Zack, 1997) or teachers who worked closely with researchers (e.g., Komatsu et al., 2018) suggests that students can engage productively in Lakatos-style activity and benefit from it, even at primary school level. Still, we know little about how non-expert teachers understand various aspects of this activity and thus whether they would have the knowledge to be able to support it in their classrooms. The present study adds to the increasing literature on the incorporation of Lakatos-style reasoning into school mathematics by exploring ordinary teachers' relevant mathematical knowledge, an area that had previously been unexplored. We analysed and compared two primary school teachers' reactions to a set of 19 illustrated classroom episodes which enabled us, in an explorative way, to shed light on their understandings of content, students, and teaching practices relevant to Lakatos-style activity. Our study offers some encouraging findings while pointing in directions for future research. The case of Alcyone and her many productive intuitive understandings suggest that it is possible for primary school teachers to have necessary (though, arguably, not sufficient) knowledge to bring Lakatos-style proof into their classrooms. Yet, the case of Nephele suggests that it is also important to identify appropriate ways to support the refinement of teachers' understandings and highlights the crucial role teacher education has to play in preparing teachers to effectively engage their students with Lakatosian techniques.

A sixth-grade student's growth in understanding written proof texts: Pre- and post-interview analyses of a teaching experiment study

Merve Dilberoğlu[1], Erdinç Çakıroğlu[1] and Çiğdem Haser[2]

[1]Middle East Technical University, Turkey; armerve@metu.edu.tr, erdinc@metu.edu.tr

[2]University of Turku, Finland; cigdem.haser@utu.fi

This study aims to describe a 6th-grade student's progress in understanding written proof texts through participating in an individual teaching experiment. The same task was administered to the student twice in an interview setting, before and a year after the teaching experiment. The student was asked to evaluate four arguments aimed to prove a given conjecture. While in the pre-interview, the student accepted all four arguments based on her Naïve Experience; in the post-interview, she rejected empirical arguments and looked for General Procedures (or Abstract Structures) that necessarily apply to the whole set of numbers under investigation. In the post-interview, spontaneous changes occurred in the student's understanding of the given arguments after she constructed her own proof for the same conjecture. Instructional design elements used in the teaching experiment might have facilitated her understanding of the structure of deductive proof texts.

Keywords: Proof comprehension, students' understanding, middle school students, individual teaching experiment.

Introduction

Reliance on empirical reasoning for validating mathematical generalizations is a faulty way of thinking pervasive among students (Harel, 2008). Many students, even after learning about secure methods of proving, are reported to retain an empirical proof scheme (Education Committee of the European Mathematical Society, 2011). Current efforts in mathematics education, therefore, aim to help students realize the limitations of empirical arguments and learn about reasoning deductively at the early grade levels (Stylianides & Stylianides, 2009). Another deficiency in students' learning about proof is holding a ritual proof scheme, in which the student judges the validity of an argument strictly by its appearance, rather than its underlying structure (Harel, 2008). The same proof can be presented in verbal, pictorial, or symbolic forms (Stylianides, 2007). However, it is the logical structure of the argument that determines its validity (Miyazaki et al., 2017). This suggests, one aspect of learning about proof is to distinguish between the structure and form of the argument.

This paper reports on the preliminary findings from an ongoing research study conducted in Turkey. The purpose of the study is to explore the processes by which a 6th grade student (1) comes to understand deductive structure of mathematical proofs, and (2) develops the skills required to prove basic theorems, by use of an individual teaching experiment methodology. Even though the form of argument representation is an inseparable aspect of the instructional design approaches used in the teaching experiment, the main focus of the study is on helping the student understand deductive structure of mathematical proof. The purpose of the research reported here is to describe the student's progress in understanding written proof texts (within and between the two interviews conducted before and a year after the teaching experiment) by using a research-based model, which allows tracking changes in the students' understanding in terms of argument form and structure. Describing the student's dynamic experiences with proof texts might elucidate the strengths and weaknesses of the instructional design approaches used in the teaching experiment study.

The model: Students' ways of understanding a proof

Ahmadpour et al. (2019) put forward a model of students' understanding of a written proof text. The model describes possible *states* of evolving understanding and the *transitions* between them. According to the model, students' understanding of a formally acceptable proof may develop into three different end-states: a Formulated Proof, a Procedural Proof, and a Formulaic Proof. If the reader is aware of the underlying deductive structure of a proof, the proof is said to be "read" as a Formulated Proof. If the reader perceives the proof "as a general procedure that can be applied to any number, as a sort of recipe for producing examples, rather than a deductive structure applicable to all numbers" (Ahmadpour et al., 2019, p. 87), the proof is said to be read as a Procedural Proof. And, if the reader considers only its surface-level form while reading a proof, it is said to be read as a Formulaic Proof. According to the model (Ahmadpour et al., 2019), processes of learning towards the three end-states follow three different theoretical pathways. They are, respectively, the Path of Structure, Path of Procedure, and Path of Form. Switching between the path-ways is possible due to the potential shifts of attention in one's understanding. In this study, the main focus is on the Path of Structure, which describes the processes through which an individual comes to understand the deductive structure of a proof. In this path, through the transitions of *generalization*, *abstraction*, and *formalization*, the student develops from the state of Naïve Experience (in which existence of confirming examples are thought to validate generalizations) to those of General Procedure, Abstract Structure and Formulated Proof sequentially. The state of Abstract Structure was intended by the teaching experiment study reported here.

Ahmadpour et al. (2019) consider understanding as a dynamic process. Accordingly, the model allows description of students' progression over time by linking *form* and *structure*, beyond merely marking the *states* of understanding at fixed points in time. *Transitions* of how one *state* of understanding develops into a next one is a major focus of the model. In this study, the pre-interview captures a fixed, consistent *state* of understanding a 6th grade student demonstrates before participating in a teaching experiment study. The post-interview captures the dynamic changes in her understanding facilitated by her interaction with the interview task.

Method

Context and the participant of the study

In Turkey, students are not explicitly taught the concept of proof at the middle school. The mathematics curriculum (Ministry of National Education [MoNE], 2018) emphasizes students' explaining their reasoning and evaluating others' in the classroom. However, to what extent the abstract structures underlying valid arguments are explicated to the students is questionable, as no detailed prescriptions are provided for teachers. Hence, the 6th grade student, Beren (pseudonym), participated in this study had no previous interaction with the notion of proof. Beren was approached based on her competence in four operations, her ability to express mathematical ideas, and her willingness to learn mathematics. She volunteered for the study along with her parents' consent.

The teaching experiment

The teaching experiment consisted of four major stages (Steffe & Thompson, 2000). The first stage aimed to prepare the student about basic number theory concepts (such as modular structure, parity, and divisibility) that would be the objects of conjectures studied throughout the teaching experiment. The second stage challenged the student's extant source of conviction, Naïve Experience, by creating a cognitive conflict through using Monstrous Counterexample Illustration (Stylianides & Stylianides, 2009). This stage triggered an *intellectual need* (Harel, 2008) in the student for learning about secure methods of proving. The third stage aimed to satisfy this need by designing tasks for her to understand the deductive structure of mathematical proofs. Then, in the fourth stage, the student was encouraged to use this understanding to practice proving a set of theorems.

The first stage introduced to the student a way of representing modular structure of unknown quantities by using a short story, which later provided her a context for explaining mathematical arguments. In this story, an unknown number of cookies evenly distributed in identical cups with some remainders were used to represent the modular structure of an unknown quantity. Based on the story, the algebraic expression defining odd numbers, 2n+1 (where n is a non-negative integer), was represented as two cups containing the same number of cookies and a single cookie. A variation of the representation was used in the fourth stage, as in Figure 1, for the concept of consecutiveness (i.e., a cup of cookies standing for n items, and another cup and one more cookie representing n+1 items).

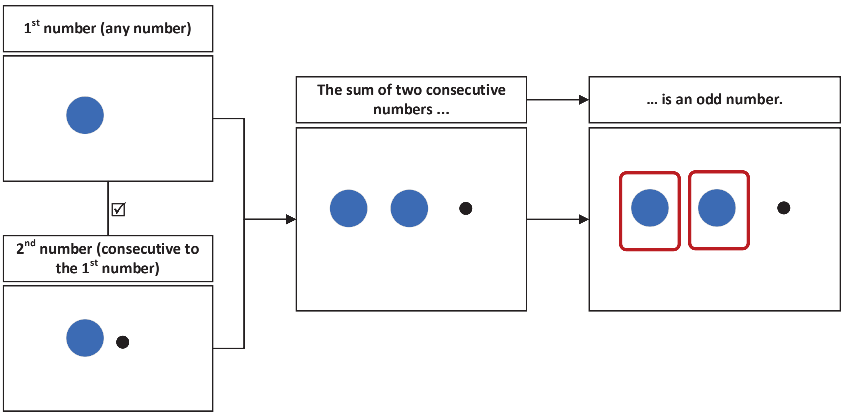

Figure 1: A flow-chart proof of "The sum of two consecutive numbers is an odd number."

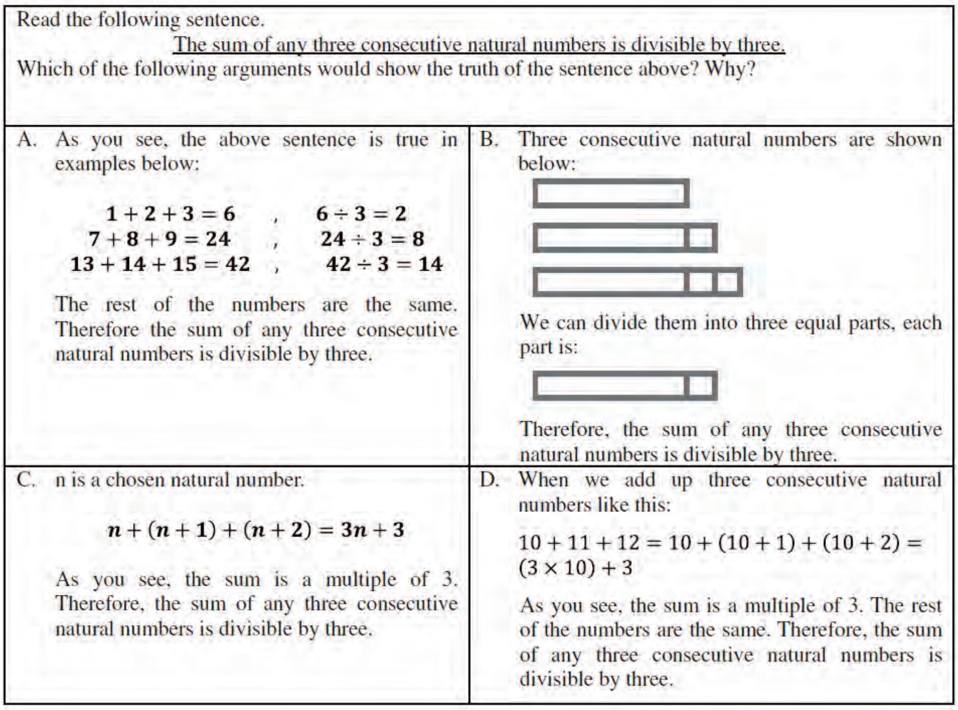
Another instructional design component, the flow-chart proof format, adapted from Miyazaki et al. (2017), was introduced to the student in the third stage. The flow-chart proof format was used with the purpose of explicating the structure of deductive arguments. Figure 1 illustrates the flow-chart proof using the specific representation developed in this study. Large circles represent the cups containing an unknown number of cookies, while the small circles represent single cookies. The checkmark between the two leftmost boxes indicates that the two objects shown are related; that is, the cups contain exactly the same number of cookies – stand for the same unknown quantity. In other cases where the two objects are not related (for example in proving that the sum of two odd numbers is an even number) cups of different color or shape are used (invented by the student), and the checkpoints are filled with a cross mark (by the student).

Data collection and analysis

The pre-interview was conducted at the beginning of the teaching experiment study. At the time of the pre-interview, Beren had just completed the 6^{th} grade. The teaching experiment took 8 weeks. The post-interview was conducted a year after the completion of teaching experiment study. The task shown in Figure 2 was translated into Turkish. Beren was asked to think aloud while reading and making decisions about each of the arguments. Probing questions were used with the purpose of capturing details of her understandings. Pre- and post-interview data were analyzed based on the model of students' ways of understanding a proof (Ahmadpour et al., 2019).



Read the following sentence.

The sum of any three consecutive natural numbers is divisible by three.

Which of the following arguments would show the truth of the sentence above? Why?

A. As you see, the above sentence is true in examples below: $1+2+3=6$, $6 \div 3 = 2$; $7+8+9=24$, $24 \div 3 = 8$; $13+14+15=42$, $42 \div 3 = 14$. The rest of the numbers are the same. Therefore the sum of any three consecutive natural numbers is divisible by three.	B. Three consecutive natural numbers are shown below: We can divide them into three equal parts, each part is: Therefore, the sum of any three consecutive natural numbers is divisible by three.
C. n is a chosen natural number. $n+(n+1)+(n+2)=3n+3$ As you see, the sum is a multiple of 3. Therefore, the sum of any three consecutive natural numbers is divisible by three.	D. When we add up three consecutive natural numbers like this: $10+11+12=10+(10+1)+(10+2)=(3\times 10)+3$ As you see, the sum is a multiple of 3. The rest of the numbers are the same. Therefore, the sum of any three consecutive natural numbers is divisible by three.

Figure 2: The task (Ahmadpour et al., 2019, p.89)

At the time of the pre-interview, Beren knew the meaning of algebraic expressions such as "2a+3", and was able to calculate the value of such expressions for specific values of the unknown "a". However, she did not know how to operate on algebraic expressions, which was essential for understanding Argument C. Such syntactical understanding was not among the goals of the teaching experiment and was not part of the instructional design. At the time of the post-interview, however, when Beren completed the 7^{th} grade, she possessed a greater understanding of the algebraic operations used in Argument C, because students learn these skills at the 7^{th} grade in Turkey (MoNE, 2018).

Findings

Two remarks are important to highlight. Although the concepts of divisibility are addressed in Turkish middle school mathematics curriculum, the learning objectives are restricted to the use of divisibility rules within arithmetic. Hence, the conjecture examined in this study was novel to Beren at the time of pre-interview. However, this was not the case in the post-interview. Beren was asked to evaluate validity of the exact same conjecture in the last episode of the teaching experiment study, as part of a proof-production assessment. She was able to produce a valid proof of the statement.

Pre-interview

Each of Beren's evaluations in the pre-interview were based on Naïve Experience. For instance, reading Argument A, she reviewed all the calculations and decided that the given examples were correct. After testing the conjecture for two other sets of three consecutive numbers, she stated:

Beren: I think the sentence is correct. I mean this option A is correct. It shows its truth definitely. It has already given examples, has done the division. I don't think there is a problem with option A.

After going through similar procedures of Naïve Experience for Arguments B, C and D, Beren summarized her thoughts about the task:

Beren: I tried each of them [the four arguments] by doing different operations and three consecutive numbers hold. […] So, there is no reason for this, I find it by trying with numbers, again.

Post-interview

In the post-interview, Beren remembered the task from the last year and sequentially explained the four arguments. Unlike in the pre-interview, she did not accept Argument A as a proof:

Beren: Now, when I read, I do not directly understand because, now, it says 'The rest of the numbers [are the same]'. How can I know without trying it? Who has proven this and according to what? […]. I'm moving on to the other. […] This does not show for sure.

Continuing with Argument B, Beren thought that it could be a proof because it was not based on specific examples. However, she could not make sense of the representations used and hence the underlying ideas communicated. She could not articulate a consistent meaning out of the realistic situations she tried to make up, as she did not consider the relationship between the sizes of the three strips. Although she could not understand Argument B, her preliminary decision was not to eliminate this option. Beren seemed to think that Argument B might be arguing for all consecutive numbers.

Beren: I said it could be a proof because it does not give us a certain number here. No matter how much you divide, it says, the three [strips]. But, still I want to look at the others. According to that… You know, I want to decide whether this is a proof or not and tell its reason based on that.

In Argument C again, Beren could not make sense of the given algebraic expression. Her focus was on the *form* rather than the *structure*. (Note that in Argument C, instead of "n", "a" was used as a variable, for the student's familiarity.)

Beren: Why it says this three? [points to '3a' in 'a + (a+1) + (a+2) = 3a + 3'] … There are three of a's, I see. […] Well, but it again gives us numbers here. It says one, two, … I mean. I think, I cannot prove with this.

Then, an instant shift of attention occurred in her understanding, marking a *transition* towards either a General Procedure or an Abstract Structure in her understanding. She associated the "+1" in the expression "(a+1)" with her previous understanding of how two consecutive numbers were related.

Beren: … like in the logic of a chart [the flow-chart proof]. Well, we were here [points to '(a+1)'] showing [this] 1 more, you know. In here, as well, I wonder, since it says a plus one, it is the extra… I mean we can transfer this into a schema. I, for this reason, think that this could be [a proof.] In fact, I think this shows certainly, as well. I think this has the logic of 'whatever number you try, it will work'.

Beren’s comments about arguments B and C reveal that she was looking for General Procedures (or Abstract Structures) that would apply to all triples of consecutive numbers. She summarized her perception of the first three arguments and then continued with reading Argument D.

Beren: I know that this (Argument A) is not [a] ‘for sure’ [argument], this (Argument B) could be, I said. But I think that this (Argument C) will be for sure.

At her first glance, Beren judged Argument D by the sentence “The rest of the numbers are the same”.

Beren: I think rather than the operations, what is written here is important. Because ‘The rest of the numbers are the same’. We want to proceed by… that shows for everything, any number, here, not one number ten, eleven, twelve. […] I think I would think a lot if it hadn't said that sentence.

Researcher: Well, let's pretend that this sentence is not there.

Beren: Still I don’t think it is [a proof] […] It's not proven for every consecutive number. […] Here you have to try and find it.

The researcher asked Beren how she would “try” in order to see if she would make use of the structure “3 times the smallest number plus 3” illustrated in Argument D, in creating other examples. But, this unintentionally prompted Beren to construct her own proof for the statement, given in Figure 3 (left).

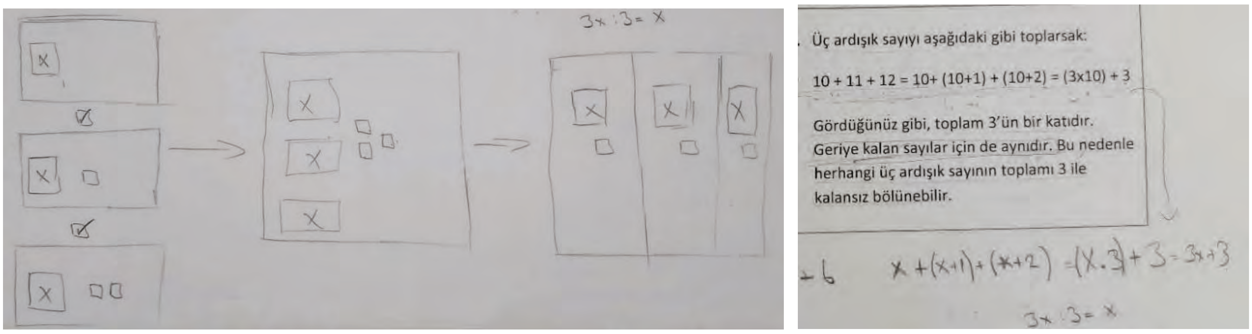


Figure 3: Beren’s flow-chart proof for the statement “The sum of any three consecutive natural numbers is divisible by 3” (left) and her formalized expression for Argument D (right)

While drawing the flow-chart, she explained her ideas in every step. Then she connected the Abstract Structure underlying this proof to that of Argument D.

Beren: Well, three consecutive numbers. In fact, it [her flow-chart proof] is [the same as] the logic in here [Argument D]. But, in here [in Argument D] it evaluates over ten.

Researcher: What if that ten is replaced by another number?

Beren: Again, it will be the same thing, but it’s saying it out of ten seems nonsense to me. For example, if it says x there, would be okay. If it says x, it would have proved for sure. It would have said 'whatever number came there... if any number comes in, it holds.' But I don't think this is okay, it’s being ten.

Then, she produced the algebraic expression in Figure 3 (right). Her explanation of this expression suggests that she perceived 3x+3 as an Abstract Structure subject to the distributive law for division.

Beren: Three x plus three. Three x is already divisible by three. We understand that, it is […] x. When I distribute three also one by one, it comes out one x… x plus one. I can prove it this way.

She also considered Argument D to well emphasize Abstract Structure of three consecutive numbers:

Beren: [Argument D] shows for ten, eleven, twelve, but it says ten plus one and plus two. It even proves more [compares to Argument A] that they are consecutive.

The above two scripts show that Beren understood the Abstract Structure behind Argument D. But, she did not accept this argument as a Formulated Proof, because these structures were not expressed in a formally acceptable way to her.

Beren: I can prove it this way [by using x]. But when I look at here [Argument D] ten, eleven, twelve, since they are consecutive, are summed, divided by three. But, is this same thing valid for two, three, four?

Researcher: Let's start with such a number [instead of ten] that… what is done here is not correct. Is that possible?

Beren: I think, it is not [possible]. Because when I do the same by x, I could show it. It holds anyway.

Note that Beren, when she created the algebraic expression "x + (x+1) + (x+2) = (x.3) +3 = 3x + 3" for Argument D, has just *formalized* the Abstract Structure of her own flow-chart proof (through her independent activity). Also note that an equivalent of the expression was given in Argument C, out of which she was not able to perceive the same structure before. This suggests thinking with the flow-chart proof format helped Beren focus on the Abstract Structure behind Argument D. She then transferred the same understanding of this structure to Arguments C and B.

Beren: I accept [Argument C]. Because I myself expressed it here [in Argument D] by x. Here it uses not x, but a. Again, an algebraic expression it uses, I mean. It is not known what this number is, it could be 1, it could be ten or it could be a hundred. That is why, to me, this is a sufficient proof.

In Argument B, she matched the three strips with the expressions x, x+1 and x+2. She explained the underlying deductive structure of the two arguments and read them as Formulated Proofs.

Discussion

Findings from the pre-interview revealed Beren's reliance on Naïve Experience, which was an expected situation for a 6th grade student who had not received any instruction on proof. On the other hand, analysis of the *states* and *transitions* observed in her understanding of the given arguments during the post-interview highlighted important aspects of the instructional design elements used in the teaching experiment study. First, the student expressed a preference for non-empirical arguments. Unlike many others reported in the literature, who simultaneously possessed deductive and empirical proof schemes after learning about proof (Education Committee of the European Mathematical Society, 2011), she did not retain the empirical proof scheme. This suggests, the cognitive conflict approach used in the teaching experiment (Stylianides & Stylianides, 2009) helped Beren achieve the intended discrimination between valid and invalid modes of reasoning.

Second, in the post-interview, Beren was not able to make sense of the Arguments B and C in her first attempts. She was not familiar with the forms of representation used. After constructing her own flow-chart proof for the given statement, Beren first *formalized* its Abstract Structure through studying Argument D (created her Formulated Proof by using a variable "x") and then, connected this Abstract Structure with the forms of representation used in Arguments B and C. Her understanding of the Arguments B and C reached to the level of Formulated Proof, which would be the ultimate goal of proof comprehension for a mathematics learner. We hypothesize that the flow-chart proofs used in the teaching experiment study helped Beren focus on Abstract Structures behind deductive arguments. For instance, divisibility of 3x+3 by three was visualized in the last action in Beren's proof, which was developed previously from the context of sharing 3 cups of and 3 single cookies among three people. Furthermore, the cups and cookies representation, evolved into the general notion of a collection and some single of the identical items, helped Beren to represent Abstract Structure of the property shared by every set of three consecutive numbers.

Beren demonstrated successful use of the Abstract Structures underlying her flow-chart proof (learned in the teaching experiment) in a novel task. This might be an indication of the strong aspects of the instructional design in supporting young students' learning of the structure of deductive proof. Also, note that Beren did not restrict proofs to necessarily have a flow-chart format or use cups and cookies representation. Examination of the aspect(s) of the teaching experiment (if any) that might have facilitated Beren's discrimination between argument form and structure is an issue of further investigation. Results may provide insights into the ways of preventing the development of a ritual proof scheme (one that is observed frequently among students) while teaching proof. It is also important to note how the administration of the interview task itself, after the teaching experiment, elevated the student's bringing together the *structure* (from the teaching experiment) and *form* (supported by the task) to understand unfamiliar proof texts. Nature of Beren's activity in the post-interview might offer directions in the design of tasks for enhancing student learning about proof.

On the dialectical relationship between truth and proof: Bolzano, Cauchy and the intermediate value theorem

Viviane Durand-Guerrier

University of Montpellier, IMAG, CNRS-UM, France; viviane.durand-guerrier@umontpellier.fr

Abstract - The question of the nature of the relationship between truth in an interpretation and proof in a mathematical theory is a complex epistemological issue. From a didactic perspective, we argue that it is worthwhile to address this issue in mathematics teaching and learning. In this paper, we illustrate this in the context of the Intermediate Value Theorem, focusing on the approaches of Bolzano and Cauchy, and we discuss possible didactic implications.

Keywords: Truth in an interpretation, proof in a theory, didactic and epistemology of mathematics, Intermediate Value Theorem.

Introduction

A recurrent issue raised by students concerns the need to prove mathematical statements that looks obvious. The prevalence of this issue has increased since the introduction of dynamic geometry software offering strong epistemic conviction through various means (Mariotti, 2006). Therefore, a crucial issue in mathematics education concerns the relationship between proof and truth. Indeed, it is well known in the literature that the motivation for proof and proving is difficult for students to endorse: most of them consider it as a teacher's requirement, not as an epistemic necessity. The need for truth is often considered to come from the possibility of raising doubt, for example because observations or results of actions are counter-intuitive, or surprising. Looking through the history of mathematics at the completeness of the set of real numbers, Bergé (2008, p. 220) points to another issue, namely the necessity, for a thorough study of Analysis, of the theoretical reconstruction of pre-constructed notions of Calculus such as the straight line or the continuity of functions. In this paper we intend to show that the relationship between *truth* and *proof and proving* is not one of subordination, as claimed by some authors considering that only what is proved is true, but rather a dialectic relationship. For this purpose, we will focus on the Intermediate Value Theorem, an existential statement that has long been taken for granted by mathematicians, who have provided proofs based on geometrical arguments.

> One of the most important theorems about the continuum is intuitively obvious: if on a plane a continuous line has one of its extremities on one side of a right line and the other on the other side of the same right line, then the continuous line cuts through the right line (Longo, 2000, p.401).

Bolzano (1817) was the first to explicitly question the validity of proofs of the Intermediate Value Theorem based on geometrical arguments, thus paving the way for the recognition of the need for explicit constructions of the set of real numbers in the second half of the 19th century.

The choice of the intermediate value theorem is motivated 1/ by the epistemological relevance of the discussion on proof and truth; 2/ by the links with the question of $\mathbb{Q}$-incompleteness /$\mathbb{R}$-completeness; 3/ by its presence in many curricula at the transition from secondary to tertiary education, mainly because of its various applications.

In the first section of the paper, we present Bolzano's view that proofs of the Intermediate Value Theorem[1] based on geometrical arguments should not be admissible, while at the same time Cauchy provided such a proof in his course at the Ecole Polytechnique in Paris (Cauchy, 1821). In the second section, we discuss both approaches, with particular reference to a paper by Hourya Benis-Sinaceur. In the last section, we discuss possible didactic implications for proof and proving in mathematics education.

Truth and *proof and proving* in the theory of equation

Bolzano's discussion on geometrical arguments in proofs of the Intermediate Value Theorem

In the preface of his paper "Rein analytischer Beweis des Lehrsatzes, dass zwischen je zwey Werthen, die ein entgegengesetzes Resultat gewähren, wenigstens eine reelle Wurzel der Gleichung liege", published in Prague in 1817, Bernard Bolzano wrote[2]:

> There are two propositions in the theory of equations of which it could still be said, until recently, that a completely correct proof was unknown. One is the proposition: that between any two values of the unknown quantity which give results of opposite sign there must always lie at least one real root of the equation. (Russ, 1980, p.159)

It is noticeable that Bolzano does not raise doubt on the truth of this proposition, despite the lack in his view of a fully correct proof. He mentioned several names of mathematicians having provided a proof for this proposition, and claimed: "However, a more careful examination very soon shows that none of these proofs can be viewed as adequate" (Russ, 1980, p. 160). He then provided arguments for this claim.

> The most common kind of proof depends on a truth borrowed from geometry, namely, that every continuous line of simple curvature of which the ordinates are first positive and then negative (or conversely) must necessarily intersect the x-axis somewhere at a point that lies in between those ordinates. There is certainly no question concerning the correctness, nor indeed the obviousness, of this geometrical proposition. But it is clear that it is an intolerable offense against correct method to derive truths of pure (or general) mathematics (i.e., arithmetic, algebra, analysis) from considerations which belong to a merely applied (or special) part, namely, geometry. (Russ, 1980, p.160).

This discussion by Bolzano brings to the fore the relationship between truth and proof and proving in Mathematics and prefigures Dedekind's concern in his essay "Stetigkeit und irrationale Zahlen" published in 1872 where he writes[3] that in teaching a course in Differential Calculus, he resorted to geometrical evidences "in proving the theorem that every magnitude which grows continuously, but not beyond all limits, must certainly approach a limiting value" (Dedekind, 1963, p. 1). He states that this is useful from a didactic point of view, but cannot be claimed as scientific, that leads him to

---

[1] In fact, he deals with the case of two images of opposite signs.

[2] We use the English translation by S.B. Russ, published in Russ (1980, pp.159-181)

[3] We use the English translation by W.W. Beman in Dedekind (1963, pp. 1-27)

search for "a purely arithmetic and perfectly rigorous foundation for the principles of infinitesimal analysis." (Dedekind, 1963, p.1)

Bolzano continues, claiming that proofs should not be simply confirmation (Gewissmachungen), but rather justification (Begründungen)[4], and then, he moved back to the Theorem he is considering:

> Consider now the objective reason why a line in the above-mentioned circumstances intersects the x-axis. Everyone will, no doubt, see very soon that this reason lies in nothing other than that general truth, as a result of which every continuous function of x which is positive for one value of x, and negative for another, must be zero for some intermediate value of x. And this is precisely the truth which is to be proved. It is therefore quite wrong to have allowed the latter to be derived from the former (…). Rather, conversely, the former must be derived from the latter if we wish to represent the truths in the science in the same way as they are connected to each other in their objective coherence. (Russ, 1980, pp. 160-161)

These criticisms concern the proofs mentioned by Bolzano at the beginning of the preface, which does not include the proof by Cauchy that was published four years later in 1821, but the criticism apply.

Cauchy's first proof of the Intermediate Value Theorem

In his famous " Cours d' Analyse De L'Ecole Royale Polytechnique", Cauchy provides two proofs of the Intermediate Value Theorem. Nevertheless, as Longo writes, in the first proof of the intermediate value theorem in his Course of 1821, Cauchy "does not go further than the intuition of continuum that comes from strings and curves traced by a pencil and their crossing. (Longo, 2000. p.403)

Later, page 403, Longo provides an English translation of the theorem and of the proof by Cauchy:

Theorem of the mean value:[5] *If the function $f(x)$ is continuous with respect to the variable x between a and b, and if we call c an intermediary value between $f(a)$ and $f(b)$, then we can always satisfy the equation $f(x) = c$ for at least one value of x between a and b.*
Proof (Cauchy, 1821): It is enough to see that the curve which has equation $y = f(x)$ will meet one or more times the line $y = c$ for at least one value of x between a and b.

Figure 1: The theorem and his proof by Cauchy (1821) (English translation in Longo 2000, p. 403)

The history of mathematics has long credited Cauchy's role in developing a solid foundation for Analysis and Calculus, leaving Bolzano's work in the shade. In the second half of the 20th century, comparisons between the work of Cauchy and Bolzano have been discussed in three papers (Grattan-Guiness, 1970; Freudenthal, 1971, Benis-Sinaceur, 1973). In the following section, we present the point of view developed by Hourya Benis-Sinaceur as an epistemological contribution to the reflection on the relationships between truth and proof and proving in a didactic perspective.

---

[4] In the French translation by Sebsetik (1964), we have *certifications* (Gewissmachungen) and *fondements* (Begründungen).

[5] We recall that Longo refers to what we have named Intermediate Value Theorem

On a historical perspective between Bolzano and Cauchy

In the abstract in English of her paper of 1973, H. Benis-Sinaceur writes:

> *SUMMARY: The purpose of this article is to show the distance between Bolzano's analytic style with his profound logical tendencies, characteristic of the late called riguor of Weierstrass, and the Cauchy's way which remains, despite the important technical innovations, rooted in traditional geometrism.* (Benis-Sinaceur, 1973, p. 97)

She underlines the desire by Bolzano to found mathematics, and to privilege the proof of a result over the result itself and its application:

> For him [Bolzano], what matters is to express explicitly and to underline the necessity of proving the results, even if they have been known and used for a long time, his own work is to try to make these proofs. (Benis-Sinaceur, 1973, p. 104)[6]

Concerning Cauchy, referring to the preface of the 1821 course, she writes:

> […] there are neither questions of founding, nor of refining the proofs, nor of rejecting geometric intuition (…). The aim is merely of doing mathematics, that is to say of solving problems and improving known solutions, by restriction, rather than by generalization, by specifying under which conditions the formulas are not a empty symbolism. (Benis-Sinaceur, 1973, p. 105)

In her paper, Benis-Sinaceur acknowledges the view of Freudenthal (1971), who against Grattan-Guinness (1970), rejected the idea that Cauchy might have plagiarised Bolzano. She emphasises the differences between the two authors' programmes, which leads to different practises: while Bolzano is primarily concerned with theoretical rigour and the search for purely analytical proofs, rejecting recourse to geometry as vicious circle, the qualities of Cauchy's course are those of synthesis rather than formal rigour (pp. 102-103). She concludes her paper by arguing that the work of Bolzano and Cauchy represent two distinct heterogeneous paths that would not meet until the works by Weierstrass, Cantor and so on, in contrast to the idea of a continuous development through the nineteenth century.

On Bolzano as a precursor of Dedekind

It is a fact that, although it is hard to believe, neither Bolzano nor Cauchy defined the real numbers (Freudenthal 1971, p. 387). As mentioned above, in a certain sense, Bolzano's programme prefigured Dedekind's programme as expressed in the preface of his essay on continuity and irrational numbers. Dedekind uses the intuitive continuity of the line to define the notion of a cut in the set of rational numbers, to prove that some cuts are not operated by a rational number, and by creating for such cuts one and only one irrational number that operate this cut. Having proved that the system composed of all the rational and the irrational numbers is a complete ordered set (namely a continuous set), he was able to prove in a purely analytic way several theorems in Calculus[7]. In a letter to R. Lipschitz of July

---

[6] Our translation from French; and the same for other quotations of the paper.

[7] For a presentation of Dedekind construction of the set of real numbers and didactic implication, see Durand-Guerrier (2016).

27th, 1876, Dedekind underlines that nothing is more dangerous than admitting existences without sufficient proof and ask how to recognise the licit and non-licit hypothesises of existences. Returning to Bolzano's geometric concerns, and to the intuitively obvious results mentioned by Longo and used in Cauchy's first proof, Dedekind's work reverses the burden of proof: if the domain of the continuous function at stake is a complete ordered set, then the equation has at least one solution, and thus the curve representing the function f will necessarily intersect the line of the abscissa (in the case of images of opposite signs).

Some didactic implications

Contribution to the discussion on the relationships between *truth* and *proof and proving*

As already mentioned, Bolzano and Dedekind's concern was with the type of proof admissible in the mathematical field in question (Analysis, Differential Calculus). They questioned and rejected as unscientific the use of proofs based on geometrical arguments and considered the need to develop a theory in which it would be possible to prove these theorems within the theory and they did so. From a didactic point of view, this underlines the importance of considering that "what characterises a mathematical theorem is the system of statement, proof and theory" (Mariotti, 2006, p.185). In Durand-Guerrier & Tanguay (2018), we showed the impact of the definitional choices of the real numbers (through Dedekind's cuts; as limits of Cauchy sequences, as unlimited decimal expansions) in the proofs of the completeness of the set of real numbers, and conversely the contribution of working on these proofs to improve the understanding of the nature of the mathematical objects at stake and the topological relationships between rational and real numbers. The R-completeness, compared with the Q-incompleteness, provides strong proof of existential theorems such as the Intermediate Value Theorem, and some fixed-point theorems (for an example, see Durand-Guerrier, 2016 and below in the next section). As argued by Bolzano, for such theorems, the geometric evidence may be misleading. Indeed, in the graphical register, it is not possible to see the difference between a curve representing a function defined on a subset of R that is dense-in-itself but not ordered-complete (e.g. the set of rational numbers), and a curve representing a function defined on an ordered-complete subset of the set of real numbers (e.g. an interval). Therefore, in the theory of equations in the set of rational numbers, the statement corresponding to the Intermediate Value Theorem is false, i.e. the existence of a solution to an equation satisfying the conditions of application is contingent. If we consider a formal axiomatic system of the theory of equations without including a completeness axiom, then there are models of this axiomatic system in which it is not possible to prove the Intermediate Value Theorem, and others in which it is possible to prove it. This was hidden in the proofs based on geometric arguments, such as the first proof of the intermediate value theorem by Cauchy (1821).

This accounts for Bolzano's point of view that what underlies the geometric truth used in the classical proofs that he criticises (the curve intersects the x-axis at a point between x_0 and X) derives from the truth of the Intermediate Values Theorem. Indeed, in a set of numbers that is dense-in-itself but not ordered-complete, the curve will always intersect in the geometric sense the x-axis, but it may not correspond to any point of the set of numbers under consideration. In our view, this supports our claim that the relationship between *truth* and *proof and proving* is not one of subordination, but rather a dialectical relationship. In the case of Bolzano, and Dedekind, a statement can be accepted as true before it can be proven. The challenge is then to elaborate a theory in which it is possible to prove this statement true. As far as Cauchy is concerned, according to Benis-Sinaceur, the requirement for "geometric rigor is not a call to a strict formalism, but a control of conformity to an "intuition" of phenomena occurring in the familiar practice of Analysis" (Benis-Sinaceur, 1973, note 13, p. 107).

Two situations aiming to discuss the relation between Analysis and graphical register

Due to the recurrent difficulties faced by students and teachers for what concerns the teaching and learning of proof and proving in mathematics, we consider that it would be valuable to put on the scene in didactical situations their dialectic relationships with truth. We briefly report two examples involving the context of discreteness-density-in-itself and continuity (completeness) and the associated graphical representations.

A fixed-point problem. In Durand-Guerrier (2016) we have presented and analysed a didactical situation involving a fixed-point problem for an increasing function, in four different cases: 1. the case of a finite segment of the set of natural numbers; 2. the cases of intervals [0,1] 2.1. of the set of finite decimal numbers; 2.2. of the set of rational numbers; 2.3. of the set of real numbers. In case 1 (thanks to discreteness) and in case 2.3 (thanks to completeness), it is always possible to find a fixed-point; it is not the case for cases 2.2 and 2.3, due to incompleteness[8]. We have shown that this situation has the potentiality for questioning with students the relationships between discreteness, density-in-itself and continuity, and the interpretation in the graphical register. For example, after conjecturing that the statement was true in the set of interval [0,1] of decimal numbers and failing to adapt the proof they did in the first case, secondary students (grade 11) solving this problem in an experimental setting raised the following question: "Is it possible that the graph of an increasing function from the set D of finite decimal numbers to itself crosses the first bisector in a point with non-finite decimal coordinates? (Pontille et al., 1996, p. 25)[9]. Prospective secondary teachers faced difficulties very similar to the secondary students for what concerns the case of finite decimal numbers and rational numbers. Moving to the case of the interval [0,1] of the set of real numbers, they generally first considered that the continuity of the function is required, and then solved the problem with the Intermediate Value Theorem. The next step was to understand that the hypothesis of the continuity of the function is not needed, and to move to a proof without this hypothesis (e.g. relying on the existence of Supremum, or by construction of adjacent sequences).

An algebraic definition of exponential. In Durand-Guerrier, Montoya and Vivier (2019), we provided empirical evidence of students' difficulties in distinguishing density-in-itself and continuity, and we hypothesised that the use of digital tools increases the need of conceptual tools to interpreting graphical representations and reconstructing the objects of Analysis. We then proposed a didactical situation with the aim with the aim of providing students with such tools.

The mathematical question consists in searching for the functions $f: E \to R$ satisfying the functional equation $\forall x \in E\ \forall y \in E f(x+y) = f(x)\, f(y)$, where E is a usual set of numbers,

[8] This situation was first presented in Pontille, Feurly-Reynaud and Tisseron (1996)

[9] Our translation from French.

$\mathbb{Z}$, $\mathbb{Q}$ and $\mathbb{R}$. We assume that $f(1) = 2$ and it can be proved that $f(0) = 1$ and f takes positive values. We ask to compute some values of f (respectively, for each set, value of f at: 3 and -3; 1/3, -1/3, 1.3; -1.3; $\sqrt{3}$ and -$\sqrt{3}$) and to draw graphical representations (on paper and with Geogebra software).

Figure 2: The task posed to students (Durand-Guerrier, Montoya & Vivier, 2019, p. 89)

While in the sets $\mathbb{Z}$ and $\mathbb{Q}$, the function is completely determined by the algebraic relation and the calculation of the image of a yields to 2^a, this is not the case for the set $\mathbb{R}$ of real numbers. In the contexts of dynamic geometry and of paper-and-pencil geometry, the graphical representation of the function in the $\mathbb{Q}$-domain provides the same graph than the exponential function on the $\mathbb{R}$-domain. However, this graphical evidence is misleading: indeed, under the given hypothesis, there are a lot of functions defined on domain $\mathbb{R}$ that satisfy the algebraic property. Therefore, the search for an analytic proof that the function coincides with the usual real exponential function is bound to fail. This should therefore lead students to question the graphical evidence. This situation was experimented in Chile and Peru with prospective teachers. The most advanced students try to prove algebraically that the image of $\sqrt{3}$ is $2^{\sqrt{3}}$, which is not possible without additional assumption about the function (e.g. the function is increasing); others admitted without proof that the function was the exponential function 2^x on the domain $\mathbb{R}$. After being asked to give a value (e.g.1) to the image of $\sqrt{3}$, students provided graphical representations that surprised them. In particular, in some cases there were two points on the same vertical, this making visible the distinction between the real line and the rational line, in other words, the distinction between a continuous (ordered-complete) domain and a dense-in-itself not continuous (not ordered-complete) domain. The first empirical results comfort our conjecture that this problem has the potential to let the need for proof emerge, beyond geometrical evidence, given that the organisation of the didactic situation allow a genuine engagement of students.

Conclusion

In this paper, we have tried to highlight the dialectic relationship between *truth* and *proof and proving* from an epistemological point of view, in the case of the Intermediate Value Theorem. In the last section, we have given two examples of didactical situations that have the potential to stage this issue at the transition from secondary to tertiary level and for teacher training. Designing didactical situation with such potentialities is a challenging issue.

Logical inferences in the view of first-year students

Christian Fahse

University of Koblenz-Landau, Department of Mathematics, Germany; fahse@uni-landau.de

Keywords: argumentation, conditionals, deductive reasoning, language.

To control for logical ability in a broader study, the study presented here investigates the understanding of inferences. The tasks consist of a conditional sentence in A, the negated or not negated antecedent (the if-clause) or consequent (main clause) of this conditional in B, and a possible inference from A and B as in the following example: (*A) If the flowers are blue, the car is rolling. (B) The car is rolling. What do A and B imply mathematically-logically, if only the propositions A and B are known and nothing else? Cross the answer with which you agree most.* □ *Given only the propositions A and B, mathematical logic implies the flowers are blue.* □ *…are not blue.* □ *One cannot infer with mathematical logic whether the flowers are blue or not.*

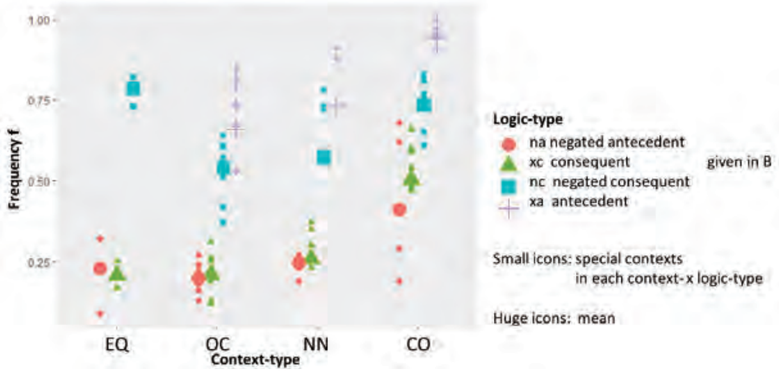
Theoretical background

The analysis of conditionals is immensely broad (von Fintel 2011), being spread out into many disciplines – philosophy, linguistics, logic, and psychology. Perhaps, the root of the matter is the following: With the word “if” one or more possible (or even counterfactual) worlds are possibly entered depending on the context. Therefore, some points have to be considered in the construction of the items: (1) *Plausibility* (Pólya 1990, Vol. 2, Ch. XII & XIII) of antecedent and consequent, the link by the two in its (2) power of (*explanatory) necessity* (Bartelborth, 2007; Müller-Hill, 2017), (3) the formulation of the *question* (v_4 in Durand-Guerrier 2003, p. 18; reasoning *from* or *about* a rule in Wason, 1968; Evans, 1997), (4) the *context* (e.g. deontic or not - Evans, 1997; Valiña & Martín, 2016), (5) implicit *quantification* (propositional, open or bounded sentences - v_7 in Durand-Guerrier, 2003, p. 18), (6) reformulations without conditionals in predicative logic or as *restrictions* (Bartelborth, 2007), (7) *material or logical* implication in A.

Present study

As a consequence of these seven issues, the items are constructed as follows: Plausibility of the antecedent and consequent (1) have to be unknown, the plausibility of the conclusion (1,2) is systematically varied by context-types, three choices for the answer are given (see example above; 3), only reasoning *from* a rule (3) in A, given as material implication (7) by abstract sentences in the present indicative (4), no quantifiers and avoiding the interpretation as open sentences in order to prevent implicit quantification (5, 6). Due to pilot studies, we did not use any negations in the conditional sentence and in a first step only contexts of every-day-life instead of mathematical ones (4, cf. Durand-Guerrier 2003, 18, v_1; also to avoid differences in content knowledge). We used four cases of plausibility in A (*context-type*): CO (cogent) - The direction of the conditional is cogent, the logic converse is not. *If the brakes are broken, the car is out of order.* OC (not cogent) - The direction of the conditional is not cogent, whereas the converse is. Specifically, the converses of the CO-Items are used. *If the car is out of order, the brakes are broken.* EQ (equivalence) - Both directions of the conditional are cogent because it is a material equivalence. *If you are a pupil, you go to school.* NN (neutral) - No available truth value, no probability, arbitrary conditional. *If the train is coming,* *the flower is yellow*. These cases are each combined with the following four logic types, realized by B: xa antecedent given, na negated antecedent, xc consequent, nc negated consequent. The convenience sample is comprised of N=593 students at the beginning of their university studies. Each combination of logic- and context-type used 2-8 contexts. Due to the multi-matrix booklet designs, a Rasch-model (N=593, infit≤1.04, outfit≤1.07, item-total-cor.≥.19, EAP-rel=.36) was applied.

Results



Even if the contexts are extremely specified (see 1-7 above) and the logic-types and negation are controlled, the context has still a great impact on the variance of frequencies. The most abundant answer in each type coincide with those given if material implication in A had been mistaken as an equivalence - in contrast to the findings and interpretation of Durand-Guerrier (2003, p. 22).

Standardized tests and the development of argumentation competency: Tensions perceived by Chilean mathematics teachers

Manuel Goizueta[1], Constanza Ledermann[2] and Helena Montenegro[3]

[3]CMM, Universidad de Chile, Chile; helena.montenegro@uchile.cl

Chile's standardized tests SIMCE and PSU have been criticized for their unintended effects in the classroom, for contributing to growing elitism in education, and for perpetuating social inequality. However, teachers' perceptions about these tests and their impact on teaching practice have seldom been considered. We focus on teachers' perceptions about the tension between the development of argumentation competency proposed by the national curriculum and the standardized tests. Resorting to in-depth interviews, we account for the systemic lack of alignment that mathematics teachers perceive between curriculum and tests. Results show that this leads to an impoverished learning experience, suggesting that curriculum and test design might not be enough to foster curricular intended teaching, and that teachers' perceptions must be taken into account.

Keywords: Argumentation, argumentation competency, standardized tests, mathematics curriculum.

Introduction

Argumentation is key to constructing participative, democratic societies. Notions such as *mathematical literacy* (PISA, 2018) express the expectation that the student-citizens engage in argumentation, drawing on scientific knowledge, attitudes, and competencies to understand reality, and participate in their communities in critical, reflective, and value-based ways. This has driven many countries to consider argumentation – under this or other denomination – to be a competency to be developed as part of citizenship education. The Chilean curriculum proposes argumentation as one of four competencies to develop at all levels of mathematics education (MINEDUC, 2019, 2015, 2012).

In the course of the last two decades, citizenship education has gained momentum through international standardized tests, such as the Programme for International Student Assessment (PISA), or the Trends in International Mathematics and Science Study (TIMSS). These tests have stimulated the need to assess competency development in students as part of educational system quality assessment efforts. Argumentation being one of the competencies the Chilean curriculum aims to develop, both the Education Quality Measurement System test (SIMCE) –used nationally to assess the quality of compulsory education at various school levels – and the University Selection Test (PSU) – given nationwide in the 12th grade to rank students for access to higher education, are expressly meant to be measuring it.

However, what is stated in the curriculum and assessment systems does not directly translate into classroom practice. Crucially, it is teachers who interpret them and make the pedagogical decisions that shape students' learning experience. They make these decisions while experiencing the tension between what is explicitly demanded by the educational system and what they perceive could best help students succeed in standardized testing. In contexts of high-stakes standardized testing – such as Chile – the resolution of this tension has enormous consequences.

Regardless of the subject, studies on the impact of high-stakes testing consistently report narrowing of the curriculum, increase of teacher-centered pedagogies, and abandonment of high-quality forms of instruction in favor of routine practices (Au, 2007; Blazar & Pollard, 2017; Meckes, 2007; Valli & Buese, 2007). Poor-quality "teaching to the test" has often been considered a consequence of standardized testing (Darling-Hammond & Adamson, 2014), even though test advocates insist that cognitively demanding tests may motivate teachers to improve and enrich instruction (Au, 2007, Peery, 2013). In the case of mathematics, previous studies at various school levels have found that test preparation activities predict poorer-quality and less ambitious mathematics instruction (Blazar & Pollard, 2017; Cohen & Hill, 2008; Meckes, 2007).

Most of these studies have resourced to classroom observation to evaluate teaching quality. Although such studies are crucial to describing high-stakes testing effects in the classroom, they typically neglect teachers' voices. Besides, they tend to consider classroom activity as a whole and do not focus on specific curricular aspects. In the present study, we draw on in-depth interviews, exploring the perceptions of Chilean mathematics teachers with respect to the tension between development of argumentation as a curriculum-proposed competency and the national standardized tests SIMCE and PSU, and its consequences in classroom teaching practice. We first present aspects of the Chilean curriculum and programs, and of the SIMCE and PSU tests. Then we explain the methodological design of our study. Finally, we present and discuss our results to account for the systemic lack of alignment that teachers perceive between the national curriculum and the standardized tests in terms of the pedagogical work necessary to develop students' argumentation skills in the classroom.

The argumentation competency in the Chilean curriculum

The national Curricular Bases (CCBB) designed by the Ministry of Education (MINEDUC) constitutes the cornerstone of the educational system. They provide a mandatory, standard framework for education in all schools, presenting educational principles, and establishing learning goals (LG) for each level of school instruction. In the case of mathematics, the CCBB establishes specific and progressive LG for the development of argumentation (MINEDUC, 2019, 2015, 2012). Table 1 presents the LG for grades 8 and 11-12.

8th grade (MINEDUC, 2015, p. 112)	11th-12th grade (MINEDUC, 2019, p. 108)
● Describing mathematical relations and situations verbally and using symbols. ● Explaining and justifying: (i) Students' own solutions and procedures; (ii) Results using definitions, axioms, properties, and theorems. ● Backing conjectures using examples. ● Assessing the arguments of others, giving reasons.	● Making decisions based on statistical evidence and/or results obtained from a probabilistic model. ● Using symbolic language and other representations to justify the truth or falsehood of conjectures and assessing the reach and limits of arguments.

Table 1: Learning goals for argumentation, grades 8 and 11-12

Within the CCBB, argumentation is understood to be part of a dialogue, expression of ideas, and collaboration aimed at convincing others of the validity of mathematical results. Students are expected to transit from an informal/intuitive to a formal/mathematical style of argumentation (MINEDUC, 2015). However, the CCBB does not provide teachers with a clear operational definition of argumentation that allows them to identify instances of the competency and to progressively assess its development.

SIMCE, PSU, and assessment of the argumentation competency

The Quality Education Agency (ACE) designs and implements the SIMCE test as part of the National System of Quality Education Assurance (SAC). The objective of SAC is "to ensure access to quality and equity in education for all students in the country, through comprehensive evaluation, pertinent inspection, and constant support and guidance to educational establishments" (CNED, 2021). SIMCE is administered in the 2nd, 4th, 6th, 8th, 10th, and 11th grade, and encompasses several subjects, including mathematics. As a basis for the SIMCE test, the Ministry of Education develops Learning Standards, which "describe the degree of curricular achievement required for evaluation and monitoring of students' performance in order to provide feedback to educational policy and to the school system" (MINEDUC, 2017, p. 5). The Learning Standards should thus allow teachers to monitor and plan for their students' progress following the CCBB. However, and despite declaring that students must develop "problem-solving, representation, modeling and argumentation competencies" (MINEDUC, 2017, p. 50), no specific competency indicators are presented, nor are milestones in expected competency development.

The Department of Educational Assessment, Measurement and Registration (DEMRE) is responsible for developing the PSU test for the process of admission to Chilean universities. On its website, DEMRE declares that the test will assess contents and competencies in line with the current curriculum. The mathematics test "will have 65 multiple-choice questions with a single answer among 4 or 5 choices, (...) it will assess the Understanding, Applying and Analyzing, Synthesizing and Evaluation competencies, (...) and will contain 13 questions that assess the competencies specified in the Curricular Bases: Problem-Solving, Representing, Modeling, and Argumentation" (DEMRE, 2020). On its website, DEMRE refers to argumentation as "the ability of the applicant to evaluate procedures, deductions, solution strategies, and inferences in various problems; to distinguish and detect erroneous arguments; and to understand chains of logical implications". However, no further information is presented about how the test allows argumentation assessment.

We must also consider the consequences that PSU and SIMCE results have, turning them into high-stakes measures for students, schools, and teachers. PSU results determine access to higher education and career options. A university degree is seen as a strong socioeconomic mobility factor in Chile, hence test results are crucial both for students and their families. Although the SIMCE test does not have direct consequences for students, results are clustered by schools and made public on official and media websites, *de facto* functioning as a school ranking tool. This affects families' preferences – hence student enrollment –economically impacting state-financed schools through a per-pupil voucher system based on attendance (Taut et al., 2009). Teachers' income is also often affected through school economic incentives linked to students' test performance (Botella & Ortiz, 2018).

Methods

The study used a qualitative methodology with a multiple-case study approach (Yin, 2009) to explore recurrent themes addressed by participating teachers during semi-structured interviews. A purposive sample of mathematics teachers (Neuman, 2006) was obtained (n=21) using two sampling criteria: i) the subjects were teaching in educational establishments located in Chile's Metropolitan and Valparaíso Regions, and ii) they taught mathematics at the 6th and 12th grade (12 and 17-year-old students respectively), in which the SIMCE and PSU tests are applied. The teachers' ages ranged from 24 to 49, and their teaching experience from 1 to 20 years.

The interview protocol included questions to investigate teachers' perceptions about argumentation and its teaching in the mathematics classroom; decision-making processes aimed at developing the argumentation competency; the relationship between argumentation competency development, and SIMCE and PSU; and the impact of these tests on teaching practice. The interview time with each participant ranged between 32 and 109 minutes. The set of basic questions was common to all, but follow-up questions differed based on answers, explaining the differences in interview duration. All interviews were recorded and transcribed for analysis.

A thematic analysis of the interviews was carried out by two researchers in order to identify recurring patterns and themes in the data and allow for triangulation (Braun & Clarke, 2006). The first stage involved open codification (Strauss & Corbin, 1998) of each of the interview transcripts. Each researcher independently identified conceptually similar codes and interview excerpts, grouping them into preliminary analytical categories. Initial coding was compared and discussed among the researchers for purpose of validation and adjustment, thereby achieving greater reliability. Then axial codification was performed on the whole data corpus (Strauss & Corbin, 1998). Key themes related to main categories were identified through an iterative process of inductive/deductive analysis, enabling elaboration of a thematic map of the analysis (Braun & Clarke, 2006). A systematic data review was conducted in order to identify negative cases, thus avoiding any confirmation bias. Finally, results were prepared in the form of narrative themes (van Manen, 1990) addressing teachers' perceptions about tensions between the development of argumentation competency and SIMCE and PSU tests, and their consequences in the mathematics classroom.

We present three main related themes and include as many excerpts from teachers' interviews as possible to allow their voices to elaborate on them. The original excerpts are in Spanish. We have tried to convey the sense along with idiosyncratic nuances when translating them into English. In the following section, secondary teachers are referred to as ST, while elementary teachers as PT.

Findings

The importance of argumentation in the mathematics classroom

There is consensus about the importance of argumentation in the mathematics classroom among participating teachers. Teachers associate argumentation with self-regulation and understanding, as opposed to mechanical and non-reflective execution of techniques. In the words of ST1:

> ST1: [Argumentation] has to do with realizing how you are thinking. That also allows you to analyze your strategies, to improve and complement them, and to understand others'. Bottom line,

> if I understand how I reason, I am also able to explain it, and being able to explain it means that I have an understanding of what I am doing. [...]. I think that is what we expect of students.

Teachers unanimously emphasize that student's argumentation allows them to assess learning and make pedagogical decisions, since knowledge and reasoning become "visible" in argumentation.

> PT5: When asking the child to explain how he solved a mathematics problem, what he did, the calculations he performed, why he did this or that, that is the way I can become aware of the mistakes he makes. I realize how he is thinking, in what way he is reasoning mathematically. That way, I can address his difficulties.

Obstacles to development of argumentation in the classroom

Despite the importance attributed to argumentation, teachers point out various obstacles to implementing activities for its development related to PSU and SIMCE tests. Their answers can be grouped into two recurring and complementary themes, i) they perceive covering curricular contents in mathematics to be the central requirement of the SIMCE and PSU tests – and of the educational system in general, having priority over development of competencies and attitudes; and ii) they feel pressured to dedicating time to activities aimed at improving students' SIMCE and PSU test scores. These two themes refer to demands perceived by teachers that impact their pedagogical decisions, particularly when selecting learning activities. Below, we elaborate on these themes together, since teachers refer to them when explaining the tensions between the development of argumentation competency and SIMCE/PSU tests, and their consequences in the mathematics classroom.

The pressure to cover curricular mathematics content emerges from teachers' interpretation of the curriculum and from the demands placed on them by senior management staff in schools. Moreover, teachers consider the time devoted to covering mathematics content to be an impediment to planning and implementing learning activities related to argumentation, as expressed by PT5 and ST5.

> PT5: The Ministry mandates delivery of all contents. They say "you have to teach all the contents within the year," which is impossible, but there is no focus on competency development. [...] So, I have always been focused on delivering content, but not on competency development.

> ST5: Both regulations and your school demand content coverage from you, and also that students be prepared to confront the PSU test answering questions correctly and doing well. Thus, one starts cutting away. Are you going to work on argumentation? Really? How much? Once? Twice a month? Damn, twice!? You will be neglecting practice and application. They (senior management staff) are going to question you. Hey, what's going on?

Teachers perceive great importance in PSU and SIMCE results and explain that in a multifactorial way. As already mentioned, student scores are grouped by school and made public. Local media present this information as a measure of a school's quality and of the chances offered for university admission. Teachers perceive that these results are presented publicly as an indicator of the quality of their teaching, impacting their job stability. The perceived importance of these tests translates into pressure to dedicate time to tasks aimed at improving test scores, pressure that is openly or implicitly exerted by school mid-level supervisors (academic coordinators, department heads, etc.). This leads teachers to adapting classroom activity, particularly those years in which students must take the tests.

> ST6: I think the [pressure] mechanisms are not visible or explicit. [...] Because a coordinator won't tell you to privilege [test] results over learning, but one way or another you get the message.

PT7: We have some autonomy in distributing our work and students' work, but always within a framework. Because, at the end we are subject to the standardized assessments, so we make decisions on that basis. One way or another, you lean towards them.

Consequences for classroom mathematical activity

When questioned about the relationship between argumentation and SIMCE/PSU tests, teachers agree that the tests do not measure argumentation competency and that their focus is on memorization, calculation, and mechanization of procedures. Crucially, they believe that in order to improve test scores, it is necessary to implement activities that are similar to the tests in the classroom. This leads them to frequently implement multiple-choice exercises similar to those that appear in the tests, leaving little to no time for other activities. In their view, the tasks they feel compelled to implement do not stimulate argumentation or are even detrimental. In summary, these teachers perceive a systemic lack of alignment between the tests and the curricular requirement to develop argumentation. Moreover, they do not just consider that argumentation is neglected in this process, but also that the overall student learning experience is impoverished.

ST6: The school where I work is focused on scores. Programs are pretty bulky, loaded with content, and focused on standardized tests, SIMCE, PSU. […] For this reason, this competency (argumentation) has not been developed. In the end, mathematics work has been centered on closed-ended question tests. [...] I even feel that this forces teachers to constantly think of multiple-choice tasks, and perhaps also that justification is unimportant.

PT2: I was talking with my colleagues the other day. Why should I care whether students practice argumentation in class? The school is going to assess me just by SIMCE results, and SIMCE does not require argumentation. They just ask you multiple-choice questions.

Discussion

The unintended consequences of Chile's standardized tests have been discussed in previous studies. It has been observed how the use of test results to rank schools within a free-market rationale perpetuates the correlation between socio-economic situation and school achievement, contributing to social inequality (Botella & Ortiz, 2018; Inzunza, 2014; Monarca, 2012). Although teachers are expected to use SIMCE test results as a formative, diagnostic tool to improve their pedagogical practice, Taut et al. (2009) have shown that just "a third of the teachers could accurately tell 'good' results from 'bad', and even fewer were able to accurately evaluate change over time and relative status comparing similar schools" (p. 135). With regard to the impact in the classroom, in line with international research (Au, 2007; Darling-Hammond & Adamson, 2014), previous studies have reported narrowing of the curriculum (Taut et al., 2009) and decreased teaching quality (Botella & Ortiz, 2018; Meckes, 2007). However, such studies have seldom taken into account teachers' perceptions of tests and their impact on argumentation. We focused on the tensions between explicit curricular demands regarding development of argumentation competency in the mathematics classroom and the implicit demands arising from teachers' perceptions of PSU and SIMCE tests.

The lack of alignment between the curriculum and the standardized tests perceived by the participating teachers is expressed in two interrelated but well-differentiated ways. On the one hand, they perceive that SIMCE and PSU tests do not allow the assessment of argumentation competency, since it is not brought into play in the tests in ways that provide evidence of its development. On the other hand, teachers perceive that the best strategy to improve students' scores is to implement multiple-choice tasks similar to those found in the tests, which do not require argumentation. That is, according to this group of teachers, not only is argumentation not measured by the tests, but its development does not help students perform well. Together with the intense pressure to achieve good scores, this results in classroom activities that marginalize argumentation and, in general, impoverish students' educational experience, particularly during the years in which they are tested (Bellei & Muñoz, 2021). Despite being aware of this impoverishment and of the fact that all of them declare that they do so reluctantly, teachers participate in strategies orchestrated by schools to improve test scores. This agrees with other studies that suggest that high-stakes testing often drives teachers "to abandon methods and materials that had been successful with their students" (Bailey, 2000, p.118) and even "engage in practices that were antithetical to their beliefs about a good instructional environment" (Valli & Buese, 2007, p. 552).

It is crucial to note that we did not interview a representative teacher sample, nor we attempted to determine whether SIMCE and PSU tests do measure students' argumentation competency and its development, as declared by test designers. Nevertheless, we have shown that this group of teachers does not perceive this to be the case and that such perception negatively impacts actual teaching practice regarding development of argumentation competency. In line with what Blazar and Pollard (2017), and Cohen and Hill (2008) say, these results suggest that curriculum and test design might not be enough to foster curricular intended teaching, as hoped by test designers and policy makers (Peery, 2013). Our results suggest that teachers' perceptions must be taken into account.

Language activities related to logical structures of proofs – a theoretical and empirical specification

Kerstin Hein

TU Dortmund, Germany; kerstin.hein@math.tu-dortmund.de

This study combines the Toulmin model and processes while proving to analyze the language activities of proving processes concerning logical structures. A case study of Alena and Jannis (both grade 10 and 15 years old) is presented in more detail. The qualitative analysis of the proving processes of Alena, Jannis, and 46 other students (grades 8 to 12) reveals insights into the development of verbal activities from the first verbal sequence to the written product, in particular: 1) The linguistic implicit logical structures in the process of proving, 2) the limited number of language activities, 3) the use of explicit logical language means in the last sequence of writing.

Keywords: Formal proof, Toulmin model, language, proving activities, language activities

Introduction

Language means (words, phrases, and grammatical forms) can have different meanings in mathematics than in everyday language (Duval, 1995; Schleppegrell, 2007); this mainly applies to the language means of proofs and proving (such as conjunctions or other logical connectors). Within the huge learning content of proof and proving, particular challenges were identified in the structural change to deductive reasoning (Fischbein, 1982) and the steps from the process to the product of argumentation, such as proofs (Albano & Dello Iacono, 2019). These challenges are also rooted in linguistic challenges, e.g., with new meanings of the exact words (Duval, 1995) and their necessary connection to the language (Ferrari, 2004). Therefore, the language of deductive reasoning requires more systematic research attention (Durand-Guerrier et al., 2011). To study the language of proving, language must be functionally extended from the words and phrases to the language activities used by these language means (Schleppegrell, 2007; Prediger & Zindel, 2017). This extension resonates with the Vygotskian perspective of this paper, as Vygotsky (1962) regards language as an artifact that is learned by using it in meaningful activities. Hence, the language of deductive reasoning is learned in the language activities involved in proving activities with logical structures. Therefore, specific language challenges have to be figured out for relevant learning contents (Bailey, 2007). This paper aims at specifying the appropriate proving activities and their language representation related to the logical structures of proofs. Therefore, this study focuses on concrete language activities to overcome the logical structures while proving from the first verbal try to the proof text. First, the specification is theoretically derived from the existing state of research and then empirically investigated using students' processes with the following research question: Which language activities do students enact in their transition from verbally arguing to writing proofs?

Theoretical Background

Logical structures

Understanding the logical structures is essential for students' transition from intuitive to deductive proof (Fischbein, 1982). The Toulmin model (1958) is widely used to analyze argumentations, particularly in mathematics education, to model logical structures (e.g., Krummheuer, 1995). In the current paper, the short version of Toulmin's model is adapted so that data, warrant, and claim are described as the logical elements *premise*, *warrant*, and *conclusions* of a proof. Additionally, the logical relations between the logical elements are considered. In line with Duval (1991), the use of a conclusion from a previous step to another as a premise is called *recycling*. In this way, a multiple-step proof can be described. Figure 1 shows the adapted model used in this study to capture students' activities with logical structures.

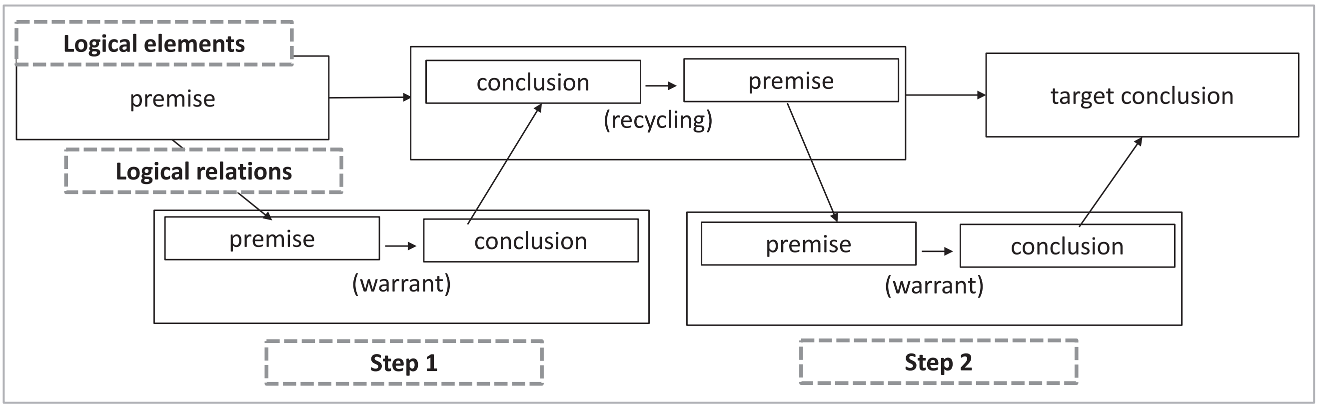

Figure 1: Adapted Toulmin Model about logical structures in proof (here two steps)

Proving activities related to logical structures

Whereas Boero (1999) has specified all proving activities in general, Heinze et al. (2008) have focused mainly on proving activities related to logical structures (for proving activities at proofs with multiple steps). Additionally, Tsujiyama (2011) emphasized the identification of the premise and target conclusion. Based on their work, the following proving activities were specified as relevant concerning the logical structure of proofs (Hein, 2021): 1.) unfolding the information in the task (premise and target conclusion), 2.) identifying warrants and their logical structure, 3.) forming logical relations between logical elements (premise, warrant, conclusion) within the proof steps, 4.) arranging and creating relations between the proof steps, 5.) finding a linear representation of the proof. It should be noted that these activities can emerge in different orders and do not have to be observable.

Language activities related to the logical structures

The state of research on logical structures in the adapted Toulmin (1958) model and the specified proving activities (following Heinze et al., 2008; Tsujiyama, 2011) is the theoretical foundation to identify the language activities:

This paper defines language activities as linguistic representations of concrete (learning) activities. Here, the main emphasis is on the linguistic representations of the proving activities related to logical structures (in the following stated as *language activities*). For every proof activity related to logical structures, a linguistic representation is described and graphically categorized to the Toulmin Model (Figure 2).

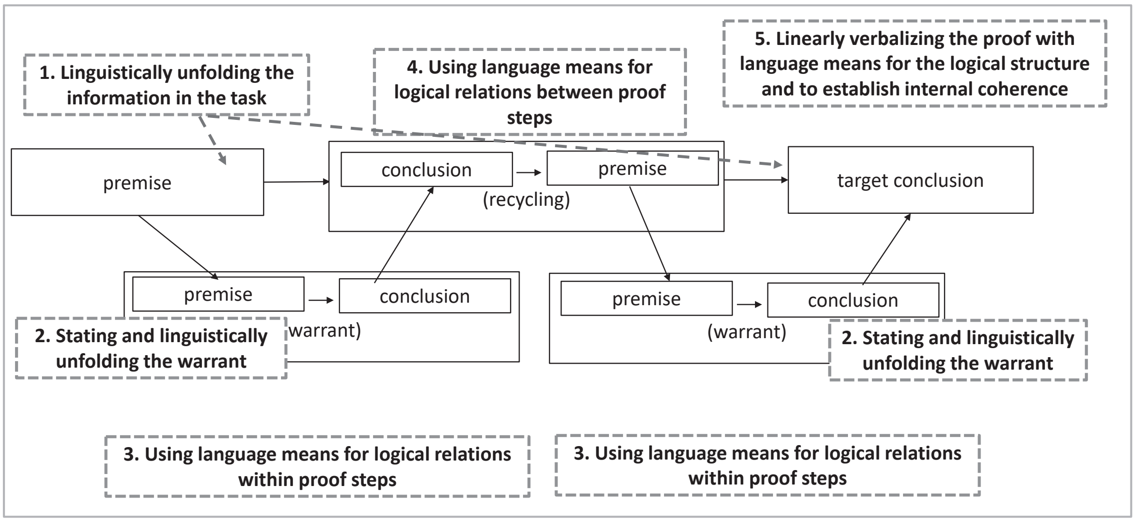

Figure 2: Language activities concerning logical structures (activities in dashed boxes)

Although these activities can be done mentally, this paper describes how these activities can be observed. The underlying assumption is that the students need first to notice the logical structures for their understanding through visible activities.

Methodology for the analysis of proving processes

Data collection

The data corpus for this paper stems from a major design research project on deductive reasoning in grades 8-12 with angle sets. A teaching-learning arrangement with verbal and graphical scaffolds was developed within the project. Whereas other publications investigate students' learning process of the logical structures (see Hein & Prediger, 2017), this paper focuses on identifying the enacted language activities. The complete data corpus consists of transcribed videos from design experiments and written proofs with 24 pairs of students (20 students in grade 8, 6 in grade 9, 4 in grade 10, 18 in grade 12). An example of the analysis is given using the case of Alena and Jannis, both tenth-graders and 15 years old (Hein, 2021). Their process illustrates the typical phenomena for the whole dataset, and the design experiments were still in a laboratory setting to gain deeper insights. The author was the teacher herself in the laboratory setting and interacted with the students to explore their learning (see Cobb & Steffe, 1983).

Methods of qualitative data analysis

The qualitative analysis of the students' language activities while proving draws upon the *Toulmin Model*, the *proving activities*, and the *derived linguistic representations*. First, the related logical structure based on the Toulmin model is coded (Figure 2). Then the proving activities are identified, respectively, as their linguistic representation. Based on the previous steps, the following tool analyzes the language activities in proving and their operationalization within the design experiment: 1.) Linguistically unfolding the information in the task: stating the premise (step 1) and target conclusion (step 2); 2.) Stating (step 1) and linguistically unfolding the warrants (step 2): stating the mathematical propositions that must be used and unfolding the conditional implication structure; 3.) Using language means for logical relations within proof steps: verbalize the logical relations with causal or conditional conjunction respectively prepositions; 4.) Using language means for logical relations between proof steps: verbalize the relation between the proof steps with logical language means; 5.) Linearly verbalizing the proof with language means for the logical structure and making text coherence: primarily through a proof text with an explication of the logical elements in their logical order, and the use of logical language means.

Empirical insights

Alena and Jannis work on their second proof within the teaching-learning arrangement (the alternate interior angle proposition as in Figure 3). They have the necessary warrants (corresponding angle proposition, transitivity proposition, and vertically opposite proposition) available on cards. The whole session, they work as a pair.

For a first overview, Table 1 summarizes the reconstruction of the language activities of Alena and Jannis for each sequence.

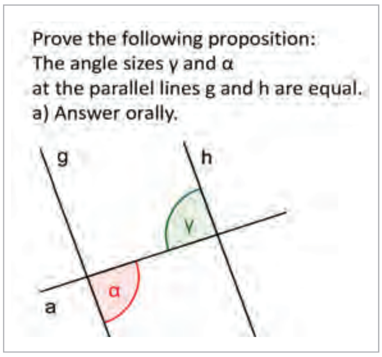

Figure 3: Task

Table 1: Reconstruction of the language activities of Alena and Jannis

Phases of proving	Reconstructed language activities (related to logical structures)
Sequence 1 Verbal reasoning	• No language activity
Sequence 2 Filling in graphical scaffolds	• Linguistically unfolding the information in the task (State the target conclusion (activity 1 step 2) • Linguistically unfolding of the warrants (activity 2 step 2) • using language means for logical relations within proof steps (activity 3)
Sequence 3 Writing the if-then-clause	• Linguistically unfolding the information in the task (activity 1)
Sequence 4 Written products	• Linguistically unfolding information in the task (activity 1) • Stating and linguistically unfolding the warrants (activity 2) • Using language means for logical relations within proof steps (activity 3) • Using language means for logical relations between proof steps (activity 4) • Linearly verbalizing the proof with language means for the logical structure and establishing internal coherence (activity 5)

Sequence 1: Verbal reasoning

In the first sequence, Alena refers to another task with a concrete alternate interior angle task (asking for gamma if alpha is 50 degrees) and points at it (Turn 578). Again, Alena and Jannis perform no language activity here.

578 Alena This is… [*16-sec break*]. Again with this… [*points on the previous task*]

In another task, Alena and Jannis, and the other students state the arguments or point with fingers at the cards with the mathematical propositions, which is possible in the design of the teaching-learning arrangement. Without the teaching-learning arrangement, the students often only state conclusions here.

Sequence 2: Filling in graphical scaffolds

In the second sequence, Alena and Jannis fill in graphical scaffolds to arrange the logical elements (premise, warrant, and conclusion) in the correct order. This process and the graphical scaffolds are described for another student pair in Hein & Prediger (2017, sequence 2). Here the focus is only on the language activities. Through the graphical scaffold, they are demanded to make explicit the target conclusion by writing it down. In the following, a few examples are presented:

581 Alena Yes, mhm. Is gamma equal to alpha?

In this way, the target conclusion from the *task's information is linguistically unfolded* (activity 1.2).

639 Alena […] So this and this is equal [*points on gamma and beta how they have named the vertically opposite angle of gamma*] and this and this is equal [*points on beta and alpha*]. It follows that this and this [*points on gamma and beta*] are equal.

Once a *warrant is linguistically unfolded* (activity 2.2) while applying the transitivity proposition.

Finally, Alena and Jannis use isolated *language means for logical relations within the proof steps* (activity 3), such as in the following example:

620 Jannis So from this [*points on a graphical scaffold*] **follows** for now that […]

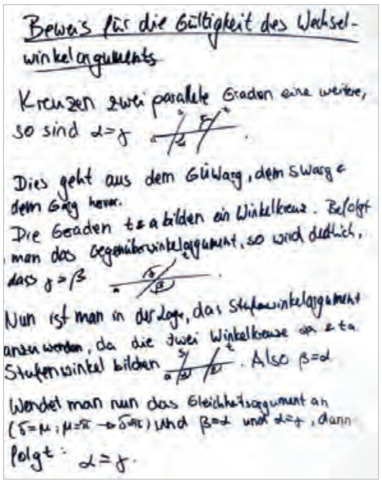
In this sequence, the students use, above all, deictic language means while filling in the graphic scaffolds which represent the logical structures. This sequence is described in detail in Hein (2021).

Sequence 3: Writing the if-then-clause

In this sequence, the students write down the mathematical proposition with "if-then" and differentiate *the premise and the target conclusion* (activity 1).

Sequence 4: Written products

Both students write proof texts independently, based on their filled graphical scaffolds (Figures 4, 5).



Beweis für die Gültigkeit des Wechselwinkelarguments
Kreuzen zwei parallele Geraden eine weitere, so sind α=γ.
Dies geht aus dem GüWarg, dem SWarg & dem GArg hervor.
Die Geraden t & a bilden ein Winkelkreuz. Befolgt man das Gegenüberwinkelargument, so wird deutlich, dass γ=β.
Nun ist man in der Lage, das Stufenwinkelargument anzuwenden, da die zwei Winkelkreuze an s & t a Stufenwinkel bilden. Also β=α
Wendet man nun das Gleichheitsargument an (δ=μ; μ=π → δ=π) und β=α und α=γ, dann folgt: α=γ.

Proof for the validity of alternate interior angle proposition

[If] two parallel lines cross another, **then** is α = γ.

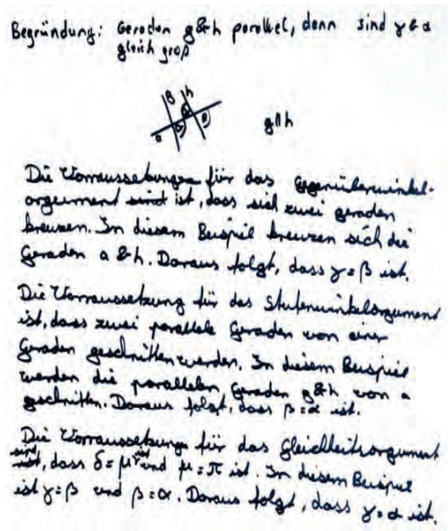
This arises from the vertically opposite proposition, the corresponding angle proposition, and the transitivity proposition [*Alena uses abbreviations chosen by herself for the propositions*].

The lines t & a form an angle intersection. If you follow the vertically opposite proposition, it becomes clear **that** γ=β.

Now, you can apply the corresponding angle proposition because both intersections s/a & t/a form the corresponding angle. **Hence**, β=α.

If you apply the transitivity proposition (δ=μ; μ=π -> δ=π) and β=α and α=γ, **it follows**: α=γ.

Figure 4: Written product of Alena (original (Hein 2021, p. 231) and translation)



Argumentation: Lines g & h parallel, then γ & α are equal.

The **premise** for the vertically opposite angle argument is that two lines cross each other. **In this case**, the lines a & h cross each other. **Thereof it follows that** $\gamma=\beta$.

The **premise** for the corresponding angle argument is that one line crosses two parallel lines. **In this case**, the parallel lines g & h are crossed by a. **Thereof** it follows that $\beta=\alpha$.

The **premises** for the transitivity argument are that $\delta=\mu$ and $\mu=\pi$. **In this case,** 13 $\gamma=\beta$ and $\beta=\alpha$. **Thereof** it follows that $\gamma=\alpha$.

Figure 5: Written product of Jannis (original (Hein 2021, p. 232) and translation)

Both students write first what has to be reasoned (the alternate interior angle proposition) and thereby *linguistically unfold the information in the task* (activity 1).

Both students use *language means for logical relations within proof steps* ("thereof.."; "in that case") (activity 3). To express the relation between the first and second step to the third step, Jannis makes explicit the conclusion of both first steps as a new premise ("The premises for the transitivity proposition are that $\delta=\mu$ and $\mu=\pi$. In this case…") and thereby *use language means for logical relations between proof steps* (activity 4). Finally, both students *linguistically unfold the warrant*, namely the unknown transitivity proposition (activity 2.2). Alena does this in brackets, Jannis, through the explicit application of the transitivity proposition. The other propositions as warrants are not unfolded.

Besides the language means for logical relations Jannis also uses nominalizations ("premise") and makes explicit the logical status of the premise. Alena uses language means of text coherence such as "this" and refers to parts of the text before in this way. She also uses temporal conjunctions ("Now"), which express no logical, but temporal relations.

Both students show *linear verbalization of the proof with language means for the logical structure* and *establish internal coherence* (activity 5), primarily through a proof text with an explication of the logical elements in their logical order and usage of logical language means.

Summary

As summarized in Table 1, Alena and Jannis perform different language activities. However, they can be identified depending on the related logical structures and concrete elements of the teaching-learning arrangement.

To sum up, activity 1 (*the linguistic unfolding of the information in the task*) can be found late, with both premise and conclusion in sequence 3. Although Alena and Jannis state the warrants in sequence 1 (here facilitated through the design of the teaching-learning arrangement), they unfold the warrant while filling in the graphical scaffolds and only make explicit the unknown warrant in their texts in sequence 4. Jannis uses language means of logical relations between proof steps only in his text. The students mainly use language means for the logical relations within and between the proof steps, particularly in the writing products.

For the other 46 students, similar language activities are empirically identified: Many logical structures remain tacit in the first sequence of verbal reasoning. When provided, conclusions are often expressed without further reasoning, and mathematical propositions are stated with the argument cards. While working with the graphical scaffolds, the students perform fewer language activities expected because of deictic language means. Such as "here" can be used instead. The premise and conclusion of the proposition, which must be proven, are stated very explicitly at later stages. The students then use more language means for the logical relations within and between the proof steps in the written products. In the texts, the mathematical content of the proof is represented through language means, with a variable degree of the explicit formulation. Sometimes, unnecessary temporal conjunctions are also used.

In summary, although many opportunities are given within the design experiments, there is a slow increase in language activities related to the logical structure.

Conclusion

In this study, the logical structures and their articulation in language are investigated to specify the language learning content for proving (as demanded by Durand-Guerrier et al., 2011). The main finding in the case study of Alena and Jannis is the following: In line with Albano & Dello Iacono's (2019) results on typical proving processes, some language activities are rarely seen in the early sequence of verbal reasoning. However, there is identifiable progress towards increasing explicitness within the four sequences. Based on previous research on the importance of language activities based on Vygotsky's (1962) theory and this study, the following implications for teaching can be derived: 1.) Increasing the teachers' awareness of the possible explicit language activities may be helpful so that the teachers can consciously demand the language activities. In particular, concerning explicitness for the logical structures (e.g., conjunctions and adverbs for logical relations). 2.) The herein described language activities are a starting point for the students to have opportunities to learn. 3.) Emphasis should be given to having the students write the proof themselves in the classroom.

It should be noted that the teaching-learning arrangement in design experiments causes the data of this study. Therefore, it is likely that students would show even fewer language activities without the teaching-learning arrangement. In addition, not all language activities have to be observable because they can also be only mental. Finally, the study's limitations are the small size of observed students and the limited number of tasks considered.

Seventh-grade students' perceptions of qualities in a mathematical argument

Sigrid Iversen

Norwegian University of Science and Technology, Norway; sigrid.iversen@ntnu.no

This paper reports on a task where seventh-grade students evaluated five pre-written arguments designed to display various proofs and non-proof arguments. The analysis focuses on what students described as qualities of the arguments. The results indicate that students appreciate arguments they perceive to understand, arguments that are short, and arguments containing text. Thus, the task approach holds the potential to unravel what students perceive as the qualities of an argument. However, there is no clear relationship between the features of the arguments and what students perceive to be qualities. Further investigation should occur to see how the task can be improved to better display aspects of valid mathematical arguments to help students appreciate these and, in turn, be able to produce mathematical proofs.

Keywords: Primary education, mathematics, argumentation, proof.

Introduction

Proof holds a prominent role in mathematics, and researchers and policymakers worldwide increasingly appreciate its importance for mathematics learning (Stylianides et al., 2017). In Norway, 'Reasoning and argumentation' is one of six core elements in the new curricula implemented since autumn 2020. It states that the students should prove that their solutions to mathematical tasks are valid (Kunnskapsdepartementet, 2020). This formulation introduces proving to the primary school curricula in Norway (age 6 to 13), but it is not clear how it could be implemented into practice (Valenta & Enge, 2020). Reasoning and proving in primary education (ProPrimEd) is an intervention-based project that aims to answer this call by developing research-based materials to help teachers implement proving into their teaching. A mathematical proof is here defined using Stylianides' (2007) definition of proof: a kind of argument that uses forms of reasoning and expression that are mathematically valid and suitable for a specific classroom community and uses true statements accepted by the same community. By this definition, it is assumed that students at all grade levels can engage meaningfully in the practice of proving.

This paper reports on a lesson in the intervention conducted in grade 7 (age 12-13). The aim was to prompt students to become aware of the qualities of a good mathematical argument as an entry into work with proving. Lannin (2005) recommends that "research should examine the types of tasks that encourage students to examine the variety of justifications and generalisation strategies that other students use" (p. 254). Thus, this study examines the potential of this task approach. In addition, possible connections between students' evaluation and the designed arguments are explored to see whether the task can help students become aware of the features of valid arguments. The research question is: *What are seventh-grade students' perceptions of qualities of a mathematical argument?*

Theoretical framework and related literature

G. Stylianides' (2008) framework defines categories to analyse students' reasoning and proving activities, following A. Stylianides' (2007) definition. The framework distinguishes between proofs and non-proof arguments, where proofs are demonstrations or generic examples. Without a specific example, a demonstration draws on the properties of and relations between mathematical objects to show why a conjecture is true. This can be done using variables or other means of representing mathematical objects. For example, a random even number could be represented as $2n$ or "pairs of shoes", depending on the community. Counterexamples, contradictions, proofs by induction and proofs by exhaustion are also considered demonstrations. A generic example draws on a particular example and explains the underlying mechanisms to show why a conjecture must be valid for all cases. The affordances of using generic examples to help students move from showing that something is true towards showing why it is true is widely recognised (see e. g. Aricha-Metzer & Zaslavsky, 2019). This suggests that generic examples are a promising entry into work with proving at the primary level.

In G. Stylianides' (2008) framework, a non-proof argument is either an empirical argument or a rationale. An empirical argument consists of showing that a conjecture holds in some cases without showing why, hence providing "inconclusive evidence for the truth" (G. Stylianides, 2008, p. 12). A rationale is introduced as a fourth category to capture arguments not covered by the three former types. It is neither an empirical argument nor a proof but an attempt to prove that either lacks reference to accepted statements or uses statements that are not accepted by the community. In this sense, a rationale can be seen as a proof that misses some of the steps or content needed to convince a given community. The categories described in this section provide the backdrop for the five pre-written arguments presented in the Methods section.

How students perceive mathematical arguments have been investigated earlier, for example, by Bieda and Lepak (2014) and Healy and Hoyles (2000). Both studies show that students are likely to accept empirical arguments as proof. In Bieda and Lepak's (2014) study, the students were the same age as those in this study and had no documented proving experience. They were given two examples of arguments to consider, one empirical non-proof argument and one proof, and were instructed to decide which argument they preferred. In addition, they were asked to describe how the one they did not prefer could be amended to be more convincing. The results indicated that students were inclined to prefer examples accompanied by explanatory text. They both had a numeric example to show that a conjecture holds and text explaining why. The students in Healy and Hoyles' (2000) study had undergone teaching of proving and were given several arguments to consider, such as empirical arguments and proofs, using various modes of representation (e. g., everyday language and algebraic symbols). Their results indicated a discrepancy between what kinds of proofs students themselves would produce and what proof they believed would get the best mark by an evaluator. The students in the study had more success evaluating proofs written in words instead of algebraic notation and found them more convincing. The authors inferred that students' informal and narrative argumentation should be exploited to develop their proof competence. The present study draws on these results by 1) using a variety of informal representations such as contexts, drawings, and narrative explanations, and 2) prompting students to reflect on their proof conceptions by asking them to evaluate and choose among a set of arguments. Both studies described above applied interviews and surveys as data collection methods, while this study will take a different approach by observing group work without the presence of a teacher. This difference allows for insight into the potential of the task.

Method

This study is a single instrumental case study, where the researcher focuses on an issue and uses a bounded case to illustrate it (Creswell & Poth, 2018). Here, the case consists of students who work on a proof-related task. The issue explored is the task's potential to increase students' awareness of the qualities of a good mathematical argument. The study was conducted in spring 2021. A class consisting of 19 seventh-grade students participated, and their regular teacher taught the lesson. According to the teacher, who had taught the group for three consecutive years, the students had not met the term argumentation explicitly in their mathematics instruction. Therefore, the study provides insight into their first meeting with this theme, and this case is thus instrumental in exploring this task as an entry into argumentation. However, previous observation and descriptions given by the teacher suggested that the class was in the habit of showing their work, that is, in detailed writing, when they worked on tasks. The data was collected through video recordings of the students working in groups of three to four, giving five groups. Because of limited access to cameras, three out of five groups were chosen to be videotaped based on the level of verbal interaction observed in earlier lessons. The data material consisted of verbatim transcripts of the video recordings of the group discussions and the groups' written responses, including the groups that were not filmed. Therefore, one group was neither recorded nor given any written reasons for their opinions and is not included in the data material. Hence, the number of participating students was 16, whereby 12 were video recorded, and four submitted a shared written response.

The task, shown in Figure 1 below, was presented to the class by the teacher in plenary along with five pre-written arguments, with no additional information given.

> Mira, one of the students in a class, said:
>
> *The five-times table is easy. When you want to figure out what a number multiplied by five is, you can just multiply it with ten and then divide the result by two.*
>
> Several of Mira's classmates were uncertain that this could be true for all possible numbers. Some said that it could be true, but they were uncertain of why. They explored Mira's conjecture and made their own arguments.
>
> Your task is to
>
> 1. Choose the argument that you think is the best one, and write down two reasons why
> 2. Choose the argument that you think is the worst, and write down two reasons why
>
> Be aware that an argument should be such that it makes us more certain that a conjecture is true for all numbers and that we understand why it is true.

Figure 1: The given task

The arguments, shown in Figure 2 below, were crafted to demonstrate different arguments based on G. Stylianides' (2008) framework and were designed to be perceived as the work of a student their age. Abi's argument is a proof in the form of a generic example, while the rest are non-proof arguments. Hannah’s and Inga’s arguments are empirical arguments using a few examples, with the distinction that Hannah gives numeric examples while Inga uses a drawing to show an example. Leo’s argument uses larger numbers and refers to using a calculator. All three are empirical arguments, while Belma’s argument is a rationale, as it contains a part of an argument but lacks logical connections and details to be convincing. None of the arguments is of the form demonstration, which emphasised the difference between generic examples and empirical arguments.

Name	Argument
Hannah (empirical argument)	Yes, it is correct. $2 \cdot 5 = 10 \quad 2 \cdot 10 = 20$ half $\quad 7 \cdot 5 = 35 \quad 7 \cdot 10 = 70$ half $\quad 8 \cdot 5 = 40 \quad 8 \cdot 10 = 80$ half
Belma (rationale)	Yes. $6 \cdot 5 = 30$ $6 \cdot 10 = 60$ It happens because 5 is the half of 10. $5 + 5 = 10 \quad 10 : 2 = 5$
Inga (empirical argument, with drawing)	$4 \cdot 10$  $4 \cdot 5$ half $4 \cdot 5$
Leo (empirical argument, larger numbers)	$3 \cdot 10 = 30 \quad 26 \cdot 20 = 260 \quad 268 \cdot 10 = 2680$ $3 \cdot 5 = 15 \quad 26 \cdot 5 = 130 \quad 268 \cdot 5 = 1340$ It is always this way. I have used my calculator to check many cases.
Abi (generic example)	It is correct, because: For example, if we want to calculate $7 \cdot 5$. That means to find out how much 7 fives are if added together. We can start by working out what 7 tens are:  Next, we can split each ten into two fives:  7 tens = 7 fives + 7 fives $7 \cdot 10 = 7 \cdot 5 + 7 \cdot 5$ Thus, $7 \cdot 5$ is the half of $7 \cdot 10$! If we use another number, not 7, then it will be just the same. It will only be a different number of tens and fives.

Figure 2: The arguments that were given to the students (translated from Norwegian)

The students were given copies of the arguments and the task and worked on it for 20 minutes before being called back to a whole-group discussion. While the groups worked with the task, the teacher and two researchers observed the groups.

The unit of analysis was a student contribution, either written or verbal. The contributions that regarded one of the arguments and described a positive or negative feature were collected. This gave 36 utterances. The further analysis was performed as an inductive qualitative content analysis (Mayring, 2015). The aim was to understand the different perceptions and their magnitude in the data material. The utterances were coded inductively to capture the feature it addressed. Codes describing related features were then collected into overarching categories. For example, the code “short, positive” and the code “long, negative” both belong to the category “short”, as they both suggest the perception that an argument should be short.

Findings

The analysis of the 36 utterances resulted in seven categories, as shown in Table 1 below. In the following, each category is elaborated on in order of appearance in the table.

Table 1: Overview of utterances by category

Categories	Explanation	Short	Text	Order	Drawing	Examples	Warrants
Frequency	15 (42 %)	7 (19 %)	5 (14 %)	3 (8 %)	3 (8 %)	2 (6 %)	1 (3 %)

The most frequent category, explanation, considered utterances related to understanding or explanation. It applied whenever a student stated that an argument was explained well or was easy to understand. Both Hannah’s, Leo’s, and Belma’s arguments were said to be easy to understand, and some students claimed that Hannah “…explained it really well”. One student spoke about Inga: “Really bad explanation. I did not understand what she meant. She just drew.” Abi’s argument is criticised: “…is hard to understand because it is long and messy”. Another negative remark about it is that “It is so much strange going on here at once”, indicating that it was considered complex by the student and might represent something the student was not used to seeing. Other students appreciated Abi’s argument: “Because he explains, for example, that the tens are divided into two”. This utterance indicates that a student noticed an essential feature of the generic argument. Other students said, “It has both writing and drawing. Very good explanation. Everyone can understand this. No difficult words were used”. Thus, Abi’s argument was either valued for its thorough explanation or was not appreciated because of its length and complexity. These examples show that both the short and the more elaborate arguments could be explained well. Hence, what students mean when they say that something explains well or is easy to understand is unclear.

The category short considers utterances about the length of the argument. Hannah’s argument was appreciated because “It is simple and short”, and about Belma’s argument, some said that it was positive “…that she used only one example”. “Leo’s and Hannah’s arguments are good because they did not have too much text to read and understand”, while “Abi’s argument is hard to understand because it is long and messy". The students appeared to value short arguments because they took up little space and took little effort to read.

Several students mentioned the presence of explanatory text, especially regarding Inga's and Abi's arguments. Abi's argument was valued because it had both writing and drawing, as indicated by the quote in the previous section. Inga's argument was the only one that none of the students preferred, and one student said: "The others have written text. That is why hers is the worst because it is easier to explain by writing than by drawing". Other utterances to support this view are: "She does not explain what it is that she has drawn", and "but she does not explain what she does". Hence, a short argument was not necessarily appreciated if the students did not find the content satisfying.

The four least frequent categories are the order of the argument, the use of drawings, the number of examples, and the warrants. Concerning the order of the argument, one student gave all the utterances, for example: "Leo just starts. Now I don't know, if I start with the first, I don't know (if it is true)". The student seemed to believe that the conclusion, whether the conjecture is valid or not, should be stated at the beginning of the argument. Two utterances were about the number of examples: "There are more examples", "checked on many numbers". This indicates an appreciation of examples and is related to the features that the arguments were meant to display. However, the task intended that the students recognise these arguments as mere examples and not convincing arguments. These utterances suggest the opposite outcome of what was intended. The use of drawings is also mentioned by a few students, either saying that it is good to use a drawing or that the quality of the drawing affected the quality of the argument. The last category, warrants, captured an utterance where the student, in a critical tone, said, while reading from Leo's argument: "I have used my calculator to check many cases. Ok?" indicating that this did not strengthen the argument.

There were few direct references to the features that the arguments were designed to display. For instance, no student commented that Hannah's and Leo's arguments only showed that the conjecture was valid for some examples or that Belma's explanation was incomplete. Instead, as shown above, some remarks suggested that it is good to have many examples. The two utterances appreciating Abi's explanation for being thorough are other examples that indicate a possible awareness of how this argument differs from the rest. Except for these few exceptions, the data shows little awareness of the features of the pre-written arguments.

Discussion

This study offers insight into how students perceive mathematical arguments for general conjectures and suggests that features like the explanation, length, and the presence of text are the qualities that the students in this group value most. However, there is no apparent relationship between students' perceptions and the features that the arguments were designed to display. These findings, along with a discussion on the methodological approach and the task's design, are addressed below.

The appreciation of empirical arguments is evident in this study, as in previous studies (Bieda & Lepak, 2014; Healy & Hoyles, 2000). The inclination to prefer explanatory text is also evident, as Bieda and Lepak (2014) also found. However, the data show that students' reactions are more nuanced. The notion of 'explain' seems to hold divergent meanings, where explanation appears to be a feature connected to whether the mere mathematical content of the argument makes sense or is possible for the reader to understand. This discrepancy might be related to the class habits, where there is an emphasis on showing one's work. To clarify how one has found the correct answer to a mathematical task. Thus, explanation, and in its extension conviction, might concern the presentation of a solution. This perspective is not compatible with assessing arguments for general conjectures. There seems to be a gap to fill to bring the students' attention to the difference between evaluating a written task solution and evaluating whether an argument shows that a conjecture must be valid for all cases. It can be understood as a necessary shift in the socio-mathematical norms in the group, concerning what can count as an acceptable mathematical explanation (Yackel, 2002). At the more practical level, the results emphasise the importance of a well-orchestrated classroom discussion where issues like the difference between showing that and explaining why are addressed. Teachers can benefit from exploring teacher moves to support students' argumentation by pressing to justify why something works. Such actions are suggested by Martino and Maher (1999), who describe questioning that can prompt students' justification when they work on mathematical problems.

Methodologically, this study provides a new lens into students' evaluation of arguments by unravelling how students in groups act without the influence of a teacher or a researcher. The results suggest that students can both explore and verbalise what they perceive to be qualities of arguments but that the nature of these qualities is often distant from what would be accepted by the mathematical community. A limitation of this approach is that it makes it impossible to get further insight into the students' meaning of the words 'explain' and 'understand', which frequently occurs in the data material. A follow-up interview where students are asked to elaborate on their conceptions of these notions could therefore be done to enrich the understanding of the case. As discussed in the previous section, this could provide further insight into how the gap between evaluating a written solution and evaluating an argument could be filled.

This study explores the potentials and challenges of a task where students evaluate others' work, which is an approach recommended by Lannin (2005). The results indicate no clear relationship between argument design and the students' evaluation, but that the task offers an entry point into discussing the qualities of a good mathematical argument. Further study should be made to explore improvements in the task. First, one possible approach is to use fewer arguments. In this task, one could reduce the number of arguments to three: one empirical example, one rationale, and one generic example, the distinction between showing that and explaining why could be highlighted in this way. Second, asking the students to argue for the conjecture themselves before being presented with the pre-written arguments should be explored to see if it might influence how they perceive the arguments. Third, one could consider the suitability of the conjecture. Durand-Guerrier et al. (2012) warn that too simple conjectures can obscure the need for proving. Therefore, it should be explored if conjectures of different complexity have different affordances in this task. Last, an extension of this task could be to find ways to highlight the deductive nature of proofs. A possible approach here is to use valid arguments where the order of the steps is altered and ask students to reorganise the steps to make the argument logical and convincing. Exploring these possibilities could be further steps toward finding fruitful ways to engage primary school students in proving.

Mathematical reasoning outside the classroom – A case study with primary school students solving math trail tasks

Simone Jablonski

Goethe University Frankfurt, Germany; jablonski@math.uni-frankfurt.de

Research findings underline the potentials of outdoor mathematics – leaving the classroom presents the students with every-day situations in which they can apply mathematics. By example, a math trail guides students along a path with several mathematical tasks to be solved on-site, e.g. by measuring or counting. Apart from long-term learning benefits and motivational aspects, it remains unclear how this form of experiential learning involves fundamental mathematics working methods and competences, i.e. mathematical reasoning. In this article, the method and results of a case study with 15 primary school students are presented concerning the frequency and qualitative use of mathematical reasoning during a math trail with eight different mathematical tasks from the areas of arithmetic, combinatory and geometry. The results show that reasoning is involved in the students' solution processes, mainly in developing a solution plan and in geometry tasks, i.e. for estimations.

Keywords: Reasoning Skills, Outdoor Education, Mathematics Education, Experiential Learning

The Experiential Learning Theory and outdoor education

The learning theories by Lewin, Dewey and Piaget have – among other aspects – the importance of experiences with the environment in common (Kolb, 1984). Still, "learning was primarily a personal, internal process requiring only the limited environment of books, teacher, and classroom. Indeed, the wider 'real world' environment at times seems to be actively rejected by educational systems at all levels." (Kolb, 1984, p. 34). In contrast, the Experiential Learning Theory (ELT) emphasizes the "central role that experience plays in the learning process" (Kolb, Boyatzis & Mainemelis, 2000, p. 1). According to the authors, activities such as concrete experiences, reflective observation, abstract conceptualization and active experimentation are essential for the learning process and, in particular, the acquisition of mathematics concepts and skills. Also, Hattie et al. (1997) highlight the importance of *out-of-class experiences* for education, i.e. in the sense of first-hand experiences and through the embodiment of "abstract mathematical concepts in concrete terms, using ideas and modes of reasoning grounded in the sensory-motor system" (Lakoff & Nuñez, 2009, p. 5).

In the context of mathematics education, the term *outdoor mathematics* describes the teaching and learning of mathematics outside the classroom in interaction with the environment. One approach is the *math trail* which describes a route with mathematics tasks to be discovered in and solved with the real-world environment (Zender & Ludwig, 2019). In the educational context, during a math trail, the students cooperate in groups of three and solve the tasks by means of mathematical activities. Furthermore, through first-hand, out-of-class experiences of mathematical concepts, math trails have the potential to foster the acquisition of mathematics skills and competencies, e.g. modelling, problem solving and reasoning (Buchholtz & Armbrust, 2018). The potential of the latter is focused on in the following.

Mathematical reasoning in the context of outdoor mathematics

Mathematical reasoning shows high relevance in the teaching and learning of mathematics at different ages, e.g. concerning the question of how task design can foster reasoning processes (Stylianides et al., 2019). In this paper, the focus is on reasoning in primary school. Therefore, a broad definition of reasoning is chosen, whereby both – arguing and proving – are regarded as subareas of reasoning. This definition is comparable to Stylianides' term *reasoning-and-proving* (Stylianides, 2008) and results in the description of reasoning through several activities, i.e. to identify patterns, make conjectures and provide arguments (Arnesen, Enge, Rø & Valenta, 2019). With the study being located in Germany, the following activities are highlighted in the curriculum for mathematics education in primary school by the Conference of Ministers of Education (KMK, 2004, p. 8): (a) question mathematical statements and check their correctness, (b) recognize mathematical relations and develop assumptions, and (c) search for and understand reasons.

Being listed as a possible potential of math trails, it is examined on a theoretical level how far outdoor mathematics and math trails, in particular, can foster mathematical reasoning in the sense of the three mathematical reasoning activities.

1. Out-of-class experiences: From ELT, it can be assumed that experiences play a major role in learning processes. In the setting of a math trail, the students have to interact with objects and situations in the real world – hereby, they collect experiences in this context. Still, it is not only the collection of real-world experiences. To solve a task of a math trail, the students have to reflect on their experiences by formulating mathematical statements and assumptions. In this reflection process, mathematical reasoning is mainly necessary in the sense of the reasoning activity (a) and (b).
2. Group Interaction: During a math trail, the students work in small groups. For the different activities, i.e. searching the task's object, planning the solving process, exchanging ideas, collecting data and validating the results, it can be assumed that the students interact with each other and reason for and against proposals and ideas. In this social process, mathematical reasoning is mainly necessary for reasoning activities (b) and (c).
3. Transfer of Mathematical Knowledge: Being outside the classroom, the students have to choose the data to be collected from all available data – whereby this number might be higher in the real world than in a school book. Hereby, the students have to transfer the mathematical knowledge that they acquired inside the classroom to a new context that was not primarily created for educational purposes. In contrast to calculation tasks where the mathematical content is often straightforward, the students have to decide (and reason) which mathematical characteristics and relations can be found in the real-world situation. In this reflection process, mathematical reasoning is necessary for the reasoning activities (a), (b) and (c).

State of the art and research question

From quantitative empirical studies, it results that math trails have the potential for positive (long-term) learning outcomes (Zender & Ludwig, 2019), motivational aspects (Gurjanow, Oliviera, Zender, Ludwig & Santos, 2019) and individual opportunities for the support of strengths and weaknesses (Buchholtz & Armbrust, 2018). With reference to ELT, math trails are a promising approach for mathematics education. Still, there has been a lack of studies to examine the process-related mathematical competences when solving math trail tasks, i.e. mathematical reasoning. From the theoretical potentials, it can be assumed that math trails foster reasoning on different levels. Still, the considerations need empirical validation. In order to focus on the aspect of mathematical reasoning in more detail, the paper focuses on the research question:

To what extent and for what purpose do primary students use mathematical reasoning while solving math trail tasks outdoors?

In particular, the focus is on the question of what characterizes the solution processes of math trail tasks concerning mathematical reasoning. From this perspective, it can finally be concluded to what extent math trail tasks are suitable for learning mathematical content and fostering mathematical reasoning.

Methodology

In June 2021, a case study with primary students was conducted to answer the research question. In total, 14 students aged 9-11 years were divided into six groups of two, three or four students. In these groups, the students followed the route of a math trail located at Goethe University Frankfurt with eight different tasks, including combinatory, geometry and arithmetic tasks (see Figure 1). The tasks do not include an explicit question that initiates reasoning.

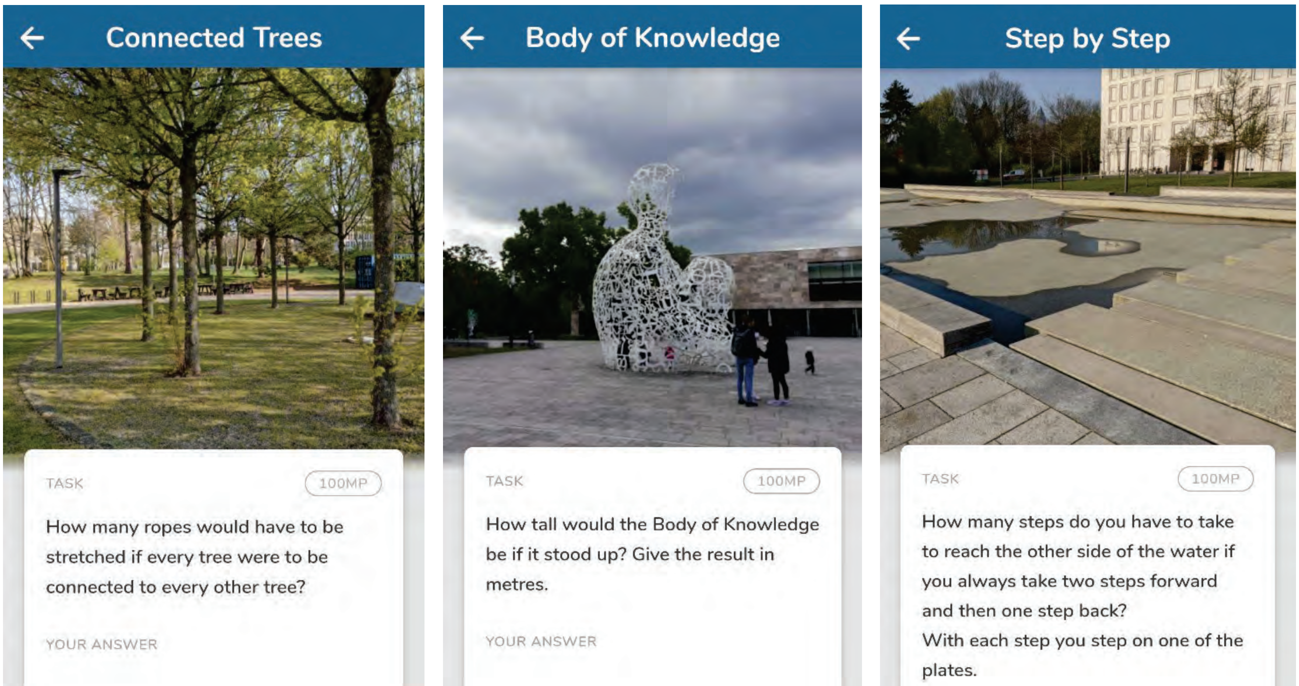

Figure 1: Three tasks from the study for combinatory (left), geometry (middle), arithmetic (right)

For the entire route, the groups needed between 45 and 70 minutes (M = 62 minutes). Hereby, the students were supported by the MathCityMap app through a map, hints and an answer validation (for more information see Zender & Ludwig, 2019). In addition, they were accompanied by a university student who filmed their solving processes and interacted with the students if clarification was necessary. This setting resembles the methodological adaptation of the *narrative walk-in-real-time interview* that Buchholtz, Orey & Rosa (2020) adapted to the context of math trails.

In total, the video material contains about 370 minutes. Especially the students' conversations during the actual solution processes are considered to analyze their way of reasoning. Therefore, the conversations are transcribed and analyzed in two different ways. First, on a quantitative level, the different mathematical activities are coded in accordance to Pólya's phases of problem solving: 'Understand Task', 'Develop Solution Plan', 'Solve Task' and 'Task Validation' (Pólya, 2004). In addition, the mathematical reasoning activities are coded and added to the respective activities in the solution processes. Through this, it is possible to specify the quantity of the students' reasoning in relation to the activities during the solution process. This is visualized by means of activity diagrams (Ärlebäck & Albarracín, 2019; see Figure 2). Afterwards, on a qualitative level, the students' identified reasoning activities are analyzed by means of a qualitative content analysis according to Mayring (2000). With this, different categories of mathematical reasoning can be identified inductively from the empirical material. The categories created in this process are to be considered disjoint. The results of the analyses on both levels are presented in the results section.

Results

Frequency of reasoning activities during the solution processes

Figure 2 shows the activity diagram of the solution processes during the math trail by one of the participating groups. The diagram includes the mathematical activities of the group according to Pólya and specifies, in addition, the activities in which mathematical reasoning is relevant through shading. The diagram gives an overview of the eight tasks of the trail, whereby the tasks from Figure 1 are Task 3 (Connected Trees), Task 6 (Body of Knowledge) and Task 7 (Step by Step). The time for navigation from one task to another is excluded in this presentation.

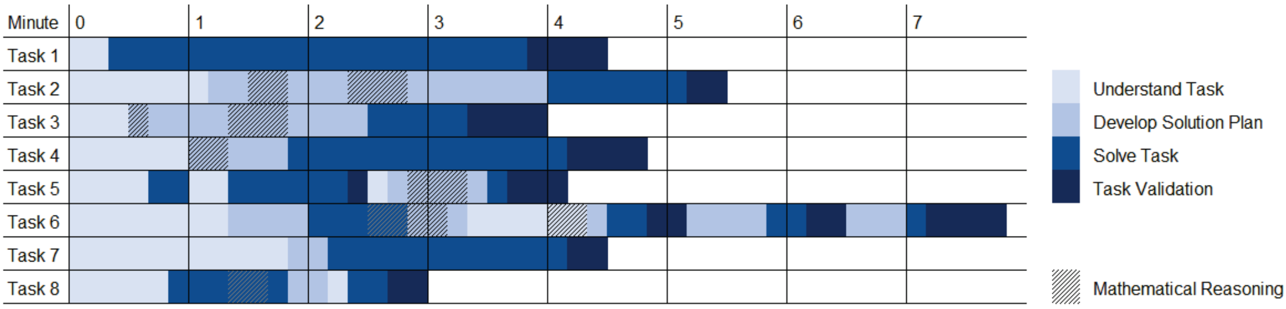

Figure 2: Activity diagram of solution processes and mathematical reasoning activities

In total, the amount of reasoning activities in this group is about 10 % of the time of the math trail task solution processes. Again, this number should be interpreted in the context of the tasks which do not include explicit claims for reasoning. During 25 % of the time, the students understand the tasks. This activity is relevant in all eight tasks. It happens mainly at the beginning of the solution processes through the actual task formulation and an analysis of the object and/or situation. In 4 % of the understanding activities, the students reasoned. The activity "Develop Solution Plan" is relevant in 26 % of the group's solution processes and – despite Task 1 – relevant in every task. In this activity, reasoning is coded most frequently, namely in 28 %. The students spend 35 % of the solution process on the actual task solving. About 5 % of this activity can be coded as reasoning activities. The group's task validation has a relative duration of 14 %. In this activity, they do not use any reasoning.

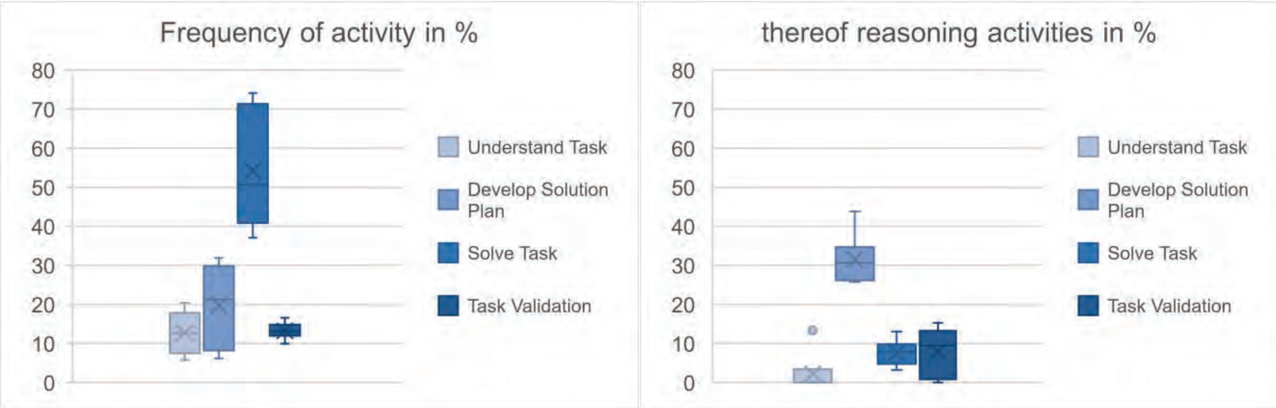

Figure 3: Quantitative overview of all solution processes and reasoning activities

Focusing on all six groups, in about 12 % of the math trail solution processes – excluding navigation – reasoning activities are coded. Figure 3 gives an overview of the frequency of the solution processes and the reasoning activities of all six groups. As a result of this, the beforehand described observations can be summarized for the sample as follows: The actual task solving activity is the most frequent activity in the solution process with more than 50 % on average. It is followed by the development of a solution plan whereby the high deviation shows differences between the groups for both activities. The activities of understanding and validating the task take both about 13 % on average. As presented in the example group, the students reason most frequently in developing a solution plan. From the 20 % of development activities, nearly one third involves reasoning activities. It is followed by the solving and validation of the task, in which 8 % of the activities involve reasoning activities. In the understanding of the task, reasoning plays a minor role.

With tasks from three different mathematical topics being involved in the study, it is possible to analyze the frequency of reasoning activities with regards to the different actions, i.e. counting in the arithmetic tasks, measuring and estimating in the geometry tasks and trying and sketching in the combinatory tasks. Hereby, it can be observed that the geometry tasks involve about two reasoning activities per task. Despite the development of a solution plan, the students reason frequently on their estimations in the activity 'Solve Task'. In the combinatory tasks, about one and a half reasoning activities are coded on average, mainly in the development of a solution plan. In the arithmetic tasks, the amount is about one reasoning activity per task. This might be explained by the comparably low duration of the activities in which the students develop a solution plan. As the activity is mostly counting, the students tend to skip the development of a plan in which reasoning is most frequent.

Categorization of the reasoning activities

The qualitative content analysis results in different categories that describe the reasoning activities for the different steps in the solution process according to Pólya (2004) in more detail. Due to the low frequency of the activity 'Understand Task', it is excluded from the qualitative analysis.

With this analysis, it is possible to identify different ways of the reasoning activities the students used. Table 1 gives an overview of the categories with a representative example from the study (translated by the author from German to English).

Table 1: Qualitative categories describing the purpose of the reasoning activities in the different steps of the solution process

	Definition	Example
Reasoning during Development of a Solution Plan		
Choose a strategy	The students reason about a strategy they might use to solve the task. Aspects such as precision and efficiency are included where appropriate.	“We should count the number of stones in one row, because there are four [rows] […] and it should be nearly the same [number of stones] in each row.”
Identify object/situation characteristics	The students use the local settings and refer to characteristics of the task object/the task situation to reason about a solution plan.	“We have to count with six people. Because it [the bench] has three parts where two persons can sit on each.”
Reasoning during Solving of Task		
Do measurements/ estimations/counts	The students reason about their approach to measuring, estimating or counting. In particular, considerations of the correct procedure are included.	*Student shows a way on a map (see Figure 4 left).* “No, this is not the shortest way. You have to go here and here and only measure up to this building.”
Perform a calculation	The students reason how to calculate, referring to known formulae and mathematical relations where appropriate.	“The first tree has 14 ropes. And then the second [tree] has only 13 [ropes], because it is already connected to the first one. […] So we have 14 plus 13 plus 12 […] and so on.” *(see Figure 4 middle)*
Reasoning during Task Validation		
Check result’s correctness	The students reason for or against a statement whether the achieved result might be correct.	*Student counts 16 regular elements on the task’s object (see Figure 4 right).* “I think it is possible with two [colors] because 16 is an even number.”
Make changes in the solution plan	The students reason why an incorrect result was obtained and how the solution plan should be changed.	“11 is too low, because we estimated 2 meters, but I think it is more. Can you stand next to the figure so that we can estimate with you?”

Figure 4: Impressions of the solving processes during the math trail

Discussion

With regard to the question to what extent and for what purpose primary students use mathematical reasoning while solving math trail tasks outdoors, the following conclusions are drawn. Math trails provoke reasoning activities without explicit questions for reasoning: The students reason especially during the activities in which they decide on a solution plan, i.e. reason about a strategy and by means of characteristics. From the theoretical considerations, in particular Kolb (1984), especially the *out-of-class experiences* and the *group interaction* seem to be relevant for the involvement of mathematical reasoning hereby. Still, the activities 'Solve Task' and 'Task Validation' involve reasoning. During the solving activities, they reason about measurements and calculations. From the theoretical considerations, especially the *transfer of mathematical knowledge* seems to be relevant, i.e. when choosing a suitable formula. During the task validation, again, the *out-of-class experience* seems to be an important factor, especially when it comes to the reflection of the solution process in the context of being outdoors.

The results are in-line with the theoretical considerations – mainly derived from Kolb (1984) and Lakoff & Nuñez (2009) – concerning the relevance of mathematical reasoning in the outdoor setting of a math trail. Still, the indicator that the tasks involve reasoning to a different amount, i.e. in relation to the mathematical topic, raises further questions. Also, the deviation between the groups indicates that the groups might follow different patterns of reasoning along the tasks. Finally, the question arises to what extent the reasoning outdoors differs from the reasoning inside the classroom in a comparable setting – on both, a qualitative and a quantitative level. Comparable data are not available at the current time. In a follow-up study, these questions will be answered to examine the potential of math trails to foster mathematical reasoning. This will be part of the MAP-Study "Modelling, Arguing and Problem Solving in Outdoor Mathematics" funded by Dr. Hans Messer Stiftung.

The use of a deductive reasoning when solving a word problem

Ieva Kilienė[1] and Rimas Norvaiša[2]

[2]Vilnius University, Faculty of Mathematics and Informatics, Vilnius, Lithuania; rimas.norvaisa@mif.vu.lt

The response of problem solvers to a request like 'Explain your answer' does not necessarily provide the assurance that the mathematical representation describing a word problem situation is correct. We suggest to compliment a traditional algebraic word problem with a request to establish a mathematical representation generalizing the problem situation and then to justify its derivation of this mathematical representation. Next, we suggest the construction of a valid deductive argument and evaluate the justification. An example executing the suggestions is given.

Keywords: Word problems, deductive argument, proof validation, magnitudes.

Introduction

Recognition of the importance of proof in school mathematics has increased during recent decades (Balacheff, 1988; Hanna, 2000; Harel & Sowder, 2007; A.J. Stylianides, 2007; G.J. Stylianides, 2008). There are several books presenting new forms of problems that are designed to engage teachers in the practice of reasoning and proving (Arbaugh et al., 2019; A.J. Stylianides, 2016). However, despite these trends in the mathematical research area, the choice of ways to learn to prove in a classroom seem to be quite poor when compared with the available resources for traditional tasks.

Usually word problems have no relationship to reasoning or proving. Their aim is to learn to apply mathematics in contexts outside of mathematics. Word problems are designed just to find an answer to the formulated question. In itself, solving word problems is a great challenge for students as well as for teachers (Verschaffel et al., 2000). By modifying word problems from a plain search for an answer to a tool for reasoning, we hope to help students to make better progress in this type of task. We therefore suggest practising mathematical reasoning in the process of solving word problems. Uncovering logical relationships in the search for mathematical representations of word problems is a way to understand solutions and to make sense of them.

Our research question is how can deductive reasoning be taught and learnt when solving word problems?

The logical connections between statements constitute an important knowledge which students should learn about a deductive reasoning in school mathematics. For example, the rules for drawing the Modus Ponens inferences appear well-developed by early adolescence according to various studies from psychological research (Stylianides & Stylianides, 2008). Therefore the modified word problems considered below are appropriate for students of lower secondary education. This immensely increase opportunities to engage in reasoning-and-proving activities (also see Chapter 5 in Arbaugh et al., 2019, for other arguments).

The discourse of a classroom should be central to the teaching and learning when using modified word problems. This facilitate the exchange of ideas between students and a teacher. Combining different levels of discourse could benefit students' deductive reasoning (p. 22 in Blanke, 2018).

Algebraic word problems

To explain the idea we comment on the supposed phases and components of solving a word problem. The solution is obtained by the following six parts of a *problem solving process* (Verschaffel et al., 2020, pp. 909–910):

> (a) the construction of an internal model of the problem situation, reflecting an understanding of the elements and relations in the problem situation; (b) the transformation of this situation model into a mathematical model of the elements and relations that are essential for the solution; (c) working through the mathematical model to derive mathematical result(s); (d) interpreting the outcome of the computational work; (e) evaluating whether the interpreted mathematical outcome is computationally correct and reasonable; and (f) communicating the obtained solution.

The question is what makes us sure that the solution that is obtained is correct with respect to the original problem. We argue that the evaluation suggested by part (e) does not provide this assurance. Part (e) refers to the answer obtained from part (c) and the interpretation made in part (d). However, the question that remains is whether the mathematical model constructed in part (b) is correct. In other words, if the solver's understanding of the problem or the transformation to the mathematical model are incorrect then the actions suggested by part (e) do not help. We therefore suggest using reasoning-and-proving activity to make sure that the mathematical model in part (b) is correct.

From now on we replace the phrase 'mathematical model' in the description of the problem solving process by the phrase 'symbolic representation', for two reasons. First, we consider traditional word problems as a tool for learning the abstract concepts of school mathematics rather than as a tool for relating mathematics to the real world. In this paper a *symbolic representation* is a generalization of the relationships in a problem expressed in terms of mathematical symbols, such as an equation, a system of equations, inequalities, and so on.

The second reason for the change in terminology is the discovery that the symbolic representations of the problem situations examined in this article are based on a suitable mathematical structure. We hypothesize that such a situation is typical for traditional algebraic word problems. The mathematical structure comes from the hidden properties of the magnitudes describing the word problem. These properties surface when we search for the premises of deductive reasoning. Thus, when considering word problems we pay special attention to magnitudes and their properties.

Now we can specify the above mentioned discovery that a mathematical representation of an algebraic word problem is based on a suitable mathematical structure. Let the three magnitudes A, B and U be given. Let $[A : U]$ and $[B : U]$ be numerical values of A and B with respect to the unit magnitude U. Then the numerical value $[A + B : U]$ of the (non-arithmetical) sum $A + B$ of magnitudes is the arithmetical sum of the numerical values $[A : U]$ and $[B : U]$, or in symbols we have the equality:

$$[A + B : U] = [A : U] + [B : U]. \quad (1)$$

For example, if A is a length and B is a length then one can take two line segments with lengths A and B, respectively. Suppose that $[A : U]$ and $[B : U]$ are the corresponding numerical values measured with respect to a unit length U. Then the numerical value of the length $A + B$ of the two end-to-end concatenated segments is obtained by the equality (1).

Magnitudes usually appear in a contextual representation of the word problem contained in part (a) of the problem solving process. Some of them are unknown and have to be found. By part (b), the contextual representation is transformed into a symbolic representation by means of the relationships between the numerical values of the magnitudes. For example, all symbolic representations of the word problems considered in this paper are equations relating numerical values of magnitudes to each other. The unit names are added back to the numerical values when the result of the computational work is interpreted, as listed in part (d) of the problem solving process.

We are now ready to name the class of word problems studied in this paper. An *algebraic word problem* (AWP) is a verbal description of a problem in which one or more questions are raised, the answers to which can be obtained by establishing and solving an equation with respect to a numerical value of unknown magnitude. This is a modification of the description of an arithmetic word problem given by Verschaffel et al. (2000).

The primary goal of our suggestion is to teach and learn mathematical reasoning in school mathematics. With this aim, in addition to the usual question in an algebraic word problem we have two tasks. The first of these is to justify a symbolic representation that answers the question, and the second is to prove the stated representation by constructing a valid deductive argument. The second task is required since in this paper a 'justification' is a broader term than a 'proof': a *justification* means a set of arguments used to give reasons why a conjecture is true. We use the symbol AWP+2T to denote an AWP together with the two added tasks. The proof, in the form of deductive reasoning, assures us that the overall solution is correct with respect to the original problem. In sum, a problem solving process of an AWP+2T has a new part, (b'), consisting of proving the symbolic representation, while parts (a) and (b) now provide a response to the first task.

Framework for reasoning-and-proving

In this paper, reasoning-and-proving activities are considered when solving algebraic word problems. Here we recall the analytic framework describing the meaning of reasoning-and-proving given by G.J. Stylianides (2008) (see also Arbaugh et al., 2019).

In mathematics, a proof of a new piece of knowledge is the final step of a work researching a mathematical phenomenon. It is preceded by asking questions, searching for patterns, making conjectures, and going back and forth. We use the mathematical component of the *analytic framework* that integrates three activities: identifying patterns, making conjectures, and providing arguments which may or may not qualify as proofs.

How does solving word problems with reasoned judgement fit into the analytic framework? Briefly, the three activities of the mathematical component correspond to parts (a), (b) and (b') of the problem solving process of AWP+2T. In other words, identification of patterns corresponds to searching for mathematical relationships in the problem, making conjectures corresponds to formulating a symbolic representation, and giving arguments should prove the correctness of the symbolic representation. Analysis of the symbolic representation of the word problem and the computational work are therefore not part of the analytic framework, and nor are they a focus of the present paper.

An AWP problem is usually described in terms of magnitudes. We interpret an attempt to understand the mathematical relationships between the magnitudes as a search for patterns in the context of the analytic framework. On what basis does a problem solver choose one possible mathematical relationship over other possible relationships? This question corresponds in the framework to the separation between plausible patterns and definite patterns. The patterning activity is called 'definite' if it is mathematically possible for a problem solver to provide conclusive evidence for the selection of one specific pattern over other patterns that also fit the data. In some tasks, the necessary information for the definiteness of a pattern is given explicitly (G.J. Stylianides, 2008; Arbaugh et al., 2019). How can we make definite choices between possible patterns when solving AWP+2T? The basis for this choice is given by the mathematical structure describing the properties of magnitudes. The structure we use below is relation (1) as explained in the preceding section.

The third and final framework activity is the construction of arguments which may or may not qualify as proofs. The term 'proof' is used with the meaning suggested by A.J. Stylianides (2007) – a valid argument based on accepted truths for or against a mathematical claim. The term 'valid' indicates that the assertions making up the argument are connected by means of accepted canons of correct inference such as modus ponens and modus tollens. The term 'accepted truth' refers to a class of statements like axioms, theorems, definitions, modes of reasoning and representational tools that a classroom community may take as shared at a given time. We call such statements mathematical. An argument that qualifies as a proof makes explicit reference to the accepted truths that it uses. Next, we elaborate on the meaning of accepted truth, since it is too narrow when solving word problems with reasoned judgement.

In the process of solving an AWP+2T problem, one needs to construct arguments proving a justification of the symbolic representation. The proof is based on a deductive argument, which is a series of statements consisting of premises and a conclusion. Clearly, the conclusion must be the symbolic representation of the problem. To specify a class of possible premises, we note that mathematical statements may not be sufficient. Statements about a word problem may refer to a contextual representation of facts about an imaginary world and may not be a part of reality. The truth of such statements is therefore of a different kind. The new term 'accepted truth in context' will refer to a class of mathematical statements as well as statements about a word problem that a classroom community may take as shared at a given time.

Definition 1. *Proof by context* is a valid deductive argument with the premises being accepted truth in context and with the conclusion being a symbolic representation of the problem.

A deductive argument is said to be valid if and only if it takes a form that makes it impossible for the premises to be true and the conclusion nevertheless to be false. Otherwise, a deductive argument is said to be invalid.

Having a precise meaning of the phrase ‘proof by context’, we can work on a definition of the term ‘justification’ by adopting the ‘proof schemes’ approach of Harel and Sowder (1998). Similarly, we suggest using three levels of justification: by external sources, as a collection of facts, and proof by context. The changes reflect the specific features of word problems. Justifications by external sources are those in which problem solvers give reasons based on (a) the ritual or the form of the appearance of the argument, (b) the word of an authority, such as a teacher, and (c) some symbolic manipulation without reference to meaning. For example, the reason is ritual if there is no mention of constant speed in situations discussing the movement of objects. Justification as a collection of facts appears when there is no mention of the logical relations between statements leading to a hypothetical conclusion. Logical connections ensure the validity of a deductive argument, leading to the third level of justification.

An example of AWP+2T

This section answers the first research question of how deductive reasoning can be taught and learnt when solving word problems. We take *any* algebraic word problem (AWP) and complement it with two tasks. The first task is to justify a symbolic representation that answers the question, and the second is to prove the justification of the symbolic representation. The symbol AWP+2T denotes the resulting modified AWP.

A solution of AWP+2T is obtained by the following modified problem solving process:

I. Justifying a symbolic representation of the problem situation.
II. Answering the word problem question.
III. Constructing and validating a deductive argument proving the stated representation.

Relating this to the traditional problem solving process described at the beginning of Section 2, Part I corresponds to (a) and (b), part II corresponds to (c), (d), (e), (f), and part III is the new (b’).

Recall the concept of a *constant speed* (Wu, 2011).

Definition 2. An object moves at a constant speed along a straight line if there is a real number v such that for each real number $t \geq 0$, the distance $s(t)$ (measured in kilometres, metres, ...) covered by the moving object during the time period from 0 to t (measured in hours, seconds, ...) is equal to the product $v \cdot t$. This number v is called the speed of the motion, and it is the derived magnitude (measured in kilometres per hour, metres per second,…, respectively) related to the fundamental magnitudes of distance and duration by the equality of numerical values

$$v = \frac{s(t)}{t}, \qquad \text{for each } t > 0.$$

This example of an AWP is taken from a Lithuanian book for teachers. The original formulation has no hypothesis of the constancy of speed. We use a justification taken from this book.

Word Problem. *Tourists walking at a constant speed planned to cover a distance between a river and a tourist camp in 6 hours. However, after 2 hours’ walking they slowed down their initial speed by 0.5 km/h and were 30 minutes late arriving at the camp.*

1. *What was the initial speed of the tourists?*

2. *Justify a symbolic representation of the problem situation.*
3. *Create and validate a deductive argument proving the justification.*

Solution I. Justification. **(1)** Suppose that the initial speed of the tourists is x km/h. **(2)** Since distance = speed × time and since the tourists intended to walk from the start to the end in 6 hours, the distance between the river and the camp is equal to $6x$ km. **(3)** In fact the tourists walked at different speeds: for the first 2 hours at the initial speed of x km/h and for 4.5 hours (since they were 30 minutes late) at a speed of (x-0.5) km/h. **(4)** The distances they travelled are therefore equal to $2x$ km and $4.5(x-0.5)$ km, respectively. **(5)** Combining the resulting distances we obtain the desired equation:

$$2x + 4.5(x - 0.5) = 6x. \tag{2}$$

II. Finding an answer. Solving this equation one obtains $x = 4.5$. Thus the initial speed is 4.5 km/h, which is the answer to the problem.

III. Deductive argument and validation.

The figure depicts a mathematical model of the trip described by the word problem. The point A denotes the location near the river where the tourists began their walk. The point C denotes the location of the tourist camp, the final destination of the trip. In between, the point B is the place where the tourists slowed down from their initial speed. The trip itself can be imagined as a moving point along the line segment AC at the speed described by the word problem.

Next we construct the deductive argument

$$P_1, P_2, P_3, P_4, P_5 \ \vdash \ \text{equation (2)}, \tag{3}$$

with the following premises.

P_1 If the length of the line segment AB is S_1 km and the length of the line segment BC is S_2 ~~km~~ then the length of the line segment AC is $S_1 + S_2$ ~~km.~~

P_2 If an object moves at a constant speed v km/h during the time duration t h then the distance covered $s = v{\cdot}t$ km.

P_3 Fact I: the distance between points A and B is travelled at the speed of x km/h in a time of 2 hours.

P_4 Fact II: the distance between points B and C is travelled at the speed of $x - 0.5$ km/h in a time of 4.5 hours.

P_5 Fact III: the distance between points A and C is travelled at the speed of x km/h in a time of 6 hours.

Now we show that the deductive argument (3) is valid (that is, that the truth of all the premises entails the truth of the conclusion).

P_6 According to premises P_2 and P_3 and the inference rule modus ponens, $S_1 = 2x$.

P_7 According to premises P_2 and P_4 and the inference rule modus ponens, $S_2 = 4.5(x - 0.5)$.

P_8 According to premises P_2 and P_5 and the inference rule modus ponens, the distance between points A and C is equal to $6x$ km.

P_9 According to premise P_1, statements P_6, P_7 and P_8 and the inference rule modus ponens, equation (2) holds true.

Evaluation of the level of justification of (2). This is done by interpreting each sentence of the justification.

(1) The unknown initial speed of tourists is called the unknown variable and is denoted by the symbol x. This is used to represent the distances travelled by the tourists. **(2)** Fact III is obtained using the hypothesis of constancy of speed. **(3)** The value of the reduced speed is obtained using the relations described by the problem statement. **(4)** Facts I and II are obtained using the hypothesis of constancy of speed. **(5)** While it is not stated explicitly, the stated equation (2) is obtained by the property (1) of measurements.

In conclusion, all the facts of the deductive argument are mentioned in the justification with no mention of logical links between them. Therefore the justification is at the second level.

Conclusions

The meaning of a symbolic representation of an algebraic word problem lies in the mathematical system of the properties of continuous magnitudes. This conclusion is confirmed by examples of solutions of modified algebraic word problems using reasoning-and-proving. The deductive argument appears to be a necessary instrument for this discovery. We do not need additional instruments to see a link between an arithmetical operation and a relationship between discrete magnitudes in an arithmetical word problem.

A stepping stone to success in solving a modified word problem is the question of how to construct a deductive argument having built a non-proof argument. For example, having built a justification at the second level, to obtain a valid deductive argument one needs to find proper logical links between statements presumably implying a symbolic representation. This is the kind of task that is familiar in propositional logic. In conclusion, solving word problems becomes an exercise in logic.

The most promising conclusion is that solving word problems with reasoned judgement in the sense of the present essay provides an unlimited source of reasoning-and-proving activities.

More examples of AWP+2T and advantages of using reasoning to solve word problems are discussed in Kilienė & Norvaiša (2021).

Word problems for developing mathematical reasoning

Mathematical reasoning is a widely analyzed topic amongst secondary and high school students. It is widely believed that mathematical reasoning is only possible for students once they are aware of various mathematical concepts, so we decided to check whether 4-year-olds are capable of mathematical reasoning. We used word problems that have been shown to develop mathematical reasoning for 8–10-year-old students in Schliemann et al. (2002). In this study, we adapted the methodology to test the word problem with a 4-year-old child and older solvers.

We analyze ides about mathematical reasoning from Thompson et al. (2012), Arbaugh et al. (2018) and Stylianides et al. (2016) and define word problem solving characteristics that develop mathematical reasoning.

A word problem develops mathematical reasoning, if solving includes argumentation, justification or patterns identification and if it uses the statements known to a presenter and a class community.

Experiment with a 4-year-old student

We adapt the word problem for 4-year-old students, who may not know how to read. We illustrate the problem and change the numbers to smaller ones. Our aim is to check if we can develop mathematical reasoning from early years and to see how students of different ages solve the same problem.

A word problem from Schliemann et al. (2002) is used:

> Table A has 3 candy bars and 2 chairs. Table B has 6 candy bars and 4 chairs. Table C has 5 candy bars and 2 chairs. Show how you would divide the candy bars equally among those at each table. Which table would you sit at? Convince us that you chose the best table. Are any tables the same?

The numbers in the original problem are such that at the first and second tables the subject gets 1 and a half candy bars, and at the third table there are 2 and a half candy bars. Our word problem (illustrated in Figure 1), using smaller numbers so younger kids do not make mistakes in computation. The solver must choose between tables where the bear character gets less than 1, more than 1 or 1 cupcake. The question is formulated in the following way: All bears are going to sit on chairs. If the bear wants to eat as many cupcakes as possible, at which table he should sit? Could you explain why?

A 4-year-old girl attending kindergarten solved this word problem. During the interview, she expressed ideas such as:

Girl:	At the first table, the bear would get one cupcake.
Interviewer:	Really? How many bears will sit there?
Girl:	Four bears. Then we need to cut this cupcake into two parts. This bear will get one part; another bear will get second part (points to chairs). Let us cut another cupcake

into two parts. This bear will get one part; another bear will get the second part (points to chairs).

Interviewer: How much would each teddy bear get?
Girl: By four parts[1].
Interviewer: How much would each bear get sitting at the middle table?
Girl: He would get two.
Interviewer: Even two? Why?
Girl: There are two chairs, three cupcakes.
Interviewer: One would get two, and the other?
Girl: Then we can cut one cupcake. One would get two and another the other two.
Interviewer: But not two whole ones?
Girl: By one and part[2].
Interviewer: And at the third table.
Girl: They will get one each.
Interviewer: Where is it best to sit?
Girl: At this table (shows to the middle table), there they will get two cupcakes each.

Figure 1: Mathematical reasoning word problem in image

Results

We interviewed different age groups with the same task. The justification was different, but correct amongst all interviewees, and we can identify that the argumentation changes during the learning period. The 4-year-old solver makes mistakes in the concepts she used, but shows correct reasoning. Our results show that we can use word problems that develop mathematical reasoning for younger kids.

[1] The 4-year-old student indicated that each bear would receive ¼ of two cupcakes. She did not say this explicitly because she has not learned fractions and could therefore not articulate the answer in those terms.

[2] Same comment as above. The 4-year-old student indicated each bear would receive 1 ½ cupcakes.

Procedures in proof construction: five proving strategies of first-year university students

Katharina Kirsten

University of Münster, Germany; k.kirsten@wwu.de

As proof construction typically presents many difficulties to university students, there is an increasing interest in student-centred forms of in-process support. This is accompanied by a need for research on how students – effectively or non-effectively – proceed in proof construction. This study therefore examines the proof-construction behaviour of first-year university students in 24 cases. Following the principles of empirical type construction, the author identified five proving strategies, each of which is characterised by a specific combination of sub-processes. Comparing these strategies to each other provides new insights into both different approaches to proving and typical obstacles. However, a comparison between successful and non-successful students did not reveal a clear relationship between the strategy used and performance. Our results suggest that the crucial aspects of proof construction are related to implementation at the microscopic rather than macroscopic level.

Keywords: Reasoning and proof, proving strategies, tertiary education, type construction.

Introduction

Dealing with mathematical proof is a complex and demanding activity that causes great difficulties for many university students (Selden & Selden, 2008). One possible reason for these difficulties is related to a lack of transparency between proof as a product and its process of development (Hemmi, 2008). Therefore, there are many reasons to place more emphasis on underlying proving processes and to specifically train proving strategies in university teaching (Karunakaran, 2018; Schoenfeld, 1985). However, so far there has been little research on which such fostering programs could be based. This study, therefore, takes a process-oriented perspective on proving, and examines how university students behave in constructing proof. By comparing successful and non-successful students, the study, moreover, aims to identify procedures that are more effective than others.

A process-oriented perspective on proving

Although proof-writing processes run differently for each individual, previous research revealed some invariances occurring across different cases. On the one hand, there are efforts to describe proving processes as a combination of recurring sub-processes. Each sub-process focuses on different cognitive demands and pursues a specific sub-goal of proof construction. Another approach refers to general proving strategies that describe typical behaviour patterns within proof construction. The paper first gives a brief overview of both approaches before connecting them.

Sub-processes of proving

In the field of reasoning and proof, various models have been proposed to describe relevant sub-processes of proof construction (G. Stylianides et al., 2017). As the models differ in their target group (school students, university students and mathematicians), they consider different demands in terms of formalisation and rigor. While some models emphasise the creative part of proving and highlight processes of exploration and discovery (Hsieh et al., 2012; Schwarz et al., 2010), others include precising parts in the same way (Boero, 1999; Stein, 1986). However, from a synthesis of existing models four sub-processes emerge that are likely to be relevant in different contexts (Kirsten, 2018):

- Understanding the problem situation represented in the proving task,
- Identifying (informal) arguments that support the purported assertion,
- Structuring single proving steps in a logical chain,
- Formulating a proof according to the requirements of the community.

Taking the process of proving from the problem-solving perspective, it is reasonable to add a fifth sub-process, that is, checking the proof's validity (Carlson & Bloom, 2005; Schoenfeld, 1985). Although validation might be implicitly included in the sub-processes listed above, it seems useful for teaching and research to make validation visible in a separate sub-process. In fact, the assumption of a total of five sub-processes proved to be empirically valid in initial studies examining university students' proving processes (Kirsten, 2018). To that effect, there is empirical evidence that the five sub-processes display basic elements of proof construction and constitute an individual's proving process. However, there is limited research on how these sub-processes interact in proof construction and how, i.e., in what order and weighting, they can be fruitfully combined.

Proving strategies of university students

Proving strategies describe behavioural patterns that are characteristic for a proving process' overall structure. A proving strategy is thus characterised by features such as dealing with impasses, incorporating metacognitive processes, or planning an approach based on understanding (Zazkis et al., 2015). Examining the problem-solving behaviour of college students, Schoenfeld (1992) identified the *wild goose chase* strategy as a frequently used but highly inefficient approach to proving: "roughly 60% of the solution attempts are of the 'read, make a decision quickly, and pursue that direction come hell or high water' variety" (p. 356). Consistent with this, Karunakaran (2018) reports that first-year students often adhere to the linear structure of their proving process and therefore have difficulty with overcoming impasses. Both strategies reported here are likely to fail, because little time is spent on carefully analysing the problem situation or students do not adapt their process to the impasses occurred. Against this background, Zazkis et al. (2015) explicitly analysed the proving behaviours of six highly successful university students with reference to Pólya's four stages of problem-solving. Their analyses revealed two promising strategies, namely the *target strategy* and the *shotgun strategy*. The target strategy describes a highly systematic behaviour, where students chose their approach on the basis of a careful problem analysis, and continuously monitor their own progress. Students, on the other hand, who use the shotgun strategy, implement many different approaches in a short period of time. They spend little time on understanding the given statement or setting up a plan, but adjust their approach as soon as it proves to be of little use. In contrast to the wild goose chase approach, the shotgun strategy thus includes a higher level of process control and is, therefore, considered to be more effective (Zazkis et al., 2015).

Combining both frameworks, it can be assumed, that each proving strategy is reflected in a characteristic combination of sub-processes. For example, the target strategy proceeds in a straight line, while the shotgun strategy moves back and forth between identifying arguments and validating.

The current study

Summarising previous findings, process-oriented research provides initial evidence that proving processes consist of at least five different sub-processes, each of which makes its own contribution to proof construction. How students combine these sub-processes though proving strategies, however, has been studied scarcely, and predominantly in relation to episodes of problem solving (Schoenfeld 1985; D. Zazkis et al. 2015). To address this research gap, the current study aims to provide a holistic analysis of student proving processes that examines the interplay of individual sub-processes.

Research Questions

The current study pursues two main goals: first, the study aims to identify recurring proving strategies, each of which is characterised by a specific combination of sub-processes in terms of frequency, duration and sequence. Given the findings of Schoenfeld (1992) and Zazkis et al. (2015), it is reasonable that some proving strategies are more purposeful than others. Therefore, in a second step, we investigate the relationship between proving strategies and students' proof construction performance. Here, the aim is to identify effective and non-effective aspects of proving strategies in order to replicate and enhance previous findings. In particular, the research is guided by the following questions: (1) Which proving strategies do university students use in proof construction? (2) Is there a relationship between the proving strategy used and the students' performance? To address these questions, the study relies on an exploratory-descriptive design that allows fine-grained analyses.

Participants and data collection

To gain insights into students' proof-construction behaviour, the author conducted task-based interviews with first-year university students, including preservice teachers (Goldin, 1997). As part of a regular exercise, students were asked to complete the two proving tasks given in Figure 1. If students agreed, one of these tasks was solved under interview conditions. As is customary in the course, students were allowed to work in groups of two or three. In the interview, however, they received no support other than a standardised version of lecture notes (Schoenfeld, 1985). Following this procedure, the author and one of her colleagues conducted a total of 97 interviews, all of which were videotaped. From this total sample, we selected those cases for fine-grained analysis that were deemed representative of the entirety of cases. For this purpose, we first assessed the students' performance in proof construction by rating their final product on a four-point scale, with a score of 4 indicating a complete and valid proof and a score of 0 describing no substantial progress (Recio & Godino, 2001). Interrater reliability confirmed very good agreement for this rating ($\kappa = .82$). Based on the assessment of proving performance, the final sample was drawn by applying a qualitative sampling plan that follows the principles of maximum variation and homogenous sampling (Patton, 1990). Thus, the final sample includes 24 proving processes that are almost evenly distributed among the different performance scores and that cover both proving tasks equally.

Task 1 Let $f : [0,1] \to [0,1]$ be a continuous function. Show that f has a fixed point, that is, there exists a $x \in [0,1]$ with $f(x) = x$.

Task 2 Consider a function $f : \mathbb{R} \to \mathbb{R}$ whicht is twice differentiable. Let $x_1 < x_2 < x_3$. Given $f(x_1) > f(x_2)$ and $f(x_3) > f(x_2)$, show that there exists a $y \in \mathbb{R}$ with $f''(y) \geq 0$.

Figure 1: Proving tasks used in the tasked-based interviews

Data analysis

In accordance with the research questions, data analysis was conducted in two stages. First, all proving processes were fully transcribed and coded leaning on Schoenfeld's (1985) method of protocol analysis. The proving protocols were partitioned into coherent episodes, each of which is assigned to one of the sub-processes listed above (Kirsten, 2018). The coding thus led to a macroscopic description of the students' processes, providing data on the frequency, duration and sequence of the sub-processes that occur (κ = .92). Based on this information, an empirical type construction was conducted in which processes with similar qualitative characteristics are grouped into types (Kluge, 2000). In particular, the transitions between sub-processes were considered in order to identify recurring sequences and empirical patterns that represent specific proving strategies. Each proving strategy thus describes a particular combination of sub-processes in terms of sequence and frequency. To identify particularly promising proving strategies, the second stage of analysis compared successful (score 3 or 4) and non-successful cases (score 0 or 1) in terms of strategy use.

Results

Our analyses of 24 proving processes revealed five different proving strategies that first-year students apply in the field of real analysis. The following section gives an overview about the proving strategies and its characteristics. Each strategy is illustrated by an exemplary process and its schematic representation.

Proving strategies and sub-processes used by first-year students

Proof constructions using the *step-by-step strategy* are characterised by a linear structure in which the individual sub-processes are run through in the natural sequence listed above. Doing so, all sub-processes are systematically built on one another, that is, each sub-process is worked through conclusively before the students move on to the next. In this strategy, the proving process is based on a careful analysis of the given statement and professes throughout. In particular, the choice of a proving approach is well-planned and highly target-oriented.

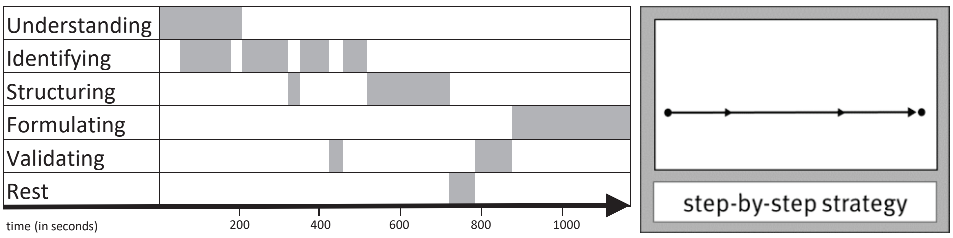

Figure 2: Exemplary sequence of sub-processes when using the step-by-step strategy (Alina & George)

The *scorekeeping strategy* is represented by proving processes in which a complete sequence of sub-processes is followed by an additional loop of brainstorming. This loop occurs rather accidentally and is initiated by a formulation process in which the students write down a response that is not satisfactory for them but serves to achieve partial points in the exercise. While formulating the response, a process of insight takes place and the students generate new ideas for proof construction. However, the students do not pursue the new approaches consistently and therefore end proof construction with a process of identifying arguments (see the case of Lisa, Pia & Laura in Figure 3).

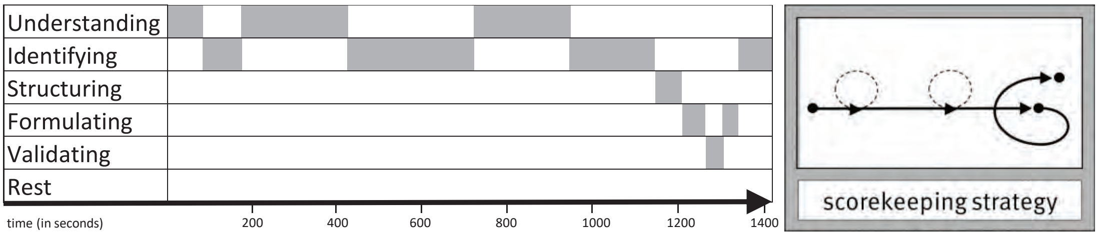

Figure 3: Exemplary sequence of sub-processes when using the scorekeeping strategy

Proving processes that are assigned to the *rebooting strategy* are characterised by a cyclical structure in which several approaches are implemented one after the other. Each cycle contains a linear, self-contained sequence of sub-processes such as understanding, identifying (informal) arguments and organising single proving steps. Thus, the rebooting strategy initially follows the step-by-step-strategy until the current approach proves to be of little use and a new cycle is initiated. The validation and rejection of an approach necessitates a restart which is characteristic for this strategy.

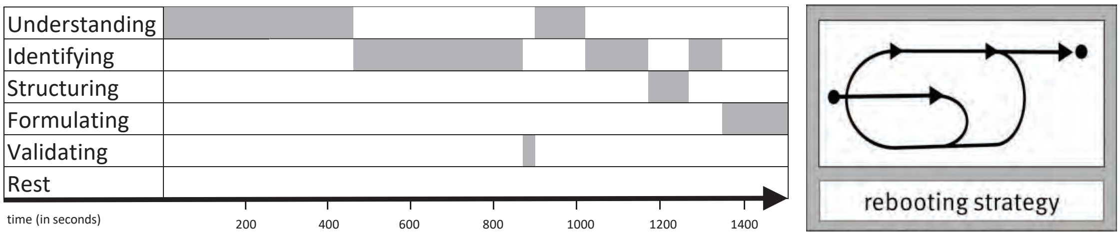

Figure 4: Exemplary sequence of sub-processes when using the rebooting strategy (Lukas & Tim)

When applying the *decomposing strategy*, a proving process shows a repeating pattern of development, elaboration and formulation, which is depicted in a staircase pattern in the schematic representation of the process. In contrast to the rebooting strategy, each cycle of development contributes to the final product, so there is a continuous progress. In our sample, students use the decomposing strategy in two different ways depending on the structure of the statement to be shown. Some proving tasks allow, for example, a distinction by cases which naturally divides the proving process into different parts. By considering sub-proofs, the complexity of proof construction is reduced and each part can be dealt with in a self-contained step-by-step approach (see the process of Andreas & Ibrahim in Figure 5). If no content or structural subdivision is created in the task, students perform a chronological division by writing down previous results from time to time. In some cases, formulating parts of the final response allows new insights and thus supports further progress.

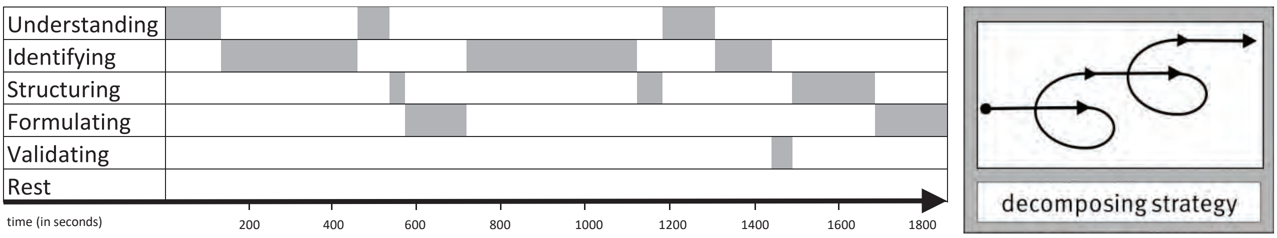

Figure 5: Exemplary sequence of sub-processes when using the decomposing strategy

The *looping strategy* describes a proof-writing behavior in which students frequently move back and forth between sub-processes. Due to an occurring uncertainty or impasse, students first return to the previous sub-process and then continue with their proving process based on the newly gained knowledge. Since the switches mainly occur between successive sub-processes such as understanding and identifying or structuring and formulating, the looping strategy basically follows a linear approach but is interspersed with mini-cycles. In contrast to the step-by-step strategy, the looping strategy thus provides several deepening loops. Doing so, the individual sub-processes are worked out in interaction with each other and are thus more closely linked.

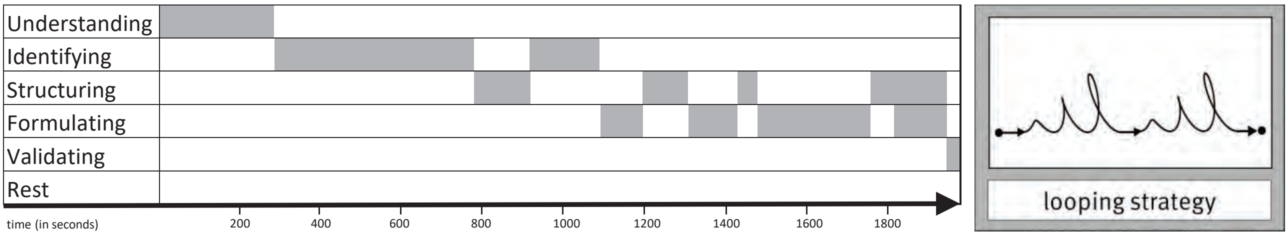

Figure 6: Exemplary sequence of sub-processes when using the looping strategy (Alina & Sascha)

Comparing the different descriptions, a basically linear structure emerges across all strategies. While the step-by-step strategy represents an idealized linear procedure, the decomposing and the rebooting strategies divide the process into linear subsequences and the looping strategy uses mini-cycles to deepen individual sub-processes within a mainly progressive procedure. Due to these modifications, each strategy places a different emphasis on the individual sub-processes.

Proving strategies and performance

To identify particularly effective strategies of proving, we compared successful and non-successful processes regarding the proving strategies used. Table 1 shows how the examined cases are distributed among the different strategies and performance categories. Each letter combination represents one proving process and refers to the initials of the students involved.

Performance	step-by-step	rebooting	decomposing	scorekeeping	looping
successful	ML, AG		FT		AS, TL
non-successful		LT, DP	AI, SDH	TH, LS, JH, OJ, LPL	MFY, JIA, LUM, LKH, DJ

Table 1: Distribution of the analysed processes among the different strategies and performances (successful = score 3 & 4, non-successful = score 0 & 1, score 2 excluded)

The distribution in Table 1 shows that with the step-by-step strategy, the rebooting and the scorekeeping strategy proof-writing behaviours exist, which are exclusively associated with a low or high performance. However, the observed pattern is only conditionally suitable for a hypothesis generation. While the low proving performance of scorekeeping is already anchored in its definition, the rebooting strategy describes an approach that, from a theoretical perspective, does have effective components because an unsuitable approach is rejected in favour of a new idea. A detailed review of the assigned cases suggests that the difficulties encountered here arise less from restarting, but rather are the result of a lack of conceptual, procedural or strategical knowledge. The decomposing and the looping strategy, on the other hand, occur across different scores. It is likely that these behavioural patterns are not effective per se, but that it is the specific implementation that matters.

Discussion and conclusion

In the presented study, we analysed the proof construction behaviour of first-year university students by looking at the frequency, duration and sequence of sub-processes typical for proving (Kirsten, 2018). Our research revealed five different proving strategies that replicate and complement previous findings. The step-by-step and the rebooting strategy are comparable to the target and the shotgun strategy reported by Zazkis et al. (2015). In addition, we identified two other strategies, namely the decomposing and the looping strategy, which can be considered as variants of the target strategy. Both strategies proceed target-oriented, but include several cycles of sub-processes in order to reduce complexity, handle impasses or create flexibility. The scorekeeping strategy is similar to wild goose chase processes in the way that students do not make progress over an extended period of time (Schoenfeld, 1985). Nevertheless, the students' efforts in this study go beyond a wild goose chase as there is a slight process control through the formulation of ideas. One possible reason for these differences is that proof construction in the university context is often associated with performance. Formulating partial solutions is a common strategy for coping with studies in the first year. Efforts in teaching should therefore aim at making this kind of strategy fruitful by valuing the late insights. In general, fostering programs such as heuristic worked examples, heuristic trainings, and learning videos should consider different types of proving strategies to provide authentic insights into proving.

Comparing successful and non-successful students, we could not establish a clear correlation between proving strategies and performance. Specifically, our results show that a proving strategy in which different approaches are implemented in the sense of the shotgun strategy is not necessarily associated with a high level of performance. As the study by Zazkis et al. (2015) only considers successful students, our results usefully complement the state of research and open the view for further aspects. On the one hand, it remains open whether proving strategies reflect an individual’s disposition or whether they are task-, situation- or proof-specific. On the other hand, our results suggest that students might fail because they have difficulties with strategy implementation. Further research should therefore analyse students’ proof-construction behaviour at a microscopic level. Especially those strategies that occur independently of performance should be analysed with particular care, as they can provide insights into effective and dysfunctional aspects of implementation.

Capitalizing on interdiscursivity to support primary school students to bridge the empirical-deductive gap: The case of parity of numbers

Jo Knox[1] and Igor' Kontorovich[2]

[1]University of Auckland, New Zealand; j.knox@auckland.ac.nz

[2]University of Auckland, New Zealand; i.kontorovich@auckland.ac.nz

Previous research has made calls for interventions to assist students in bridging the empirical-deductive gap. We respond to this call in a larger commognitive study that involved small groups of primary school students who discussed parity of natural numbers with a teacher-researcher. As part of this study, a learning environment was created based on the construct of interdiscursivity – elements of task design that afford students to draw on and expand their familiar empirical approaches in situations where deductive arguments are needed. The study aims to explore how interdiscursivity can support students in taking their first deductive steps. In this paper, we analyze the activity of two 8-year-olds to learn how the interdiscursive elements contributed to their discursive growth. The central finding pertains to the activity of the teacher-researcher, who played a key role in realizing the interdiscursive potential of the designed environment.

Keywords: Proof and proving, primary school students, discourse, commognitive framework

Introduction

Research has shown that primary school students are capable of engaging in proving and generating valid mathematical arguments (Stylianides, 2007). However, a wealth of research corroborates what Stylianides and Stylianides (2017) describe as "key and persistent problems" (p. 124)—students' reliance on a few confirming cases as proof and the difficulty of transitioning from empirical to deductive arguments. To address these problems, Stylianides and Stylianides (2017) call for studies into classroom-based interventions, highlighting a particular need for research at the primary school level. The researchers foreground three desired characteristics of such studies: an explanatory theoretical framework to identify key features to which the impact of the intervention could be attributed, a narrow and well-defined scope, and an appropriate mechanism to trigger and support changes in students' learning to prove.

In her doctoral research, Knox (2021) has been addressing this call by using the commognitive framework, focusing on parity of natural numbers, and designing a learning environment to support primary school students in bridging the empirical-deductive junction. This paper presents a snippet of this research. We begin with the commognitive conceptualization of this junction, describe the designed environment, and analyze two students' collaborative activity in this environment.

Commognitive framing of the study

The commognitive framework (Sfard, 2008) views *mathematics* as a historically established discourse, when *mathematics learning* is construed as a lasting change in the ways one participates in this discourse. A discourse about natural numbers (or a *numerical discourse*) is in our focus, when we distinguish between its two versions—*empirical* and *deductive*. The main objects of the empirical discourse are specific numbers, and it can be characterized with *keywords* that signify them verbally (e.g., “six”), *mediators* that point at them visually (e.g., the symbol “6”, Numicon tiles in Figure 1), *narratives* about them and their properties (e.g., “6 is even”), and *routines* that involve them (e.g., substantiating that 6 is even). Deductive numerical discourse enables communicating about numbers without specifying their quantities. This communication becomes possible through the usage of such keywords as “an even number” and such symbolic mediators as “2n + 1”. Deductive numerical discourse also allows for generating universal statements, such as “the sum of two odds is even”.

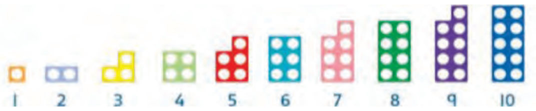

Figure 1: Numicon tiles

In commognitive terms, the deductive version of numerical discourse *subsumes* the empirical one since everything that can be said and done in the latter holds in the former. But deductive discourse affords much more. This is useful in situations that can be handled within both discourses. For instances, the narrative “3 + 5 is an even number” can be substantiated through either executing the addition and consequent arguing that the sum is even, or through resorting to the universal narrative stating that “odd + odd = even”.

The deductive numerical discourse summons specific ways for substantiating universal narratives. Here, showing that such a narrative holds for particular numbers is usually not viewed as an acceptable substantiation. Moreover, the deductive and empirical numerical discourses differ in their usage of some keywords. For instance, in the former, “odd” and “even” are conventionally interpreted as “all odds/even” or “the set of odd/even numbers”; in the empirical version, these words act as adjectives that describe properties of specific numbers. In commognition, discourses that differ in their underpinning rules and the use of the same keywords are called *incommensurable*.

Like many theories informed by Vygotsky’s work, commognition suggests that learners’ transitioning from a familiar into a new and incommensurable discourse, requires the support of a more knowledgeable other. The commognitive stance has traditionally assumed that at such junctions, a learner’s motivation to adopt the rules of a new discourse would initially be to meet the approval of the teacher and the learner would focus on repeating the steps of a shown procedure (*ritualistic participation* in terms of Sfard, 2008). Yet, the ultimate goal is for the learner to eventually realize the productiveness of the new discourse and participate in it for themselves.

Cooper and Lavie (2021) argue that carefully designed tasks can support learners to by-pass the ritualistic stage in their transition between incommensurable discourses. By drawing on the much-explored construct of intersubjectivity (e.g., Wertsch, 1984), Cooper and Lavie (2021) propose *interdiscursivity* as a discursive mechanism whereby learners may be eased into a new and incommensurable discourse via “the blending of discursive elements from different discourses” (p. 1). Specifically, the researchers hypothesize that a change in learners’ routines might be facilitated by tasks that capitalize on elements of the learner’s existing discourse in such a way that these elements “simultaneously [hold] meaning in an emerging discourse” (p. 8). Accordingly, in this paper we address the research question: “How can interdiscursivity support primary school students in taking their first steps in a deductive numerical discourse?”

The study

To pursue our research aim, a set of *concept cartoons* (Keogh & Naylor, 1999) with three characters was designed, each with a speech bubble featuring contradicting statements on parity. In each cartoon, two statements were universal, while the third statement foregrounded the "sometimeness" of the previous statements (see Figure 2); we refer to the statements of the latter type as *bilateral*. In empirical numerical discourse, refuting one statement with a counterexample would be considered sufficient to endorse the other statement without the need to substantiate it for all relevant cases. Hence, the inclusion of bilateral statements was part of the interdiscursive design to support students' move away from empiricism.

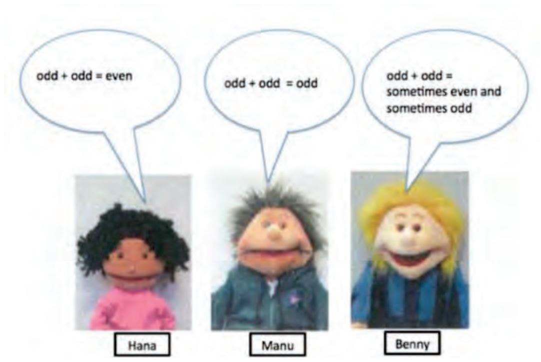

Figure 2: The "odd + odd" concept cartoon

Another element of the designed environment were *generic strips* – long and folded paper bands with both ends exposed (Figure 3). Generic strips bear an interdiscursive potential in the sense that they can visually mediate numbers in both empirical and deductive discourses. In the former, the strips can stand for specific numbers, in a way which is not very different from Numicon tiles (Figure 1) that the students were familiar with from their school studies. On the other hand, the strips can also be treated as a generic odd or a generic even number, by focusing on the exposed edges and visually concealing the precise number of dots by folding the strip. We envisaged the introduction of the generic strips might provide the students with the material means for communicating about numbers and their parity in a nonspecific way. For instance, by drawing on the students' familiar deeds with Numicon tiles, they may be able to use the generic strips to show that "*nonspecific* odd number + *nonspecific* odd number = *nonspecific* even number".

Figure 3: Odd and even generic strips

Twenty-eight Year 4 students (8- and 9-years old) from two New Zealand schools participated in the larger research. The participants were selected by their teachers to be withdrawn from their class to work in groups of four with the first author as a teacher-researcher (*TR*). The group work was video-recorded with two cameras and students' written artefacts were added to the data corpus. Each group session was transcribed in its entirety and analyzed with commognitive tools to identify instances of students' discursive development (i.e., changes in the use of keywords, visual mediators, narratives, or routines). The question underpinning the analysis was whether and how the designed interdiscursive potential of the designed environment was realized to support the students in their substantiation of universal statements in the deductive numerical discourse.

Findings

In this paper, we present a case of a single group, which was selected due to its affordances to illustrate the role of the interdiscursive environment in students' learning to substantiate universal statements. We provide excerpts to show three episodes where the group made their first steps towards deductive discourse: (1) facilitating dissatisfaction with an empirical discourse, (2) interdiscursivity in action, and (3) the students' uptake of these new discursive features in a deductive substantiation. The collected data affords focusing on two students in the group: Jane and Zara.

Prior to the first episode, Jane and Zara, classified numbers presented as Numicon tiles and written numerals as odd or even. Here, they had provided substantiations that referred to the generic structure or properties of odd and even numbers. For instance, they used the terminology of "in twos" and "doubles" to substantiate that 6 is even. When substantiating that Numicon 5 is odd, Zara said, "Instead of adding two on, you add on one and then it wouldn't be even… every time you have an even number it has to be in twos." The students' attention to numbers' structures thus placed them favourably for considering the structure of generic odd and even strips.

Dissatisfaction with an empirical substantiation of a universal narrative

In this episode, TR has just introduced the "odd + odd" concept cartoon to the students.

240	Jane:	Yeah, that's right [referring to Hana's narrative "odd + odd = even"]. […]
242	TR:	What about Manu ["odd + odd = odd"]?
244	Jane:	It's wrong. […]
246	TR:	Whereas Benny says…
247	Jane:	Odd plus odd equals sometimes even and sometimes odd [reading Benny's statement in the cartoon].
248	Danny:	No wrong. See watch this [holds up two Numicon tiles of "3" and fits them together to make "6"]. 
249	Jane:	I sometimes think that's right [referring to Danny's demonstration in 248] because, um it might be— 'cos three and three—but what if there's another number and we add them together? […]
253	Jane:	So, because an odd and odd, like a three and three, equals odd [probably meant even] but if you put it together, they're a small number... But some odd numbers are like really big—we don't, we can't even count them—they might not, they might be odd but can't go even." […]
282	Zara:	Okay, so two odd numbers can sometimes make an even number.

In what appears as an attempt to convince Jane that "odd + odd = even", Danny visually mediates the even sum using two Numicon tiles of "3" [248]. This is an implementation of an empirical substantiation since it shows that the universal statement is correct for this example without accounting for all pairs of odd numbers. Jane, in turn, appears dissatisfied with Danny's choice of "small" numbers rather than with him resorting to an example in the first place. On the other hand, her use of the word "sometimes" [249], mimics the bilateral narrative and may be interpreted as a realization that Danny's demonstration does not account for the universal scope of the statement, and especially for numbers that are "really big, we don't, can't even count them" [253]. This utterance provides an opportunity for TR to offer discursive tools for students to communicate about numbers of this sort as part of ushering them into deductive discourse. Notably, the window is not open indefinitely as Zara seems to capitalize on Jane's doubt [253] to endorse the bilateral statement [282].

Interdiscursivity in action

To take advantage of Jane's uncertainty, TR introduces an odd generic strip.

298	TR:	Is it an odd number or an even number [holds up an odd generic strip]?
299	Jane:	Odd. […]
303	TR:	So, Jane, you think it's an odd number. […]
305	Zara, Jane:	[together] Yeah.
306	TR:	How do you know it's an odd number?
307		[Jane, and Zara point to the unpaired circle at the end.]
308	TR:	What are you pointing at Jane?
309	Jane:	'Cos, that. It's like that [traces the unpaired circle].
		[Then counts the circles visible on the top layer] It's nine. And nine's an odd number.
310	TR:	It's nine. Did you need to count it to recognize it's odd?
311	Jane:	No.
312	TR:	What were you looking at, that showed you it's odd?
313	Jane:	Cos if it's like that, it would be even [covers the unpaired circle with her finger]. But since there's one more [removes her finger].
314	TR:	Ah, so it's like the extra one that makes it odd, is that right?
315	Jane:	Yeah. […]
328	TR:	Would that be an odd number [points to the even generic strip]?
329	Jane, Zara:	[together] No.
330	TR:	No. How did you know straight away?
331	Jane:	Because there're no extra bits [points to the ends of the even generic strip].
332	TR:	Ah [holds up the folded odd generic strip]. Okay so we'd need two that kinda look like this [i.e., two odd generic strips to represent "odd + odd"]? Zara, are you happy with that?
333	Zara:	[nods.]
334	Jane:	Yes and … there's the same amount of dots on each one [side], [points to the pairs on the even generic strip] but that one there [points to the "extra one" on the odd generic strip], there's one more on one side. […]

This episode presents the full span of moves that TR undertakes to capitalize on generic strips and equip the group with discursive tools to communicate about generic (rather than particular) odd and even numbers. She starts with introducing each strip as a number that is either odd or even [298; 306; 328] and presses the students to engage with the structural features of the strip and draw on them in their substantiations. In [309], we see Jane harking back to empirical discourse, aiming to base her substantiation of the strip's oddness on counting; just as she did a short time ago with specific numbers. Then, TR steers Jane away from counting [310] towards substantiations based on the strip's edges [310, 312, 330]. Notably, TR does not enable students to "get away" with just pointing at the structural features of the strips but she asks them to generate verbal narratives [308; 312; 330]: she also rephrases students' narratives and models substantiations [314].

This teaching seems to work for Jane and Zara as their substantiations gradually change to become in tune with the rules of a new "discursive game". Indeed, the students cooperate with the underpinning assumption that a long strip, not all parts of which are visible, stands for a number, and that its parity can be determined by edges only [299; 305; 307; 311]. Jane shifts from providing gestural responses to communicating verbally [e.g., from 307 to 309]. Moreover, she does not only abandon her counting substantiation [309], but also independently generates substantiating narratives through introducing new phrases ("extra bits" [331], "same amount of dots", and "one more" [334]).

The students' uptake of new discursive features in a deductive substantiation

In the following episode, TR prompts the group to draw on the previous conversation regarding a second nonspecific odd having "one more" [Episode 2, 334], to substantiate "odd + odd = even".

335 TR — So … She [Jane] said that with odd numbers there's one more and with another odd number is there going to be an extra one again? […]

337 Jane: — …if it was like three then we could put it there [picks up Numicon 3-tile and connects it with the odd generic strip].
And then it's not gonna be like that and there's gonna be one left no more [puts the Numicon tile down and runs her finger around the "extra one" of the strip].

338 TR: — Is it like a jigsaw puzzle so they kind of fit together?

339 Jane, Zara: — [together] Yeah. […]

341 Zara: — Yes, so if you have something like a square. If you have something like this [draws a rectangle].

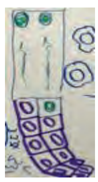
342 Jane: — A rectangle.

343 Zara: — Yes, it's an oblong. So, if you have like two circles on each then it will be even [draws two circles in the rectangle]. And just keep on going down [draws two lines going down from each of the circles]. But if you added on an extra one here, then it wouldn't be even [draws the extra circle at the bottom-right]. […]

345 TR: — Can we use another colour to show how another odd number would fit with that [referring to Zara's drawing in the previous episode, line 343]?

346 Jane: — Yes [picks up a pen to add onto Zara's drawing].

347 Zara: — So, then if you put like another one there ["one" is taken here to mean another "odd"] then it would be even [referring to her



drawing]. [Jane draws one extra purple circle in a square to form a rectangle and continues to add pairs of purple circles to extend the rectangle.]

In this episode, we see changes in Zara and Jane's communication. First, they now endorse the "odd + odd = even"-statement, which marks a shift from where they were in the first episode. Second, the episode captures a development in their substantiations. Initially, Jane chooses a numeric example (Numicon 3-tile) to "add to" the odd generic strip, and, by running her finger around the exterior of the latter, she visually mediates the generic "even" rectangular shape created by the two odds. This gesture can be viewed as Jane divorcing from the "counting-the-dots" approach that was previously evident [309]. In turn, Zara introduces the generic word "square" [341] and instantly replaces it with Jane's "rectangle" [342]—two nouns that had not been previously used by TR. These nouns, coupled with Zara's sketches [341-343] offer even more abstract realizations of even and odd numbers than the generic strips. Zara's narratives underscore that the structure of the sketched rectangle determines its parity (i.e., "if you have like two circles on each side" and "if you added an extra one"), when the precise number of paired circles is irrelevant and can "just keep on going down". This may be interpreted as a marker of her first independent steps in the generic talk on numbers' parity that is necessary for deductive discourse.

Note that TR still has a role to play in leading students' discourses. She asks the students to draw "another odd number" [345] so that the two figures "fit together…like a jigsaw puzzle" [338]. Here, she signals to the students that they can use the structural features of odd (i.e., "an extra one") to substantiate their endorsement of "odd + odd = even", rather than perform a calculation.

Summary and Concluding Remarks

This paper offers a snippet of Knox's (2021) larger research into young students' first steps in a deductive version of a numerical discourse. This research contributes a New Zealand case to the international body of knowledge on how young students generate deductive arguments to substantiate universal statements (e.g., Stylianides, 2007). Moreover, with commognition as its explanatory theoretical framework to identify key features to which the impact of the intervention could be attributed, a narrow and well-defined scope, and with interdiscursivity as a mechanism to trigger and support changes in students' learning; this research specifically addresses Stylianides and Stylianides (2017) call for research into proving at the primary school level.

Knox (2021) takes Cooper and Lavie's (2021) theoretical proposal to an empirical test drive by investigating how interdiscursivity can be mobilized to assist students to by-pass ritualistic participation in a new discourse that is incommensurable with their familiar one. The two distinctive features of the designed environment are bilateral narratives and generic strips. In the case of a single group of students, we illustrated how the bilateral narrative played a role in triggering one student's dissatisfaction with empirical substantiations with "small numbers" and interest in accounting for numbers that are "really big […] we can't even count them". This interest opened the door for introducing a way of talking about parity that does not rely on counting. Generic strips were designed to have meaningful interpretations in an empirical and a deductive version of the discourse. These artefacts laid the grounds for providing students with the discursive apparatus to communicate about generic odds. In the analysis, we highlighted the roles that these features had in the development of Jane and Zara's substantiations of "odd + odd = even".

It seems unlikely that the potential of the two abovementioned features would be fully realized without the guidance of the knowledgeable other. In accord with many researchers (Cooper & Lavie, 2021; Sfard, 2008; Stylianides, 2007), our analysis stressed the crucial role of the teacher in facilitating students' discursive developments. Conceptualizing the empirical-deductive gap as an instance where substantial discursive change is required, teachers' actions emerge as a key feature of an interdiscursive environment. To put it differently, we suggest that pre-designed features can set up the stage for interdiscursivity, but it is the teacher who can make the environment interdiscursive.

The presented case of Jane and Zara was relatively successful and concise, but it is silent about the other two members of the group. Furthermore, Knox's (2021) larger research showed that some students' journeys were longer and more complicated, while some did not seem to reach the target. Moreover, even when some students appeared to participate in a midway discourse, they still often fluxed between it and the more familiar empirical arguments. Hence, metaphorically speaking, interdiscursivity does not appear to us as a train that takes learners from an empirical to a deductive station, but a bridge on which students can walk in both directions. Nevertheless, we propose that interdiscursivity may be of interest for further research to explore how students can be assisted in bridging the empirical-deductive gap.

Building up Professional Knowledge on Fostering Primary Students' Data-based Argumentation – an Intervention Study

Jens Krummenauer[1] & Sebastian Kuntze[2]

Engaging students in argumentation based on statistical data is seen as an important aim of statistics education from primary school on. For being able to provide related learning opportunities to students and to help students to further develop in data-based argumentation, teachers need corresponding professional knowledge. As prior research had shown that teachers often do not have such professional knowledge, we investigated in a quasi-experimental intervention study with N = 57 student teachers whether it is possible to build up professional knowledge on fostering data-based argumentation. The results provide evidence for the efficacy of the intervention approach and point to implications for its implementation in future courses.

Keywords: Argumentation, professional knowledge, statistical literacy, awareness, intervention research.

Introduction

Fostering students' argumentation is emphasised frequently as a key element of the mathematics classroom. In the past decades, a wide body of research into different aspects of teaching and learning of argumentation (for an overview see e.g. Stylianides et al., 2016) has emerged, for instance with a focus on engaging students in argumentation (e.g. Bezold, 2012; Jablonski & Ludwig, 2021) or on teachers' professional knowledge related to fostering students' argumentation (e.g. Ayalon & Nama, 2021). However, argumentation based on *statistical data* has been largely unexamined so far, in particular with a specific focus on children in primary school. Addressing this gap in research, a series of studies (e.g. Krummenauer et al., 2020; Krummenauer & Kuntze, 2018) has been conducted. The findings provided evidence that argumentation based on statistical data is possible for many students in primary school and that students' data-based argumentation can be fostered in the primary mathematics classroom. However, creating learning opportunities related to students' data-based argumentation requires that teachers have corresponding professional knowledge; an awareness of possible learning opportunities related to data-based argumentation can be expected to be a key element of such professional knowledge. First empirical research (Krummenauer & Kuntze, 2021a, 2021b) has implied that many primary school teachers do not have such an awareness, which points to a need for research on how a basis of professional knowledge related to fostering students' data-based argumentation can be build up during student teachers' university education. The intervention study reported on in this contribution addresses this research need by evaluating the efficacy of an intervention approach with a particular focus on raising student teachers' awareness of learning opportunities for fostering primary students' data-based argumentation.

In the following section, we present the theoretical framework of the study and give a brief overview of existing research. Subsequently, we specify the research questions and outline the design of the intervention study, before presenting results and discussing implications as well as limitations of the study.

Theoretical Framework

Data-based Argumentation as a Key Idea of Statistics Education

Within the wide body of literature on statistics education, the relevance of processes of argumentation for dealing with statistical data is highlighted frequently. Ben-Zvi and Garfield (2004), for instance, describe a key goal of statistics education as "Being able to properly evaluate evidence (data) and claims based on data […]" (p. 3). Gal (2002), to give only one further example, defines two core elements of statistical literacy as "[…] people's ability to *interpret and critically evaluate* statistical information, data-related arguments, or stochastic phenomena […]" (p. 2) and " […] their ability to *discuss or communicate* their reactions to such statistical information […]" (p. 3). Although the importance of argumentation for dealing with statistical data is emphasised in numerous publications, there has hardly been any systematic research with a specific analysis focus on primary students' data-based argumentation. In response to this research need, a series of interrelated empirical studies (e.g. Krummenauer et al., 2020; Krummenauer & Kuntze, 2018, 2021c) has been conducted, specifically focusing on primary students' data-based argumentation, which we consider as a specific case of argumentation in which statistical data is used for substantiating certain statements (e.g. Krummenauer et al., 2020). A first key finding of these studies was that many students in primary school are able to evaluate data-related claims and can develop corresponding data-based arguments in appropriate task contexts. Further, the studies have shown that primary students' data-based argumentation can be fostered effectively in the mathematics classroom. However, in order to foster students in further developing their data-based argumentation in the mathematics classroom, it is necessary that teachers provide appropriate learning opportunities to their students, such as appropriate statistical data and corresponding impulses facilitating processes of data-based argumentation; for this, teachers need corresponding professional knowledge.

Teachers' Professional Knowledge on Fostering Students' Data-based Argumentation

Such professional knowledge may include, for instance, knowledge about possible learning scenarios (e.g. what kind of data sets could be provided to students as a basis of argumentation), knowledge on how to initiate processes of data-based argumentation in the classroom, or knowledge about possible difficulties of students as well as corresponding possibilities of supporting students' learning (see e.g. Krummenauer et al., 2020; Krummenauer & Kuntze, 2018). Beyond only possessing (potentially inactive) knowledge, the extent to which teachers are able to *use* such professional knowledge can be assessed when teachers *analyse* in profession-related requirement contexts, such as classroom scenarios or responses of students (Kuntze & Friesen, 2018). The term *analysing* has been defined by Kuntze, Dreher, and Friesen (2015) as an "awareness-driven, knowledge-based process which connects the subject of analysis with relevant criterion knowledge and is marked by criteria-based explanation and argumentation" (p. 3214).

Consequently, whether or not professional knowledge is actually used by teachers in their analysis largely depends on teachers' *awareness* of relevant criteria (Kuntze & Friesen, 2018). As defined by Kuntze and Dreher (2015), we consider criterion awareness as "a part of professional knowledge which influences the readiness and ability of teachers to use related professional knowledge elements in instruction-related contexts" (Kuntze & Dreher, 2015, p. 298). Related to fostering students' data-based argumentation, this includes, for instance, to be aware of potential opportunities for students to engage in data-based argumentation through textbook material or in classroom situations. As described in the model by Kuntze and Friesen (2018), teachers' criterion awareness is crucial for processes of analysing, as it can activate relevant professional knowledge for teachers' analysis. Conversely, a lack of criterion awareness would have the consequence that a teacher would not apply corresponding professional knowledge in the analysis (and in subsequent actions based on such an analysis), even if the teacher held relevant knowledge (Kuntze & Friesen, 2018). Therefore, a particular focus on fostering teachers' awareness related to students' data-based argumentation appears to be a promising intervention approach with high relevance for teachers' classroom practice.

Existing Research on Professional Knowledge related to Fostering Students' Argumentation

Several studies exist with a focus on student teachers' and in-service teachers' professional knowledge related to fostering argumentation in the mathematics classroom (e.g. Ayalon & Nama, 2021; Bleiler et al., 2013; Brunner, 2019). As reviewed by Stylianides et al. (2016), many of these publications report on weaknesses in teachers' professional knowledge in this regard. This is also the case in a prior empirical study with $N = 44$ in-service primary school teachers (Krummenauer & Kuntze, 2021a), in which the participants did not show an awareness of learning potentials related to data-based argumentation in most of their analyses.

Further, there are some publications reporting research on building up professional knowledge in in-service and student teachers related to argumentation. Brunner (2019), for instance, reports on an intervention with kindergarten teachers. The author describes a positive development of their professional knowledge during the intervention and concludes that it is possible to successfully establish argumentation practices through professional development activities. In contrast, Melhuish and colleagues (2020) report on a long-term intervention study with the aim of fostering teachers' noticing related to argumentation processes, which had only small effects on teachers' professional knowledge. The authors highlight, that they found a large discrepancy between teachers' self-reports and teachers' actual performance regarding their argumentation-related noticing.

To our knowledge, however, there are hardly any studies with a specific focus on building up professional knowledge related to fostering primary students' *data-based* argumentation during teacher university education. It is therefore largely unclear what effects can be reached by means of an intervention focussing on building up awareness of learning opportunities related to data-based argumentation and to what extent possible effects are stable after the intervention.

Research Questions

Consequently and responding to this research need, the study reported in this contribution addresses this research need with a particular focus on the following research questions:

RQ1: Is it possible to increase student teachers' awareness of learning opportunities related to fostering primary students' data-based argumentation by means of an intervention?

RQ2: How stable are possible intervention effects?

Methods

Study Design and Sample

The study is designed as a quasi-experimental intervention study with three points of measurement. The first two tests were conducted right before and after the intervention, which was implemented in two university courses with different course formats: the first course had a regular, weekly seminar format with weekly sessions of 90 minutes, whereas the second course was conducted as a compact course taking place on 4 days within a period of 7 weeks. As a third group, a non-treatment control group was included in order to control for possible re-test effects. In the intervention groups, the intervention was implemented in 3 parts (each approx. 90 minutes, excl. testing time). Approximately five weeks after the intervention, a follow-up test was administered to the participants of the intervention groups.

The sample consisted of $N = 57$ student teachers; $n = 28$ of them participated in the weekly course, $n = 10$ in the compact course, and $n = 19$ in the control group. Most participants were in their third semester (about 70 %; average: $M = 4$ semesters). About 50 % of the participants studied mathematics as a minor subject, the other half of the sample studied mathematics as a major subject.

Data Collection

For assessing the effects of the intervention, a questionnaire instrument was used, which had been already successfully used and validated (inter-rater reliability: $\kappa = .84$) in a prior study (Krummenauer & Kuntze, 2021a). The questionnaire consists of eight items, which are different types of vignettes to be analysed by the participating student teachers. The vignettes represent different kinds of profession-related requirement contexts (e.g. Buchbinder & Kuntze, 2018) which require teachers to be aware of learning potentials related to data-based argumentation in order to generate appropriate learning opportunities for students. In a dichotomous, criteria-based top-down rating, it was analysed whether the student teachers' analyses indicated that the participants were aware of learning potentials related to fostering data-based argumentation. For being rated as "successful analysis", an answer had to contain a reference to relevant aspects of the data contained in the vignette, and a corresponding learning potential related to data-based argumentation had to be described. Further details about the design of the instrument are described in Krummenauer and Kuntze (2021a, 2021b).

Design of the Intervention

In accordance with the theoretical framework introduced above, the main focus of the intervention is to build up awareness of learning potentials related to fostering students' data-based argumentation. In the intervention, this was combined with building up practical knowledge on possible learning environments, such as knowledge about what kind of data can be used for data-based argumentation in primary school, or what impulses can be given by teachers in order to engage students in data-based argumentation.

In the first part of the course, the student teachers were asked to develop data sets which they consider as suitable for primary students and to develop corresponding impulses they would provide to their students (e.g. questions or claims to be evaluated based on the data by students). This first part of the course is intended to activate and formatively assess the prior knowledge of the participants, and to gain a basis for the further seminar work. In a subsequent step, the data-sets and corresponding questions were discussed in the seminar according to their learning potential for students' data-based argumentation. After a presentation phase focussing on characteristics of data sets which facilitate data-based argumentation and possibilities of providing stimuli to engage students in data-based argumentation, the course participants jointly discussed and further developed their data-sets and corresponding stimuli in several steps. After a joint discussion of the further developed material, further classroom material was presented and discussed with the participants. The participants were asked to think of corresponding stimuli (and, if necessary, to modify the material) in order to develop awareness of learning potentials related to fostering data-based argumentation in different contexts.

Results

Figure 1 shows the development of the mean percentage of answers rated as a successful analysis for each group. The performance in the pre-test of all three groups does not differ significantly from each other, which was assessed by means of a Kruskal-Wallis test ($H(2) = 2.331$, $p = .312$). The spread was also relatively low ($SD_{\text{pre-test}} = 0.93$), so that all three groups entered the study with a relatively low and relatively equal awareness related to learning potentials to foster students' data-based argumentation.

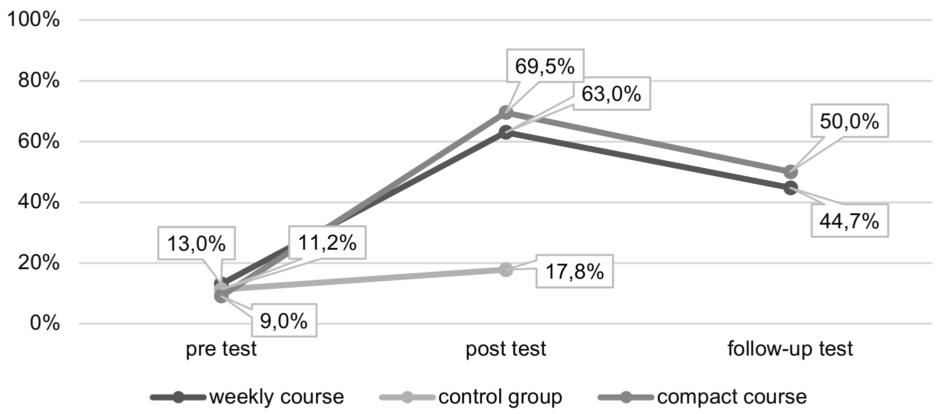

Figure 1: Sub-group comparison of mean percentages of answers rated as a successful analysis

In order to assess whether the changes between pre-test and post-test within the groups are statistically significant, we analysed the difference of answers rated as a successful analysis between pre-test and post-test ($\Delta_{t0,\ t1}$) by means of a further Kruskal-Wallis test. The test revealed significant group differences ($H(2) = 49.398$, $p < .001$). Corresponding post-hoc tests showed that both intervention groups differed significantly from the control group (weekly course: $Z = 19.291$, $p < .001$; compact course: $Z = 21.840$, $p < .001$). The small increase in the control group is statistically non-significant ($Z = -.504$, $p = .614$). The effect size between pre-test and post-test is $d = 4.66$; this large effect size parameter (Lenhard & Lenhard, 2016) has to be interpreted against the relatively low and homogeneous ($SD_{\text{pre-test}} = 0.93$) pre-test performance. In the follow-up test, the effect size dropped around one-third from $d = 4.66$ to $d = 3.19$.

In order to further explore the individual development of the participants of the intervention groups, we further analysed the differences between pre-test and post-test ($\Delta_{t0,\ t1}$) (see Figure 2) and between the post-test and follow-up test ($\Delta_{t1,\,t2}$) (Figure 3). As shown in Figure 2, the participants solved in the post-test between one and seven items (out of eight items) more than in the pre-test (M = 3.9 items). From the post-test to the follow-up-test, the performance of 58.1 % of the participants of the intervention groups was reduced (between 1 and 6 items); 29 % of the participants in the intervention groups had the same test result, and 12.9 % solved one item more than in the post-test (Figure 3).

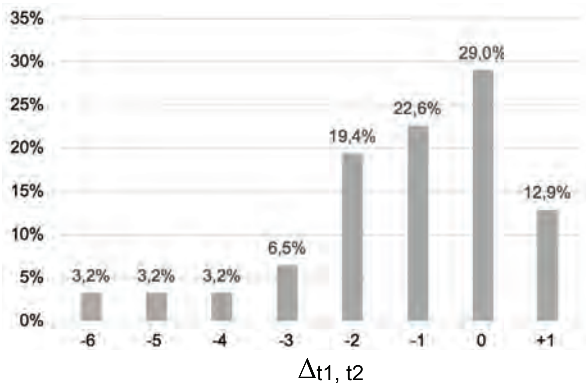

Figure 3: Individual development ($\Delta_{t1,\,t2}$) of the participants of the intervention groups

Discussion and Conclusions

Before discussing the key results of the study, we would like to consider limitations of the study. A first limitation is that the sample of student teachers is not representative for a larger population, and it was not possible to randomise the assignment of the participants to the different groups, so that generalisations to other groups of students need to be reflected carefully. Additionally, although the overall sample size is satisfactory, the size of the sub-group of the compact seminar is relatively small, which needs to be considered when comparing the results of the sub-groups.

Regarding the first research question, the results have shown that it was possible to increase student teachers' criterion awareness in the domain of fostering data-based argumentation substantially in both courses by means of the intervention. The intervention implemented in the compact course appears to be similarly effective as the implementation in the weekly course. The effect size of the intervention corresponds to a large effect (e.g. Lenhard & Lenhard, 2016), and all students improved at least for one item after the intervention. Regarding research question 2, the results show that the effect of the intervention decreased about one-third in effect size by the follow-up test a few weeks after the intervention. This implies that there is still a substantial effect, but that the effects of such an intervention should be stabilised over a longer period, which could be addressed in future implementations of the intervention. However, the decrease of the performance pertains not the whole intervention group, as about 40 % of the student teachers participating in the intervention successfully analysed the same or even a higher number of items in the follow-up test.

Children's norms of explanations in explanation videos

Jessica Kunsteller[1]

[1]University of Dortmund, Germany; jessica.kunsteller@tu-dortmund.de

Explanation videos are becoming more popular in mathematics education. Most of them are made by teachers who are explaining mathematical topics. In this project, primary school students create their own videos addressing other children who have the same age. This paper will give a brief introduction into the project and first observations of children's norms of explanations in explanation videos will be presented.

Keywords: Explanation videos, norms, explanation, (meta-)discursive rules, primary school

Introduction

In recent years, digital media, such as explanation videos, have moved into the focus of mathematics-education research (Ball, Ladel & Siller, 2018). Explanation videos (e.g., Kulgemeyer, 2020 in physics), video podcasts (e.g., Kay, 2014 in mathematics in university) or instructional videos (e.g., Sharma, 2018 in mathematics in college) are primarily used by teachers to impart knowledge in order to explain mathematical content. So far, there have been few empirical studies showing that learners create videos themselves. However, initial studies emphasize that the independent production of explanation videos has a positive effect on learning mathematics (Kay, 2014). In this paper, a project is presented in which the learners themselves create so-called *explanation videos* (Kulgemeyer, 2020) for other learners in their age. For this purpose, an interview study was carried out with children from the third and fourth grade of primary school (aged 8-10 years). In the interviews, they work in tandems on tasks which contain arithmetic tasks. Based on these tasks, they then plan and produce a video for other learners their age. According to Prediger, Erath & Opitz (2019) learning mathematics is led by language. Learners negotiate mathematical content through language (Voigt, 1995). Tiedemann (2017) shows that the use of language in mathematics lessons is also guided by *norms*. Erath (2017) points out that explaining is a practice which is characterized by regularities. Experts for explanation videos have also set up criteria for explanation videos (e.g., Kulgemeyer, 2020). But which rules and norms do children use in an explanation video? One request of the project's research is to elaborate *rules* (Sfard, 2008) and *norms* (Voigt, 1995) which the learners use while explaining mathematical content during the planning and producing of the videos.

(Meta-)discursive rules and norms

Human interaction is shaped by rules (Sfard, 2008). For instance, when you greet a person, they return it by greeting back. Or, if you get a present, you say "thank you". The examples given are based on rules of courtesy. As Voigt (1985) pointed out classroom interaction is also led by patterns and routines. Sfard (2008) distinguishes between two sorts of rules: "object-level rules" (pp. 201f) and "meta(-discursive) rules" (ibid.). Object-level rules are based on the mathematical content, like mathematical rules and definitions (ibid.). Metarules relate to the adaptation in the respective situation. According to Sfard (2008) they are usually not formulated explicitly, but take place in classroom conversations:

> More generally, object-level rules are narratives about regularities in the behavior of objects of the discourse, whereas metarules define patterns in the activity of the discursants trying to produce and substantiate object-level narratives. […] Metarules are also made distinct by being mainly tacit, and by being perceived as normative and value-laden whenever made explicit. (pp. 201f)

Sfard (2008) points out that metarules could become norms by referring to the works of Voigt (1995) and Yackel & Cobb (1996). Rules and Norms have in common that they both lead to an interaction with observable regularities (Sfard 2008). But they differ due to their commitment (ibid.). Due to Sfard (2008) for a rule to become a norm, it must fulfill two conditions: The rule must be widely known within the respective social group. And the rule must be accepted within the group. In this study, interviews are carried out with tandems of the same school class (aged 8 to 10). The interviewer and the children can be viewed as a social group. Furthermore, the children come from a social group, their school class. Thus, the first condition is fulfilled if both of the children are listening. The second condition is fulfilled if both of them accept the rule. In other words, if one student establishes a rule and the other student does agree to the prior statement, the rule becomes a norm.

Explanations and Explanation Videos

Explanations and their importance are often emphasized in mathematics education (e.g., Erath, 2017; Hanna, 2000). To describe a scientific *explanation*, Hempel & Oppenheim (1948) highlight the indispensability of causality. For example, in the “Discovering Pac” (Nührenbörger et al., 2019, p. 76) in Figure 1 (left) learners could observe the phenomenon that the result of both calculations is 12. It could then be questionable why the result is 12. Thus, the equality of the sums has to be explained. It can be explained by, for example, changing the first term by minus two and changing the second term by plus two (see ibid.). This change makes it clear that the tasks are the same and therefore also have the same result ((10 - 2) + (2 + 2) = 8 + 4). The underlying law here is the constancy of the sum ($\forall\ a, b, x \in \mathbb{N}: (a - x) + (b + x) = a + b$). The stated explanation is using an example and a general form, the equality of totals to explain the equality of the sums.

Following Kulgemeyer (2020) *explanations videos* are “short videos (usually between 5 and 10 min) with the goal to explain a particular content area” (p. 2444). In this sense the intention of *explanation videos* is to explain a mathematical content. Kulgemeyer (2020) points out a “framework for effective explanation videos” (p. 2450) for teachers who teach physics to plan and optimize their explanation videos. Similarly, Kay (2014) formulates “key components” (p. 24) for video podcasts. In terms of Sfard (2008) one can say that these topics are norms for explanation videos in the context of physics education. As Erath (2017) pointed out explanations are also led by implicit regularities. But which norms of explanations do children establish while planning explanation videos? First observations will be elaborated at the empirical part of the paper.

Methodology and Methods

The research concern of this article is to reconstruct and categorize students’ norms of explanations in explanation videos. As part of a first pilot, eight semi-standardized interviews were carried out with four tandems each from the third and fourth grade of primary school (students at the age of 8-10) whose learning level in learning mathematics are similar to each other. Three sessions (à 45 minutes) were held with each tandem. At first, they learn how explanation videos are constructed to get familiar with the method:

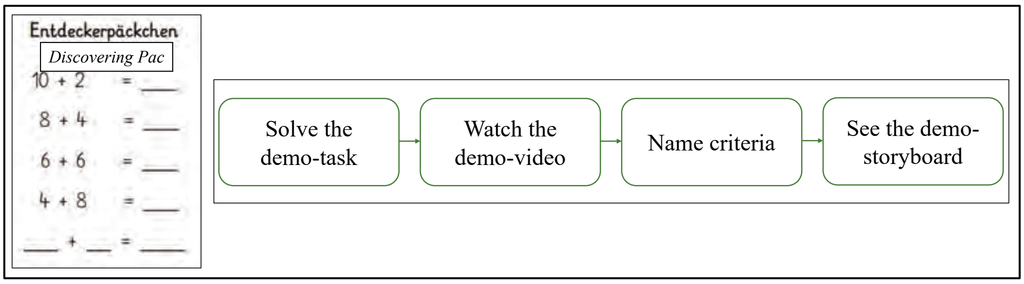

Figure 1: Left: The demo-task; Right: Procedure for introducing explanation videos.

Primarily, they solve a Discovering Pac (see Figure 1, left), which is familiar to them. Subsequently, they watch an explanation video of this task to emphasize the most important facts about explanation videos (e.g., only the hands can be seen, images and writings are used). This task was chosen because it is not too demanding in terms of the mathematical content so that the learners focus ever more on the method. Nevertheless, the task discovery and explanation. Then they get a *storyboard* in which the images and the spoken text of the explanation video are planned (see Figure 2). The interviewer explains that the pictures are outlined and the text of the corresponding pictures is prescribed.

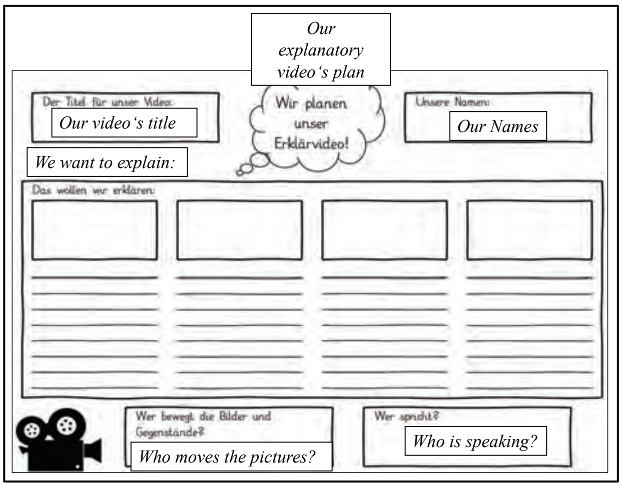

Figure 2: The storyboard, which the students use to plan their video

After this introduction they solve the first task. The learners are asked to discover and explain the mathematical content together. The mathematical tasks differ between the third and fourth grade because of the tasks' complexity.

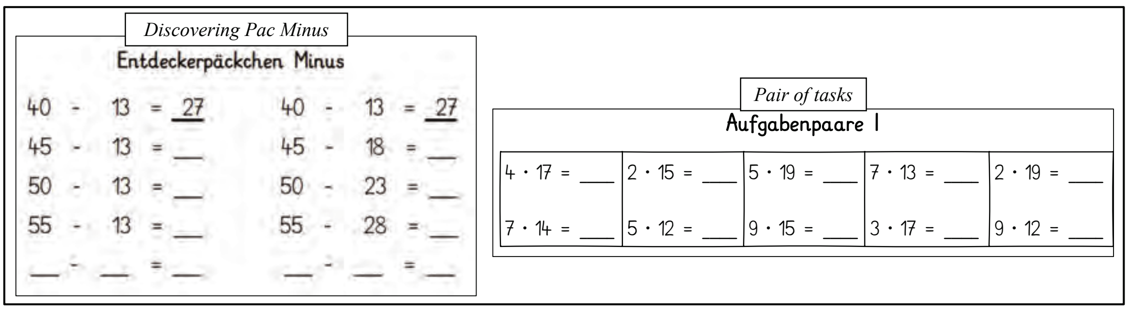

Figure 3: Left: Second task for the third grade; Right: First task for the fourth grade

After the editing, the tandems write a storyboard together to plan their video. The learners are told that they would record their video for children their age who are learning at home because of the Covid-19 pandemic. The video should help the fictional children to solve such tasks. After planning the video, the learners record their video and revise it at their own request. This first shooting cycle, consisting of developing the content, writing the storyboard as well as the video production and revision, was repeated by solving a similarly structured task. The purpose of the repetition is to focus more on the content, not on the method.

In this paper children's norms of explanations in explanation videos will be categorized. The qualitative analysis is based on an interactionist point of view (see Voigt, 1995). The rules and norms are reconstructed with regard to Sfard (2008). The interviews were videotaped and transcribed (rules of transcription, see Kunsteller, 2018). The following students' quotations were translated and transcribed by the author.

Empirical examples

First observations of children's norms of explanations in explanation videos will be expounded. Due to the shortness of the paper, they will only shortly be stated. For a better understanding, only excerpts of interviews by two tandems are shown. Nevertheless, the shown norms could also be confirmed in other interviews. The given examples do not claim to be a complete list of norms. Consequently, they can be expanded. Furthermore, they could be similar to the criteria that are set on explanation videos (e.g., Kulgemeyer, 2020).

Norms concerning the video's layout

After Hülya and Yao (third grade) watched the demo-video they had to tell if the person in the video explained the mathematical content well. Both agreed and Hülya added:

53	Hülya:	"yes she explained that well ... I would make the writings a little bigger' because if you always take a camera like that, you don't always see the writings so well."

Hülya's statement can be interpreted that if a person explains a content well the presentation of the explanation is also important. Since Yao does not disagree, they implement a norm which concerns the video's layout. It can be argued that an explanation in an explanation video should not only be good in terms of content but also in terms of layout. Hülya could mention this because the content could also be influenced by legibility. Norms of this kind concern the external shape of the explanation video. For instance, in a different scene, Hülya and Yao wanted the numbers to be written more properly. Nevertheless, these norms have an influence on the quality of the explanation. Yet, this seems to be relevant for the children. One reason could be because they have to learn to write correctly in primary school, so they talk about this while planning the video. It could be assumed that children would set this kind of norms as well for explanations in explanation videos in a different subject (e.g., biology) because the norm concerns aesthetics in a broader sense.

Norms concerning mathematics education

Once Hülya and Yao have processed the discovering pac of subtraction, they plan their video. First of all, they talk about the discovering pac which they use for their explanation. Meanwhile, the following situation arises:

727	Hülya:	"I think we could make an image with balloons (*brings hands together and apart*) because that <u>explains</u> it well too"
728	I:	"mhm. you could think about it."
729	Yao:	"or with candies"
(Afterwards they write the minuend of their discovering pac down)		
752	Yao:	"yes. and if we do this (*points at the third column of the storyboard, see Figure 2*) with balloons then it would be funny then three could pop. broken."
753	Hülya:	"(*laughs*) good"

Hülya says that they could use an "image with balloons" (727) to explain the content. She points out that the image would explain it "well" (ibid.). "It" (ibid.) could refer to the discovering pac of subtraction which they want to explain. Yao seems to like that idea and suggests to use "candies" (729). Since Yao agrees with Hülya's idea and even suggests a new idea, it can be argued that they are establishing a norm. That Yao likes her idea is also confirmed during the further process, when he picks up the example again and also extends it. Furthermore, Hülya laughs afterwards and classifies the statement as "good" (753), she seems to agree with Yao's suggestion. According to Hülya and Yao, an explanation in an explanation video should be funny and demonstrative. In addition, it can be assumed that they base their explanations on examples from math class. In German mathematics books, subtraction is often represented by the disappearance of objects (e.g., the bursting of balloons). This example could be used because they could assume that other children also know these examples. Consequently, their examples would ease the understanding of the content. Norms of this kind concern examples which are used in math books which are led by mathematics education's ideas. Furthermore, they implemented a norm that an explanation in an explanation video should be interesting or funny. As the interview progresses, the children develop their own discovering pac (see Figure 4 without the circles). At the end of writing the discovering pac, the following situation occurs:

909	Yao:	"should we *(shows at their own discovering pac)* circle it here so that the children could better- ... *"*
910	Hülya:	"<u>maybe</u>'"
911	Yao:	"should I do it'"
912	Hülya:	"<u>yes</u> but <u>please</u> use this color here *(gives him a turquoise pen. Yao circles the operands, see Figure 5, left)* […]"

Yao suggests to circle numbers in the discovering pac. One reason why he suggests the circles could be that the circles could simplify the understanding of the discovering pac for the other "children" (909). In Turn 912 Hülya agrees and suggests a special color for the circles. Due to the fact that she does not intervene how Yao circles the numbers she seems to agree with the way it does it. Thus, it can be argued that they implement a norm that circles and colors are important to express or underline an explanation in an explanation video. Like in the example this norm is led by mathematics education's ideas. In Germany it is common that students learn to use colors to highlight their discoveries (Nührenbörger et al., 2019). Furthermore, the highlighting is guided by the idea that the other children should understand their explanation. Thus, it can be claimed that they implement a norm that explanations in explanation videos should be understandable for (other) children. A different interpretation that the students are highlighting operands is that they could transfer it from the demo-video, in which the operands are outlined as well. In accordance with this interpretation, this would lead to the norm that components of the demo-video should be included in the video. Nevertheless, this norm is led by mathematics education's ideas. Since the students seem to identify this highlighting as relevant for their video and they could know it from German mathematics books.

In the following an image is shown which Hülya and Yao use in their video. The image is showing some learning materials made out of wood which are used in primary school to explain arithmetic tasks. Hülya and Yao use these materials to explain their discovering pac. Again, this usage underlines the fact that their explanations are led by mathematics education's ideas.

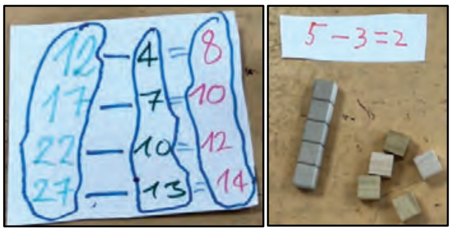

Figure 4: Extracts of images in Hülya's and Yao's explanation video

Norms concerning the mathematical content

Jasper and Bastian (fourth grade) want to explain the pairs of tasks (see Figure 3, right). They already decided to push the sheet of paper with the pairs of tasks in the focus of the video. Jasper had written the calculation for the first pair of tasks. At the end of writing the calculations he suggests:

460	Jasper:	"we could do that *(points to the first pair of tasks)* with pushing this in here *(points to his calculation),* this one without calculations *(points to the second pair of tasks)*, because actually they are simple, # this one *(points to the third pair of tasks)* again with"
461	Bastian:	" #yes but .. it doesnt matter if its easy or not, we should just explain it, for the difficult things, so that they understand you understand'"
462	Jasper:	"yes *(nods)"*

Jasper indicates that he wants to push his calculations of the first pair of tasks into the focus of the video as well. Then he states that the calculations for the second pair of tasks are not necessary because "they are simple" (460). At this point Bastian intervenes and states that not only "difficult things" (461) should be explained because it is important that the other children ("they", ibd.) understand their explanations. Since Jasper agrees (462) it can be argued that they implement the norm that even when the person itself understands the mathematical content it should be explained for another person. This example shows that you can explain or rather prove mathematical contents in different ways (Hanna, 2000) and that the acceptation of the explanation depends on the addressee (Heintz, 2003). Like the previous norm this kind of norm seems to be special for mathematics. Since it focuses different ways of explanations.

Statements and Outlook

Experts usually create videos with the intention that learners understand the mathematical content better. In this project, the children are the ones who explain the mathematical content. However, they are not experts, so the explanations are not necessarily complete and correct from a mathematical point of view. Nevertheless, the brief insight shows that the learners establish different norms on their explanations. Mostly, these norms are led by the desire that the other children understand their explanations. The following norms were elaborated:

- Norms concerning the video’s layout
- Norms concerning mathematics education
- Norms concerning the mathematical content

Tiedemann (2017) elaborates norms of the language in mathematics lessons. She points out that a “grammatical norm” (ibid, p. 51) is set when a fixed linguistic structure has to be used by the students. Similarly, to this grammatical norm the children underline the external shape or the layout for the explanation in the videos (e.g., height of numbers, readability). Still, these aesthetic norms are also guided by the wish that their explanation is better transported through the external shape. Likewise, Kay (2014) mentions the topics “readability” (p. 24) and “layout” (p. 24) for creating video podcasts as well. As already pointed out norms concerning the video’s layout could be named as well in other subjects. In contrast, the last two norms seem to be specific to mathematics or mathematics education. Norms concerning mathematics education accentuate that the children’s explanations are led by their mathematical socialization. Kay (ibid.) and Kulgemeyer (2020) also state the topic “highlighting” (p. 2450) but they use it in order to emphasize important aspects. Whereas the students use the highlighting of several numbers as a part of the explanation. It can be interpreted that the highlighting helps them to formulate their explanations. Furthermore, those norms give indications what seems to be a good explanation for the children. These indications as well as the norms for explanations will be elaborated in further publications. As a next step it is possible to investigate how students evaluate explanations of self-made videos by other students. By asking children if and why they like or dislike the video one could get a deeper insight of children’s norms of explanations in explanation videos.

Student teachers' proofs and refutations on cyclic quadrilaterals

Magdalini Lada[1] and Tore Alexander Forbregd[2]

Norwegian University of Science and Technology (NTNU), Trondheim, Norway;

[1] magdalini.lada@ntnu.no, [2] tore.a.forbregd@ntnu.no

We follow and analyze three teacher students' behavior while they engage in a task with the goal of the reinvention of the characterization of cyclic quadrilaterals in terms of their opposite angles. We show how, during the exploration of the problem, the teacher students go through cycles of proofs and refutations, in the sense of Lakatos, and we discuss the role of the teacher educator in supporting and conceptualizing these processes. Our results may have the potential to be used in designing mathematical activities aiming at scaffolding teacher students´ knowledge for teaching proof.

Keywords: Proof, counterexample, conjecture, task design, teacher knowledge.

Introduction.

Lakatos' *Proofs and refutations* (1976) marks the turn that Philosophy of Mathematics took towards fallibilism, the view that mathematical knowledge is corrigible and advances through a process of criticism and revision (Van Bendegem, 2018). Lakatos used the history of Euler's formula for polyhedra and its proofs as a basis for describing the road to mathematical discovery and at the same time presenting different views, over time, on what a satisfactory result and a valid proof consist of.

Besides its philosophical importance, Lakatos' work is also significant from a pedagogical point of view since it provides us with a window to original mathematicians' work presented in an educational setting. The idea of using Lakatosian notions in designing, implementing, and analyzing authentic mathematical activities is not new (Lampert, 1990). Several researchers have used Lakatos' ideas to develop frameworks that can be used for analyzing students' behavior in proving activities in various levels of mathematics education from primary (Komatsu, 2010), to secondary (Komatsu, 2012) and into undergraduate level (Larsen & Zandieh, 2008). Other studies have focused on designing activities that foster methods of proofs and refutations (Komatsu & Jones, 2017), or on teachers' mathematical knowledge for teaching Lakatosian proof (Deslis et al., 2021). Our study adds to this growing body of research-based literature first by providing some more examples of Lakatosian notions and processes, this time from teacher education, and second, by suggesting elements of instructional design aiming to build teachers students' mathematical knowledge for teaching Lakatosian proof. For the purpose of this article, we consider Lakatosian proof as it is described in (Deslis et al., 2021). However, discussed in the last section, authentic Lakatosian proving activities need to be further understood and defined. We seek to answer the following questions: 1) In which ways do teacher students' attempts to reinvent a characterization of cyclic quadrilaterals parallel the methods of Lakatos' proofs and refutations? And 2) How can teacher educators design and implement tasks that support teacher students' mathematical knowledge for teaching Lakatosian proof?

Theoretical background.

With starting point the naive conjecture "All polyhedra satisfy the formula $V - E + F = 2$", where V stands for vertices, E for edges and F for faces, and Cauchy's proof (Lakatos, 1976, p. 7), and after counterexamples are discovered, Lakatos described techniques for improving the conjecture and its proof. In this process crucial role is played by the type of counterexamples. Lakatos referred to counterexamples refuting the initial naive conjecture as *global* and to those refuting at least one step of the proof as *local* (ibid., p.11). According to the type of the encountered counterexample, a method was suggested that would lead to an improved conjecture or/and proof. We only mention here those methods that are needed for analyzing our findings.

One of the first methods, *exception barring,* was proposed when the global and local counterexample of a picture-frame polyhedron was discovered and was initially described as restricting the domain of the conjecture to exclude the counterexample, without reference to the proof (ibid., p. 28). As opposed to this, *lemma incorporation* was suggested as investigating the proof to identify the step which is refuted by the counterexample and incorporating it as a condition in the domain of the conjecture (ibid., p. 35.) Later in the discussion the exception barring method is generalized to include "a whole continuum of exception barring attitudes" (ibid., p. 39), according to how much the proof is used to determine the domain of the conjecture, with lemma incorporation being the limiting case. Lemma incorporation can also be used in the opposite way to expand the domain of a conjecture that has been previously restricted by exception barring. According to Lakatos this is the approach of the *best exception-barrers* and it involves starting with a restricted *safe domain*, devising a proof, examining the proof for imposed conditions that were not used, and generalizing the initial modest theorem by incorporating only those conditions that proof relies on (ibid., p. 40).

Mathematicians' views on *satisfactory* results are voiced via Lakatos' fictional student Omega at a point where different proofs, corresponding to different domains had been proposed, like Gergonne's (ibid., p. 63) and Legendre's (ibid., p. 64) proofs, none of which was including the *local but not global* counterexample of the great stellated dodecahedron (ibid. p. 65). According to Omega, "a proof should explain the phenomenon of Eulerianness in its entire range" (ibid., p.67). Omega suggests that when encountering a local but not global counterexample, it might be needed to invent a "completely different, more embracing, *deeper* proof" (ibid., p. 62).

Two opposite paths towards mathematical discovery are discussed in (Lakatos, 1976). The first one, which Lakatos calls *analysis,* involves starting with a naive conjecture, to which one arrives by trial and error, and testing it by drawing consequences (ibid., p. 80). This path we learn later, can be followed even without a conjecture to start with. One can pretend that "the result is there and device an analysis" (ibid., p. 83). The other direction, which Lakatos called *synthesis* (ibid., p. 81), is what we normally call a deductive proof. For this direction too, starting with a conjecture is not necessary. One can immediately "device a synthesis […] from a related proposition that is known to be true" (ibid., p. 83). In this way, synthesis corresponds to another term introduced by Lakatos, *deductive guessing,* as opposed to naive guessing, and to what Herbst (2004) refers to as building reasoned conjectures. As an aid to support students' deductive guessing, Herbst proposes the *generative mode* of interaction between a student and a diagram which involves, among others, drawing new features on the diagram, transforming its shape and size, and changing location or orientation.

Method.

The course and the participants.

This study was conducted within the context of a course titled Historical and Philosophical Aspects of Mathematics aimed at student teachers in their 4th year of a five-year master program for grades 5-10 in a Norwegian university. Our informants are three of the courses participants and have gotten the fictional names Marie, Lars, and Siri. Our data consists of their solutions to a task included in one of the course's mandatory assignments supplemented by semi-structured follow-up interviews. The assignment was given after the last teaching session, which had focus on proof and proving. During the session, after an introduction to Lakatos' proofs and refutations were concepts like conjecture, proof analysis, global and local counterexample, and their role in proving were presented, the students discussed how Lakatos' ideas could be used in the mathematics classroom and how a teacher can support pupils in engaging in Lakatosian proof. Their discussions were based on the papers by Komatsu (2012) and Larsen & Zandieh (2008) that the students had read in advance as preparation.

Task selection.

The task included in the students' assignments was meant to function as a starting point for involving them in genuine mathematical activity by reinventing a mathematical result. For this purpose, we considered the following characteristics that the target result should be: 1) new for teacher students but within reach using tools from school mathematics, 2) analogous to previously established result known to teacher students, and 3) valid under certain conditions – necessary or/and sufficient.

The characterization of quadrilaterals in terms of their opposite angles, which can be formulated as "A quadrilateral is cyclic if and only if its opposite angles are supplementary", has all the above characteristics. It is not normally included in the school curriculum in Norway, but its proof is based on the inscribed angle theorem which is. Also, our students are familiar with the circumcircle of a triangle which can serve as the motivation for investigating a similar question for quadrilaterals. Nevertheless, we decided to include this as the first part of the task, which was formulated as follows:

a. Prove that the three perpendicular bisectors on the side of a triangle meet at one point and that this point is the center of a circle that goes through the triangle's vertices.
b. Investigate if a similar result holds for quadrilaterals. State a conjecture and try to prove it.

Three students, all having delivered different solutions, were chosen for the follow-up interviews.

The interviews.

The three students were interviewed after the end of the course and before the exam. The interviews varied from 40 to 50 minutes and took place in a digital environment. The interviewers were the authors of the paper where the first author was, in addition, the teacher of the course. With the students' different solutions as a starting point, we intended first to get an insight on how each one had arrived at their solution and then try to stimulate them to continue the investigation and reach a deeper result. Following Lakatos' heuristic methods, we aimed to offer, or lead the students to discover, counterexamples to their claims or arguments, anticipating that this would lead them to modify the proposed claim or argument. The initial goal was to lead the students to formulate and prove the characterization of cyclic quadrilaterals as those that where opposite angles are supplementary. This goal soon showed to be too optimistic, so we ended all interviews once a necessary condition was conjectured by the students, namely "If a quadrilateral is cyclic, then its opposite angles are supplementary". As a tool to assist in exploring the problem, we used the dynamic geometry software Geogebra on a shared screen. In Marie's interview, the researcher controls the software and shares his screen, while in the other two interviews, the students do so.

Analysis.

In what follows, the first author is referred to as the teacher, the second as the researcher. The analysis is based on and structured over Marie's interview, but supplementary comments based on data coming from the other two students are also included.

Surrendering.

Marie presents in her solution a random quadrilateral with two circles drawn, each one going through two of the vertices. She concludes that "it will therefore not work to make a circle that goes through all vertices at the same time, but one can make a set of circles so that all vertices lie on one of them".

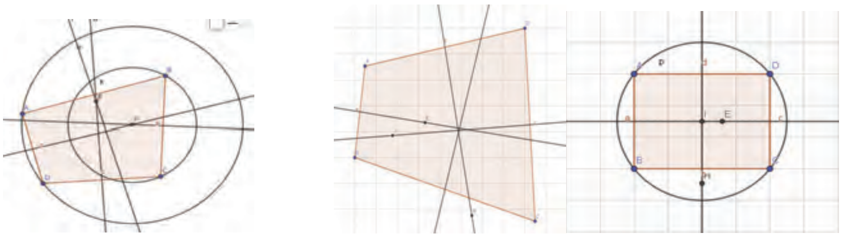

Figure 1: Marie's multiple circles and Lars' two examples

When asked if she had an initial feeling that led to her strategy the student replied that she thought it should not work (to have a circumscribed circle for a quadrilateral) since she had never heard of it. The drawing she presented was her first move towards dealing with the task and since it confirmed her suspicion, she decided to end the investigation following the method of surrender (Lakatos, p. 14). She seemed to think that this was enough for what the problem was asking: "I got a result and I thought, ok, I found it out".

Another student, Lars, that had managed to come a bit further in his investigation and had concluded that some quadrilaterals are cyclic while others are not, explained in the interview that if he was to go any further and try to find out what all cyclic quadrilaterals have in common, this should have been explicitly asked for as the next part of the problem. He also felt that his conclusion was enough.

The two ways of using lemma incorporation.

In the interview, Marie admitted that she could have worked more with the task, which was the starting point for us to trigger her to investigate a bit further. The teacher asked the student if she could think of any quadrilateral that could be inscribed in a circle.

Marie: If I had drawn a quadrilateral with right angles, and maybe equal sides, a square, then I would have gotten a center if I am right […] I just see that when the sides are equal you will get this diagonal's cross and you can have the center there.

Teacher: What is it that makes it work for squares? Can we find more classes?

Marie: All rectangles then? Because then you will get that diagonal's cross […] which is equally far [from the vertices]

Marie retreats to quadrilaterals with right angles and equal sides, which includes only squares, as the safe domain of her theorem. She argues that, in this case, the diagonals' intersection point can be used as a center for a circle that goes through all vertices. This argument can, of course, work for any quadrilateral having right angles, that is, any rectangle. It can thus be incorporated as a condition expanding the domain of the theorem. Marie manages to do so as soon as the teacher turns the focus on the argument. This process parallels what Lakatos (1976) described as a combination of exception barring and lemma incorporation.

Siri, another of our students, used lemma incorporation to restrict the domain of her claim. She had overgeneralized from rectangles the property that the perpendicular bisectors of opposite sides coincide and stated that "all parallelograms are cyclic" because of this reason. When encountering a local and global counterexample offered by the researcher - a random non-rectangular parallelogram - she restricted the domain to include this property as a condition ending up with only rectangles as the domain of the theorem.

More local counterexamples and the need of a deeper proof.

Recognizing that the argument concerning the intersection point of the quadrilateral cannot be used to include other classes than rectangles the educators suggest that we look at the problem in another way, namely starting with a quadrilateral that lies on a circle. All drawings and their manipulations are performed and shared by the researcher as the discussion goes on.

Researcher: If you start at the opposite end can you draw a quadrilateral that lies on a circle?
Marie: … (seems confused)
Teacher: so if you start by drawing a circle
Marie: then I can set two random…, if you want to have a rectangle then, parallel lines anywhere on the circle so that you get four intersection points

Marie aims at constructing an inscribed rectangle, but her instructions lead to a non-rectangular isosceles trapezoid. This is a local counterexample since it refutes her argument but still supports the conclusion of her theorem. At first, Marie gets surprised with the outcome and resists in expanding the domain of the theorem.

Researcher: Was this a rectangle now?
Marie: No, it wasn't ... (laughs)
Researcher: What does this tell us?
Marie: That it is possible to draw a quadrilateral in a circle. But it doesn't say anything about the center, the intersection point of the perpendicular bisectors.

The researcher draws the perpendicular bisectors to confirm that the intersection point coincides with the circle's center. This seems to confuse her even more.

Marie: Now I am so confused that I don't know anymore
Researcher: What did you get confused about?
Marie: About what I have done in the problem

The researcher explains the steps that led us from starting with a circle to drawing an inscribed isosceles trapezoid and eventually Marie accepts that the domain should be expanded.

Marie:	So, while it works for trapezoids and rectangles and squares, it is just for my odd quadrilateral that it doesn't work…that it doesn't have any parallel sides.

Here, there is a missed opportunity of offering or leading the student to discover another counterexample. Maria has not noticed that the trapezoids need to be isosceles. This could have led to focusing on investigating earlier and more naturally the properties of the angles of cyclic quadrilaterals. Instead, the researcher chooses to focus on the parallel sides' condition imposed by the student and draws a random inscribed quadrilateral with no pair of parallel sides to offer as a counterexample. The student gets surprised once more.

Marie:	It works here too
Researcher:	You seem surprised
Marie:	I am confused
Researcher:	Why are you so surprised? If you think what we have done until now…
Marie:	Here it makes sense because we have kept us in a circle, but when I tried to do it the opposite way it didn't work, or at least I couldn't make it work

Assuming that the conclusion is true for a random quadrilateral – that is, the quadrilateral is cyclic - and drawing consequences was particularly challenging for all three students that we interviewed. This heuristic method, which parallels what Lakatos called analysis (Lakatos, 1976, p. 80), can, in our case lead to discovering the necessary and sufficient conditions so that a quadrilateral is cyclic, and synthesizing the proof arriving in a final theorem. However, the student here does not seem to be aware of this possibility. Similar reactions were observed with the other two students we interviewed. The teacher educator, at this point, paused and explained how taking this direction can help us explore the properties that all cyclic quadrilaterals have in common.

Arriving to a conjecture by generative interaction with diagrams.

The researcher now sets it as a goal to describe all quadrilaterals inscribed in the same circle and asks the student how she would go on towards this goal.

Marie:	it was easy to start with the squares because all vertices are equally far from a center…but in such rare quadrilaterals it is hard to find a center.

Because of symmetry, it is easy to visualize the center for the case of squares and rectangles. The student knows that the diagonals' intersection point is equally far from the vertices of a square and reasoned from this to get her initial conjecture/theorem. Even with the diagram showing a "rare" quadrilateral inscribed in a circle the student hesitates to take further action.

At this point the researcher interacts with the diagrams to lead the student to arrive at a new conjecture. In what follows, we describe some of the actions the researcher took.

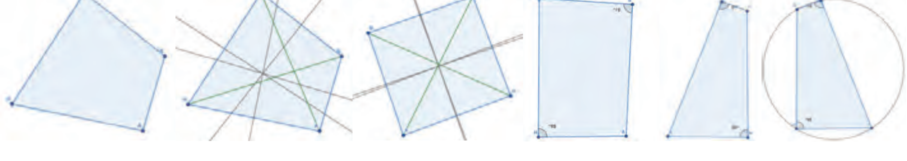

Figure 2: Generative mode of interaction

The researcher removes both the circle and circle's center from the drawing to move the focus away from the circle's center. To show to the student that the argument must be about something different from the diagonals the researcher draws the diagonals and the perpendicular bisectors and shows that it is only in the case of the rectangles that the intersection points of those coincide. To turn the focus to the angles, he marks and measures a pair of opposite angles, moves around the vertices, and lets the student observe what happens to the angles and make a hypothesis. After discussing what changes and what remains the same the student manages to arrive at the conjecture: "if a quadrilateral is cyclic their opposite angles are supplementary", which ended our investigation.

Although the mode of interaction with the diagram is generative, the way the student reaches the conclusion is rather empirical. The conjecture lays on observations, while the reason it works is still hidden and, to get closer to what Lakatos would call deductive guessing, one needs to make it visible.

Discussion and conclusions.

Several methods Lakatos (1976) described were observed during our students' explorations. A difference between our task and the problem the fictional students of Lakatos were investigating is that while for the Euler formula the number of supportive examples, together with what was then thought to be a polyhedron, made it natural to consider all polyhedra as the domain of the naive conjecture, in the case of quadrilaterals one quickly realizes that most of them are not cyclic. This resulted in our students restricting the domains of their theorems too much. Then, counterexamples like the isosceles trapezoid that Marie came upon or a random quadrilateral inscribed in a given circle, although local in the sense that they refuted her main argument, cannot be considered as non-global since they were not included in the domain of the conjecture/theorem. For the same reason, the method of analysis as exemplified in our investigation which lacks a broad naive conjecture, would be starting by assuming that a quadrilateral is cyclic and drawing consequences. Another deviation is that in Lakatos' classroom the counterexamples stem from the definition of a polyhedron and how this changed over time while theorizing. In our activity, this interplay between defining and proving, is absent. Although the criteria under which our task was designed were adequate for capturing some Lakatosian processes, authentic Lakatosian activities should also invite for exploring the role of definitions in proving and, in the opposite way, the role of proving in concept formation.

Our students' solutions showed that they stopped their investigation before reaching a mathematically satisfactory result. From the interviews, it became clear that presenting a partial solution like Marie's and Lars', as shown in figure 2, was experienced by the students as satisfactory enough for the purpose of the problem. Besides the students' reluctance to further investigate the problem, it was also revealed that they might lack the techniques for doing so. This became apparent when we suggested working with the problem in the opposite way, starting with a circle and drawing an inscribed quadrilateral to determine necessary conditions for a random quadrilateral to be cyclic. The students seemed confused and could not anticipate what this would lead to. These findings, call for negotiating the didactical contract and offering more tasks that demand taking on responsibility in mathematical discovery in general and in exploring necessary conditions in particular. The same conclusion regarding instructional norms is also supported by analyzing how students interacted with the diagrams. The dynamic software environment that we used during the interviews, and which the students also used spontaneously when working independently with the problem, proved to be a useful tool for finding examples, counterexamples, and possible arguments. But just offering this as a tool was not enough to build reasoned conjectures. As Herbst (2004) also concluded, norms have to be breeched in engaging students in generative interaction. A reformulation of the task may also be needed to assist students in deductive guessing. Last, conducting the study in a physical classroom environment may enable the students to interact more independently with the diagrams.

Our analysis gave insight into our students' mathematical knowledge for teaching Lakatosian proof, particularly the component Deslis et al. (2021) called knowledge of content. It revealed that the students could not always use examples in ways that would lead them to a satisfactory mathematical result, without further guidance. This, in turn, might translate into students' low competency in guiding pupils in using examples in productive ways, which is associated with the students' knowledge of teaching (Deslis et al., 2021). These observations suggest that besides exposing students to tasks that would naturally engage them in Lakatosian proof, instruction that aims to build their mathematical knowledge for teaching should also include discussions centered on specific Lakatosian techniques that can be followed after a supportive/counter example has been encountered.

“I would (not) teach proof, because it is (not) relevant to exams”: changing beliefs about teaching proof

Gabriel Chun-Yeung Lee

University of Oxford, United Kingdom; chun.lee@education.ox.ac.uk

Experts in mathematics education agree that reasoning and proof are essential and should be made central to learning mathematics. However, some school teachers tend to focus on procedural skills because of different beliefs unfavourable for the teaching of proof. To encourage teachers to teach proof, I developed and studied an intervention for preservice teachers in Hong Kong. In this paper, I report the findings of this study regarding changing Hong Kong preservice teachers’ beliefs about teaching proof, particularly their beliefs about the relevance of proof to examinations.

Keywords: Beliefs, intervention, preservice teachers, proof.

Introduction

Proof can play different important roles in learning mathematics, including, but not limited to, justifying, communicating, and explaining mathematical knowledge (Knuth, 2002). Consequently, many experts in mathematics education suggest that learning activities involving proof and proof-related reasoning should spread through school mathematics at different levels and in different content areas. Noting that teachers are the key decision-makers for what students will experience in classrooms, researchers have carried out studies on teachers’ proof-related knowledge and beliefs (e.g., Knuth, 2002) and have identified different difficulties that the teachers often have with (teaching) proof (e.g., Stylianides et al., 2013). Few intervention studies have been conducted to explore a resolution to these difficulties (e.g., Buchbinder & McCrone, 2020). To address the need to encourage teachers to teach proof, I conducted a 4-cycle design-based research study (The Design-Based Research Collective, 2003) that aimed to develop an intervention to change Hong Kong preservice teachers’ beliefs about teaching proof, through iterations of implementation, evaluation, and revision (McKenney & Reeves, 2014). In this paper, I report the findings of the fourth research cycle, focusing on the change in the participants’ beliefs about teaching proof, particularly their beliefs about relevance of proof to examinations.

The context: Hong Kong

Depending on different factors (e.g., classroom culture, curriculum & policy), students’ opportunities to learn proof can vary in different contexts. In Hong Kong, the place of proof in school mathematics is ambiguous. On the one hand, Hong Kong students seem to have more opportunities to be exposed to proof than their counterparts in other countries (Leung, 2005). For example, proof is introduced early in junior secondary mathematics, under the topics of “Pythagorean theorem” and “deductive geometry” in Year 8 (CDC, 2017). On the other hand, there are indications that proof has a marginal place in Hong Kong classrooms. The majority of the tasks that appear in textbooks or exam papers are non-proof-related and focus on students’ routine procedures, for example, applying formulae and solving equations. Few tasks focus on developing and/or assessing students’ proof and argumentation skills (e.g., Lee, 2021; Wong & Sutherland, 2018). Moreover, some Hong Kong teachers prioritise the development of students' skills in routine procedures over proof (e.g., Lee, 2019). The observed hesitation of Hong Kong teachers in teaching proof indicates that there is a need for interventions with (preservice) teachers. As the findings regarding the place of proof in the Hong Kong mathematics curriculum are also consistent with the results of studies conducted in other countries, it is believed that a study in developing an intervention that changes preservice teachers' beliefs about teaching proof is in the international community's interest.

Theoretical background

Beliefs refer to a statement of relation among ideas or objects that an individual holds to be true (Philipp, 2007), which might have influences on the way a teacher teaches mathematics (Furinghetti & Morselli, 2011). Beliefs about teaching proof are multidimensional. They include, but are not limited to, beliefs about the nature and roles of proof in mathematics and in education, beliefs about teaching, and beliefs about students (e.g., ability, motivation). Different dimensions of beliefs are interrelated and related to emotions, such as anxiety about producing proof and interest in proof; the more positively a teacher views proof, the more likely s/he values proof and provides students with related activities (e.g., Fraiser, 2010; Kotelawala, 2016). Research studies reported that many teachers agree on the importance of proof in mathematics but they often have difficulty in teaching proof because: (a) they, themselves, have cognitive and/or attitudinal difficulties with proof (e.g., Stylianides et al., 2017), (b) they believe that proof is not accessible to *all* students (e.g., Knuth, 2002), and/or (c) they believe that proof is not indispensable in school mathematics (e.g., Lee, 2019).

Preservice teachers enter teacher education programmes with pre-existing beliefs about mathematics and its teaching, which are often based on their previous learning experiences. Although beliefs are often considered to be resistant or slow to change, there is evidence (e.g., Yoo, 2008) that preservice teachers' beliefs about teaching proof can be changed after a programme, a course or even an intervention of relatively short duration, if they are provided with alternative learning experiences (Liljedahl et al., 2021). In this study, I developed an intervention that provided preservice teachers with alternative experiences of learning and teaching proof, which were different from the teacher-talk approach they had mainly experienced in the past.

Intervention design

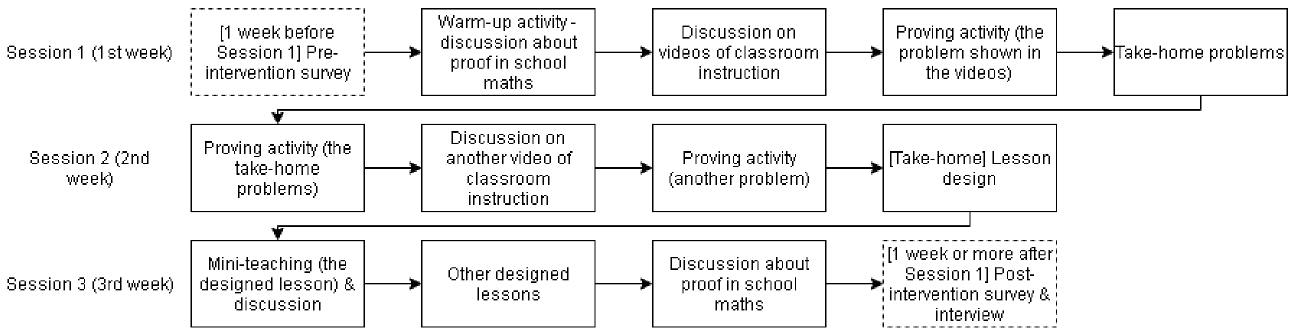

Figure 1: Design of the intervention

In this study, an intervention was designed for Hong Kong preservice teachers. The intervention consisted of three weekly extracurricular workshops. Each of the workshops lasted two hours. In the first three research cycles (July 2018–August 2019), the intervention design was trialled with different groups of preservice teachers. The trials enabled evaluations of the intervention design, informing revisions of the design. The intervention design in the fourth research cycle (Figure 1) differed from that in the first research cycle; in general, the participants (a) engaged in proving activities that emphasised learning mathematics through proof and argumentation, (b) discussed the role of proof in school mathematics, (c) watched and discussed videos of classroom instruction involving proof and argumentation, and (d) planned a lesson and trialled it with peers (Table 1).

Table 1: Examples of activities of the intervention

Type of activities	Example
Proving activities	What is the divisor of the sum of any *three* consecutive integers? What about *four*, *five*, and so on?
Discussions on the role of proof	When and how does proof appear in the previous task? What is the role of proof in this task?
Videos of classroom instruction	[*TIMSS 1999 Video Study – HK3 Polygons*] What did the teacher do in the video? Why? When did proof appear?
Lesson design and mini-teaching	Use what you have learnt in the workshops so far to develop a less on "Area of a circle"

Methods

The fourth research cycle took place between September and November 2019. The intervention was not conducted with one single group, but multiple small groups. Twenty-seven Hong Kong preservice teachers attended the intervention. Among them, 18 participants attended all sessions of the intervention whereas 6 attended only one session.

Table 2: Examples of questionnaire items

Type of items	Example
Likert items: Beliefs about the importance of proof	Making proofs improves mathematical thinking.
Likert items: Beliefs about the relevance of proof to examinations	Knowing how to make proofs is very important in excelling an examination/a test in school mathematics.
Likert items: Enjoyment and interest in proof	Making proofs arouses my curiosity.
Likert items: Anxiety about proof	I feel myself under pressure when I make proofs in mathematics lessons.
Likert items: Negative reactions when failing to produce proofs	Not being able to prove upsets me.
Open-ended questions	Should we implement tasks of proof and proving in mathematics class? Please briefly explain.

A questionnaire, consisting of Likert items and open-ended questions (Table 2), was designed, and used to gather information about preservice teachers' beliefs about teaching proof before and after the intervention. A subset of the teachers was invited to attend individual interviews after the intervention so that they could explain their beliefs about teaching proof, elaborate on their responses to the questionnaire and give their feedback about the intervention. The intervention was also audio-recorded and fieldnotes were made as supplementary data. Among all participants, 23 completed the pre-intervention questionnaire, 7 completed the post-intervention questionnaire, and 12 attended the post-intervention interviews. Pre- and post-intervention data were coded separately according to different dimensions of teachers' beliefs about teaching proof. The coded data were then compared to identify differences and, in turn, changes in their beliefs about teaching proof after the intervention.

More data were expected, but due to pro-democracy protests since June 2019 and the coronavirus pandemic since December 2019, several planned interventions were deferred and eventually cancelled. However, despite a reduced amount of data, analysis of the available data was sufficient to show the effects of the intervention on the participants' beliefs about teaching proof.

Results

I analysed 12 sets of pre-post data, indicating the corresponding 12 participants' beliefs about teaching proof and their changes after the intervention. In this paper, I first discuss the general findings in relation to the changes in the participants' beliefs about teaching proof, particularly their beliefs about the relevance of proof to examinations, then use selected data excerpts to illustrate the changes in the participants' beliefs about the relevance of proof to examinations and discuss how the intervention facilitated such belief changes.

In general, the participants developed more positive beliefs about teaching proof after the intervention. The analysis of the Likert items showed the participants maintained agreement that proof is essential to mathematics and developed more positive and less negative emotional dispositions towards proof, and more participants reported agreeing that proof is related to examinations. The analysis of the open-ended questions also showed that more participants reported valuing the explanatory power of proof and being willing to teach proof regularly. Having said that, a few participants reported and maintained some of their worries about teaching proof (e.g., students lacked ability and interest, class time was not enough). Worries about students' ability to learn proof remained influential in the participants' beliefs about teaching proof. After the intervention, however, these worries no longer discouraged these participants from teaching proof, but rather prompted them to consider different approaches for teaching proof.

In the following, I use Participant 4's data as an example of my analysis. Before the intervention, although Participant 4 was able to relate proof to the development of mathematical understanding, he believed that teaching proof was not related to examinations and was therefore not essential:

> Participant 4: […] I think, for secondary school students, proof is not so important to them. In relation to exams, [proof] is not so important, but proof can allow them to learn why this [mathematical statement/ concept/ idea] is true, making them not to learn by rote, but to understand a theorem and its principle, for applying the theorem more easily or knowing when to apply it.

At the beginning of the intervention, Participant 4 also revealed his belief about the relationships between school mathematics, proof, students, and examinations. He believed that a number of students learn mathematics merely because it is a compulsory subject for all students in Hong Kong and prefer learning by rote over learning proof, so he believed that these students are relatively weak with proof:

> Participant 4: I think there must be a portion of students who are not interested in mathematics. To them, learning mathematics is for taking [the Hong Kong public exam]. So, there must actually be a portion of students who rely on [learning] formulae by rote [and learning] examples by rote, for taking exams. Therefore, when seeing non-proof tasks, and when [seeing] tasks that can be solved by simply applying methods [that

they] have learnt by rote, s/he [the student] can easily solve [the tasks], answer correctly. However, when [seeing] proof tasks, [particularly] those that are not standard, they [the students] do not know how to apply [the methods] to solve [the tasks], so […] these students might be weaker with proof tasks.

Yet, after the intervention, Participant 4 developed a deeper understanding of the relationship between proof and the development of mathematical understanding and became aware that proof can play important roles in preparing students for examinations. Particularly, he developed a belief that learning proof is helpful for students to develop knowledge and skills in solving proving and non-proving tasks:

Participant 4: [Before,] I thought there were not many proving tasks in [exams], so [students] could still achieve good results without proof. However, [now] I think [proof] can not only be [helpful in] proving tasks, but also helpful in other tasks. I think proof can be related to other domains.

Participant 4 attributed his learning in and changes after the intervention to the discussion about proof and the videos of classroom instruction, which allowed him to explore and reflect on different views about proof and teaching. Particularly, Participant 4's experience of the intervention provided alternatives to his pre-existing beliefs about what proof is and about approaches for teaching proof. Moreover, after seeing how primary students could learn mathematics through argumentation and proof in a video, Participant 4 became aware that students have the ability to learn mathematics through proof and argumentation. To him, the ideas of teaching proof conveyed in the intervention were positive and he wanted to apply them into his future teaching:

Interviewer: What did you experience and learn in [the intervention]?

Participant 4: In fact… at the beginning [of the intervention], [the instructor] asked everyone's views about proof. Using [the discussion about which tasks in exams are proof-related] as an example, it could be seen that there are some people [who hold views] that are different from my view. This might, in turn, reflect [an idea that] students [have different views about what proof is]. Second, video… [I] watched two videos; [I] saw more, different approaches for teaching, [for example,] that [video] of teaching children even and odd [numbers]. That teaching approach [was something that] I have never experienced. I [started to] thinking about my teaching approach, and whether some of [my] lessons can involve that approach. [I also] saw that they [the primary students] were able to think [argue the meanings of even and odd numbers], [indicating that] probably older, secondary students should have this ability as well. [After the intervention, I started to] consider more about this aspect.

Participant 4's change exemplifies one possible way how the intervention facilitated changes in the participants' beliefs about teaching proof, particularly their beliefs about the relevance of proof to examinations. The intervention, through discussions about roles of proof in learning mathematics and videos of classroom instruction, provided the participants with alternative experiences of learning and teaching proof. These experiences challenged the participants' pre-existing beliefs about teaching proof (e.g., "proof is always difficult, algebraic and formally presented", "proof is separate from other domains of school mathematics") and broadened their horizons by conveying that proof can be accessible to most (if not all) students and can be communicated via different representations as long as the representations are accessible to and accepted by the students. Consequently, the revised ideas of proof and teaching mathematics allowed the participants to discover more connections between proof, learning mathematics and examinations, and in turn to develop more positive beliefs about the relevance of proof to examinations.

I do not claim that all participants became convinced of the relevance of proof to examinations after the intervention. Rather, I assert that the participants gained *more positive* beliefs about the relevance of proof to examinations. In other words, after the intervention, whilst there were participants becoming convinced that proof is relevant to examinations (as exemplified by the case of Participant 4), others continued to believe that proof is not indispensable but helpful to students when preparing for and taking an exam. For the latter case, since the majority of tasks appearing in exam papers require students to apply formulae and solve equations and only a few require students to produce a proof or an argument (Lee, 2021), the participants continued to believe that proof is not necessary for students to pass an exam. Yet, after the intervention, they became aware that proof is somewhat related to examinations: proof can promote students' mathematical understanding and reasoning, implying that teaching proof can help students do better in examinations.

In summary, during the intervention, the participants were provided with alternative experiences of proof (different from their past experiences), which challenged their pre-existing beliefs that discourage teaching proof (e.g., proof is not related to examinations, proof confuses students). The participants had positive experiences with proof (e.g., they deepened mathematical understanding via proof) and developed positive emotions about proof (e.g., excitement, interest), helping them replace their pre-existing, discouraging beliefs by beliefs that encourage teaching proof (e.g., proof can promote students' mathematical understanding and reasoning, proof can help students prepare for examinations). Having said that, beliefs that have basis in external factors, particularly in quantitative information (e.g., the number of proving tasks in exam papers and textbooks), seemed to be difficult to change (e.g., it is possible to pass an exam without proof).

Summary and discussion

There is some evidence that teachers' beliefs about and practices of teaching proof are affected by examinations (e.g., Frasier & Panasuk, 2013; Lee, 2019; Nyaumwe & Buzuzi, 2007), in Hong Kong and in other countries. This paper demonstrates that whilst (a) some counterproductive beliefs of preservice teachers about the relevance of proof to examinations (e.g., "Students can pass exams without proof") are difficult to change if the composition of tasks appearing in exam papers is not changed (curricular aspect), (b) more positive beliefs (e.g., "Proof can promote students' mathematical understanding, which in turn helps preparing for and doing better in exams") can be developed after an intervention that is carefully designed to provide preservice teachers with positive experiences of proof. In other words, for an effective intervention that aims to change preservice teachers' beliefs about teaching proof, it is important to create alternative experiences of learning and teaching proof in which preservice teachers can deepen their mathematical understanding through proof and can translate such experiences into their future teaching.

It is believed that this study is in the international community's interest for three reasons. First, the findings of this study are consistent with other studies that involved interventions with preservice teachers in which the participants developed more positive beliefs and emotional dispositions towards (teaching) proof (e.g., Buchbinder & McCrone, 2020; Yoo, 2008). These consistent findings in different settings not only provide evidence that it is possible to change preservice teachers' beliefs about teaching proof (which are often considered difficult to change) during teacher training, but also show that it is possible to generalise each finding to other settings.

Second, in contrast with other interventions that were implemented in regular courses and lasted about a semester, the intervention of this study was designed as extracurricular workshops and took place within a month. The short-duration format allowed the intervention design to be tested and revised multiple times within a relatively short period of time, thereby enhancing the validity of the study's findings. This study also explored and showed the possibility of changing preservice teachers' beliefs about teaching proof after an intervention of a short duration, responding to a "challenging but important question for mathematics education researchers: *Would it be possible to design classroom-based interventions of short duration in mathematics classrooms that could help alleviate significant problems of students' learning in mathematics?*" (Stylianides & Stylianides, 2013, p. 339).

Third, I reported different changes in the participants' beliefs about teaching proof after the intervention in this study. The findings also demonstrated why some beliefs (e.g., belief about roles of proof in learning mathematics) changed and some (e.g., belief that students can pass exams without proof) remained unchanged. In other words, some beliefs about teaching proof are dependent on external factors (e.g., the proportion of proof to tasks that require only procedural skills in exam papers) and often remain unchanged if the corresponding external factors remain unchanged, and some are dependent on one's past experiences and can be revised if positive and inspiring experiences of proof are provided (e.g., during courses of university mathematics and mathematics education).

Future work should continue to design (and improve) positive and inspiring experiences of proof for (preservice) teachers and explore and validate the effects of different designs on beliefs about teaching proof (ideally, both immediate and delayed effects) with larger samples (ideally, together with comparison or control groups). In order that dimensions of beliefs about teaching proof can be quantitatively measured for pre-post analysis and statistical modelling, it is also important to conduct studies to develop practical instruments.

This study seeks to capitalize on the pedagogical potential of visual proof documents called Proof Without Words (PWWs) to advance proof learning in secondary mathematics. The data is drawn from design-based research (DBR), in which a PWW document was iteratively redesigned to lead students to generate more detailed and rigorous proof attempts. The gap-filling theoretical framework for proofs in mathematics education was used to evaluate students' written proof products when working on initial vs. redesigned PWW versions. The results reveal a substantial positive effect of the PWW redesigned version on the quality of students' products. They suggest the potentiality of five proposed PWW design principles in promoting secondary students' proficiency in proof-related activities.

Keywords: Proofs Without Words, gap-filling, design-based research, secondary level proving.

Introduction

Mathematical proofs are fundamental in mathematics as they verify the truth of mathematical statements. Nevertheless, the importance of proofs goes beyond this function as they carry mathematical knowledge, ideas, and methods to propel further scientific developments (Rav, 1999). Notwithstanding the importance of proofs in mathematics, we witness a decline in proof-related activities in schools (Kotelawala, 2016), partly due to the difficulties students at the secondary level encounter in proof activities (e.g., Miyazaki, Fujita & Jones, 2017). This abdication of proofs at the secondary level widens the gap between school and university mathematics and may further reduce students' chances of pursuing and persisting in postsecondary STEM studies (Clark & Lovric, 2009). It is then imperative to develop new approaches to foster students' interest and success in learning mathematical proofs.

The approach used in this study relies on Proofs Without Words (PWWs) – diagrammatic learning resources that allude to a proof process and scaffold its discovery. In PWW-based activities, students are given a PWW and requested to discover a proof and write it down. This paper focuses on a particular geometry PWW task of the Pythagorean Theorem, shown in Figure 1 (Garfield PWW - adapted from Nelsen, 1993, p. 7):

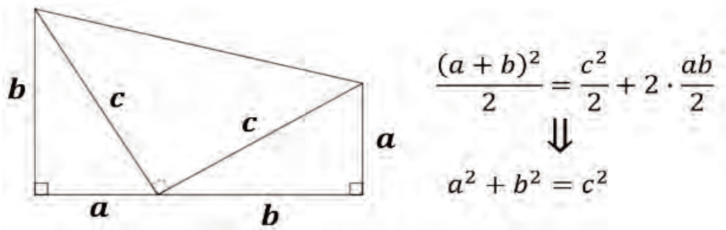

Figure 1: "discover and write down the proof implied by this diagram"

Theoretical underpinnings

Proof Without Words (PWWs) activity at the secondary level

Ever since the seventies, PWWs have started to be published in journals like the *Mathematics Magazine* and *The College Mathematics Journal*, designated primarily for mathematicians. Given a PWW, an experienced mathematician can efficiently perform some mental actions to develop a formal proof: Translate diagrammatical information into verbal conjectures, construct a chain of justified arguments while filling in necessary gaps using prior knowledge. Without these mental actions, many mathematicians would not consider a PWW a proof in and of itself (Biehler & Kempen, 2016). Therefore, in this paper, we refer to PWWs as learning resources and not as proofs. Still, mathematicians value PWWs because of their elegance, mathematical beauty, and the insights they encapsulate (Arcavi, 2003). Mentioning these qualities, Nelsen (1993) advises math teachers to share PWWs with their students.

Nevertheless, are PWWs as accessible for secondary students as they are for experienced mathematicians? In other words, can secondary students develop proofs based on the visual clues given in a PWW? A previous exploratory case study demonstrated that the answer is not straightforward positive (Marco, Palatnik & Schwarz, 2021). On the one hand, providing a PWW led most students to generate proof attempts containing the proof's key idea(s). However, students' written proof attempts were meager, lacking details such as justifications, articulation of constructional procedures, and generality arguments. Figure 2 presents such a proof attempt that most mathematics educators will probably not accept as valid proof for the Pythagorean theorem. Therefore, we launched a design-based research program to find new ways to redesign PWWs to make students produce more detailed and rigorous proof attempts.

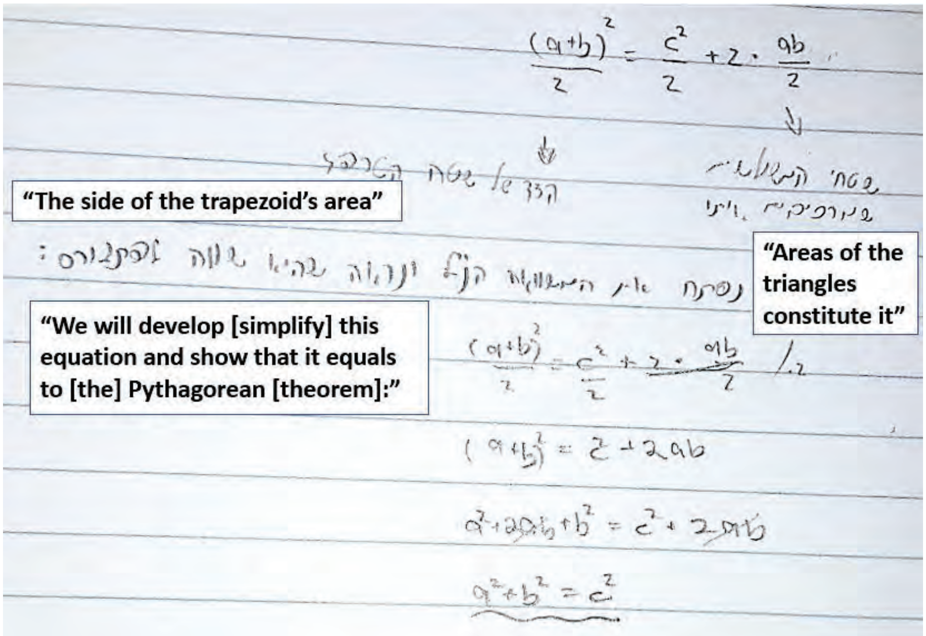

Figure 2: A student's proof attempt based on Garfield PWW

Gap-filling theoretical framework

The idea of *gap-filling* was introduced in literary theory. Gap-filling is a reader-oriented theory that emphasizes the reader's role in sense-making when reading a text. It conceptualizes any text as a system of gaps, which the reader constantly needs to fill by adding information to construct meaning (Perry & Sternberg, 1986). In a passage from literary theory to mathematics education, we suggested gap-filling as a theoretical framework for activities around mathematical proof-document (Marco et al., 2021). We defined a gap in a proof document as missing information essential for a specific reader's understanding. Accordingly, gap-filling is any action the reader takes to add information to complete what she identifies as a gap. For example, in Figure 1, the connection between the diagram and the equation $\frac{(a+b)^2}{2} = \frac{c^2}{2} + 2\frac{ab}{2}$ is not indicated and constitutes a gap. In Figure 2, the student takes action to fill this gap – she brings in the notion of area calculations only implicitly represented in the PWW. After a first DBR iteration, we listed nine gap-filling actions, presented in Table 1, that we expected students to perform while working on the Garfield PWW in consequent iterations (Marco, Palatnik & Schwarz, under review):

Table 1: The gap-filling actions we expected students to perform in the Garfield PWW

#	Description of the gap-filling action(s)
G1	Identifying what is given (an arbitrary right triangle with sides a, b, and c) and what should be proved ($a^2 + b^2 = c^2$).
G2	Specifying the construction procedures through which the trapezoid is obtained.
G3	Justifying the congruence of the two triangles with sides a, b, and c (SAS congruence theorem)
G4	Verifying that the third middle triangle is isosceles and right-angled (by angle calculations).
G5	Proving that the whole figure is a right trapezoid (by definition).
G6	Recognizing the theorem can be derived from calculating the trapezoid's areas in two different ways.
G7	Calculating the areas of all the different figures (using area formulas) and writing an equation such as $\frac{(a+b)^2}{2} = \frac{c^2}{2} + 2\frac{ab}{2}$.
G8	Simplifying the equation to $a^2 + b^2 = c^2$ (algebraic manipulations)
G9	Explaining why the proof that is constructed based on a particular case can be seen as general proof.

Note that not all the gap-filling actions in Table 1 are of the same nature. We divided the gap-filling actions into four categories: *Constructional* (G2), *justification of a figure's properties* (G3, G4, and G5), *key-idea* (G6, G7, and G8), and *generalization frame* gaps (G1 and G9). As mentioned above, in early DBR iterations, almost all students filled key-idea gaps, but only a few identified or filled gaps from the other three categories (Marco, 2021; Marco et al., 2021; Marco et al., under review).

The five PWW design principles

In our three-year DBR, we probed for practical design principles that invite the filling of subtler gaps other than the key-idea gaps (Marco et al., under review). After three DBR iterations, we came up with five tentative PWW design principles with which we redesigned Garfield PWW (Figure 3). The process through which these principles were recognized and established cannot be expounded within the limits of this paper (for more details, see Marco et al. under review). Also, we do not claim these five principles are exhaustive and are yet to be considered hypothetical (Van den Akker, 2013; Bakker, 2018). We investigate if when these principles are enacted in a PWW's redesign, more gap-filling from Table 1 takes place. The five principles are:

1. *Key idea discoverability* – Ensure the discovery of the proof's key-idea(s) with minimal scaffolding. We showed that students tend to fill key-idea gaps of PWWs even if no adjustments are inserted. This finding is an encouraging one that we wish not to impair. So, all changes in the PWW must not risk the discoverability of the key ideas.
2. *Theorem's conditions distinctiveness* – Distinguish theorem's givens from other elements of the proof. Herbst (2004) observed that students are not used for producing a proof "unless the conclusion to be proved, and the conditions under which that conclusion is true, are stated for them" (p. 133). Therefore, the visual grammar should indicate which parts of the diagram are given and conceived through construction. In this manner, the distinction creates a timeline (Dimmel & Herbst, 2015) in which the given parts precede the constructed ones.
3. *Constructional visibility* – Present construction procedures. Construction procedures have a significant epistemic role in geometry proofs. Without verifying how a diagram is conceived, no general truth can be established. If a teacher aspires students to generate rigorous proofs based on PWWs, we suggest the diagram to tell the construction story. In line with Dimmel and Herbst (2015) and Alshwaikh (2018), we found dashed lines and arrows to be well understood as representing constructional procedures.
4. *Figure's properties concealment* – Avoid marking figures' properties. Hewitt (1999) warns teachers not to inform students with necessary mathematical properties that can be deduced. In our study, when a property was marked, most students perceived it as a given and did not justify it. So, if the diagram conceals a figure's property, it prompts students to conjecture it is true. Students are then more likely to gap-fill it by constructing a sub-proof. In this manner, the PWW-based activity combines conjecturing and proving that are regularly applied by geometry teachers as separate proof-related activities (Aaron & Herbst, 2019).
5. *Human agency* – Present the diagram as obtained by human activity. Morgan (2016) upholds that presenting mathematics as abstract, symbolic, and the absence of human agency may prevent students from accessing mathematics. Following this line, Alshwaikh (2018) argues that when diagrams tell a story and include human agency, they communicate better with learners.

Research questions

What impact does a PWW, redesigned according to these five design principles, have on students' gap-filling actions?

Method

This section introduces the redesign version of Garfield PWW and explains how the design principles are implemented. Taking a quantitative approach, we seek to evaluate and compare students' gap-filling actions when working on the initial PWW version (Figure 3, left) vs. on the final redesigned version (Figure 3, right). We then present the participants and describe how we collected and analyzed the data for this study during the second and fourth DBR iterations.

Material

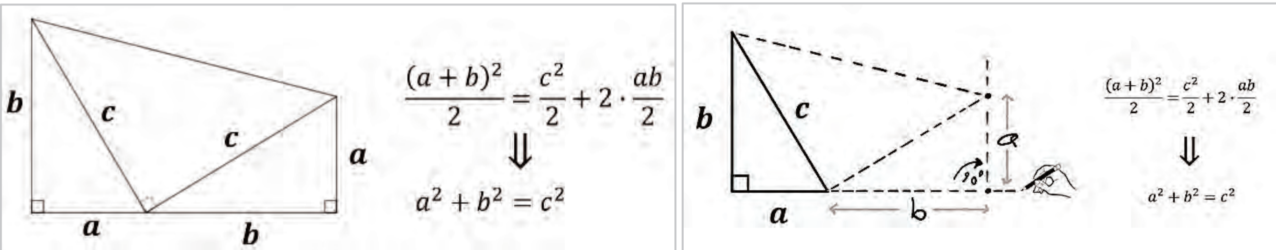

Figure 3: Garfield PWW initial version (left) and redesigned version (right)

How does this redesign implement the five design principles? Due to space restrictions, we will only focus on the third and the fourth principles, which are dominant in this redesign.

Constructional visibility: For denoting construction procedures, we used dashed lines, handmade inscriptions, gray-color arrows, and a drawing hand icon. We used continuous bold strokes only for the leftmost arbitrary triangle and printed letters *a*, *b*, and *c*, to indicate that these are the only givens in this diagram. We prolonged the perpendicular dashed lines more than needed to appear as rays created with a straightedge. The newly assigned segments a and b are denoted in gray handwritten letters and arrows on these perpendicular dashed lines. We escaped using the square notation for the rightmost right angle because it could lead students to perceive it as one of the theorem's givens. Instead, we used a circular arrow with a handmade inscription of "90°". This notation signifies that this measure stems from a deliberate human construction activity.

Figure's properties concealment: We left the middle right angle unmarked and omitted the "c" notation from the rightmost triangle hypotenuse since both can be inferred from triangles' congruence.

Participants

144 Israeli students of ages 15-16 participated in four DBR iterations. In the second DBR iteration, 37 Grade 10 students from two mathematically advanced classes from the same school participated. In the fourth DBR iteration, 72 Grade 10 students from another school participated. The fourth DBR iteration occurred at the beginning of the school year before students were grouped into different mathematics streams. All students were familiar with the Pythagorean Theorem since Grade 8 and had experience solving proof-related exercises in geometry. Most of the students in our study were not introduced to any proof of the Pythagorean theorem when they were eighth-graders, and the vast majority were not familiar with PWWs.

Procedure

The PWW-activity consisted of three phases: (1) Students collaborated in small groups to discover a proof while having the Garfield PWW at hand. (2) Each student individually wrote and submitted a proof attempt and (3) completed a proof comprehension test. In this paper, we only report on the students' submitted written proofs produced in phase (2). To assess students' written proofs, we used the notion of gap-filling. The quality of proofs was based on the number of gaps, from Table 1, that students identified and correctly filled. When grading students' written proofs, we marked 1 for any identified and correctly filled gap, 0 for overlooked gaps, and 0.5 for identified gaps that were not adequately filled (i.e., partially or inaccurately filled). We then calculated the mean gap-filling rate (GFR) for each gap in each version. To answer our research question and assess the impact of the redesigned version on students' gap-filling actions, we undertook a two-tailed t-test assuming unequal variance. The null hypothesis was that there would be no differences in gap-filling rates between the initial and redesign version of Garfield PWW.

Results

Table 2 presents the GFRs in the initial and redesigned version of the Garfield PWW.

Table 2: The average gap-filling rates (GFR) in the initial (I-V) and redesigned (R-V) versions

	G2: Explaining the construction	G3: Why are the triangles congruent	G4: Why the middle triangle right	G5: Why the whole figure a right trapezoid	G6: Calculating area in two different ways	G7: Assigning an area formula for each figure	G8: Algebraic operation to obtain the theorem
I-V GFR (SD), N=37	.02 (.34)	.17 (.23)	.18 (.3)	.24 (.43)	.92 (0.28)	.89 (.24)	.78 (.4)
R-V GFR (SD), N=72	.34 (.48)	.61 (.48)	.50 (.47)	.45 (.48)	.94 (0.22)	.93 (0.24)	.91 (.25)
t-test TE2 vs. TE4	$p < .0001$	$p < .0001$	$p < .001$	$p < .05$	N/S	N/S	N/S
Effect size Hedge's g	0.887	1.002	0.756	0.462	/	/	/

In the three gaps from the category of proof's key ideas, we see no significant differences between the two PWW versions. However, in the categories of *constructional* gaps (G2) and *justification of a figure's properties* gaps (G3, G4, and G5), the GFR are significantly distinct, with the redesigned version having much higher GFRs with substantial effect sizes. Note that increasing GFR in G2 stemmed from more information about the construction that the redesigned version provides. Contrastingly, each justification of a figure's properties gaps, G3, G4, and G5, increased even though the clues about this property were omitted. For instance, the middle triangle was marked right-angled in the initial version, and in the redesigned version, it was not. Remarkably, significantly more students filled G4 given the redesigned version.

Discussion

Testing the redesigned version of the Garfield PWW, we found that more secondary students filled constructional gaps if the construction procedure was displayed in the diagram. Contrastingly, students were more likely to fill gaps associated with the justification of a figure's properties when the property was not explicitly evident in the diagram. We assume that behind the latter finding lies students' need to remove doubts about figure properties when interacting with the diagram. If a PWW leaves doubt about the truth of a figure's property (i.e., not marking a right-angle mark), students will try to verify it by constructing a sub-proof. Removing a mark that reassures a figure's property invites students to conjecture this property is true. After conjecturing, they naturally turn to prove it out of their own epistemic need for certainty (Marco et al., 2021). By doing so, they engage in an authentic mathematical inquiry in which conjecturing leads to formal proving (Aaron & Herbst, 2019).

In our redesigned version of Garfield PWW, we implement five design principles that we gleaned from the data of a broader DBR (Marco et al., under review). We elaborated here on two of these principles and showed their unequivocal effect on students' written proof attempts. As usual, the list of principles remains hypothetical and non-exhaustive (Van den Akker, 2013). Further research with students from different age groups and various PWWs could lead to their development. These design principles have proved beneficial in leading students to fill more gaps in the case of Garfield PWW and are likely to be generalized for other geometry PWW-activities. However, they can serve as a starting point for more research on the use of PWWs in mathematics education. Investigating to what extent these principles are helpful in redesigning PWWs in other domains of mathematics (i.e., progressions, algebra, and calculus) is an exciting avenue for future research.

We used the notion of gap-filling to assess students' written products and compare the effectiveness of two versions of the same PWW. Gap-filling theory can change our perspective about how students learn from mathematical texts and shift our focus when designing them. Instead of exposing all the information we wish the student to engage with and understand, we need to carefully present the minimal information that still enables identifying and filling certain gaps. So, designing a proof document is not just about designing what it contains but also designing what it lacks. Well-adjusted gaps in proof-documents may help rekindle proving activities as central in mathematics education.

What number makes sense? Standard word problems with non-standard wording

Karolína Mottlová[1] and Jana Slezáková[1]

[1]Charles University, Faculty of Education, Prague, Czech Republic;
karolina.mottlova.ruzickova@gmail.com, jana.slezakova@pedf.cuni.cz

In the reported experiment, we focus on word problems of the type What number makes sense, which comes from Singapore textbooks. This problem was set to primary school 5th graders. In the analysis of the experiment, we focus on mathematical reasoning involving argumentation and on communication observed in pupils' discussions while solving the problem. We comment on pupils' reactions in terms of three approaches (mathematical, linguistic, real contextual) of which we have kept record also in our previous experiments.

Keywords: Argumentation, word problems, declension, multiplicative relations, Singapore math.

Introduction

Word problems represent a problematic area for both pupils and teachers. Pupils are not always motivated to solve them, as in word problems they practice stereotypical solving strategies they do not always understand. Teachers see pupils' problems in solving word problems mainly in the lack of logical thinking or insufficient level of reading literacy, which is manifested, for example, by incorrect understanding of the text or the meaning of the words. This is why pupils often produce a wrong solution and use incorrect or inappropriate argumentation (Vondrová, 2013).

Different approaches to word problems can be observed in different countries. Within the frame of the Czech project "Support of the integration of mathematical, reading and language literacy in primary school pupils" (TA ČR, 2020), Singapore approach to word problems was used. "Singapore outperforms the rest of the world in the OECD's latest PISA survey, which evaluates the quality, equity and efficiency of school systems" (OECD, 2016). This, for example, leads to "to the promotion of approaches from Shanghai and Singapore in England, with 'Singapore maths' gaining considerable popularity" (Hough et al., 2019, p. 4523).

Various types of problems from Singapore textbooks (created with the help of researchers from the Université du Québec à Montréal) support the development of many skills in pupils as well as different approaches to the problem, which are the essence of their argumentation (Savard & Polotskaia, 2017). "Mathematical reasoning and communication are two key process skills in the framework of the Singapore school mathematics curriculum (Ministry of Education (Singapore), 2012) that have been advocated for a long time" (Chua, 2017, p. 115). Mathematical reasoning is an inherent part of solving word problems of the type What number makes sense? (Kaur & Har, 2009) and communication takes place, among other, in the discussions of the solution, which was used in our experiments. This approach to word problems has not yet been researched in the Czech Republic, which motivated us to commence research using this approach in one type of word problems.

Theoretical framework

We work with the following definition of a word problem: A word problems is a "verbal description of problematic situations that give rise to one or more questions whose answers can be obtained by applying mathematical operations to the numerical data present in the problem" (Verschaffel et al., 2000, p. 641). We agree with this definition. When starting the research with the type of word problem "What number makes sense?" (Fig. 1) we regarded it as a non-standard word problem (Slezáková et al., 2021). Having studied the definition of a non-standard word problem (Jimenez & Verschaffel, 2014), however, we classify this type of a problem as standard with non-standard wording. What makes the problem look 'non-standard' is the way the text is organized.

Do the number make sense? | 32 2 80 5 |

There were __ children at a party. Ms Sally bought __ packets of sweets. There were __ sweets in each packet. During the party, she gave __ sweets to each child and had none left.

Figure 1: What number makes sense?

This type of word problems has two parts. The first part is the instruction: "Fill in the missing information in the word problem." and the data that will be filled in. The second part is a problem situation with missing numerical data. These are replaced by underscores. The order of the numbers given in the first part does not have to correspond to the order of blanks in the problem. The pupil's task is to fill in the numbers in such a way that the problem makes sense from the point of view of

a) **mathematics**, i.e. the filled in numbers make a problem situation that is mathematically meaningful, in other words the numerical data are in additive or multiplicative relation (e.g. the following holds for the numerical data 2, 3, 4, 5: $2 + 5 = 3 + 4$). Pupils prefer to look for relations between numbers, which comes out of their experience and beliefs gained while solving word problems, which is that we get a result with the help of one or more arithmetic operations with numbers from the assignment while ignoring connections to real-life experience (De Corte & Verschaffel, 1985; Nunes et al., 2016).

b) **language**, i.e. the filled in data are grammatically correct (in Czech e.g. declension). With respect to language, researchers focus especially on simplification of sentence formulation (Plath & Leiss, 2018) or the length of words and sentences (Bergqvist et al., 2018). The issue of grammatical correctness with respect to declination characteristic of Slavonic languages has not yet been subject to research in the area of word problems,

c) **real-life context**, i.e. the filled in data make a meaningful real-life situation. Pupils tend to use their real-life experience more often while solving word problems (Van Dooren et al., 2019) and thus get a clearer picture of the problem situation better (Cooper & Harries, 2002). The problem situation can be mathematically meaningful but nonsensical in a real-life context.

Research questions

The main goal of our experiment was to analyse pupils' reactions when solving a word problem and to find out: What arguments for completing the text of the word problem with the given numbers will pupils use? Specifically, will they be sensitive to the linguistic aspect of the problem? Further partial goals that arose while conducting the experiment were: to compare approaches from two different classes from different schools, to gain evidence on whether this problem is suitable for a discussion leading to cooperation or involving conflicting opinions, which reinforces argumentation, to find out whether pupils are aware that the task has more than one solution.

Methodology

Let us now introduce the studied word problem (see Figure 2).

Number 10, 5, 4 and 2 fled from the text. Put them back in their places and check that they make sense. Children brought pheasants to a rescue station. They brought __ pheasants. They bought grain in __ packages. There were __ kg of grains in each of the packages. That means that if divided fairly among them, each pheasant would get __ kg of grain.

Figure 2: The problem 'Pheasants', translated from Czech

From the mathematical point of view, the problem has four solutions that are meaningful as the numbers are in a multiplicative relation (e.g. 4 x 5 = 2 x 10). With respect to real-life context, this situation is not a conflicting one since all four solutions make a possible real-life situation. However, when we look at the problem from the linguistic point of view in Czech, the problem has only two solutions, namely 5, 2, 10, 4, or 10, 4, 5, 2. Otherwise the text is not grammatically correct (declension in Czech). We are aware that each language is specific (Daroczy, 2015). The impact of a country's language and culture on the way pupils argument, verify and prove while solving problems was also discussed in the CERME11 TWG1. (Stylianides et al., 2019)

Let us now explain readers who do not speak Czech the linguistic reasons for selecting the right numbers in the blanks. The first, third and fourth blanks are in the Czech original in a sentence with "be" (was, were "*bylo*" or "*byly*"). What matters is the last letter in the word: "o" or "y". The word "*bylo*" works only with the numbers 5 or 10. The word "*byly*" needs the word 4 or 2. In case of the second blank, the relevant word is the preposition "in" (in Czech "*v*" or "*ve*"). The form "*v*" can be followed only by the numbers 5 or 10. The form "*ve*" can be followed only by the numbers 2 or 4.

Research participants

Two fifth grade classes (A, B) took part in the experiment in 2021. There were 18 pupils in class A and 24 in class B (10 to 12-year-old pupils). Pupils from each class were working together online for 45 minutes. The lesson included a discussion with the pupils' argumentation on the solutions. The online lessons were recorded and transcribed. The pupils' personal data were anonymized.

Analysis of pupils' work

We present the most interesting pupils' reactions in the lessons that point out their approach to the problem. Both individual and mutual reactions in the episodes are grouped with respect to their nature: 1. Pupils' first immediate reactions, 2. Reactions that show different approaches to problem solving, 3. Incorrect or inappropriate argumentation in a pupil's reasoning, 4. Correct argumentation in a pupil's reasoning. Each is followed by our commentary. The pupils are coded A or B, depending in the class they are from. The number specifies the individual pupil.

1. The first immediate pupils' reaction

Pupil A1 — I'm ready. It's as if there were 10 shoppers. They bought 5 packages. The children brought pheasants to the rescue station. I thought it was 10 but I'm not really sure.

Commentary: Pupil A1 already had experience with this type of problem because he had solved a simpler one at the beginning of the lesson. He tried to fill in the first two numbers, but he was not sure if he had understood the wording of the problem.

Pupil B1 — I know. I think it's in pairs, it's vice versa 2, 4 ,5 … no, not this way. Wrong.

Commentary: The impulsive reaction of pupil B1 could have stemmed from his need to show off in front of the teacher and other classmates. That might be the reason why he did not comment on the numbers in the text very meaningfully. He decided about numbers 2, 4 that the numbers went in pairs but soon realized the mistake.

2. Reactions that show different approaches to problem solving

Pupil A1 — I think instead of 10 there will be 2. Because 10 must be down there. 10 must be the kilograms of grain, I found out because a pheasant is quite heavy in fact.

Teacher A — So the picture showing the size of the pheasant helped you?

Pupil A1 — Yes.

Pupil A2 — Well, pupil A1 said there must be 2. But it doesn't make sense when I read it *´bylo jich 2´*. [there were two - problem in declension]

Pupil A3 — There can be *´bylo jich 5´* [there were five], that makes sense. It can't be 10, because 10 is a lot.

Commentary: Pupil A1 approached the problem from the point of view of real context, which was strengthened by the fact that his classmates showed him what a pheasant looks like in a picture from the Internet. Thus, the picture was the basis for his argumentation, namely that the pheasant needs a lot of grain because it is large (in his words 'heavy'). Pupil A2 approached the task from the linguistic point of view. He realized the correct placement of numbers depended on declension. His argument was important for the thinking of the other classmate A3. They presented arguments with other possible numbers corresponding to the declension (5 and 10). Pupil A3 rejects the number 10 from the given numbers, from the point of view of the real-life context - 10 pheasants brought to the rescue station are too many and therefore it would be necessary to prepare far more grains for them.

Pupil B2 — I've solved it. I realized it can't be '*bylo jich* 4' [there were four] because it's not right from the point of Czech. It must be *´bylo jich 10 5´* [there were 10 5].

Pupil B1 — You know what? '*Bylo jich*', it must be there 100%. Grammatically it must be 5 or 10. Because it can't be '*bylo jich 2 nebo 4'* [there were two or four].

Pupil B3 — I think the second number could be a two because 10 and 5 are grammatically correct in the previous case … aha … they are both divisi … no, 10 is a divisible number. And two is also divisible and I think that could be it.

Pupil B1 — No, that wouldn't make sense grammar wise. It's definitely wrong.

Commentary: Pupil B2 approached the problem from the linguistic point of view. She focused on the verb ‘to be’. This motivated her classmates to the same approach. Pupil B1 reacted by listing all the possibilities, which he classified according to declension. Pupil B3 added an argument based on mathematics to the declension argument. She focused on common characteristics of numbers 2 and 10 as numbers divisible by two, which did not bring her to the solution.

3. Incorrect or inappropriate argumentation in a pupil’s reasoning

Pupil A5	I was now calculating for myself. I decided there could be 5 pheasants. Then the 2 kilograms, [unsure], in fact that it would be the 4 kilograms and I calculated that 1 pheasant gets 2 kilograms, another one also 2 kilograms and then I got 5 pheasants and 10 kilograms altogether.
Pupil A6	Those 2 packages and 4 kilograms of grains in each of them. It means it’s 8 altogether. 2 times 4 equals 8. And it wouldn’t make sense that each gets 10 kilograms if there are only 8.

Commentary: Pupil A5 approached the problem from the mathematical point of view. Intuitively she was aware of the multiplicative relation between the numbers 2 and 5. There is a multiplicative relation between the numbers but not between these two. Pupil A6 then applied the multiplicative relation on the numbers used by pupil A5, which led to a number that is not offered. He based his argumentation contradicting pupil A5 and her solution on this.

Teacher B	[the filled in numbers are 5, 2, 10, 4]. How much grain did they have altogether?
Pupil B1	Four. No, ten. Ten.
Pupil B4	No, there were two packages, so 2 x 10 …
Pupil B5	There were two packages and, in each package, there were 10 kilograms of grain. 2 x 10 is twenty.
Pupil B1	Yes, this made me confused. They had 20 kilograms. You’re right.
Teacher B	And how did they divide it fairly among the pheasants?
Pupil B1	Well, they had each pheasant have 4, because there are 10 and to make it fair.

Commentary: Teacher B invited the pupils to check whether the previously proposed solution was correct. Pupil B1 was not able to answer the teacher’s question. Pupil B4 wanted to formulate the correct solution but was interrupted by pupil B5, who completed the argument in the same way as pupil B4 was planning to. Probably thanks to the safe environment in the classroom, pupil B1 acknowledged his mistake. The teacher wanted to check if pupil B1 really understood the problem, so he asked the pupil to argue the right solution. Pupil B1 was not able to do that.

Pupil A7	There were 4 pheasants, they bought for them grains in 2 packages and, in each package, there were 5 kilograms of grain so together in the 2 there were 10 kg of grain.
Teacher A	Why 4 pheasants?

Pupil A7	Because it works like that. 4 pheasants, they scatter the grain on the ground and they can divide it somehow. This is how it works on farms, that they scatter the grain on the ground. They don't let them peck it to pieces. They don't put the package in the coop. [muted laughter]
Teacher A	How many pheasants were there?
Pupil A7	There were 4 pheasants and each had 2 packages with 5 kg of grain.
Teacher A	And now each has 2 packages or they have 2 packages together?
Pupil A7	They have them together. So, each pheasant couldn't have 10 kilograms, in fact. [enthusiastic reaction] I get it. There were 5 packages and, in each package, there were 2 kilograms of grain.

Commentary: As in the situation in class B, there was communication between one pupil and the teacher, who tried to use questions to make the pupil argue the solution. Pupil A7 first tried to find a solution by trial and error. After the teacher's first question, he tried to argue from the point of view of the real-life context, which could have also been his attempt to make the class laugh (it certainly made him laugh). Unlike pupil B1, he perceived the context in the problem better, so after the third question from the teacher he became aware of the mistake and enthusiastically came up with a new solution, which, however, was not correct.

4. Correct argumentation in a pupil's reasoning

Pupil A6	I think there are 10 kg of grains in each package. Because there are 2 packages and in each package there are 10, which is 20 and these 20 kg can be divided among 5 pheasants. That is 4.

Commentary: Pupils A6 felt no need to express explicitly that the numbers are multiplied or divided but obviously he understood the multiplicative relations.

Pupil B2	The first is 5, they brought 5 pheasants. They bought 2 packages for them. Each package was 10 kg. 10 x 2 is 20. And each had 4 and there were 5. Because 5 x 4 is 20.

Commentary: Pupil B2 stated explicitly in her argumentation that the numbers are multiplied. She did not use division. She was aware of the multiplicative relation between the four numbers.

Conclusion

These two experiments showed that pupils from two fifth grades react similarly to this type of word problems. First came positive reactions of pupils facing a new type of problem. However, both of these reactions contained incorrect or meaningless arguments that were not related to the problem itself. Examples of reactions in different approaches to the problem show that these pupils had richer experience with language than younger school pupils (Slezáková et al., 2021) and therefore they focused on the language aspect of the problem, which helped them solve it. The choice of the number was argued with the declension rule. In this case, the linguistic aspect was helpful, reducing the number of possible solutions. On the other hand, we are aware of limitations of language in a word problem. Still, it can bring new possibilities in the area of interdisciplinary relations between mathematics and language and it also gives more space for argumentation. Other arguments for filling in the numbers were the mathematical and the real-life context aspect. Extracts from the episodes in the 2nd and the 3rd points prove that the problem could provide potential opportunities for, among other, two key processual skills, mathematical reasoning (i.e. also argumentation) and communication, which is formulated in the Singapore curriculum. All this happened despite the unfavourable conditions of online education. Pupils actively listened to each other and used the arguments of others. The work of the whole class led to discussion and mutual support while searching for various solving strategies. In the final extracts of correct argumentation of the solution, we see similar reactions showing pupils' insight into the multiplicative relations between the numbers. What makes these reactions different is that the pupil does not feel the need to express explicitly that it is either multiplication or division.

These experiments showed that problems of the type What number makes sense? can be the opportunity to the development of pupils' argumentation skills and moreover they connect mathematical and language skills. While solving this type of problems, pupils naturally reason and justify their thinking processes. We are at the beginning of our research and in the future will conduct experiments with a wider set of problems, greater research sample and longer intervention. We would like to focus on the following questions: Will pupils use previous experience with this type of problems to solve new problems? How will pupils' approaches vary depending on their age? Will language aspects in other countries project into pupils' argumentation in problem solving?

Proving as multimodal argumentation: an investigation based on Toulmin's scheme

Andreas Moutsios-Rentzos

National and Kapodistrian University of Athens, Greece; moutsiosrent@primedu.uoa.gr

In this theoretical paper, we discuss mathematical argumentation and proving as multimodal text. It is argued that such a perspective is in line with the everyday experiences of mathematics and school mathematics. The PROving-as-MultimOdal-TExt analytical tool (ProMoTe) is presented, which draws upon Toulmin's scheme to address proving and argumentation as multimodal text. Two exemplary implementations and their implications on research and practice are discussed.

Keywords: Argumentation, proof, Toulmin, multimodal argumentation, multimodality.

Arguments, proofs, mathematics, and school mathematics in a multimodal reality

Mathematical argumentation is at the crux of everyday mathematical practice, whilst the notion of mathematical proof lies at the heart of modern mathematics. Specific forms and norms of reasoning about well-defined objects with fundamental properties constitute axiomatic systems that need to be consistent, independent, and complete. Within these constructions, mathematical proof serves as the gatekeeper, assigning to a mathematical conjecture the status of mathematical knowledge (Mariotti et al., 2018). It seems reasonable to expect that the importance of both mathematical argumentation and proof would be also evident in the school mathematics curricula and the mathematics teacher education programmes. Nevertheless, mathematics education researchers reveal that opportunities for reasoning and proving are limited in the mathematics textbooks (Davis, 2013; Hanna, 2000; Stylianides & Silver, 2004). Importantly, in school mathematics, proof seems to act as a dichotomizing, rather than a unifying, practice that crucially affects the way that each mathematics learner positions himself/herself with respect to mathematics. For example, it seems that these opportunities are often linked with those tasks that are more demanding or with proofs to (already known) theorems (Hanna & de Bruyn, 1999; Nordström & Löfwall, 2005). Moreover, everyday mathematics teaching practices, include an amalgam of verbal, non-verbal, emotional, and embodied aspects, which are also part of mathematical argumentation and proving. Diverse semiotic systems (for example, linguistic, visual, audio, gestural etc) are present in the mathematics classroom and the students are required to make meaning from and amongst them, as they are engaged with mathematics. The complex relationships amongst the meanings related to the different semiotic choices (for example, mutually reinforcing, antagonistic, or complementary) that sometimes co-exist during the utterance of a mathematical argument are of the interest of this paper.

In this paper, mathematics argumentation is conceptualised to be communicated as a multimodal text, in the sense that it involves the employment of more than one semiotic system (cf. Kress, 2010; O'Halloran, 2008); including, verbal and non-verbal aspects in diverse semiotic systems, as well as implicit, explicit, cognitive and affective aspects. This led to the development of an analytical tool (Proof-as-Multimodal-Text; ProMoTe), with the purpose to gain deeper understanding of the complexity of the multifaceted communicational interactions that are at work when teachers and students are engaged in argumentation and proving.

Toulmin’s scheme in mathematics education

Toulmin, in his seminal book *The Uses of Argument* (Toulmin, 1958), developed a scheme to analyse the logical micro-structure of an argument. According to the scheme, each argument includes the following components (see Figure 1): Data, Warrant, Backing, Qualifier, Rebuttal, Claim. A Claim is drawn upon some facts (the Data), based on a rule (a hypothetical statement; the Warrant) that associate such facts to this claim. This relationship is valid to a degree of certainty (the Qualifier) unless there is a case of refuting this relationship (the Rebuttal). The applicability of employing a warrant in the specific argument is supported by a categorical statement (the Backing) that identifies the broader system within this warrant may be utilised.

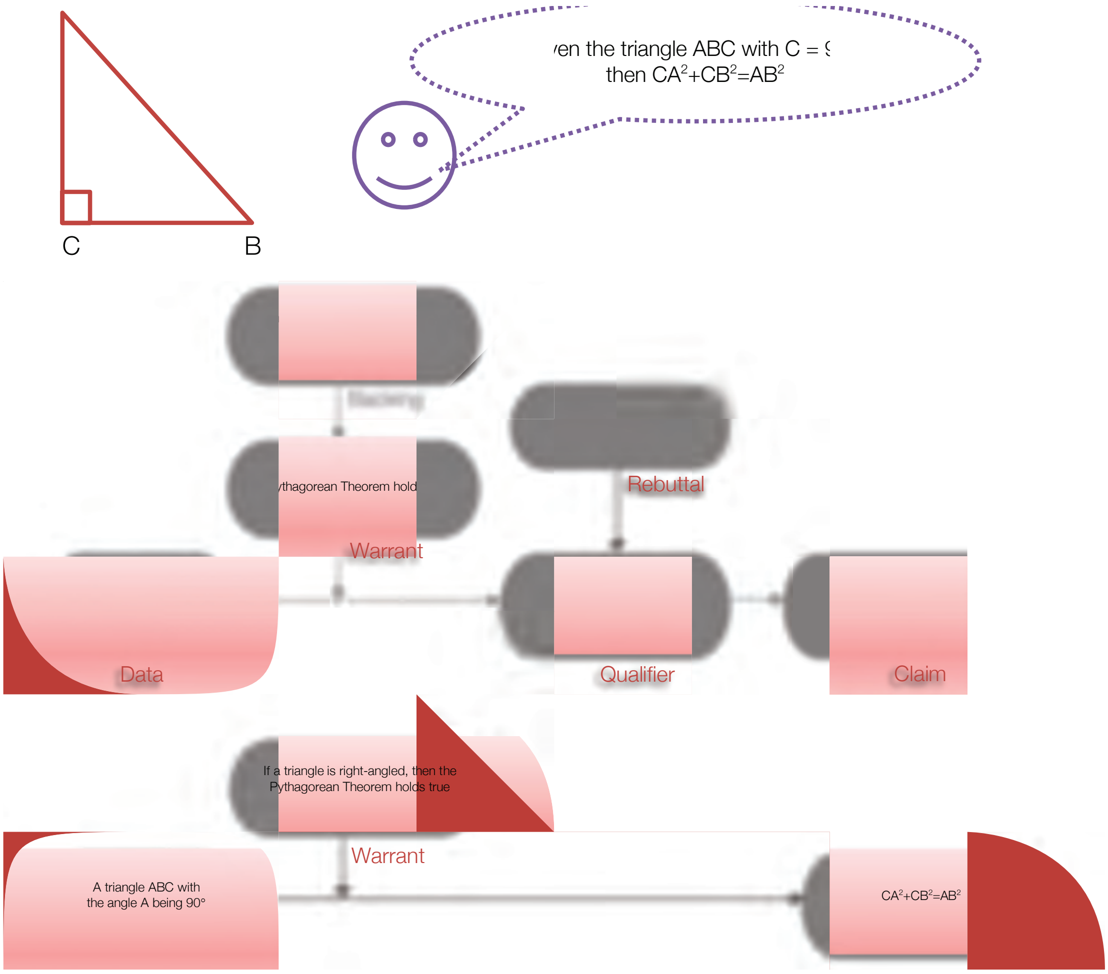

Figure 1: An example of applying Toulmin’s scheme; full (up) and a restricted version (below)

In Figure 1, two versions of Toulmin’s scheme are applied to analyse the argument posed by a student who saw the red triangle: “Given a triangle ABC with C = 90°, then $CA^2+CB^2=AB^2$.” Considering the full scheme, the Claim is an algebraic relationship with geometrical meaning that links the lengths of the sides of the right-angled triangle ABC, given the Warrant of the Pythagorean Theorem which holds true for all (no Rebuttal, absolute Qualifier) right-angled triangles within the system of the Euclidean Geometry (the Backing). Note that not all components of the analysis are explicit (verbally or else); the Warrant, the Backing, the Qualifier, and the Rebuttal are usually implicit and are hypothesised by the analyst (for example, the researcher or the teacher). Moreover, in our example, the data provided to this student draw upon different semiotic systems (numerical, figural), whilst the students' answer combines (natural) language with algebraic symbolism.

Though the scheme was not designed specifically for mathematical arguments, it has been widely utilised in mathematics education research. Initially, it was employed in restricted versions (Krummheuer, 1995). Nevertheless, Inglis et al. (2007) argued for the necessity to utilise the full version of the scheme to gain deeper understanding of in-class mathematical argumentation and its development towards a proof. They showed that students faced difficulties due to their inappropriately linking qualifiers and warrants (for example, an inductive warrant with an absolute qualifier). Various mathematics education researchers agree with employing the full version of the scheme, whilst others propose expansions of the scheme drawing upon other theoretical tools (Aberdein, 2005; Conner et al., 2014; Krummheuer, 1995; Pedemonte & Balacheff, 2016; Simpson, 2015). Moreover, researchers have employed Toulmin's scheme to investigate collective argumentation (Knipping & Reid, 2013), the teachers' supporting the students' mathematical argumentation (Conner et al., 2014), and the development of teaching tools about argumentation and proof (Hein & Prediger, 2017; Moutsios-Rentzos & Micha, 2018).

The fact that mathematical argumentation and proving involves both verbal and non-verbal aspects in diverse semiotic systems, as well as implicit and explicit aspects led to the development an analytical tool (ProMoTe) that acknowledges the mathematical argument as a multimodal text.

The PROof-as-MultimOdal-TExt analytical tool

A series of small-scale studies have been conducted to incorporate Toulmin's scheme within a tool to analyse the micro-structure of multimodal mathematical argumentation. The Proof-as-Multimodal-Text (ProMoTe) tool was designed to analyse multimodal arguments according to Toulmin's scheme, also identifying the *explicit* and the *implicit* elements of the arguments (see Figure 2).

ProMoTe Elements	Data	Warrant	Claim	Qualifier	Rebuttal	Backing
Explicit						
Verbal						
natural language						
symbols (numbers, symbols etc)						
Non-verbal						
written (figures etc)						
embodied -sensory (gestures etc)						
Implicit						
Verbal						
mental (non-explicitly communicated verbal warrants etc)						
Non-verbal						
mental (non-explicitly communicated non-verbal warrants etc)						
embodied -bio-metric (heart-rate etc)						

Figure 2: The Proof-As-Multimodal-Text (ProMoTe) analytical tool.

The explicit/implicit differentiation reflects what is considered to be overtly present for those engaged in the mathematical argumentation. Explicit elements include those verbal and non-verbal aspects of the mathematical argumentation that are in some way sensory-present to those who are engaged in the communication. Explicit verbal elements may include natural or mathematical language, whilst explicit non-verbal elements may be classified as written or as embodied-sensory (for example, gestures, posture, voice pitch etc). On the other hand, implicit elements include aspects of the argumentation that are only mentally present (for example, a non-explicitly communicated warrant; the Pythagorean Theorem in Figure 1), or they are not consciously present (for example, biometric data, such as heart rate or salivary cortisol measurements). Moreover, element types that are hypothesised by the analyst (for example, researcher or a reflective practitioner) may be also included in this category. Notably, ProMoTe allows for the identification of both cognitive and affective aspects of mathematical argumentation.

The analysis of each argument according to ProMoTe is designed to be conducted in three complementary stages/layers. First, the argument is decomposed according to Toulmin's scheme with respect to its explicit verbal elements. Subsequently, the non-verbal explicit elements are considered. The third stage/layer concerns the identification and/or assumption of the implicit elements.

In this paper, two exemplary implementations of ProMoTe are presented from a study[1] conducted in 2018 in a Greek high school (14 years old). Video-recorded data (only the teachers were visible; informed consents were obtained) of eight teaching hours were collected and analysed. Two restricted versions of ProMoTe were utilised (respectively, one including Data, Warrant and Claim, and one including Data, Warrant, Claim and Qualifier) to analyse one teacher's multimodal mathematical argumentation focusing on both cognitive and affective aspects.

The first example (outlined in Figure 3) concerns a teacher's argument regarding the slope of a linear function. He attempts to exemplify the property that when the slope of a linear function is positive, then the function is strictly increasing. He utilizes the example of $f(x)=3x$ to argue that "when α is positive [referring to the general form $f(x)=\alpha x$], the line goes upwards". The analysis reveals that the teacher's arguments are essentially two completely different ones that are co-developed simultaneously: a) a deductive argument discussing the graph of the specific function as a special case of the general rule he had presented a few moments earlier, and b) an inductive argument about the general rule that is verified by the specific example. At the same time, the teacher explicitly non-verbally shows the specific example and verbally utters the general rule. The students are implicitly required to differentiate between these two arguments, which warrants link which data with which claim. Importantly, not all the elements of the ongoing argumentation are legitimatised to be temporary stable; that is to be written on the blackboard.

---

ProMoTe Elements	Data	Warrant	Claim
Explicit			
Verbal			
natural language	*"…when α is positive…"*	-	*"… the line goes upwards"*
symbols			
Non-verbal			
written	α=3 of the graph of the function f(x)=3x as depicted on the blackboard	Visual inspection of the graph	The graph of the function f(x)=3x as depicted on the blackboard
embodied -sensory			Upwards gestures over the straight line Followed by a movement of the hands from left to right on the horizontal axis
Implicit			
Verbal			
mental	The graph of f(x)=3x is a line going upwards, with α=3>0	Inductive	In a function f(x)=αx, when α>0 then the graph is an increasing straight line
	α=3>0	When the slope of a straight line is positive, the angle of the line with the horizontal axis is less than 90°	The line is strictly increasing
Non-verbal			
mental			

Figure 3: Implementing the ProMoTe analytical tool (example 1)

In the second example, the same teacher, teaching in another cohort of students of the same grade, presents a textbook exercise and asks the students to create the graph of the function y=3x. He argues: "The function y=3x is of the type [raises his voice a little, makes intense hand-movements, his eyes were bulging out] … y= αx, then it is a straight line". The application of ProMoTe (see Figure 4) contrasts a standard verbal analysis which would identify only one argument, by revealing two arguments that work in parallel: the first is "The function y=3x is of the type [raises his voice a little, makes intense hand-movements, his eyes were bulging out] … y= αx" and the second argument is "then it is a straight line".

The decomposition of the second argument is in line with the standard analysis, as it involves only verbal explicit and implicit elements (see Figure 4, below). However, regarding the first argument, ProMoTe allowed us to identify the role of non-verbal affective elements in argumentation in the micro-structure of argumentation (see Figure 4, up). It appears that the teacher amplifies the presence (cf. Perelman & Olbrechts-Tyteca, 1969) of the whole argument by providing three implicit non-verbal affective warrants, as depicted in the ProMoTe tool. At the same time, the argument is also based on the implicit data that "Raised voice, intense hand-movements and eyes bulging out imply that emphasis is given and attention is required", as well as on the implicit warrant of the teacher's authority, on the implicit claim that "When the teacher emphasises something and/or draws attention to something, then this is correct and/or important", and on the implicit qualifier "certainly".

Notice that the teacher's argument draws simultaneously on cognitive and affective aspects, though they appear to inform different aspects of the mathematical argumentation. There seems to be an implicit dimension, essentially forming an implicit argument about the affective warrants. Explicitly and implicitly the teacher's verbal argumentation seems to promote deductive argumentation. At the same time, his implicit and explicit non-verbal argumentation appears to legitimatise his authority as means for the validation of mathematical argument, as the embodied-sensory authority-derived warrants together with the deductive implicit warrants are linked with the qualifier "certainly", which may communicate inappropriate warrant-qualifier couples as acceptable (Inglis et al., 2007).

ProMoTe Elements	Data	Warrant	Claim	Qualifier

Concluding remarks

In this paper, we approached argumentation and proof as multimodal text, with the purpose to design a tool that may prove to be helpful in analysing the complexities of everyday mathematics argumentation and proving. We presented the implementation of the ProMoTe tool on a teacher's multimodal argumentation. The ProMoTe tool appeared to be helpful in identifying the specific ways that different verbal and non-verbal semiotic systems are explicitly and implicitly orchestrated in the different elements of mathematical argumentation as decomposed according to Toulmin's scheme. The PRoMoTe tool helped in revealing aspects of the teachers' argumentation that may allow for the construction of inappropriate sociomathematical norms (Yackel & Cobb, 1996) about argumentation and proving (cf. Moutsios-Rentzos et al, 2019). Though researchers have considered multimodal aspects of argumentation (Krummheuer, 1995), ProMoTe allows for the different lines of argumentation that may be developed within and/or across different semiotic systems to be visible (cf. O'Halloran, 2008). Considering the rapidly evolving and technologically expanded mathematics classroom (cf. Hanna et al., 2019), which includes the digital, the hybrid and the virtual, and the relevant radical transformations of the educational processes, settings, and power-relationships, it is posited the multimodal mathematical argumentation (further amplified by technology) is at the heart of mathematical practices, thus rendering crucial the development of appropriate analytical tools that explicitly address multimodality to gain deeper understanding of the complex phenomena. Ongoing research is focusing on utilising the ProMoTe tool in mathematical multimodal argumentation about tasks concerning measurement and area, on including implicit non-verbal embodied-biometric and digital data, as well as on investigating the incorporation of ProMoTe in a teacher education programme.

On the implementation of proving in primary school

Melanie Platz

Saarland University, Germany; melanie.platz@uni-saarland.de

The project Prim-E-Proof aims to generate substantial learning environments to support proving skills at the primary level. The learning environment "The Pythagoreans" on the theorem "the sum of two odd numbers is always even" is constantly further developed through design science research. The evaluation showed that the majority of the primary school pupils use empirical justifications and that the solutions of younger primary school children do not seem to differ much from those of older ones. A first concept for the reflection of justifications is supposed to support learners in developing valid justifications and teachers in implementing proof in primary school.

Keywords: Primary education, "inhaltlich-anschaulich" proving, reasoning, instruction support.

Introduction

"Reasoning" can be understood as a generic term for forms of argumentation and proof (Brunner, 2014, p. 31). However:

> A formal-deductive understanding of proof is not suitable to describe the aspect of reasoning in primary school [in Germany]. The same is valid for the "inhaltlich-anschaulich" [a loose translation could be "content-visual"] proving, although its use in primary education is undoubtedly possible. However, a content-visual proof also aims at proving the validity or non-validity of general mathematical facts such as rules, conspicuousness, relationships, or the like. The detachment from the individual case, the generalization, represents an indispensable aspect of content-visual proofs. In contrast, mathematics lessons often require reasoning to lend validity to a very concrete example or a particular assertion. (Peterßen, 2012, p. 20)

Stylianides (2016) formulates two crucial goals from a pedagogical standpoint that can be reached through a more central place of proving in the mathematical experiences of children:

> First, elementary students will have more opportunities to learn deeply in mathematics and engage with it as a sense-making activity. Second, when students get to secondary school they will not only be better prepared to engage with proving, which they will see as a natural extension of their prior mathematical experiences, but also better able to reason mathematically in disciplined ways […]. (Stylianides, 2016, p. 10)

In the context of primary school, especially the research perspective of Blum and Kirsch (among others 1991), together with Wittmann and Müller (among others 1990), which Reid and Knipping (2010, p. 43) call a "preformalist" research perspective, seems suitable. In content-visual proofs, preformalists loosen the requirement that proofs must be formal. Still, they expect deductive reasoning to be used and that proofs based on intuitive or obvious foundations are as convincing (or even more convincing) as formal proofs (ibid.). A *content-visual proof* is based on a concrete, visually perceptible object, on which something general is proven and which is usually presented in an iconic way. It can be understood as an object of a more general kind by trained observation. To produce a content-visual proof, the more general in the special of an example must be mentally seen

(Krumsdorf, 2015). But in particular, to disengage from examples, i.e., to generalize the effects of operations, confronts primary school children with a problem that they cannot solve spontaneously and without support (Sturm, 2018). Another challenge for primary school learners is that the *content-visual proof* must be verbalized. What is initially subjectively found to be universally valid can be socially shared and recognized by others (Wittmann & Ziegenbalg, 2007). The pupils face the requirement of generalizing without knowledge of the algebraic language. They interpret a general structure into the given mathematical signs and use the signs they know from other contexts to describe the general patterns and structures (Akinwunmi, 2012). Besides the challenges for learners, proving in primary school brings challenges to teachers that make an implementation into mathematics teaching difficult. These are:

> […] the weak knowledge that many elementary teachers have about proof (factor 1) and their presumed beliefs that proving is an advanced mathematical topic beyond the reach of elementary students (factor 2); the high pedagogical demands placed on elementary teachers who strive to engage their students in proving (factor 3); and the inadequate instructional support offered or available to elementary teachers about how to achieve that goal in their classrooms (factor 4). (Stylianides, 2016, p. 21)

Melhuish et al. (2020) evaluated the efficacy of a 3-year teacher professional development program with participants from 25 elementary schools. They concluded: "Even when teachers are engaged in a PD designed to promote high-level reasoning forms (in our case justifying and generalization) and are provided with relevant definitions, teachers may continue to revert to nonstandard views of those reasoning forms." (p. 63). This emphasizes the complexity of designing support measures for teachers.

The *Prim-E-Proof* project's objective is to develop *substantial learning environments* for primary school mathematics lessons, among others inspired by the tasks stimulating *operative proving* in the primary school book *Zahlenbuch* (based on Wittmann & Müller, 1990), to support proving skills with a particular focus on the factors identified by Stylianides (2016). Wittmann (1998) characterizes substantial learning environments based on four criteria. They must (1) represent central goals, content, and principles of mathematics education; (2) provide rich opportunities for students' mathematical activities; (3) be flexible and easily adaptable to the particular circumstances of a given class; (4) integrate mathematical, psychological, and pedagogical aspects of teaching and learning holistically and therefore offer a broad potential for empirical research. The starting point is the theorem: *the sum of two odd numbers is always even*.

The learning environment "The Pythagoreans"

The tasks within the learning environment are as follows:

(1) *What was again an even number, and what was an odd number?* With this question, the childrens' previous knowledge is linked up.

(2) *In the past, calculation stones were used for calculating instead of reversible tiles. The Pythagoreans alienated the calculating stones to perform mathematical proofs – among other things about even and odd numbers. These calculation stones of the Pythagoreans were further developed*

in this applet [besides the applet also analog material is provided]. *Let me show you what the applet can do* [the functions of the applet (www.melanie-platz.com/Steinchen-Applet/Steinchen.html, see Fig. 1) are presented]. *How might the Pythagoreans have represented even and odd numbers with stones? Use the applet and represent an even and an odd number.* To avoid a defensive reaction (Platz, 2019) and to be able to arouse a need for proof and thus provide rich opportunities for mathematical activities for pupils, a historical digression (Krauthausen, 2018) is initiated.

(3) *Always add two odd numbers. What do you notice?* Bezold (2009, p. 37) describes four activities or steps in an argumentation chain. The first two activities are stimulated by this task: the discovery of mathematical features as *prerequisites* for argumentative activities. *Step 1* represents the description of discoveries (ibid.) or a reference to common prior knowledge (Neumann et al., 2014).

(4) *Why is this so? Give reasons!* With this task, *step 2* of the argumentation chain, according to Bezold (2009), the questioning of discoveries, and *step 3,* the finding of justifications or ideas for justification of mathematical regularities and connections, are stimulated.

Research Questions

In this paper, the following research questions are targeted: *RQ(1) Which level of proving do learners working on the learning environment "The Pythagoreans" reach when providing support measures to support and supplement the learners' activities?*; *RQ(2) Which consequences can be drawn for the further development of the learning environment?*

Methods and procedures for collecting and analyzing data & obtained data

A multiple case study (Yin, 2018) using qualitative data collection and analysis methods was conducted. A clinical interview with only key questions defined and the requirement to follow children's thinking is analogous in principle to classroom management in implementing a substantial learning environment (Wittmann, 1998). The collected data can provide information "[...] about teaching/learning processes, thinking processes and learning progress of students [...]. On the other hand, they help to evaluate and revise the learning environments to design teaching/learning processes even more effectively." (ibid., p. 339).

A course concept for student teachers, who did not have experiences with proving in primary school before, was developed: the students elaborated various support options for the learners that were applied (if necessary) depending on the proof phase, e.g., variation of suitable materials or representations (Krauthausen, 2001), variation of appropriate example-based proof processes (approaches) (Krumsdorf, 2015), use of Big Numbers (Martin & Harel, 1989) or merely presented examples (Krumsdorf, 2015) or use of pre-exercises for proof (Brunner, 2014). Before the students performed the clinical interviews, the learning instruction was focused which should help to enable them to support and supplement the children's activities with suitable impulses that do not go too far and to be a rich source of reliable factual information for the children (Wollring, 2008).

The learning environment was tested by student teachers at the University of Münster in the winter semester 2020/21 and the University College of Teacher Education Tyrol in the summer semester 2021 in 40-minute clinical interviews with primary school children (grades 1-4). The interviews were videotaped and transcribed. The solutions of 17 pupils were analyzed regarding the handling of examples (abstraction) and generalization, the level of justification, the need for support during proving and classified in proving levels. Almeida (2001, p. 55) adds *'proof' by authority* (level 1) and *'proof' by intuition* (level 2) implied by Cobb (1986) to Balacheff's (1991) widely accepted descriptions of the levels of proving: (3) *'proof' by naive empiricism*, (4) *'proof' by crucial experiment*, (5) *proof by generic example* and (6) *proof by thought experiment*. Proofs on levels 5 and 6 can be regarded as valid.

Results & Discussion

RQ(1)

Analyzing the proving level of the pupils from grades 3 and 4 (8-12 years), seven pupils used empirical justifications, three *generic examples*, and one a *proof by thought experiment*. Two could not be convinced that the assertion is true. This draws a similar picture to the results of a study of the proof perceptions and practices of "nineteen year ten pupils" (p. 55): Almeida (2001) observed that the majority of pupils preferred empirical justifications. In our case, four younger children (grade 1 & 2, 6-7 years) were interviewed, and the approach to proving did not seem to differ that much from that of the older children. Neumann et al. (2014), who assessed students' mathematical reasoning skills from two 3rd grades, five 4th grades, and five 6th grades, observed something similar. The comparison of the groups showed no significant differences between grades 3, 4, and 6 (n=243). Focusing on the proving skills of the youngest pupils, one interesting case is the following: Emma (grade 1, 7 years) was asked by the interviewer, what pattern all the odd numbers have in common and how she can tell straight away that she laid an odd number with the tiles. Emma explains: "[…] because you can't always count two together with them. For example, you can't count to four now, when in steps of two, two, four, then one tile is missing." (see Fig. 1, middle). Then this scene follows:

1	Interviewer:	And if you then put two such numbers together? (...) What happens then (...) with the steps of two?
2	Emma:	(...) Then it works.
3	Interviewer:	Then it works.
4	Emma:	Yes
5	Interviewer:	Um (hesitating). Why is this always the case?
6	Emma:	(...) Hm (thoughtful) (...) Because (...) the odd numbers are odd numbers?

Stimulated by the interviewer, Emma uses the self-chosen example 3+3=6 to show that the sum of 6 is even by counting in steps of two (see Fig. 1, right).

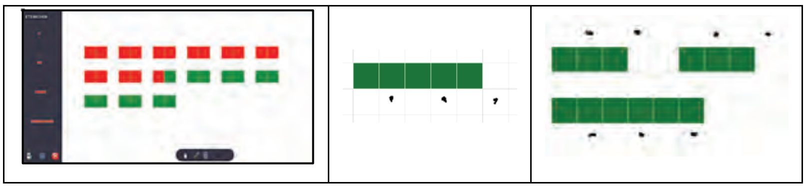

Figure 1: Screenshot of the "Steinchen-Applet" and visualization of Emma's solution

Emma describes odd numbers through the basic idea of dividing by grouping (pairing) the tiles (counting in steps of two). If no tile is missing to form a pair, it is an even number. If there is a tile missing, it is an odd number. Emma does not express the proof idea (that the two individual tiles can be joined together and that an even number can be produced when forming the sum by pairing). She just states "then it works" (*turn 2*) and responds to the *why-question* of the interviewer (*turn 5*)

"Because the odd numbers are odd numbers?" (*turn 6*). Afterward, Emma verifies with an example that her procedure works. The reaction of Emma to the *why-question* could be compared to the "I see it this way" (cf. *proof by intuition*) described as an answer of children to the question "Why? How do you know?" by Freudenthal (1978, p. 262) focusing on a geometric context. This can be transferred to the geometric-visualized pattern structuring in our case: "One thing I know for sure today: the answer is not an excuse, it is true. It is not a symptom of guessing, nor is it a confession of powerlessness in linguistic expression. On the contrary: that the child sees it prevents the linguistic effort." (ibid., p. 263). Consequently, Emma seems to start with a *proof by thought experiment,* because she verifies the statement by appealing to the structural properties of mathematics independent of examples. In *turn 6,* she seems to switch to a *proof by intuition* and is based on stimulation by the interviewer directed to a *proof by a generic example* (which is not completed).

RQ(2)

The mathematical reasoning competencies of the students mostly do not correspond to the curricular requirements of the educational standards, which can also be attributed to a lack of meta-knowledge of the students regarding mathematics-specific reasoning (Vogt, 2020). But a targeted further development of mathematical reasoning skills in primary school mathematics lessons seems to be possible in principle (Bezold, 2009; Peterßen, 2012; Vogt, 2020). Peterßen (2012) reports on a study where most grade 3 pupils (n=20) used valid justifications in the categories *generic example* and pure *thought experiment* to validate a claim; empirical justifications accounted for only about one-quarter of the students' justifications. "One possible explanation could be the culture of justification already embedded in the class. The students were used to being asked *wh*y over and over again. Furthermore, the quality of pupils' explanations was also the subject of the lesson." (ibid., p. 63). Understanding proof in the following way makes the negotiation for a common argumentation basis apparent: "A set of propositions that are accepted as true, together with inferences that are accepted as admissible, shall be called a basis of argumentation. Reasoning based on a given argumentation basis be called a proof concerning that argumentation basis." (Fischer & Malle, 1985, p. 180). In terms of a common argumentation basis, Peterßen (2012, p. 348) emphasizes the *reflection of justifications* with pupils. Pupils need to understand what is required of a justification, i.e., which justification is accepted or rejected, when, and why. Justifications in themselves and their respective persuasiveness should be made the subject of teaching. Such a reflection of justifications was not stimulated in the learning environment *the Pythogoreans*: The tasks enable to pass through the four activities or steps in an argumentation chain described by Bezold (2009) as mentioned above. Comparing this argumentation chain with the *process model of the proof process of experts* (the seven phases do not necessarily have to be passed through in the order given here; rather, a frequent alternation between these phases is to be expected, especially for experienced mathematicians), the first three phases seem to coincide partly: (1) *Finding a conjecture from the mathematical problem field*. (2) *Formulate the conjecture according to common standards*. (3) *Exploring the conjecture with the limits of its validity; making connections to mathematical framework theory; identifying suitable arguments to support the conjecture* (Reiss & Ufer, 2009, p. 162). The phases (4)-(6) are not stimulated with the tasks: (4) *Selecting arguments that can be organized in a deductive chain to form a proof*. (5) *Fixing the chain of arguments according to current mathematical standards*. (6) *Approximation to a formal proof*

(Phase (6) is only realized in a few cases. Usually, the proof found in phase (5) is reviewed and, if necessary, published by the mathematical community at conferences and in the context of peer review.) (ibid.). (7) *Acceptance by the mathematical community* (ibid.), whereby in the school context, this role of the mathematical community is usually performed by the teacher. As the model is based on an expert's (optimal) proof process, it cannot directly be transferred to purposes of teaching (ibid., p. 163), but it can be used as a starting point for the development of a teaching concept. With this intention, the reflection of justification is focused for helping students understand what is required of a justification (Peterßen, 2012) and to find a common argumentation base (Fischer & Malle, 1985) to be able to select arguments that can be organized in a deductive chain to form a proof (phase (4)). In the next step of the project, the reflection of justifications is focused on, which is supposed to be done via analyzing authentic pupils' solutions. These solutions can include errors or not. What should be emphasized is that most of the pupils' answers are not wrong; the pupils just had another understanding of the argumentation base. The *reflection of errors or justifications that are to be rejected* can lead to negative knowledge (Oser et al., 1999). This includes two main components: the differentiation knowledge (To what extent does something not belong to a specific item, concept, or procedure?) and the error knowledge (What must not be done in a particular situation?). The use of solutions of other (anonymous) pupils can be justified because not each error has to be done by oneself to learn from it, and pupils usually prefer to work on mistakes from others (Prediger & Wittmann, 2009). The aim of *reflecting "good" solutions or justifications that are to be accepted* is not for every child to learn and use as many ways of proving as possible. It is essential that they find ways to prove according to their individual preferences. This way, the lack of familiarity with adequate tools (Krauthausen, 2001) and the interpretative openness of figural representations (Krumsdorf, 2015) in tile-proofs can be counteracted. Training in the flexible perception of different states (one representation, different perspectives) can be supportive. It can be helpful if the same situation can be experienced and explicitly compared using different representations (ibid.). For analyzing the students' solutions, the teacher can guide the pupils through stages with increasing metacognitive demand similar to those proposed by Prediger & Wittmann (2009, p. 8) for analyzing errors: (1) *Find calculation errors or errors in the procedure of the student* (What is wrong here? Justify why.; What rule was broken?). (2) *Compare two solutions* (Here are two different solutions. Which one is better?). (3) *Explain the procedure of a student* (How did the student think here?). (4) *Reconstruction of the reason why a justification was given that must be rejected/accepted* (What idea is behind the solution?; Explain why the justification is rejected/accepted.). (5) *Development of optimization measures* (How would you help the student?; What would you do same wise/different?). The following scene could be used as starting point for a discussion (especially items (3)–(5); in comparison with Emma's solution also (2)): After checking on several examples, Ben (grade 3, 8 years) was asked why his procedure (pairing) always works:

Ben: If you can partition the little tiles exactly. Then it must be an even number. But. (5) Two odd numbers make an even one. (...) Because it remains. If you divide them up, there is always one remaining. And if you combine the one leftover with the other one/ one is left over. If you then put them together, you have two again. And (..) if you had three odd numbers now, they would have remained odd.

Conclusion & further Development

Peterßen (2012) identifies the following aspects that positively affect the development of reasoning competence and a subjective need for reasoning: discovery learning as a teaching principle, good tasks, regularity, pupil-focused communication, and subject-specific competent teachers. By developing substantial learning environments that should be implementable regularly, discovery learning is realized, and good tasks are designed. Focusing on the reflection of justifications, informative scenes from the clinical interviews will be extracted and prepared for use in the primary school classroom. Melhuish et al. (2020) suspect that

> […] the ability to notice complex mathematical-reasoning forms (a necessary prerequisite for fostering them in classrooms) may rely not only on providing teachers with mathematical definitions and rich examples but also on promoting explicit connections between definitions and the examples themselves. (p. 64)

With the focus of promoting explicit connections between definitions and the example scenes, teacher training courses will be developed, building on the experiences of Melhuish et al. (2020) and the concept *professional vision* (Sherin, 2007) to support teachers subject-specifically and in pupil-focused communication.

Acknowledgment

I thank all the students and participating children for their excellent work and patience!

‘Reasoning’ in national curricula and standards

David A Reid

University of Agder, Norway; david.reid@uia.no

I examine the use of the word ‘reasoning’ in the 2020 Norwegian national mathematics curriculum, in the 2000 National Council of Teachers of Mathematics (NCTM) Standards and in the 2003 Education Standards of the German Kultusminister Konferenz (KMK). I identify differences in usage, make comparisons to the classification of aspects of reasoning proposed by Jeannotte and Kieran (2017), and suggest expanding their framework by addressing the distinction between the activity of reasoning and the process of reasoning, and also addressing the goal of reasoning. Specifically, the use of reasoning to explain is neglected in their framework.

Keywords: Reasoning, Argumentation, Proof, Mathematics curriculum, Language

Introduction

The differing meanings and usages of terms related to argumentation and proof have been discussed in the literature and related to differences in language (e.g., Sekiguchi & Miyazaki, 2000), professional context (e.g., Godino & Recio, 1997), and epistemological perspectives (e.g., Balacheff, 2008). Here I will contribute to this literature by examining the use of the word ‘reasoning’ in the 2020 Norwegian national mathematics curriculum, in the 2000 National Council of Teachers of Mathematics (NCTM) Standards and in the 2003 Education Standards of the German Kultusminister Konferenz (KMK). I will identify differences in usage, make connections to related terms such as ‘argumentation’ and ‘proof’, and suggest a framework for further discussion of these differences.

Related literature

Jeannotte and Kieran (2017) conducted a thorough survey of the ways mathematical reasoning is described in the mathematics education literature and they propose a conceptual model, based in a within a commognitive theoretical framework, to describe mathematical reasoning. In their model they distinguish between structural and process aspects. The structural aspect refers to the form of the reasoning: deductive, inductive or abductive. The process aspect is more complex, and is divided into three processes related to the search for similarities and differences, validating, and exemplifying. The first two processes are further divided into subprocesses.

The search for similarities and differences includes generalizing, conjecturing, identifying a pattern, comparing, and classifying. By ‘generalizing’ they mean inferring something from a given set that applies to a larger set containing it. Conjecturing is characterized by the epistemic value it assigns to an inference: probable or likely. These two processes can (and perhaps often) occur together, but they are distinct. One can generalize with making a claim that the generalization is probable, and one can make a claim that an inference is probable that does not involve generalizing from a subset to a set. Jeannotte and Kieran use ‘identifying a pattern’ to refer to the process of identifying a relation among a set of objects, but this relation need not be extended to a larger set (as in generalizing) nor given a probable epistemic value (as in conjecturing). Comparing can occur along with the other process, and is necessary for identifying a pattern. Comparing, however, refers only to the observation of similarities and differences, without identification of a relation between the objects. Classifying involves making a class of objects based on shared properties.

Processes related to validating include justifying, proving and formal proving. Validating refers to any process that is directed towards changing epistemic value, towards higher or lower likelihood. Justifying is validating that includes a search for data, warrants and backing to modify epistemic value. Proving is validating that specifically modifies epistemic value to truth. It is linked to a set of accepted truths, the use of deductive reasoning (at least in its final stages), and particular, socially accepted, forms of expression. Formal proving is proving that meets stricter criteria for the accepted truths used and the final forms of expression. As Jeannotte and Kieran put it, "formal proving relies on mathematical theory built a priori and on formalized realizations (axioms and theorems)." (2017, p. 13)

Jeannotte and Kieran list a final process, exemplifying, which they say supports the other processes. It consists of producing examples which can then allow patterns to be identified, conjectures and generalizations to be made, and which can be used to justify claims.

It should be noted that Jeannotte and Kieran considered other aspects of mathematical reasoning that were not directly included in their final model, as they felt that the distinctions that they had made captured these other distinctions. One distinction they encountered in the literature but did not explicitly include is the activity/product dichotomy, which separates the product of reasoning from the inaccessible mental activity that gives rise to it. They also considered the inferential nature of mathematical reasoning, that is, the origin of novel ideas through reasoning, and the goal and functions of mathematical reasoning, which refers to the purpose of reasoning which is often verification but might also be exploration or explanation.

Jeannotte and Kieran found that there is no universal agreement on the meaning of 'mathematical reasoning' in the research literature, but they were able to, by considering carefully the ways this term is used, to identify key aspects of it. They note that policy documents like curricula and standards around the world emphasize mathematical reasoning as a goal, but that the description of it in such policy documents "tends to be vague, unsystematic, and even contradictory from one document to the other" (p. 2). Nonetheless, such policy documents seem likely to have a stronger influence on what teachers think mathematical reasoning is, and hence what goes on in classrooms with the goal of fostering mathematical reasoning, than the research literature. Hence, I have chosen to examine one such curriculum document and two national standards documents to explore the use, and hence the meaning, of 'reasoning' in them. I have been informed by, but have not strictly applied, Jeannotte and Kieran's framework, in order to allow for the possibility that distinctions are made in policy documents that differ significantly from those included in Jeannotte and Kieran's framework.

The Norwegian mathematics curriculum

The current Norwegian curriculum (Kunnskapsdepartementet 2019a, b) lists *Reasoning and argumentation* as one of six "core elements", each of which is described in a paragraph. The other core elements are: *Exploration and problem solving, Modelling and applications, Representation and communication, Abstraction and generalization,* and *Mathematical fields of knowledge* (which includes number, algebra, functions, geometry, statistics and probability).

The official English translation of the *Reasoning and argumentation* core element is:

> **Reasoning** in mathematics means the ability to follow, assess and understand mathematical chains of thought. It means that the pupils shall understand that mathematical rules and results are not random, but have clear and logical grounds. The pupils shall formulate their own **reasoning** to understand and to solve problems. Argumentation in mathematics means that the pupils give grounds for their methods, **reasoning** and solutions, and prove that these are valid. (2019b, p. 3, bold added)

An important distinction in the original is missing from this translation. The original text is headed "Resonnering og argumentasjon" and reads:

> **Resonnering** i matematikk handlar om å kunne følgje, vurdere og forstå matematiske tankerekkjer. Det inneber at elevane skal forstå at matematiske reglar og resultat ikkje er tilfeldige, men har klare grunngivingar. Elevane skal utforme eigne **resonnement** både for å forstå og for å løyse problem. Argumentasjon i matematikk handlar om at elevane grunngir framgangsmåtar, **resonnement** og løysingar og beviser at dei er gyldige. (2019a, p. 2, bold added)

Notice that the word 'reasoning' in the English translation is used for two Norwegian words, 'resonnering' and 'resonnement'. The word 'resonnering' does not have a dictionary entry of its own. It is formed from the verb "resonnere" (to reason) with the suffix "-ing" to make it a noun. The word 'resonnement' is a noun means 'thinking, way of thinking, concluding'. Both are nouns, but 'resonnering' is closer to the verb form and is used to refer to the process of reasoning, while 'resonnement' refers to the product of reasoning. Recall that the activity/product dichotomy is a distinction that Jeannotte and Kieran chose not to specifically include in their model. However, in this case, where the language allows this distinction to be explicitly marked, the authors of the Norwegian curriculum have chosen to do so. This suggests that the dichotomy is an important one to them, and that teachers being guided by the curriculum might make a similar distinction. It also reminds us that this distinction is harder to observe in languages like English that have only a single word for reasoning.

Sources

One of the influences on the Norwegian curriculum is the work of Mogens Niss and his colleagues (e.g., Niss & Jensen, 2002; Niss & Højgaard, 2019). The idea of 'chains of thought' originates from Niss's work. For example, Niss and Jensen (2002) write:

> [The reasoning] competence consists, on the one hand, in being able to follow and assess a mathematical reasoning, i.e. a chain of arguments put forward by others in writing or in speech in support of a statement (p. 54, my translation)

However, Niss and Jensen also say that the competence involves:

> understanding what a mathematical proof is and how it differs from other forms of mathematical reasoning, e.g., heuristic reasoning resting on intuition or on consideration of specific cases, and to be able to determine when a mathematical reasoning actually constitutes a proof and when not. (p. 54, my translation)

and

> consists of being able to devise and implement informal and formal reasoning (on the basis of intuition), including transforming heuristic reasoning into actual (valid) proofs. (p. 54, my translation)

The 'reasoning' in the Norwegian curriculum does not mention intuition, consideration of specific cases, or heuristic reasoning, and its emphasis on "clear and logical grounds" suggests that such reasoning is not included.

Summary

The description of reasoning in the Norwegian curriculum touches on several characteristics: the process of reasoning involves following, assessing and understanding mathematical chains of thought; it is related to the grounds of mathematics; the product of reasoning can be formulated; and giving grounds for that product is central to argumentation. It excludes heuristic reasoning and reasoning based on specific cases and intuition, which Niss and his colleagues include as mathematical 'reasoning'.

The NCTM Standards

The 2000 NCTM *Principles and Standards for School Mathematics* have influenced curricula both in the United States and internationally. The structuring of the Norwegian curriculum into core elements may have been influenced by the structure of the NCTM *Standards.* Three of the core elements (*Exploration and problem solving, Reasoning and argumentation,* and *Representation and communication*), have, at least in part, the same names as four of the NCTM 'Process Standards' (*Problem solving, Reasoning and Proof, Communication,* and *Representation*). A fourth (*Modelling and applications*) is very similar in content to the NCTM's *Connections* standard.

The NCTM standard *Reasoning and Proof* is described in a four page long general section, as well as in separate sections for the Pre-K–2, 3–5, 6–8 and 9–12 grade bands. The general section begins with a listing of four goals:

> Instructional programs from prekindergarten through grade 12 should enable all students to—
>
> - recognize reasoning and proof as fundamental aspects of mathematics;
> - make and investigate mathematical conjectures;
> - develop and evaluate mathematical arguments and proofs;
> - select and use various types of reasoning and methods of proof. (p. 56)

The goal "develop and evaluate mathematical arguments and proofs" is also the central focus of the Norwegian core element *Reasoning and argumentation.* However, the NCTM standard is broader as it includes making and investigating mathematical conjectures. Conjecturing is not mentioned in the Norwegian curriculum but the core element *Exploration and problem solving* includes "searching for patterns, finding relationships" (p. 2). This parallels the NCTM's "note patterns, structure, or regularities in both real-world situations and symbolic objects" (p. 56) in the *Reasoning and Proof* standard.

The NCTM Standards also includes the ability to "select and use various types of reasoning and methods of proof." (p. 56). This suggests that, like Niss, the NCTM sees mathematical reasoning as including several kinds of reasoning. One distinction the NCTM makes may be similar to Niss's distinction between heuristic reasoning and proofs:

> At all levels, students will reason inductively from patterns and specific cases. Increasingly over the grades, they should also learn to make effective deductive arguments based on the mathematical truths they are establishing in class. (NCTM, 2000, p. 59)

Several characteristics of reasoning are evident in the description given.

> People who reason and think analytically tend to note patterns, structure, or regularities in both real-world situations and symbolic objects; they ask if those patterns are accidental or if they occur for a reason; and they conjecture and prove. Ultimately, a mathematical proof is a formal way of expressing particular kinds of reasoning and justification. (p. 56)

The asking if patterns are accidental or if they occur for a reason parallels the Norwegian curriculum's "pupils shall understand that mathematical rules and results are not random, but have clear and logical grounds" (Kunnskapsdepartementet 2019b, p. 3) but for the NCTM reasoning includes deciding if a pattern occurs for a reason, while the Norwegian curriculum is more narrowly focused on rules and results that have reasons.

The NCTM associates reasoning with analytic thinking, though what the distinction is between them is not clear. Later the *Reasoning and Proof* standard states "Classrooms in which students are encouraged to present their thinking and in which everyone contributes by evaluating one another's thinking provide rich environments for learning mathematical reasoning" (NCTM, 2000, p. 57). This further suggests a link to a mental activity.

The NCTM is also explicit about what 'proof' means; the Norwegian curriculum does not mention 'proof'. For the NCTM there is an emphasis on proofs being formulated and expressing a particular kind of reasoning, which the passage quoted earlier (from p. 59) suggests is deductive reasoning.

For the NCTM, reasoning is related to understanding.

> Being able to reason is essential to understanding mathematics. By developing ideas, exploring phenomena, justifying results, and using mathematical conjectures in all content areas and—with different expectations of sophistication—at all grade levels, students should see and expect that mathematics makes sense. (NCTM 2000, p. 56)

Similarly, the Norwegian curriculum states "The pupils shall formulate their own reasoning to understand" (Kunnskapsdepartementet 2019b, p. 3).

Summary

The word 'reasoning' in the NCTM Standards is used more broadly than in the Norwegian curriculum. It includes not only giving reasons, but also making conjectures. These two activities are associated with deductive and inductive reasoning, respectively. Proof is formulated deductive reasoning. As in the Norwegian curriculum, in the NCTM Standards, 'reasoning' is connected to a mental activity, to understanding, and to finding the reasons underlying a pattern, rule or result.

The KMK Standards

In 2003 and 2004 The Standing Conference of the Ministers of Education and Cultural Affairs of the Länder in the Federal Republic of Germany (KMK) issued educational standards for mathematics for the different German school forms. The first one, issued in 2003 for middle schools ending at Grade 10, is my focus here.

The KMK Standards are structured into competences, analogous to the NCTM's Standards and the Norwegian curriculum's core elements. They are *Argumentation, Problem solving, Modelling, Using representations, Dealing with symbolic, formal and technical elements,* and *Communication*. The names of these strongly parallel the names of the NCTM Standards with the exception of *Modelling* (which the NCTM calls *Connections*) and *Argumentation* (which the NCTM calls *Reasoning and Proof*).

The naming of the *Argumentation* competence reveals an interesting linguistic difference between German, English and Norwegian. German has not adopted a word based on the French *raisonner,* and it seems to lack a direct equivalent. Possible translations for the verb 'to reason' include *schlussfolgern* (to conclude) and *begründen* (to give reasons for, to justify). The noun form 'reasoning' can be translated as *logisches Denken* (logical thinking), or *Argumentation* (argumentation). It is interesting that the question "How is the word 'reasoning' used in the KMK Standards?" can be answered briefly "It isn't", and also that the question cannot even be asked in German.

However, we can compare the use of *Argumentation* in the KMK Standards to the use of 'reasoning' elsewhere. The *Argumentation* competence states that:

> Mathematical argumentation … includes:
>
> - Posing questions that are characteristic of mathematics ("Does there exist ...?", "What changes if...?", "Is that always so?") and expressing justified conjectures,
> - Developing mathematical arguments (such as explanations, justifications and proofs)
> - Describing and justifying solution methods. (p. 8, my translation, original in Appendix)

Conjecturing, or at least expressing and justifying conjectures, is included under *Argumentation*, similarly to the NCTM's *Reasoning and Proof*. Developing mathematical arguments and describing and justifying solution methods are both found in both the Norwegian curriculum and the NCTM Standards. Those documents, however, include references to "chains of thought" (Kunnskapsdepartementet, 2019b, p.3) and students presenting "their thinking" (NCTM, 2000, p. 58). These refer to the mental process of reasoning. The KMK Standards, however, do not mention this process and instead focuses on the observable social product of reasoning.

The three kinds of argument named: explanations, justifications and proofs ("Erläuterungen, Begründungen, Beweise" in the original, KMK, 2003, p. 8), suggest different goals for an argument: explaining, justifying, and doing so in a way acceptable to the mathematical community. However, these terms are themselves not defined, and so this connection to goals might not have been what the authors had in mind. If this is what is intended, then these goals overlap with those expressed in the

Norwegian curriculum. which refers to “understanding”, ”give grounds” and “prove” (Kunnskapsdepartementet, 2019b, p. 3). Similarly, the NCTM Standards (2000) state that “being able to reason is essential to understanding mathematics” and that “a mathematical proof is a formal way of expressing particular kinds of reasoning and justification” (p. 56).

Conclusion

Examining the Norwegian curriculum and the NCTM and KMK Standards shows that one distinction Jeannotte and Kieran made, between processes related to the search for similarities and differences and processes related to validating, is also useful for describing a key difference between the Norwegian curriculum and the two Standards documents. In the Norwegian curriculum only processes related to validating are included under the core element *Reasoning and argumentation.* Processes related to the search for similarities and differences, such as conjecturing, are instead included under *Exploration and problem solving*.

Jeannotte and Kieran’s wider distinction, between processes and structures is also interesting, as only the NCTM Standards mentions different structures of reasoning, specifically inductive and deductive reasoning. This may be simply because the other two documents are much shorter.

One difference that Jeannotte and Kieran’s framework does not capture is that between the mental activity of reasoning and the social product of reasoning. This distinction is important in the Norwegian curriculum and reflected in the words used. Though the NCTM Standards uses ‘reasoning’ to refer to both the activity and the product, both are included in the descriptions. The KMK Standards, however, refer only to the product, as ‘Argumentation’. This activity/process distinction reflects most strongly the possible influence of language on the mathematics curriculum in this area. As Jeannotte and Kieran were working within a commognitive theoretical framework, which denies the existence of a split between mental activity and social discourse, it is not surprising that this distinction is not captured in their framework. It does, however, seem to be an aspect of the use of the word ‘reasoning’ in policy documents, and therefore worth attending to.

A final distinction not captured in Jeannotte and Kieran’s framework, but important in the policy documents, is the distinction between different goals of reasoning. The explicit listing of explanations, justifications and proofs as three kinds of arguments in the KMK Standards is also reflected in the other two documents, but seems impossible to capture in the categories listed by Jeannotte and Kieran. The goal of explanation, which is perhaps the most important in educational settings (Hanna, 1989) seems not to be included at all in Jeannotte and Kieran concept of ‘reasoning’.

To capture the way the word ‘reasoning’ is used in policy documents, it would be useful to add a fourth process, *explaining*, to Jeannotte and Kieran’s search for similarities and differences, validating, and exemplifying. Furthermore, some way to make a distinction between mental activities and social discourse seems to be needed. It is not evident how this could be added to Jeannotte and Kieran’s framework, except perhaps as a third aspect.

Appendix

The original text of the Argumentation competence in the KMK Standards is as follows:

Mathematisch argumentieren

Dazu gehört:

– Fragen stellen, die für die Mathematik charakteristisch sind („Gibt es ...?“, „Wie verändert sich...?“, „Ist das immer so ...?“) und Vermutungen begründet äußern,

– mathematische Argumentationen entwickeln (wie Erläuterungen, Begründungen, Beweise),

– Lösungswege beschreiben und begründen. (KMK, 2003, p. 8)

Changing the significance of argumentation and proof in final secondary school examinations – a comparison between Hungary and Thuringia

Kinga Szűcs

University of Erfurt, Faculty of Education, Department of Mathematics and Didactics of Mathematics, Germany; kinga.szuecs@uni-erfurt.de

Argumentation and especially proofs play a crucial role in mathematics as a science. To convey an authentic view of mathematics in school, arguments and proofs should play an important role in mathematics classrooms, too. Analysis of textbooks, curricula and examination tasks provide relevant insight into the role that proofs play in mathematics education. This paper compares the weight and the content of arguing and proving tasks in final secondary school examinations in two educational administrations which share similar recent political, social, and educational history.

Keywords: Secondary school mathematics, exit examinations, mathematics tests.

Introduction

Because of verifying mathematical knowledge, proofs play, without any doubt, an essential role in mathematics as a science (Hanna & Barbeau, 2008). Moreover, Rav (1999) emphasizes the unique value of proofs in mathematics, based on their function as a means for gaining and systemizing mathematical knowledge. He concludes: “Proofs, I maintain, are the heart of mathematics, the royal road to creating analytic tools and catalysing growth.” (ibid., p. 6). In addition, Heintz (2000) declares, proofs would constitute mathematics and, mathematics would define itself by proofs. In any case, demonstrating proofs must be only seen as one of the main activities in mathematics.

Among mathematics-education researchers, there is a consensus about the key role of proofs both in mathematics classrooms and curricula (e.g., Hanna, 2000; Harel, 2008; Mariotti, 2006; Nardi & Knuth, 2017). The reasoning behind this, however, can fundamentally differ. While Harel (2008), for instance, underlines the way of thinking which becomes manifest in proofs, Hanna (2000) emphasizes the function of promoting mathematical understanding. Beyond that, Nardi and Knuth (2017) point out an active view of learners and plead for proofs in school because they are “critically important to knowing and doing mathematics” (p. 267). Different reasoning, indeed, leads to pursuing various objectives as well as to varying implementations when teaching proofs in mathematics classrooms.

In particular, cross-national research on curricular documents, such as educational standards, curricula, and textbooks, can provide an essential contribution to detecting the above-mentioned differences in regard to the objectives and implementations of proofs in mathematics education. This approach was taken by Jones and Fujita (2013), who investigated the implementations of national curricula in the geometry chapters of textbooks in England and Japan. Despite noticing many similarities between the geometry curricula, they identified differences in the two countries regarding the treatment of proofs. Whereas in England a low ratio (6.9 %) of proof-related tasks was found, the ratio was much higher (26.2 %) in Japanese textbooks. This result can be explained by the fact that the Japanese curriculum explicitly stipulates proofs only for geometry, whereas the English curriculum requires them also in the domains of numbers and algebra. Based on a comparative analysis of textbooks, teacher guides of textbooks and curricula, Miyakawa (2017) identifies differences between France and Japan regarding the nature of proofs to be taught in geometry. He finds that implicit differences in geometry theory as well as in the principal function of proof related to that theory influence the nature of proof in geometry education. In addition, there is a wide range of national analyses of textbooks related to the role of proof, for example, in Australia (Stacey & Vincent, 2009), in the USA (Stylianides, 2009), and in Hong Kong (Wong & Sutherland, 2018).

According to Karp and Shkolnyi (2021), not only textbooks and curricula, but also final exams have a high impact on mathematics education. They also state that the scholarly literature related to final exams in mathematics is not extensive. Moreover, none of the reported studies in their very recent article is explicitly linked to argumentation or proof. With the cross-national study presented in this paper, the author aims to contribute to this research gap.

The final secondary school examination in Thuringia and Hungary

Even if during the last decades, emphases have changed several times in mathematics education, proofs still play an important role in Hungarian mathematics education. A similar development can be seen in Thuringia, these days a German federal state. Hungary and Thuringia share a very analogous recent history on the one hand, while having both experienced substantial changes to their educational systems about the same time, on the other. Following the political changes in 1989, the democratization of the school system took place in the 1990s in both places. For different reasons, a second transformation took place around 2005. In Germany, the Standards for the General Certificate of Secondary Education in Mathematics (Kultusministerkonferenz, 2004) were established, and all federal states started to implement them in their curricula. Meanwhile, Hungary established a new, modernised final secondary school exam in mathematics at that time (Lukács, 2006).

For better understanding of the current research, I describe in the following passage some essential changes, which were applied to the final secondary examination in mathematics in both places. Note that the final secondary exam is carried out in each place at different levels of ability and in different kinds of secondary schools. This paper focuses on the main group addressed by this type of examination: learners in grammar school (Gymnasium, gimnázium) taking a basic course in mathematics and taking the secondary school exam between 2001 and 2020.

Table 1 shows the changing of the main exam characteristics in both places over time. The data demonstrate different tendencies in Hungary and Thuringia: in Hungary, one main structural change took place in 2005, while the characteristics of the examination in Thuringia were changed stepwise. Both places, however, share the characteristics that at the beginning of the 2000s only complex tasks were assigned, whereas in 2020 a mixture of elementary and complex tasks characterize the examination in mathematics, the latter being (partly) elective. Elementary tasks (such as calculating the first derivative of a polynomial function) require only a few cognitive steps. In contrast, complex tasks (such as sketching a curve that is models an every-day problem) not only need the use of several cognitive steps but also often require combining different kinds of information. In addition, in Thuringia over the last twenty years, not only have the total exam points available increased twice, but also the length of time for the exam has been significantly extended.

Table 1: main characteristics of the final secondary school examination in mathematics

<table>
<tr><th>time period</th><th>Hungary</th><th>Thuringia</th></tr>
<tr><td>2001</td><td rowspan="2">180 minutes
total score: 80
6 complex tasks and 1 additional proving task</td><td>210 minutes, total score: 60
1 (out of 2) and additional 2 (out of 3) complex tasks</td></tr>
<tr><td>2002 – 2004</td><td rowspan="2">210 minutes (270´ from 2011), total score: 60
4 – 5 elementary tasks and 2 (each out of 2) complex tasks</td></tr>

total score: 100
12 elementary tasks and 2 (out of 3) additional complex tasks</td></tr>
<tr><td>2014 – 2016</td><td>270 minutes, total score: 60
7 – 8 elementary tasks and 2 (each out of 2) complex tasks</td></tr>
<tr><td>2017 – 2020</td><td>(270 in 2017) 300 minutes, total score: 120
7 – 8 elementary tasks 1 complex task and 1 (out of 2) additional complex task</td></tr>
</table>

Research questions

Against the background of the high significance of proofs in mathematics as a science as well as in mathematics education, this paper investigates, to what extent has been changed their weight and content in mathematics education in these two states. Such an analysis can give insight into the claims implemented in mathematics education and addressed to the learners at the end of their secondary education. The notions "argumentation" and "proof" are used in different ways in the related literature. However, in this paper both, mathematical argumentation and proof, are understood as realizations of reasoning in mathematics, based on Brunner (2014). The research presented in this paper was led by the following question: To what extent have the expectations at the end of secondary education related to mathematical argumentation and proof in Hungary and Thuringia been changed in the last two decades? Are the tendencies in those places similar? Which conclusions can be drawn about the role of proofs, based on the identified tendencies?

Methodology

The methodology used in the study was already successfully applied and detailed described in Szűcs (2021). A short summary of this is to identify temporal alterations based on existing tasks and guidance material for marking and evaluating. Documentary research was chosen as an appropriate method for data collection. In addition, qualitative content analysis, which allows for the systematic and theory-based processing of big textual data, was selected for data examination.

Documentary research

Original examination tasks, as well as the relevant guidelines for marking and assessment, are the primary sources of the study. *The nature of the source material* in the places that were researched is insignificantly different. Whereas examination tasks, including guidance material, are in the public domain in Hungary, this is not the case in Thuringia. However, materials for the whole period under analysis could be reconstructed in both places based on the public sources of the Hungarian Ministry of Education, on the unpublished sources of the Thuringian Ministry of Education and, on the information available from task developers (Fried, 2004; Skorsetz, 2005). However, based on the authority of the providers, we can conclude, that all sources are authentic, reliable, and trustworthy.

Structuring qualitative content analysis

Since models and categories related to argumentation and proof in mathematics already exist, a special type of qualitative content analysis, the so-called structuring qualitative content analysis, was deemed to be appropriate. In addition, this method is particularly useful for identifying temporal tendencies, which is extraordinarily relevant for the current research questions.

Table 2: excerpts from the encoding manual

category	**reasoning with mathematical tools**
definition	Argumentation is based on mathematics, but not necessarily on deductive steps.
standard example	Three books were taken from a bookcase and put back arbitrarily. […] Demonstrate, that it is not possible that exactly two of the three books are in the right place. (2009, part C, task e)
explanation	Systematic testing of all ways is possible.
encoding rule	Reasoning based on concrete examples is possible and productive.
category	**logical reasoning with mathematical tools**
definition	Deductive steps are identifiable, but they are not necessarily formal.
standard example	Three points, A (3;0;5), B (6;4;3) and D (0;4;3) are given, in a Cartesian coordinate system. Show that A, B and C explicitly determine a plane ε. (2001, part 2.1, task a)
explanation	Definition of linear dependence and vectors must be deductively applied.
encoding rule	Deductive application of definitions, theorems and methods is needed, but no formal proof.
category	**formal-deductive proof**
Definition	formal chain of deductive steps
Standard example	(a_n) is a sequence of numbers with $a_n = \frac{n+1}{n}$, $n \in \mathbb{N}$ and $n \geq 1$. Show that (a_n) is not a geometric sequence. (2002, part C, task a)
explanation	Formal notation and, the generality of the claim suggest that a formal proof is expected.
encoding rule	Requirement of a formal proof must be recognized.

To determine *basic material,* it is necessary to define the terms “argumentation” and “proof”. A viable definition of argumentation, which includes the notion “proof”, was given by Schwarzkopf (2000). It means a social interaction in school, in which a need for reasoning is indicated, and afterwards, this need is tested to be satisfied. According to this, all examination tasks have been rated as argumentation tasks, in which a need for reasoning was clearly indicated, meaning tasks contained verbs such as “show”, “reason”, “prove” etc. Note that searching for keywords is a popular method to identify argumentation tasks when analysing textbooks (Mariotti et al., 2018). The set of tasks containing at least one of the listed verbs is called the basic material. A *set of categories* has been specified, according to Brunner (2014). She identifies four categories based on the cognitive level needed for reasoning in mathematics classrooms, which enables a qualitative differentiation between the expected arguments. Excluding the type “everyday-arguing”, the following three types have been applied to the data: reasoning with mathematical tools, logical reasoning with mathematical tools and, formal-deductive proving. The *encoding* was carried out as follows: Each coded text passage was mapped to one of the three categories. This mapping process was supported by the information given in the guidance material. Table 2 shows excerpts from the encoding manual; the tasks have been translated into English by the author of this paper.

After encoding, *results were prepared* as follows: Based on the marking instructions, the score of each argumentation task, and its related mathematical domain were recorded. The total score of each category was calculated for each year and, afterwards, their proportion of the whole exam was determined. Tasks of choice, in the meaning of alternatives, were noted. Scores of the three categories added up to a total argumentation score for each year. Within this total score, the proportion of each mathematical domain was also calculated. Table 3 gives insight into this process, based on the Thuringian data from 2002.

Table 3: Encoding the arguing tasks from Thuringia in 2002

year	task	category	score		proportion of the exam	domain
2002	part A1, task b	log. reasoning with math. tools	1	average: 1.5 (A1 and A2 alternatives)	2.5 %	calculus
	part A2, task a	log. reasoning with math. tools	2			calculus
	part C, task a	formal-deductive proof	2		3.3 %	calculus
	total of argumentation tasks		3.5		5.8 %	

Results

Comparison of the changing of quantitative aspects in the final secondary school examination

Tendencies related to the volume of argumentation tasks and the type of reasoning are shown in Figure 1. The data suggest – similarly to the findings of Miyakawa (2017) – that there are differences in the nature of argumentation tasks between Hungary and Thuringia, which can be traced back to different implicit views on mathematics. In Hungary, before the new examinations in 2005, a high proportion (15.31 %) of argumentation tasks was present and, those tasks required only formal-deductive proofs. However, the introduction of the new exam led not only to the halving of the proportion of these tasks (7.75 %) but also to the complete absence of formal-deductive proofs. Hungary experimented between 2005 and 2016 by addressing argumentation tasks, which do not require deductive reasoning but gave up on that in 2017. Hungary seems to be a country, in which proofs in school mainly have the function of demonstrating a specific, deductive way of thinking (Harel, 2008). In Thuringia, in contrast, formal-deductive proofs did not play an important role in the period under investigation. However, the proportion of argumentation tasks was relatively constant over the time in question (12.7 %–15.8 %) and increased in the last four years to over 20 %. The proportion of tasks requiring logical reasoning with mathematical tools varies between 5.8%–14.5%, but they are complemented by an increasing number of tasks requiring reasoning with mathematical tools. Thus, it could be inferred that argumentation plays an important role in Thuringia, too, but the focus is more on applied mathematics.

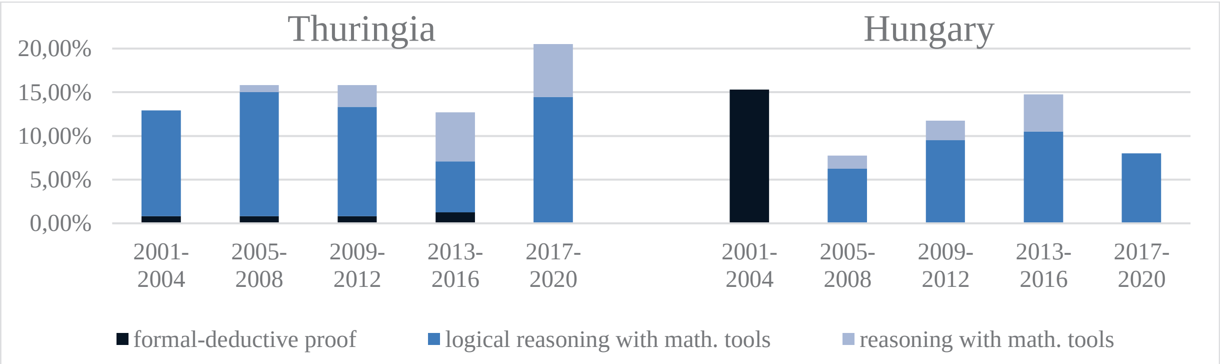

Figure 1: changing of the types of reasoning in final secondary school examinations over time

Comparison of the changing of qualitative aspects in the final secondary school examination

The above-described quantitative tendencies regarding the type of reasoning also have a qualitative component. Changes related to the specific mathematical domains are presented in Figure 2. Each percentage expresses the proportion of the score of the domain related to the total score of argumentation tasks.

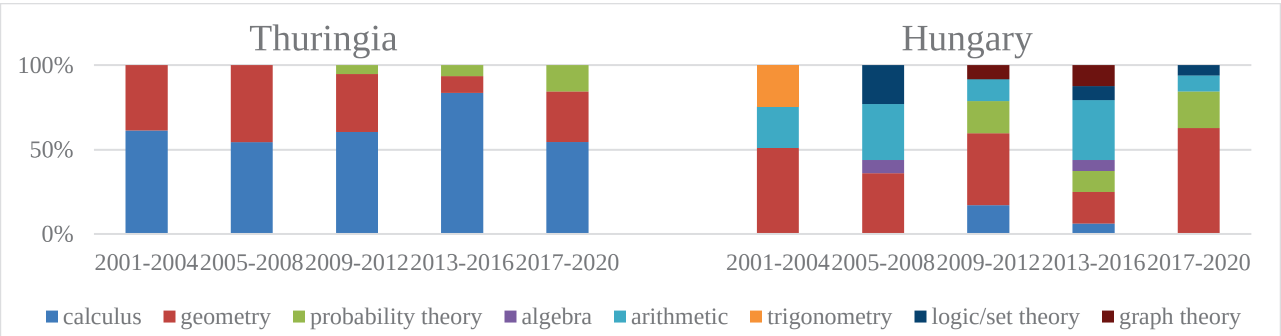

Figure 2: changing of the mathematical field of reasoning tasks over time

Significant differences between the two places in the study can also be observed regarding domains. Whereas only three mathematical domains are used in Thuringia, the argumenation tasks in the final secondary school examination in Hungary become more varied over time, covering up to seven different domains. Furthermore, calculus dominates constantly in Thuringia, but it is barely evident in Hungary. In addition, while geometry is noticeable but not dominant in Thuringia, it is the main mathematical domain of argumentation in Hungary. Mathematical reasoning is more spread across various domains in Hungary than it is in Thuringia. These findings are similar to the results which compare England and Japan (Jones & Fujita, 2013) and can traced back to different values of the final secondary school exam in those two places: Whereas this type of examination rounds upper secondary school education in Thuringia, it finishes the entire secondary education in Hungary.

Summary and open questions

Even if argumentation and proof form the main parts of mathematics as a science leading to the view that they should play a key role in mathematics education, they are only moderately included in final secondary school examinations in Hungary and in Thuringia. Especially alarming is the fact that formal-deductive proofs currently play no role in those examinations. However, slightly different routes led to the current situation: In Hungary, formal-deductive proofs disappeared after the structural change of the exam in 2005, while they have never been focused on in Thuringia. Moreover, mathematical reasoning is spread across more various mathematical domains in Hungary than it is in Thuringia. These results may allow us to infer different views of mathematics in the two places. However, further analysis of curricula, textbooks and classroom activities would be needed to investigate those views and confirm this inference.

Chinese teachers' professional noticing of students' reasoning in the context of Lakatos-style proving activity

Despite the pedagogical values of Lakatos-style proving activity in school mathematics, little is known about how teachers react to students' reasoning in this kind of activity. As an attempt to unpack the underlying decision-making processes, this study examines teachers' noticing of students' justification and refutation of conjectures in the context of Lakatos-style proving activity. Twelve Chinese pre-service and in-service secondary mathematics teachers participated in semi-structured, vignette-based interviews where they were presented with realistic classroom scenarios. These were based on actual classroom episodes reported in the literature and covered various aspects of Lakatos-style reasoning in the context of geometry. Findings show that teachers can better notice students' justifications than students' refutations, and better notice students' valid arguments than invalid arguments. Key themes are identified to characterise their noticing of various student arguments.

Keywords: Proof, Lakatos, Justification, Refutation, Professional noticing.

Introduction

In the form of fictional classroom discussion, Lakatos (1976) described how mathematicians constructed and utilised mathematical knowledge through a zig-zag reasoning process. Some aspects of Lakatos-style reasoning, such as conscious guessing and the zig-zag path of reasoning, were suggested by mathematical educators (e.g., Lampert, 1990) to be applied in some school mathematical activities for engaging students in authentic mathematics. Some empirical studies also showed that school-age students can perform in line with Lakatos-style reasoning, but most of them paid attention to students' proving processes (e.g., Komatsu, 2016; Reid, 2002), while few studies focused on the role of teachers. It remains unclear how teachers deal with various types of students' responses throughout different phases of Lakatos-style proving. To address this research gap, one promising attempt is to investigate teachers' professional noticing by focusing on how they pay attention to and make sense of particular instructional situations (Jacobs et al., 2010). We explore teachers' professional noticing of students' reasoning in the context of Lakatos-style proving activity. In this paper, we focus specifically on how teachers notice students' uses of examples and counterexamples during the justification and refutation of conjectures, which potentially can inform students' further refinement of the conjectures or proofs thereof.

Theoretical framework

Lakatos-style proving process

Using Lakatos' (1976) book and some mathematics education studies that discussed the implementation of his approach in school mathematics (e.g., Reid, 2002; Komatsu, 2016; Deslis et al., 2021), we identified five phases of the Lakatos-style proving process to capture some aspects of Lakatos-style reasoning: First, a conjecture is formulated through conscious guessing (Phase 1). Then the conjecture is tested through examination of supportive examples (Phase 2). A proof may be constructed to further validate the conjecture (Phase 3). Yet, counterexamples may emerge that refute the conjecture or the respective proof (Phase 4), thus necessitating the refinement of the conjecture or the proof (Phase 5). Note that Lakatos' philosophy is more complex than this 5-phase framework. It also emphasises other aspects (e.g., the crucial role of the interplay between defining and proving).

Justification and refutation schemes

We utilised a framework of students' justification and refutation schemes to conceptualise how students justify and refute conjectures in diverse ways, reflecting different degrees of mathematical sophistication. This framework was constructed drawing on previous research on students' proof schemes (Balacheff, 1988; Harel & Sowder, 1998; K. Lee, 2016; Stylianides & Stylianides, 2009; Deslis et al., 2021). There are four levels of justification schemes. Students at the lowest level (Naïve empirical justification) believe that examining a few examples which are easy to check (e.g., examining the example "x = 1" for validating the conjecture "for any natural number, 2x is an even number") can prove a mathematical generalisation. Students at a higher level (Crucial experiment justification) also accept example-based proofs, but they believe that the examples need to be strategically identified following some rationale (e.g., examining a set of odd numbers "x = 1, 3, 5, 7, 9…" for the above-mentioned conjecture). Students at the next level (Nonempirical justification) believe that it is not sufficient to validate a conjecture based on a subset of examples, but unlike students at the most advanced level (Deductive justification), they may not recognise the role of deductive inferences in proof. There are also four levels of refutation schemes. Students at the least advanced level (Naïve refutation) regard counterexample(s) as exception(s), and still consider a conjecture to be true regardless of the existence of counterexample(s). Students at the next level (Empirical refutation) think it is insufficient to refute a conjecture based on a single counterexample and need to see more counterexamples to be convinced that the conjecture is false. Students at the next level (Single counterexample refutation) believe that it is sufficient to refute a conjecture based on a single counterexample. Students at the most advanced level (General counterexample refutation) accept the sufficiency of a single counterexample in refuting a conjecture and recognise further that identifying the common properties of counterexamples can support the refinement of the conjecture.

Noticing

Despite various conceptualisations of teacher noticing, it is generally considered to involve at least two components, *Attending* and *Interpreting* (e.g., Es & Sherin, 2008). Jacobs et al. (2010) additionally introduced a third component, *Deciding*, which works with the other two components in integrated ways to lay the foundation for teachers' responses to students' mathematical thinking. This idea has been used in much later research (e.g., M. Y. Lee & Francis, 2018). Following Jacobs et al.'s (2010) conceptualisation, we define teacher professional noticing as an integrated set of three key processes: (1) selectively *attending* to noteworthy students' strategies in particular instructional events; (2) *interpreting* students' understanding reflected in these strategies; and (3) *deciding intended responses* to students (as opposed to executing actual responses).

Research methods

Data were drawn from semi-structured interviews with twelve Chinese teachers. For a diversity of teacher profiles, these participants included four pre-service teachers, four novice teachers with an average of 2.75 years of teaching experience, and four experienced teachers with an average of 17.75 years of teaching experience in junior high school for students aged 12-15. They were recruited through convenience sampling.

The one-hour interviews were conducted online. The participants were presented with a set of classroom vignette episodes showing how students solved a geometric proof task (see Figure 1). These episodes were adapted from actual classroom scenarios reported in Komatsu et al.'s (2014) research on Lakatos-style proving, guided by the above-mentioned theoretical frameworks. They reflect the five phases of Lakatos-style proving and diverse students' understandings in a format of classroom discussion, trying to make the episodes sufficiently realistic to elicit teachers' responses in the context of Lakatos-style activity (Skilling & Stylianides, 2020). We chose to present teachers with comic-style episodes because Lakatos-style proving activity is believed to be scarce in existing Chinese classrooms. Also, comic-style episodes allowed us to provide participants with sufficiently realistic but also abstract enough information, aiming to direct their attention to critical aspects of the classroom practices of interest, and allow them to form their interpretations of such context (Herbst et al., 2011). Note that we did not study what teachers actually noticed in real classrooms. Instead, we attempted to explore what they might notice in the context of Lakatos-style proving activity.

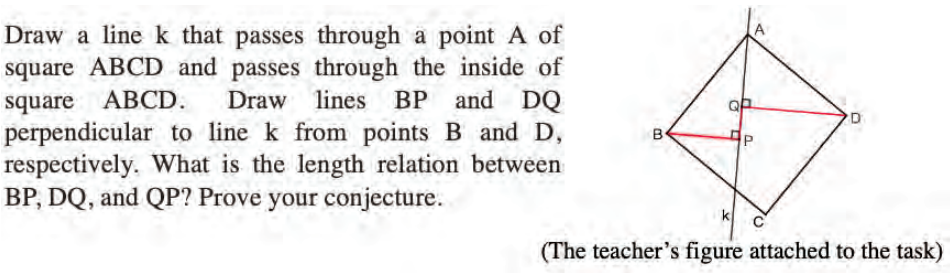

Figure 1: The geometric proof task (Komatsu et al., 2014) presented in the vignette episodes

Based on the above rationales, we designed eleven episodes around this proof task, among which there were four episodes about justifications and four episodes about refutations of the conjecture (i.e., irrespective of the position of line k, PQ = DQ − BP). These eight episodes respectively reflected each level of Justification and Refutation schemes, covering Phases 2-4 in the Lakatos-style proving process. Figure 2 shows two sample episodes translated from Chinese to English.

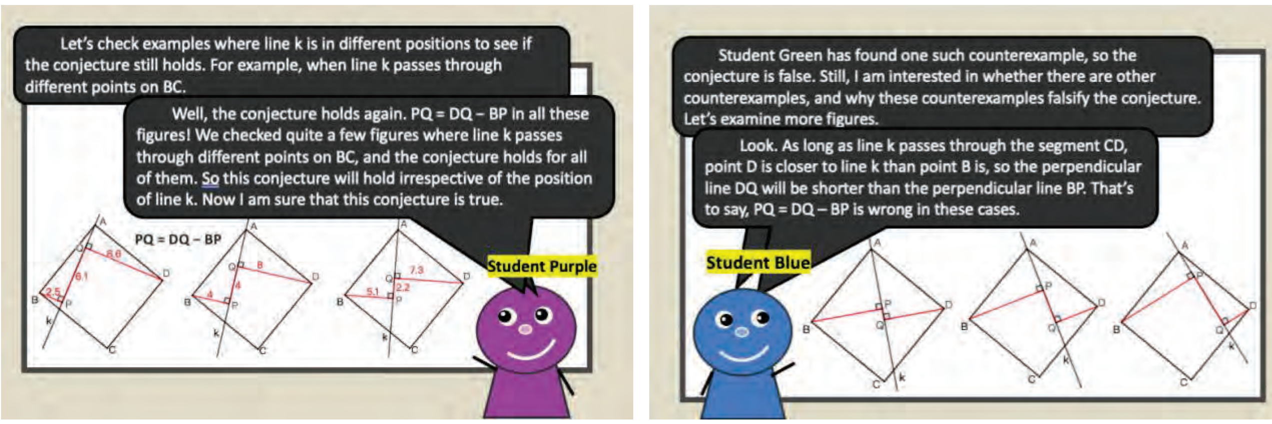

Figure 2: Crucial experiment justification (Left) and General counterexample refutation (Right)

After seeing each episode, participants were asked to describe (i) the students' thinking and/or actions that they attended to, (ii) how they interpreted the students' understandings, and (iii) how would they respond to the students, corresponding to the *Attending*, *Interpreting*, and *Deciding* aspects of teachers' professional noticing. Following Jacobs et al.'s (2010) coding scheme of teacher noticing, teachers' responses were coded based on the extent of evidence that teachers demonstrated in their consideration of students' reasoning. Specifically, responses about the *Attending* aspect were coded on a 2-point scale: Evidence (1) and Lack of evidence (0), and responses about the *Interpreting* and *Deciding* aspects were coded on a 3-point scale: Robust evidence (2), Limited evidence (1), and Lack of evidence (0) (Jacobs et al., 2010). After coding teachers' responses into the various categories, emerging themes were identified for each category to capture its characteristics (Corbin & Strauss, 1990). Double counting was applied for responses that related to more than one theme.

Findings

Overview of teachers' professional noticing

To capture participants' noticing of students' justifications and refutations, mean scores of the *Attending, Interpreting,* and *Deciding* aspects were calculated for each of 8 episodes. Given that the two lower levels and the two higher levels of Justification and Refutation schemes describe students' invalid and valid reasoning, respectively, we calculated the average scores of each pair of levels as a more stable measure of teachers' noticing of (in)valid justification/refutation arguments (Table 1).

Participants had on average higher scores in noticing students' justifications than refutations, across each aspect of teacher noticing – Attending (0.75 vs. 0.54), Interpreting (1.29 vs. 1.13), and Deciding (1.31 vs. 1.29). Although participants showed the same averages (1.29) in interpreting students' valid and invalid justifications, they showed higher averages in attending to (0.96 vs. 0.54) and deciding how to respond to (1.42 vs. 1.17) students' valid justifications than invalid justifications. A similar pattern emerged from participants noticing of students' refutations.

Table 1: Means (SD) for teaches' scores of noticing students' justification and refutation

Component skill (Scale)	Justification			Refutation		
	Invalid	Valid	Overall	Invalid	Valid	Overall
Attending (0-1)	0.54 (0.51)	0.96 (0.20)	0.75 (0.44)	0.46 (0.51)	0.63 (0.49)	0.54 (0.50)
Interpreting (0-2)	1.29 (0.55)	1.29 (0.46)	1.29 (0.50)	1.13 (0.68)	1.13 (0.54)	1.13 (0.61)
Deciding (0-2)	1.17 (0.56)	1.42 (0.65)	1.31 (0.59)	1.08 (0.65)	1.50 (0.66)	1.29 (0.68)

To supplement the average scores and give a more complete picture of teacher noticing, Table 2 shows the number of teacher responses which were coded as showing different extents of evidence.

Attending to students' strategies

Regarding the *Attending* aspect, responses with evidence mentioned exact mathematically important details of specific students' strategies, as described by our theoretical framework. Most participants gave evidence of attending to students' justifications, except to a student's Crucial experiment justification. Meanwhile, most participants demonstrated evidence of attending to Single counterexample refutation, but they did not demonstrate evidence of attending to other types of refutation. This may explain partly why participants had higher averages in attending to students' justifications, especially valid justifications, than other types of student reasoning.

Table 2: Number of teacher responses which were coded as showing the different extent of evidence

	Justification (Total: 48 teacher responses)		**Refutation** (Total: 48 teacher responses)	
	Invalid (Total: 24)	**Valid** (Total: 24)	**Invalid** (Total: 24)	**Valid** (Total: 24)
Attending	Evidence (N=13) Lack of evidence (N=11)	Evidence (N=23) Lack of evidence (N=1)	Evidence (N=11) Lack of evidence (N=13)	Evidence (N=15) Lack of evidence (N=9)
Interpreting	Robust evidence (N=8) Limited evidence (N=15) Lack of evidence (N=1)	Robust evidence (N=7) Limited evidence (N=17)	Robust evidence (N=7) Limited evidence (N=13) Lack of evidence (N=4)	Robust evidence (N=5) Limited evidence (N=17) Lack of evidence (N=2)
Deciding	Robust evidence (N=6) Limited evidence (N=16) Lack of evidence (N=2)	Robust evidence (N=12) Limited evidence (N=10) Lack of evidence (N=2)	Robust evidence (N=6) Limited evidence (N=14) Lack of evidence (N=4)	Robust evidence (N=13) Limited evidence (N=9) Lack of evidence (N=2)

Among the lack-of-evidence responses, some of them omitted mathematically important details of the students' strategies. This characteristic was evident in 8/12 teacher responses to a student's Crucial experiment justification. To illustrate, 7 teachers mentioned that this student tested *more examples* compared to another student who only tested one example, but they did not comment on the unique feature of this student's reasoning, that is, the *strategic selection* of examples. Some other lack-of-evidence responses included information that was inconsistent with the students' strategies. This was notable in teachers' responses to students' invalid refutations (9/24). For example, regarding the episode about Empirical refutation, 3 teachers wrongly noted that the student wanted to find *all* counterexamples, whereas the student just suggested finding *more* counterexamples.

Interpreting students' understandings

Concerning the *Interpreting* aspect, robust-evidence responses exactly described what the students did and did not understand (as suggested by our theoretical framework), citing details of the students' mathematically important strategies. Eight participants gave robust-evidence responses for interpreting a student's Naïve empirical justification. Yet, when interpreting other types of student arguments, no more than 4 participants provided robust evidence. This may partially explain teachers' slightly higher average scores in interpreting justifications (1.29) versus refutations (1.13).

The majority of limited-evidence responses omitted some details of students' (mis)understandings. This characteristic existed in more than half of teachers' responses, except those for interpreting Naïve empirical justification and Empirical refutation. For example, when interpreting a student's General counterexample refutation, a teacher expressed appreciation of this student's idea of comparing three counterexamples to examine the conjecture, but she did not elaborate on this idea.

Some limited-evidence responses contained descriptions inconsistent with specific student strategies, although they precisely mentioned some (mis)understandings of these students. To illustrate, commenting on a student's Empirical refutation, a teacher said this student's idea (i.e., finding more counterexamples so that we can be convinced) was acceptable in refutations, although she also mentioned that using one counterexample can already refute the conjecture. By contrast, another teacher misinterpreted that this student would like to test *all* counterexamples, and all descriptions this teacher provided were inconsistent with the student's strategy details. This was unclear whether this teacher understood the student's strategy, so this response was coded as "Lack of evidence".

Some teachers' limited-evidence responses contained descriptions as if based on teachers' assumptions rather than on the vignette provided. For example, a teacher assumed that the student with Naïve refutation ignored the counterexample because "this student was stubborn and was not willing to hear others' ideas", but this was hard to justify based on what the student said.

Deciding how to respond based on students' understanding

Around half of the teacher responses for valid justifications (12/24) and refutations (13/24) gave robust evidence when deciding how to respond to a student, while much fewer responses for invalid justifications (6/24) and refutations (6/24) showed robust evidence. In these robust-evidence responses, teachers demonstrated explicit consideration of the students' reasoning and how their proposed responses could further these students' thinking (as suggested by our theoretical framework). For example, in a robust-evidence response for a student's Crucial experiment justification, a teacher made use of one mathematically important aspect of this student's strategy (i.e., asking the student to analyse common properties of these strategically identified examples) to facilitate the student's progression from testing examples to giving a proof:

> Teacher: I will appreciate the student's spirit of exploration, and I will remind him these are only some examples…The student needs to learn how to analyse…whether there are common properties among different figures (i.e., examples). If there are, can we start proving this conclusion with geometric proof? He has drawn a lot of figures, and we need to find their common properties.

Limited-evidence responses demonstrated teachers' uses of students' reasoning in deciding how to respond but in a general or unproductive way. To illustrate, 4/12 teachers proposed very similar responses (e.g., simply asking students to give a proof) for students' Naïve empirical justification and Crucial experiment justification, even though both types of student reasoning indicated different levels of mathematical sophistication (as reflected in students' way of identifying examples to validate the conjecture). Some teachers suggested to the student who ignored the counterexample (Naive refutation) to find more counterexamples or accepted the idea of the student with Empirical refutation to find more counterexamples, in order to convince both students that this conjecture was refuted. But they did not remind the students that one counterexample can already refute the conjecture, and this was not conducive to students' development of refutation ability.

Unlike responses with robust or limited evidence, lack-of-evidence responses cited few or no details of the specific students' reasoning (e.g., "I will let the student think more and then examine based on his idea…I think it will be better if I allow students to inquire rather than directly telling them the answers"), leaving open the question of whether teachers consider these students' reasoning.

Discussion and Conclusion

To conclude, our results show that teachers may be less able to notice students' refutations than justifications. When the students in our vignettes gave invalid arguments (regardless of whether for justification or refutation), teachers were less likely to attend to and decide how to respond to their thinking. Noticing with non-robust-evidence may hinder teachers from making use of students' reasoning to engage students in Lakatos-style zig-zag processes of conjectures, proofs, and refutations.

For instance, many participants noticed that compared to the student with a Naïve empirical justification, the student with a Crucial experiment justification tested more examples. Yet, they did not point out that these examples were strategically identified. In other words, teachers may be sensitive to whether students' reasoning is example-based, but they may pay limited attention to and interpretation of students' ways of identifying supportive examples. Their neglect of such a mathematically important strategy may partly explain why some teachers suggested to both students a very similar next step (i.e., directly asking them to switch from example-based reasoning to giving a proof), without using each student's existing reasoning as a starting point for his/her further development. By contrast, like a teacher's robust-evidence response that we quoted above, one productive use of a student's Crucial experiment justification can be letting this student analyse the common properties of the strategically-identified examples for the further construction of a proof.

For students' refutations, despite the wide recognition of the role of a single counterexample in refutation, some teachers still allowed or even encouraged students who had a Naïve refutation or an Empirical refutation scheme to examine more counterexamples to confirm the conjecture was false. This may not be conducive to students' understandings of the minimally necessary and sufficient way of refutations. Yet if teachers can emphasise the role of a single counterexample and meanwhile support students' investigation of more counterexamples to find out their common properties that refute the conjecture (as described by the General counterexample refutation), students may have opportunities to experience the process of refining a conjecture based on analyses of counterexamples.

Overall, this study constructs a picture of teachers' professional noticing of students' thinking in justification and refutation in the context of Lakatos-style activity, which was seldom investigated in previous research. This can help us (as a field) to better understand in such context how teachers attend to and make sense of students' justifications and refutations in different ways, which in turn may shape what learning opportunities teachers offer to students in the follow-up refinement of the proof or the conjecture. To better prepare teachers to implement Lakatos-style proving activity, further training on their professional noticing, especially their noticing of students' refutations and invalid justifications, is needed. Finally, we acknowledge Sherin and Star's (2011) critique of research on teacher noticing that we indirectly learn what teachers notice from what they express in their comments, but the underlying mechanism of teacher noticing is still unclear. In a further study, we will try to unpack such a mechanism by considering how teachers' views (e.g., their views of proofs, teaching proof, and noticing) condition teachers to notice.

Introduction

Learning and teaching arithmetic and number systems through activities in kindergarten and school is a relevant and broad field in mathematics education. In kindergarten, children start to develop a number concept of natural numbers with counting and subitizing. Primary school aims at evolving a deep conceptual understanding of numbers and basic arithmetic operations. The transition from natural numbers to rational numbers is a key challenge for mathematics education in the first years of secondary school. Only if students have a deep understanding of natural numbers, will they be able to develop conceptual understanding and procedural skills in rational numbers. Even if a great variety of topics comes with learning and teaching arithmetic and number systems there are common goals, such as developing conceptual understanding and building number- and structure-sense as foundations for flexibility in mental and written arithmetic operations. Research in arithmetic and number systems does not only focus on typical content, but also on models for teaching and learning, approaches for heterogeneous and inclusive classrooms, analogue and digital tools to support understanding, and, not to forget, teachers' competencies and cultural practices.

Working Group 2 was formed in 2011 and has developed as a forum for discussing theoretical and empirical research on the teaching and learning of arithmetic and number systems. Over the last decade, our work has aimed to acquire and enhance knowledge about students' understanding and meaningful learning in this content area regarding different ages and achievement levels. The scope of the TWG comprises kindergarten to 12th grade and emphasizes research-based specifications of domain specific frameworks, concepts and goals, analysis of learning processes and learning outcomes in different classroom cultures, as well as innovative teaching and diagnostic approaches that attend to both procedural and conceptual knowledge.

This year, we faced the same variety of topics as in previous conferences, but even more diversity in theoretical approaches and measurements. This was a great opportunity to negotiate our understanding of terms and clarify our theoretical and methodological approaches. The group intensively discussed 15 papers and 6 posters in the plenary whole group as well as in small groups.

Discussed papers and posters

The presented and discussed papers and posters can be pooled in four thematic groups: Number sense, understanding of basic ideas, strategies in mental arithmetic, teaching approaches and methodological approaches.

Number sense

Nathalie Bisaillon explores the role of groupitizing (the ability to recognize structured quantities without counting) in building internal representations of quantities to enhance students number sense. Three activities are presented to highlight the links between groupitizing skills, the construction of dynamic and imagistic mental representations and the comprehension of numeration. It is hypothesized that the use of these activities with 7–8-year-olds would enhance their number sense.

Brumm Leonie and Elisabeth Rathgeb-Schnierer present their initial study on comparing strategies in numerosity estimation in grade 3 students. Their interest focused on using two and three-dimensional tasks, and the relationship between strategies and task characteristics. The aim of the study is to reveal effective strategies which lead to high estimation accuracy according to the type of task. (poster)

Zübeyde Er and Perihan Dinç Artut investigate the strategies of gifted students in grade 5 in number sense problems. Twenty-one students undertook twenty-five questions in a number sense test where both opinions and answers were analysed. The results of this test revealed that the majority of strategies used are rule-based strategies not number sense based.

Elvira Fernandez-Ahumada, Natividad Adamuz-Povedano, Enrique Martinez-Jimenez and Jesús Montejo-Gámez present a review of instruments on assessment of number sense and mature number sense. The authors highlighted the existence of 10 instruments, of which the majority focused on the assessment of early number sense, mainly for ages between 3 and 8 years, while there are far fewer instruments for the assessment of the so-called mature number sense. (poster)

Astrid Junker investigates counting strategies of one first-grade student with a high proficiency in foundational number-sense (FoNS). A task-based, semi-structured counting interview was conducted with the aim to qualitatively analyze counting strategies. The results suggest that a student with proficiency in number-sense does not necessarily exhibit flexible counting strategies in the number range 10-20.

Pernille Bødtker Sunde and Judy Sayers investigate perspectives of six Danish first-grade teachers on teaching and learning number and addition. Data was gathered by a semi-structured interview with open-ended questions that allow to reveal teachers' emphasis in teaching on number. Data was analyzed based on the FoNS framework. The results show that teachers hardly mention estimation, quantity discrimination and number pattern when they report on their teaching practice in first grade.

Understanding of basic ideas

Marei Fetzer and Kerstin Tiedemann developed a theoretical approach in how to introduce multiplication to support children's understanding of this operation. The theoretical approach makes the distinction between basic ideas (Grundvorstellungen), strategies and representations of multiplication. The authors illustrate their approach through a German textbook example.

Aurelien Ovide, Lalina Coulange and Grégory Train examine the potentials of a specific approach for teaching and learning fractions. Data was collected throughout teaching experiments, one designed by Brousseau for 5th graders and others designed by the author for 8th graders. The results highlight the potential of commensuration meaning to enable students to access a broad conceptualization of multiplicative comparison relationships between fractions.

Strategies in mental arithmetic and flexibility

Claudia Corriveau, Doris Jeannotte and Sandrine Michot investigate how the way the manipulatives are used on a fraction task influence the students' reasoning. The methodological and analytical work is based on the concepts of affordance and didactic variables. The analysis shows that introducing familiar manipulatives in new tasks forces the students to develop new ways of doing and thinking.

Timo Flückiger and Elisabeth Rathgeb-Schnierer present the development and piloting of a standardized, semi-structured interview guide designed to capture second and third graders abilities in flexible mental calculations. This interview guide will allow for more generalizable conclusions on the cognitive elements sustaining the solution process based on students' explanations and justifications of solution methods. (poster)

Ioannis Papadopoulos and Michail Karakostas investigate students' strategy choices when performing mental and written fraction arithmetic. They find that the written algorithm was the preferred strategy in both mental and written calculations. The students' arguments for their choice of the algorithm was accuracy, speed and easiness, although the algorithm was in fact the most time-consuming strategy for all items.

Maria Pericleous investigates how a number line can be used as a vehicle for mathematical understanding. The author uses concept cartoons as a tool to support the role of the number line to foster and develop conceptual understanding of simple calculation strategies. Nineteen participants, ages 7-8 years old, engaged in whole class discussion drawing on their perceptions of constructing and reading open number lines.

Anders Månsson addresses the inter-coder reliability of three researchers when categorizing mental computation strategies of prospective elementary teachers (PETs). PETs' mental computation strategies were captured questionnaires (15 two-digit addition problems) and categorized by strategies described in literature. Based on the high consensus in categorization, the author concludes that the questionnaire and the categories are appropriate and reliable to investigate PETs' strategies.

Steven Van Vaerenbergh, Irene Polo-Blanco, Lara González-de Cos and Juncal Goñi-Cerveradeveloped investigate the strategies used by students with an autism spectrum disorder diagnosis when solving Cartesian product problems. An exploratory and descriptive investigation was conducted with 26 students (6-12 years). Results show a low success in solving problems by the participants, but a variety of correct strategies were found, predominantly operation strategies.

Cristina Zorrilla, Pedro Ivars, Ceneida Fernández and Salvador Llinares present a study in progress that aims to examine characteristics of the transition from natural to rational numbers when grade 6 students (11-12 years old) solve multiplicative structure problems. Data was collected throughout a teaching experiment (with three phases), a pre-test, an instruction, and a post-test. Preliminary results show different levels of success according to the numerical set used and the type of problem solved.

Teaching approaches

Silke Friedrich and Elisabeth Rathgeb-Schnierer investigate whether students work on open-ended tasks according to their learning and performance levels. This initial study compares 160 grade 3 students' attitudes and achievement levels in mathematics, compared to the complexity of the equations individuals created. Results suggest that those who scored highly in achievement tests invent particularly complicated equations. (poster)

Laura Korten presents the development of a diagnosis-guided support programme for primary school students with mathematical learning difficulties. The programme will be conducted by university students, which will stimulate, develop and refine their own fostering and supporting competences. Initial results suggest university students need specific criteria to enable them to support children's strategies more effectively. (poster)

Sze Man Yeung and Taro Fujita introduce and provides some examples of productive practices in the context of a study that aims to investigate how learning environments of productive practices can be embedded into the daily lessons as a part of the curriculum for basic skills and higher-order skills training. Number pyramids in a grade 2 classroom will be used, and students' mathematical thinking processes while doing productive practices will be analyzed. (poster)

Methodological approaches and tools

Mayu Akoi and Carl Winsløw pursue the aim of elaborating a large-scale model of an arithmetic curriculum. Based on the Anthropological Theory of Didactic they created an epistemological reference model for the entire domain of arithmetic in a Japanese primary school from grades 1 to 6. The model allows observed lessons to be evaluated in the context of the entire curriculum as well as the comparison of different curricula.

Einat Heyd-Metzuyanim, Avital Elbaum-Cohen and Michal Tabach introduce a tool for analyzing the arithmetic discourse of students. This tool allows to map students' participation in the discourse on a continuum between ritual and explorative. Therefore, the individual performance of a student is assessed based on eight characteristics (e.g., objectification, flexibility or focus on process or procedure) that enable to construct a ritual/explorative ratio.

Anna Lisa Simon, Benjamin Rott and Maike Schindler introduce the use of eye-tracking analysis to explore students' strategy use when naming and locating numbers on a marked number line. When measuring response time, they found that the use of reference points, e.g. gazing at the nearest reference point, was more efficient than strategies based on counting procedures, such as counting from the beginning of the number line.

Summary

The discussed theoretical and empirical projects show a huge variety, but also common goals for current and future research: We aim to investigae students' development of conceptual knowledge, number sense, flexibility and adaptive expertise in arithmetic. Additionally, we intend to develop and evaluate teaching approaches that lead to a deep understanding of arithmetic and number systems.

How to map larger parts of the mathematics curriculum? The case of primary school arithmetic in Japan

Mayu Aoki[1] and Carl Winsløw[2]

[1]University of Copenhagen, Denmark; mayu13ak@gmail.com

[2]University of Copenhagen, Denmark; winslow@ind.ku.dk

We present a methodological discussion of how to elaborate different scale epistemological reference models and in particular, present a large-scale model for the domain of arithmetic in Japanese primary school, based on the national program and selected textbooks. Our theoretical base is the Anthropological Theory of Didactic (ATD), specifically the notion of praxeology and the levels of didactic codetermination. We also briefly discuss our motivation for creating such models, namely to analyse how students experience shifts between mathematics in different school systems.

Keywords: Japanese arithmetic curriculum, An epistemological reference model, The Anthropological Theory of Didactic

Introduction

When we observe mathematics teaching in a classroom, we observe teachers and students interacting on tasks like “Let us think ways of calculating 12+3” or “Let us calculate 29 × 3” etc., normally introduced by the teacher; we may want to understand how the activity promotes various types of learning. Other questions may be difficult to answer from what we observe in the class, like: where do the specific mathematical tasks come from? Why do the students encounter difficulties? etc. In my doctoral research project, I am interested in pupils who attend (or attended) mathematics teaching in different school systems (Japanese, Swedish and Danish). For these and many other questions in educational research, we need to include information on conditions and constraints in a wider context, even if we just want to analyse the phenomena observed within certain classroom situations.

A metaphor may be useful here. The world map gives us a prices idea of the location of the countries we want to look for. For instance, we can see that Germany is located on the European continent and Kenya on the African continent. With a more detailed map, we can find out more details (e.g., what cities are there in Germany?). In other words, we are able to look up and compare since we have a map. Even when preparing a holiday in a small beach town, we need to know how it is situated in relation to other locations like airports and so on.

In the same way, when analysing a classroom episode on the teaching of addition of fractions in grade 3, to understand the actions of teachers and students, a wider “map” of the knowledge at stake in the subject (or even in the school institution) may be needed. The main point of the present paper is to show how the anthropological theory of the didactic (ATD) can be used to define different scales of such a “school knowledge maps” (also called epistemological reference models), and to develop a methodology for the specific purpose of creating “large scale” models that shows how a mathematical domain is structured over several school years within a specific school institution. Concretely, we present an epistemological reference model for the domain of arithmetic in Japanese primary school, along with a methodological discussion of how that model was produced, based on certain official documents along with textbook material. It is also a main point that the ATD allows us to connect such large-scale models directly with more detailed models of specific parts of the domain which are more commonly used in ATD analysis of classroom episodes.

Theoretical Framework and research question

Our study adopts the anthropological theory of the didactics (ATD) proposed by Yves Chevallard from the early 1980s (Bosch & Gascòn, 2006), more precisely, the notion of praxeology and the levels of didactic codetermination. According to ATD, any human knowledge and practice can be described by using the notion of praxeology. Praxeologies are made of a practical block: a type of task (T) and a technique (τ) and a knowledge block: a technology (θ) and a theory (Θ). In addition, Chevallard proposed the levels of didactic codetermination for researchers to identify conditions and constraints at different levels. The scale of levels of didactic codetermination are constituted of nine different levels: 1. *Subject* 2. *Theme* 3. *Sector* 4. *Domain* 5. *Discipline* 6. *Pedagogy* 7. *School* 8. *Society* 9. *Civilisation* (Bosch & Gascòn, 2006). Concretely, for instance, the quadratic formula, polynomial equations, polynomials, and algebra constitute a subject, theme, sector and domain, respectively (Artigue & Winsløw, 2010). The school subject of mathematics is a discipline. Higher levels determine all disciplines and will not be modeled here. The first three levels (1-3) are defined by praxeologies (Artigue & Winsløw, 2010). A subject corresponds to a few praxis blocks, while a theme and a sector are determined by a shared technology and a shared theory, respectively.

We can now formulate our research question for this study: How to elaborate an epistemological reference model for an entire domain of school mathematics, in the sense of the official domain to be taught in a given school system, when the model is required to cover several years of teaching, and still with a level of detail that would make it useable to situate a concrete teaching situation and to compare with how the domain is taught in other school systems? As a case (considered here), how to do this for the domain of arithmetic and grade 1-6 in Japanese primary school?

Note that this paper is mainly about how to develop a method based on a strong theoretical paradigm, and methodology is therefore more important in this paper than the products we exhibit from the concrete case mentioned in the research questions, in order to illustrate it our methodological approach.

Methodology 1: choice of data (and how to get the data)

Before describing the process of elaborating an epistemological reference model, we explain the selection of materials for the case, which could be similar (yet different) according to the context. There are two levels of official programs in Japan: a general course of study for primary school (SHOGAKKO GAKUSHU SHIDO YORYO) and a primary school *teaching guide* for the Japanese course of study in mathematics (SHOGAKKO GAKUSHU SHIDO YORYO KAISETSU SANSU-HEN). Both are issued by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The former includes the basic act of education, general educational goals, and an outline of contents for teaching in each discipline. By contrast, the latter is published in each discipline and contains more detail than the course of study. When more detail is sought, we consider also mathematics textbooks authorized by MEXT. These are published by commercial textbook companies, based on the first mentioned documents, and are selected and distributed by schools. The three levels of material are interconnected, and tightly aligned. The primary sources of our modeling approach are the teaching guide for mathematics (refered to in the sequel as the *program*), and one selected textbook series. The textbook is published by TOKYO SHYOSEKI publishing company, and is widely used both in Japan, and in the supplementary schools that will later be a main focus of our research. From the program, we mainly use a table that summarizes mathematical contents for teaching in each grade. This table is extremely useful for elaborating large-scale models since it specifies that, for instance, teaching addition and subtraction of 2-digit numbers occurs in grade 1. One can say that the table specifies the location of themes and sectors. Then, the textbook can be used to develop more detailed, local models (example given in table 2), in other words, at the subject level in terms of types of task and techniques. This is why we use the program rather than the general course of study to develop our models. It is also easier to model because what is shown in the general course of study school is similarly explained in the programme, with additional detail. In fact, we can elaborate the large scale model based on the program to some extent; however, textbooks are needed to specify more closely the types of task and techniques to be taught.

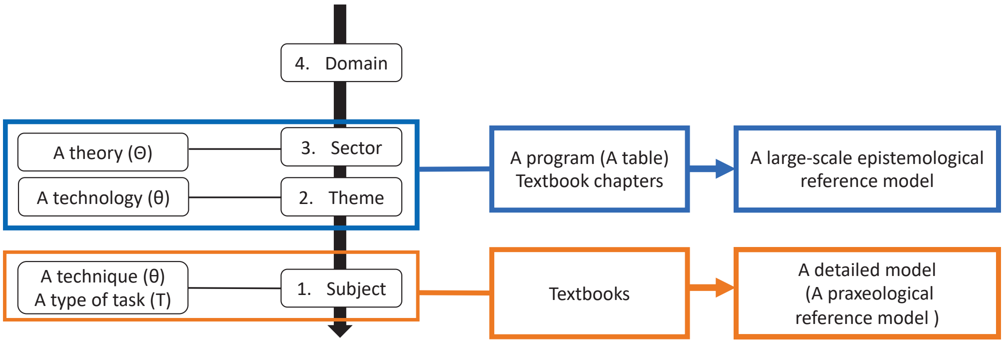

Figure 1: How to elaborate different scale models

The process of elaborating a large-scale epistemological reference model is then as follow:

1. Browse through the table for the domain of arithmetic, dividing it into sectors.
2. Identify themes within each sector from the table, and to clarify and substantiate these further, refer to the detailed description in the program and to practices exhibited in relevant textbook chapters.

The method of constructing detailed models of themes is then as follow:

1. Browse through relevant textbook chapters, and analyse all examples and exercises to identify types of tasks and the corresponding techniques; in conjunction with that, when we identify types of tasks and analyse techniques. (In Japan, as textbooks are strongly aligned with the program, it is justified for many purposes to base the model on just one textbook system.)
2. Whenever a task is encountered which does not belong to a type of task already identified, a new type is added to the model. The end result covers the theme in question.

The second part of our approach is similar to the one employed in the study by Wijayanti and Winsløw (2017). They elaborate praxeological reference models for certain themes related to proportion, as they appear in a range of different Indonesian textbooks. However, our method to categorize and situate different themes and sectors, is new.

Methodology 2: analysis of data (examples and overall outcomes)

We now present a large-scale epistemological reference model for the domain of arithmetic in Japanese primary school in grades 1-6 (Table 1), based on the above methodology. After the long table presenting the result, we provide further details of how the method was applied.

Table 1: An epistemological reference model 1 for the domain of arithmetic

Sector$_{1}$: Representation of (positive) rational numbers	Grade

Th.$_{2\text{-}19}$: Subtraction of 4-digit numbers			■			
Th.$_{2\text{-}20}$: Subtraction with decimal numbers (until 1/10)			■			

Th$_{.2-21}$: Subtraction with decimal numbers (until 1/100)						
Th$_{.2-22}$: Subtraction with fractions with the same denominator (total is less than 1)						
Th$_{.2-23}$: Subtraction with fractions with the same denominator (total is more than 1)						
Th$_{.2-24}$: Subtraction with fractions of the different denominator						
Th$_{.2-25}$: Subtraction using approximate numbers						
Th$_{.2-26}$: Subtraction using letter such as a, x						
Th$_{.2-27}$: Multiplication of 1-digit numbers (multiplication table)						
Th$_{.2-28}$: Multiplication of simple 2-digit numbers						
Th$_{.2-29}$: Multiplication (2-digit numbers or 3-digit numbers $\times$ 1-digit numbers or 2-digit numbers)						
Th$_{.2-30}$: Multiplication using approximate numbers						
Th$_{.2-31}$: Multiplication of decimal numbers in which a multiplier is whole numbers						
Th$_{.2-32}$: Multiplication of decimal numbers						
Th$_{.2-33}$: Multiplication of fractions						
Th$_{.2-34}$: Multiplication using letters such as a, x						
Th$_{.2-35}$: Division in which a divisor and a quotient are 1-digit numbers						
Th$_{.2-36}$: Division (simple calculation in which a divisor is 1-digit numbers, and a quotient is 2-digit numbers)						
Th$_{.2-37}$: Division using approximate numbers						
Th$_{.2-38}$: Division (calculation in which a divisor is 1-digit numbers or 2-digit numbers, and a dividend is 2-digit numbers or 3- digit numbers)						
Th$_{.2-39}$: Division of decimal numbers in which a divisor is whole numbers						
Th$_{.2-40}$: Division of decimal numbers						
Th$_{.2-41}$: Division of fractions						
Th$_{.2-42}$: Division using letters such as a, x						

In our model, representation with rationale numbers and operation with rational numbers were identified as the two sectors, corresponding to theories developed throughout the six years of primary school. This is because the domain of arithmetic is roughly divided into two parts in the table of the program: number and operations, and it is also justified by the details (roughly, themes) appearing in these parts. In Japan, negative numbers are taught only in secondary school. Hence, rational numbers do not include negative numbers in this context. Within the sector1 and 2, we identified twenty-one themes (for instance, representation of 3-digit numbers, Representation of fractions) and forty-two themes (for instance, addition with fractions of the different denominator), respectively, based on the table of the program. Table 1 shows in which grade(s) a given theme is to be taught.

We finally show a more detailed model of one particular theme: Addition of 1-digit numbers (Table 2), with types of tasks (T) and technique (τ), along with examples of tasks from the textbooks. This is the kind of model presented and used (more extensively) by Wijayanti and Winsløw (2017).

Table 2: A praxeological reference model of one theme: Addition of 1-digit numbers

Type of tasks	Technique	Example of task	
T_1: The addition of 1-digit numbers (cardinal numbers, cases of combination)	τ_1: Put the two sets or quantities together and count the result	t_1: Write the equation. We put 2 pencils and 5 pencils in the box. How many pencils do we have in total?	
T_2: The addition of 1-digit numbers (cardinal numbers, cases of increase)	τ_2: Counting up from an augend by the addend	t_2: Write the equation. There are 4 flowers in the vase. The girl puts 3 more flowers in there. How many flowers are there in total?	
T_3: The addition of 1-digit numbers (ordinal numbers).	τ_3: Converting a given ordinal number into cardinal number based on a figure, then use τ_2.	t_3: Sora is 6th from the front. Behind Sora, there are 4 people. How many people are there in total?	
Conclusion

In this paper, we have shown how ATD can be used to answer a methodological question: how to elaborate a large-scale model of a curriculum. As a concrete case we have shown different scale models for the domain of arithmetic in Japanese primary school. Such a model can be used, for instance, to precisely situate observations from a lesson in a larger context.More generally, the levels of codetermination (subject, theme, sector) and praxeologies allow us to elaborate different scale models and relate them to each other. We acknowledge that the form and characteristics of study programmes and textbooks may vary from country to country. For instance, our next step will be to develop similar models for the domain of arithmetic in primary school in Denmark. However, the Danish curriculum is (roughly speaking) less explicitly structured than the Japanese one; therefore, the precision of the model will be different. We will later use the model to address the main questions of my PhD project: how the domain of Japanese arithmetic, defined by MEXT, transposes to the Japanese supplementary school in Denmark (held on Saturdays), and how the students there experience it, as they attend Danish school on working days.

Taking advantage of groupitizing skills to better understand numeration

Nathalie Bisaillon

Université de Montréal, Canada; nathalie.bisaillon@umontreal.ca

Number sense is one of the pillars of arithmetic learning. Among other things, its acquisition allows to understand our numeration system. Understanding this numeration system remains a challenge for many students. The purpose of this theoretical essay is to explore the role that groupitizing might have in building internal imagistic and dynamic representations of quantities to help students better understand our decimal numeration system. Three activities issued from a didactic sequence will be presented. These activities are intended for students at the end of Grade 2 and the beginning of Grade 3 (ages 7-8) who are having difficulty with the concept of numeration. They were developed as part of our thesis.

Keywords: Number sense, Groupitizing, Internal representations, Numeration, Arithmetic learning.

Introduction

Number sense is a key part of learning arithmetic in elementary school. Sayers et al. (2016) differentiate three different conceptions of number sense. The first is an innate or preverbal conception. It considered the ability to perceive accurately small numbers (from 0 to 4 elements) or, roughly (without counting each element), quantities that are in the range of single to double, for example 4 and 8 or 10 and 20 (Dehaene, 2001; Jordan & Levine, 2009). The second is what grade one children need to understand about number and number relationships. This understanding requires instruction. Sayers et al. (2016) call it the foundational number sense (FoNs). They identified eight distinct and not unrelated FoNs components : number recognition, systematic counting, awareness of the relationship between number and quantity, quantity discrimination, understanding different representations of numbers, estimation, simple arithmetic competence and awareness of number patterns (Sayers & Andrews, 2015; Sayers et al., 2016). The third conception is called applied number sense and it refers to “those core number-related understandings that permeate all mathematical learning” (Sayers et al., 2016, p. 473). It is characterized by a flexibility in number manipulation that reflects a true understanding of the concept of numeration that goes beyond the correct execution of techniques or routines (Bobis, 2007; Reys, 1994). A good acquisition of number sense is necessary to manipulate numbers according to the operations requested, to estimate an answer to invent calculation procedures (Reys, 1994). Yet, some 7–8-year-old students still seem to have some difficulties acquiring this level of understanding. The present study considers more the applied number sense but refers to some elements of the FoNs, particularly the awareness of the relationship between number and quantity, the understanding of different representations of numbers and the awareness of number patterns.

In Quebec, Koudogbo (2013, 2017) studied 7–8-year-old students from a regular classroom. She wanted to assess their understanding of numeration, an important component of number sense. Her results suggest that the underlying principles of the number system are difficult to grasp and understand by students of this age, similar to those identified in research conducted in the 1980s.

Indeed, Bednarz and Janvier-Dufour (1984a; 1984b; 1986) noted that many students did not perceive the multiplicative role of the grouping principle in quantity processing. However, the work of Bednarz and Janvier-Dufour (1984a; 1984b; 1986) shows that it is possible to support students so that they develop and demonstrate a true understanding of numeration. In addition, the studies by Jordan and Dyson (2016) on number sense suggest that developing FoNs by taking advantage of students' ability to count globally when items are organized in groups of 4 or fewer, which is called groupitizing (Starkey and McCandliss, 2014; Wender and Rothkegel, 2000), would lead to a better understanding of the number system.

Therefore, we wanted to understand the links between groupitizing and numeration. To do this, we first defined what the decimal numbering system is. We then defined what it means to understand this system. We have retained a key element in the understanding of this system that many students struggle with (Bednarz & Janvier-Dufour, 1984a, 1984b, 1986; Koudogbo, 2013; Koudogbo et al., 2017), namely the perceived relevance of groupings, and detailed it. Links to groupitizing skills and perceived relevance of groupings were then established. These concepts have also been detailed. Finally, activities developed within the framework of our thesis are presented to show the role that groupitizing skills could have in the construction of internal imagistic and dynamic representations of quantities, facilitating the understanding of the number system.

Numeration is a "system comprising symbols and rules for using these symbols to write, represent and name various numbers" (Patnaude & Mathieu, 2019). Understanding our numeration system requires being able to make and dissolve groups, groups of groups or exchange a group of a certain order for a higher order unit or vice versa (Bednarz & Janvier-Dufour, 1984a, 1984b, 1986). Before understanding the concept of equivalence, it is necessary to understand the role of groups, and more particularly, groups of ten. The grouping strategy is triggered by a task using large numbers of objects to count. Figure 1 is a good example of this. To be able to count a large quantity at a glance, it is necessary to form groups of ten (tens) and ten groups of ten (hundreds). This makes it easier to access the cardinal (or number of elements) of this collection thus organized.

counting one by one the organized collection

Figure 1: Example of visual and global organization of 324 elements

Grouping simplifies memorization more than the tedious task of one-to-one counting of items. As mentioned previously, despite its capital importance, few students see the relevance of using grouping and few students can explain how grouping helps organize a collection (Bednarz & Janvier-Dufour, 1984a, 1984b, 1986). Also, few students are able to form dynamic and imagistic mental representations of groups and groups of groups (Thomas et al., 2002).

What if we took advantage of groupitizing skills to help students build dynamic mental representations of quantities? Learning to place items correctly for small sets or elementary constellations could help students group large quantities to see them better. Research by Wender and Rothkegel (2000), Starkey and McCandliss (2014) and Clements (1999; 2019) has provided insight into this strategy by finding that items placed in small groups of 2 or 3 are counted faster than if they are placed in a disorganized array. This ability is called groupitizing.

In the 2000s, researchers in cognitive science questioned the impact of quantity organization on counting skills. Wender and Rothkegel (2000) measured the time adults took to count small amounts. They found that this time is shorter when items are organized in small “subitizable” groups, whether they are in classic configurations, such as dots on a die, or other subsets that are easy to count at a glance. Their conclusion is that structuring the quantity has a major impact on counting performance. They proposed the term groupitizing to designate this global recognition strategy. These authors conclude that the idea of groupitizing would support the development of the desired flexibility in addition and could also lead to a better understanding that larger numbers are formed by nestling smaller numbers together. In other words, counting with small groups would later facilitate the perception of the role of grouping in our numeration system.

Somewhat more recently, Starkey and McCandliss (2014) looked at the impact of small group organizations that respect the limits of perceptual subitizing (ability to instantly recognize numbers less than four (Clements, 1999)), on the effectiveness of counting in students, from preschool to third grade, which led them to the groupitizing strategy proposed by Wender and Rothkegel (2000). They found counting speed is increased when small groups are present, especially when the groups meet the limits of perceptual subitizing. Images displaying 5, 6, or 7 dots, of equal size, were shown to students. The dots could be 3 or 6 mm in diameter and the space they occupied ranged from 5 cm by 5 cm to 10 cm by 10 cm. Starkey and McCandliss’ (2014) results show that counting speed is influenced by whether the quantity is organized in small groups or not. They also compared students' scores on groupitizing tests with standard arithmetic tests and found that students who performed better on groupitizing also performed better on arithmetic. They conclude that groupitizing contributes to the understanding of our symbolic numeration system.

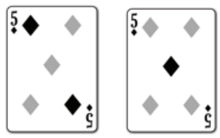

Figure 2: Example of global recognition

Groupitizing is what allows global recognition, the ability to recognize quantities without needing to point out each of the individual elements (Brissiaud, 2005). This ability is called conceptual subitizing by Clements (1999). The quantity is organized and structured, respecting the sensory limit of our perceptions, which is three or four elements. This skill helps develop number abstraction and arithmetic strategies (Clements, 1999). For example, in figure 2, it is possible to see on the card on the left that 3 + 2 = 5. It is also possible to see on the card on the right that 2 + 2 = 4 and 4 + 1 = 5. This global recognition relies on perceptual subitizing skills. It is also about a global count which makes it possible to perceive the figures as a whole, without going through sequential counting, enumeration. This involves finding the quantity of a collection from the composition or the decomposition of a constellation (Clements, 1999; Hunting, 2003; Van Nes & De Lange, 2007). This flexibility of representation enriches number sense (Brissiaud, 2005). It is not simply a matter of recognizing constellations, but playing with different arrangements and spatial structures (Battista et al., 1998; Braconne-Michoux and Marchand, 2021). This will eventually support calculation skills (Brissiaud, 2005; Van Nes & De Lange, 2007).

This flexibility will alleviate some frequently encountered difficulties by students, such as the recall of numerical facts in addition (Brissiaud, 2005; Fayol, 2012). Indeed, they will have a mental representation of the quantity.

Thus, our perception of the role of groupitizing in our numeration system may be linked to our ability to "groupitize". In this paper, we have chosen to use the word *groupitizing* rather than *conceptual subitizing* to better emphasize the idea of small group counting based on subitizing skills. Global counting and groupitizing are unfortunately undervalued in our school culture which is frantically focused on sequential counting. Twomey and Dolk (2011) insist that the ability to group is the crux of the matter, as students must give up these one-to-one counting strategies.

The proposal in this article is to first allow students to see, through problem-solving activities, that when placing items to be counted in small subitizable groups, it is easier and faster to count them. Then, through other activities, giving the students the opportunity to create a dynamic and imagistic mental representation of quantity. Finally, to allow them to reuse these observations and these mental representations to better understand the numeration system.

We wanted to verify this hypothesis within the framework of our doctoral thesis. We have designed a didactic sequence allowing students to develop a better understanding of number sense. This sequence gives them the opportunity to develop dynamic and imagistic mental representations thus taking advantage of their groupitizing skills. This gives the students the opportunity to experience activities related to their development of number sense. We present three activities in this article to highlight the links between groupitizing skills, the construction of dynamic and imagistic mental representations and the comprehension of numeration.

Activities

The didactic sequence created within the framework of our thesis consists of ten 60-minutes periods. Two activities are offered during these periods: an activity to train subitizing and groupitizing skills and an activity aimed at a central concept of the number system. An a priori analysis was carried out for each of these activities and links were made between each activity to allow students to reuse what they have learned in a following activity.

Through this sequence, students first have the opportunity to become aware of the role of their groupitizing skills in counting. When the quantities are arranged in a subitizable manner, they are easier to see and count. Students can practice using these skills and, in the process, build a dynamic and imagistic mental representation of quantities. Then follow-up activities allow them to reuse their groupitizing skills with larger quantities encouraging a shift to the grouping principle. Arranging the elements in subitizable patterns makes it possible to perceive larger and larger sets of elements as a whole. Students then can practice using grouping to count groups and groups of groups. Other activities then build on these visual skills to introduce counting and equivalence. Here, too, students are given opportunities to practice. There is a back and forth between problem solving, allowing students to discover concepts (groupitizing, grouping, numeration) and activities in which it is possible to use the acquired knowledge. Three of the twenty activities developed are briefly presented in this article: Baby Birds, Jewels of her Majesty and The Shepherdess and the Witch (Lyons & Bisaillon, 2011).

Baby Birds

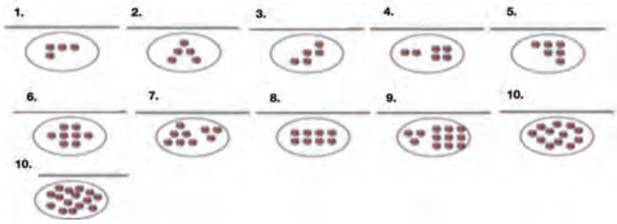

Figure 3: Case of the Baby Birds activity

The goal of this activity is to get students to establish the relevance of groupitizing for counting, memorizing, and reproducing a quantity. This activity is a problem-solving activity: A magpie cries over the fate of her young:" At each meal, it's the same crisis! If I do not put exactly the same amount of food in front of each of my young, they squabble and scramble. One day, some of them will end up falling from the nest. I do not know what to do to avoid that". The instructions are as follows: "Help the mother Magpie to feed her young. Observe the nest carefully. How could you make sure that you have the correct amount of fruit "? Pictures of baby birds in a nest are shown on an IWB for exactly two seconds (see Figure 3). Students must place the tokens on the model nest in front of them, respecting the layout of the baby birds shown on the screen. Students can explore and manipulate the material. They also have the opportunity to share with their peers the strategies they used. When returning to the large group, at the end of the activity, all the nests are shown on the screen and the teacher leads a discussion about the more difficult arrays.

In this activity, students become aware of the role of their groupitizing skills. Various constellations have been chosen, allowing them to start from their basic subitizing skills to then process larger and larger and larger quantities. The chosen constellations are not prototypical since the goal is to get the students to see the importance of correctly placing lots of tokens in order to count them better. For the last two cases, the baby birds are placed in a representation that is not subitizable, that is, one that is not organized into small noticeable groups of four elements or less. The goal is to provoke a reaction in the students and get them to see that when the items to be counted are well arranged, it is easier to form a mental representation of them.

Jewels of her Majesty

The goal of this activity is to make students aware of the relevance of grouping to count large quantities. It is also about getting them to build on the development of their groupitizing skills to see the usefulness of placing groups in a subitizable arrangement. This activity provides the context for the activity and initiates a discussion with students about their strategies associated with grouping. It also allows students to develop their awareness of number pattern.

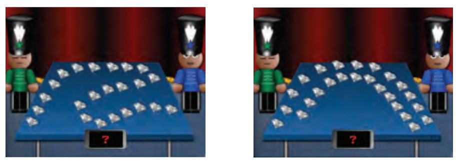

Figure 4: The two introductory scenarios for the Jewels game

This activity is a problem-solving activity: “Greengard and Blueguard are responsible for guarding the jewels of the Kingdom. Greenguard often dozes off and something tells him that his colleague is taking advantage of this. But how to prove it? Greenguard does not know how to count, but he has a good eye... He rearranges the diamonds: "If things are moved, I will know!". Figure 4 shows the two jewel arrangements of jewels proposed to students. In both cases, the arrangement of the jewels is not subitizable, to make students realize the limitation of the strategies used by Greenguard (a long line does not allow you to "see" rapidly see the quantity and to initiate a discussion about better counting strategies.

The Shepherdess and the Witch

The purpose of this activity is for students to reinvest the fruits of their learning in the activities they have done to date. They have had the opportunity to see the role of subitizable collections and their usefulness in forming a mental representation of quantities and the usefulness of counting instead of sequentially. This activity is a bridge between enumeration and numeration. A representation using the principle of enumeration shows all the elements to be counted and it is always possible to count them one by one. A representation using the principle of numeration shows higher order units resulting from the substitutions of the different groups (such as tens, hundreds, etc.), which no longer allows direct visual access to all the elements of the set to be counted (see Figure 5 presented below). This activity also allows students to develop their awareness of the relationships between number and quantity and number pattern. It takes place in two parts and is based on a scenario that is presented to the students on the IWB.

Figure 5: Example of one group of ten and six sheep

Episode 1

This first episode is a problem-solving activity. Shepherdess Bella is responsible for looking after the kingdom's sheep and she must make sure to bring them all back at the end of the winter or else Emperor Notsokind will be very unhappy. She knows that she will have to count the sheep every day, but this is made more difficult by the sheep continuously moving to have access to fresher and greener grass to eat. There are 16, a group of ten and a group of six (students use tokens). Students are asked the following question: "Do you have any ideas on how to help Bella count the sheep faster?". This is a way for the students to use the knowledge acquired in the Jewels activity, namely the relevance of forming groups. The expected answer here is to place them in groups so that they so that they can be counted more easily and circumvent the mobile sheep problem. Astuzia, her sister the witch, comes to her aid by giving her a magic flute that precisely follows these recommendations. When she plays the flute, the sheep stand in groups of ten and the sheep that are not in groups of ten place themselves in a subitizable constellation (Figure 5). They remain motionless long enough to be counted. Bella embodies the strategic boundaries of enumeration and Astuzia helps demonstrate the basics of numeration. The students have time to count the ten sheep grouped together one by one, for. This episode introduces an important kind of group, groups of 10; it also serves as an introduction to the next episode.

Episode 2

Figure 6: Triangles of 10 and mixted notation

When winter comes, Bella brings all her sheep back to Emperor Notsokind, who is very satisfied. The following spring, Bella is still responsible for the sheep, but this time there are sheep and despite using the magic flute, she cannot count the sheep as they are too numerous to count. Students are asked the same question: "Do you have any ideas on how to help Bella count the sheep faster?" This is a way to reuse the knowledge and skills acquired in Jewels, or the usefulness of counting. Astuzia comes to the rescue and introduces the ten-triangle, where we no longer see 10 sheep, which is an unconventional configuration for groups of ten. She's going to show Bella that she can count groups of ten (count by leaps). Mixed notation is also introduced to allow Bella and the students to keep track of the number of sheep (Figure 6). The end of this second episode leads to an activity in which students are asked to practice using the knowledge acquired in the first and second episode.

Conclusion

Classroom use of the activities proposed in this sequence by teachers with 7–8-year-olds would enhance the importance of number sense for elementary school students. The role of imagistic and dynamic mental representations in the understanding of these concepts would also be highlighted.

Furthermore, this implementation would confirm that interventions allowing the construction of various mental representations, by relying, among other things, on the aptitudes of groupitizing as early as preschool age and would contribute to a reduction in the number of children having difficulties with the construction of number sense. This research focuses on 7–8-year-old students, but these numerical teaching tools have the possibility of greatly improving number sense in all elementary school-aged students.

The pandemic made it impossible for us to try-out these activities and didactic sequence. We hope to do an in-class experimentation of these number-teaching sequences and strategies very soon so that we can present the results in the near future.

Strategies in numerosity estimation
Comparison of students with high and low accuracy

Leonie Brumm[1] and Elisabeth Rathgeb-Schnierer[2]

Keywords: Estimation strategy, numerosity estimation, elementary school students.

Introduction and theoretical framework

Estimation is an important part of everyday activities and is present in everybody's life. Generally, an estimation encourages methods that lead to reasonable, not necessarily accurate results. Estimation is also defined as mental comparison and measurement (Schipper, 2009). Consequently, it includes a varied set of processes which differ depending on the task and type of estimation. In recent English literature, four types of estimation are distinguished: Measurement, computational, numerosity and numberline estimation (Sayers et al., 2020). This project refers to numerosity estimation. It requires translating a non-numerical quantitative representation into a number (Siegler & Booth, 2005).

Accordingly, estimation is conceived as problem-solving process. Every common problem requires different mathematical knowledge and flexible ways. Adaptive problem solving is one crucial goal of mathematics education (Siegler & Booth, 2005). Furthermore, research results suggest that students who are gifted estimators show better arithmetic skills in terms of counting, number sense, mental computation, strategy flexibility, and conceptual understanding (e.g., Booth & Siegler, 2006; Crites, 1992). Particularly, numerosity estimation influences the development of number knowledge with increasing numbers (Wessolowski, 2014). So, another reason for fostering estimation abilities is the great impact for the development of arithmetic skills (e.g., Luwel et al., 2005; Siegler & Booth, 2005).

Despite the importance of numerosity estimation, there is a lot more known about other basic numerical processes (Booth & Siegler, 2006). However, previous research shows various strategies in numerosity estimation. Furthermore, the accuracy in estimating quantities increases with age. The performance as well as the adaption to task characteristics seemed to increase with age. In general, former studies show that strategy choices in numerosity estimation depend on specific problem characteristics. (e.g., Crites, 1992; Siegler & Booth, 2005).

Aim

According to previous research, the present study focuses on comparing strategies in numerosity estimation in two- and three-dimensional tasks of students (third grade) with high and low accuracy in estimation. Another emphasis is on investigating the exhibited strategies in relation to task characteristics. Further, the project targets to reveal strategies which lead to high estimation accuracy according to the type of task. We are also interested in correlations of arithmetic skills and numerosity estimation abilities.

Method

Data will be collected by two discretely developed instruments. We developed a numerosity estimation test to assess estimation accuracy. The test results facilitate to select the students for semi-structured interviews. The semi-structured interviews intend to reveal estimation strategies.

The test is digitally implemented in an online survey software. The final test will include 21 estimation tasks with different characteristics. A task consists of a number of elements that is to be estimated. After structuring different types of tasks, seven tasks were chosen for the estimation test. So, following characteristics will be considered in the test: Dimension (2D/3D), arrangement (structured/unstructured) and elements (equal/unequal). It is important to regard that on a screen it is only possible to see a representation of a three-dimensional quantity. Amongst others, that is one reason why not all summarized task characteristics were chosen. Every of the chosen seven tasks will appear three times in a different number range. The number range up to 50, from 50 to 100 and from 100 to 150 is covered that way. Overall, the students can see the picture for a certain time. After this time expired, the students still have time to adjust their result with a slider. Before the test starts, an introduction of estimation as well as an instruction how to use the test are intended. Students who made accurate and less accurate estimates in the test will be part of the interviews. A semi-structured guideline will be developed. It will mainly contain tasks of the estimation test. For evaluating the interview, it will be videotaped. The use of both instruments enables new perspectives on numerosity estimation. Besides, other constructs like linguistic and arithmetic skills will be surveyed.

The pilot study of the numerosity estimation test (N = 31) shows that the test is reliable. The Cronbach’s Alpha of the 2D subscale is $\alpha = .81$ and $\alpha = .80$ for the 3D subscale.

Didactic variables related to the use of manipulatives and their impact on students' activity: an illustrative case around fractions

Claudia Corriveau[1], Doris Jeannotte[2] and Sandrine Michot[3]

[1]Universite Laval, Faculty of Education, Quebec, Canada; claudia.corriveau@fse.ulaval.ca

[2]Universite du Quebec a Montreal, Canada; jeannotte.doris@uqam.ca

This study investigates the use of manipulatives by a pair of students working on a fraction task. Extending previous work on the role played by the manipulatives in students' activity, we now focus on the linkage of 1) different choices made around the task and the manipulatives and 2) students' activity. The theoretical underpinnings allow envisioning the manipulatives through the concept of affordance. It also helps to picture which didactic variables are at stake when using manipulatives. The analysis of Tim and Nick's mathematical activity allows us to better understand how the way the manipulatives are used serve as breaching elements and lead them to reason differently.

Keywords: Manipulatives, Number sense, Fractions, Affordance, Reasoning.

Introduction

In this paper, we draw on our previous research presented at the 10th CERME meeting (Jeannotte & Corriveau, 2020) about the role played by the manipulatives in students' activity when solving an arithmetical task. We aim to show how some choices made around different variables impact the students' activity. The paper reports more precisely on how subtle changes in the conditions put into place around the use of manipulatives can destabilize enough students to doubt their ways of reasoning. In the first section, a problem statement specifies what we intend to study. The concepts of affordance and didactic variables are then theoretically explicated to frame our methodological and analytical work. The third section presents an illustrative case.

The use of manipulatives

The use of manipulatives when teaching and learning arithmetic and number sense at the elementary level is recommended, even prescribed in education internationally (e.g., OECD, 2019). However, simply using manipulatives will not necessarily increase student success in mathematics. Carbonneau, Marley and Selig (2013, p. 397) mention that "instructional variables either suppress or increase the efficacy of manipulatives," but argue there is a lack of research that identifies these variables. Research on manipulatives mainly focuses on whether the manipulatives support student achievement in mathematics (e.g., Moyer, 2001). However, the way it is used is rarely made explicit. What were the choices regarding its use? When it comes to manipulatives, it is as if the only variable considered was its use or non-use. Nonetheless, we consider that many variables are at stake and play different roles in students' activities.

The few research that studies students' mathematical reasoning when they use manipulatives shed light, indirectly, on some of these variables. For example, the use of familiar manipulatives may mislead students (McNeil & Jarvin, 2007) or, for the same task, two different materials lead students to engage in different reasonings (Jeannotte & Corriveau, 2020). The familiarity and the type of manipulatives are two examples of variables among others that can shape the students' mathematical activity. These variables can therefore be of different natures.

In this paper, we present a fraction task that students solve using Pattern blocks. We aim to show how the choices made around different variables introduce breaching elements that impact the students' activity and promote the development of different ways of doing.

Conceptual framework

With the aim of better understanding how the use of manipulative impacts students' activity and what different variables are at stake when introducing manipulatives in a mathematical task, our theoretical underpinnings convoke the concepts of affordance and of didactic variables.

We call **affordances** the relational properties of an object within a certain environment that are bound to certain actions. For example, a pen will generally be seen as an object to write with. Moreover, "[w]hether or not the affordance is perceived or attended to will change as the need of the observer changes, but being invariant, it is always there to be perceived" (Gibson, 1977, as cited in Brown et al., 2004, p. 120).

In a mathematics class, each manipulative has its own properties and, with pupils and the whole class actions, generates different affordances (Jeannotte & Corriveau, 2020). In other words, the affordance realized in the classroom relies not only on the tool itself, but rather on the exploitation of it, on the educational context and how it is driven by the teacher (Drijvers, 2003). In that regard, we observed that students mainly rely on what they are used to do with a specific kind of manipulatives to solve a task rather than what they do without it or what they must do according to the task. Thereby, working with familiar manipulatives for novel purposes might drive the attention of pupils in an "undesired" direction (McNeil & Jarvin, 2007). This does not mean that a same type of manipulative should always serve the same kind of task. On the contrary, it is by breaching these familiar ways of working with it that students will reason and make new mathematical meaning of its use. The concept of breaching (from ethnomethodology) refers to a subtle breakage of what is familiar. By varying different aspects related to the use of manipulatives, it is possible to place the students in conditions familiar enough for them to engage in the task but sufficiently unfamiliar so it resonates as a conflictual use of the manipulatives. In a way, it plays into how students perceived the affordances of the manipulative and leads them to explicit usual ways of reasoning with it and renewing these.

Didactic variables are defined as parameters, linked to the design of a teaching situation, which can vary according to the teacher's choices, and which can lead to a change in the students' mathematical activity (Brousseau, 1981; Grugnetti & Jaquet, 2005). There are three categories of didactic variables: those related to conditions (e.g., the choice to have students work in groups of 3), those related to the use of tools (e.g., the choice to use a single sheet of paper in a group) and those related to the problem (e.g., the choice to use fractions in a problem, rather than whole numbers, to modify its difficulty).

The concept of didactic variables aims at designing teaching situation. However, it might also be a powerful methodological tool. Varying these didactic variables related to manipulative may act as breaching elements as discussed above.

Methodology

We use an illustrative case that emerged from data collected within MathéRealiser-project, a collaborative research project undertaken with elementary teachers from first to sixth grades. In collaboration with five of them, we have created a task (titled "twelfth") that aims to develop different reasoning to represent fractions using pattern blocks. We experimented "Twelfth" into two fourth-, two fifth-, and one sixth-grade classes of about twenty students each. The task was implemented with different choices according to teachers' rationales (mainly based on students' abilities and familiarity with fractions). In this paper, we present an analysis of students' activity regarding the use of manipulatives when solving the task.

The task "Twelfth"

"Twelfth" is, at first sight, a common task in which students are asked to represent a certain fraction with pattern blocks. Students work in pairs; they receive a kit of Pattern blocks (Figure 1) and are asked several questions. These can be divided into three categories:

1) The given fraction is a twelfth and students must represent a third (the piece representing a twelfth varies): e.g., *the green triangle (blue rhombus, red trapezoid, etc.) is worth 1/12, represent 1/3 of the same whole.*
2) The given fraction is a twelfth and students must represent other varied fractions (unit and non-unit): e.g., *the blue rhombus is worth 1/12, represent 1/24 of the same whole; the red trapezoid is worth 1/12, represent 5/6 of the same whole.*
3) The given fraction varies, and students must represent varied fractions: e.g., t*he yellow hexagon is worth 2/5, represent 1/15 of the same whole.*

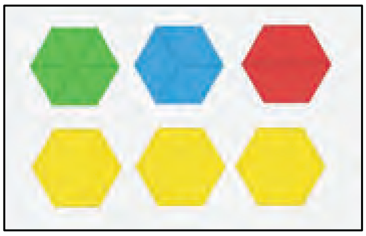

Figure 1: kit of pattern blocks available to each pair of students

The didactic variables

While elaborating the task with the teacher, we had to make several choices. For example, the choice of manipulatives was discussed. Because of their availability and familiarity, we chose to use Pattern blocks. These manipulatives have different characteristics that can lead to different affordances.

Another example is the limitation of the number of pieces given to encourage varied strategies. We purposely did not want the student to be able to represent the whole with the same piece repeated as many times as the inverse of its value (e.g., 12 times for a twelfth). When a question such as "if a red trapezoid represents 1/12, how can you represent 1/3?" was asked, the whole could not be represented with twelve red trapezoids. For some questions, it was not possible to represent the whole at all. Bellow, we present a list of choices made regarding the design of the task. We indicate the corresponding didactic variable.

- Didactic variables related to conditions:
  - Students were asked to work in pairs (to foster communication)
  - Questions were asked during their work (to encourage substantiation)
- Didactic variables related to tools:
  - Choice of pattern blocks (known, diversity of affordances possible)
  - Students shared a single kit (to foster communication)
  - Limit number of pieces in a kit (to encourage the renewal of strategies)
  - Allowing or not the use of paper and pencil (to keep track of work and answers)
- Didactic variables related to the problem:
  - Choice of fractions (to encourage the renewal of strategies)
  - Asking about finding a fraction from a given fraction (as a breaching element)

Description of the analysis

To analyze, we listened to the videos with the transcripts in support. From this new listening, we reconstructed a table showing the different phases of the activity. The table contains three columns. The first column gathers the time of the video. In the second column, which is descriptive in nature, we portray in detail students' actions and their important comments and moves. We also used a colour code to identify four key actions related to manipulatives in the students' mathematical activity: the **representation** of fractions or of the whole (in yellow), the **resolution** which corresponds to solving (in green), the **validation** used to convince themselves (in cyan) and finally the **explanation** when they explain their solution to the teacher or researcher (in pink). In the third column, of an analytical nature, we pointed out two types of information: breaching elements (highlighted in bold in the table) and an interpretation of the use of the manipulatives for each key action.

Results: The illustrative case of Tim and Nick

The analysis presents the case of Tim (10 y.o.) and Nick (11 y.o.), two fifth-grade students who are both perceived by their teacher as quick-witted, particularly in mathematics. They generally succeed very well in mathematics. We present the analysis of their work below. We take up the salient elements in terms of affordance and breaching, and we relate it to the use of the manipulatives.

Q1. "If a triangle represents one twelfth, can you represent the third of the same whole?"

Before the question is even asked, Tim says they got the answer. He uses two hexagons as a whole. While Tim raises his hand to present their solution, the teacher asks: "can you represent the third of the same whole?" This question acts as a breaching element as Tim stops and starts to reflect. He had anticipated the question would be about finding the whole. Nick and Tim think aloud, "one third, one third…" It seems Tim calculated mentally and then, adds two rhombi on top of the two hexagons. The student perceives that covering one part of the whole by overlaying pieces (property of manipulatives) makes the fraction visible. Nick wants to validate. To do so, he counts "one third, two thirds and three thirds" pointing with his finger over the whole but without moving any pieces. When a researcher asks them to explain their solution, they argue that one-twelfth means there are twelve triangles in the whole. "The third of twelve is four." Therefore, the answer is four triangles. Their explanation relies on calculation, but they also overlay four triangles on the two hexagons using once more a property of Pattern blocks (Figure 2). When asked to validate, they answer that four triangles “fit” three times in two hexagons. They complete the validation by effectively making three-thirds “fit” on top of the two hexagons. The limitation of the pieces is not a problem as they use four triangles or any equivalence (two rhombi or one trapezoid and a triangle) to represent each third. They are able to completely cover the whole. The ways of using manipulatives are familiar to Tim and Nick.

Figure 2: Overlaying pieces on top of the whole

Q2. “If a rhombus represents one twelfth, can you represent the third of the same whole?”

Tim and Nick use three hexagons as a whole. When they count the number of rhombi fitting in the whole to validate (“3, 6, 9...”), they realize this is not enough. “There are not enough hexagons,” Tim says, surprised. Based on Tim’s reaction, we hypothesize that when they work with Pattern blocks, the hexagon, or some hexagons, is commonly used as a whole (affordance). To solve this impasse, Nick uses two trapezoids to complete the whole (Figure 3a).

Then, the resolution seems to result from mental calculations. Tim says they need four rhombi. They overlay the three rhombi and two triangles on top of the whole (Figure 3b). Again, overlaying is employed, and the limited number of pieces necessitated the use of different pieces (affordance).

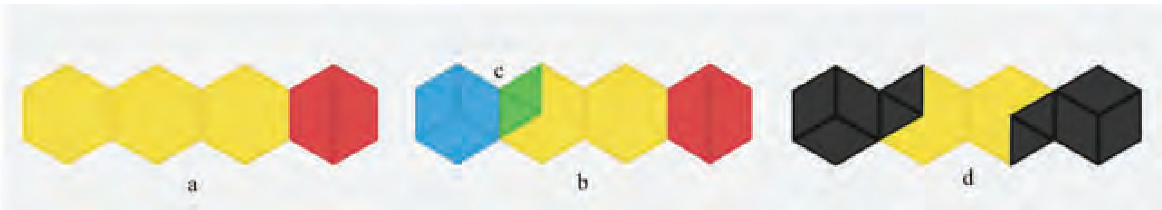

Figure 3: Tim and Nick’s actions during question 2

They try to validate using the manipulatives. However, this is difficult. The properties of the manipulatives make impossible to perceive the same “pattern” of a third displayed in the represented whole. Indeed, the format of a third initially represented (Figure 3c) cannot be used three times to complete the whole (Figure 3d). The limited number of pieces makes impossible to completely cover the whole, as they did previously (question 1). Nick tries to move the pieces to see if he can display the same pattern (Figure 3c) three times. He has difficulties doing so. Both Tim and Nick know this is not easy and could engender mistakes, so they use a marker (hatched triangle in Figure 4a) to realize the validation. However, they count the marker as being part of the second third (Figure 4b). They represent a third, but it laps the one originally represented (see Figure 4c for a right possibility). We hypothesize this confusion is linked to the need to move the pieces and the wish to use the same pattern (we hypothesize this is based on the usual ways of doing). Because they cannot validate their solution this way, they try to resolve it another way. Tim decides to rely on triangles. He perceives that a rhombus is formed with two triangles. Twenty-four triangles constitute the whole. “One-third of twenty-four is eight” (Tim). This comes back to three rhombi and two triangles. Tim and Nick are happy. Nick tries to validate using the manipulatives. However, they cannot complete the validation.

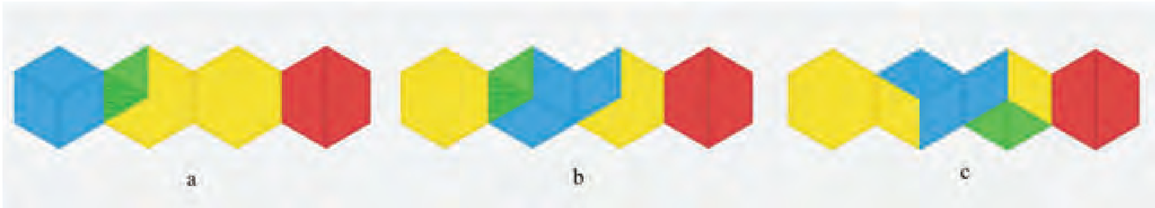

Figure 4: Using the triangle (hatched) as a marker

Q3. “If a trapezoid represents one twelfth, can you represent the third of the same whole?”

Tim and Nick put three hexagons in front of them. Tim picks up the trapezoid and says: “it must fit twelve times in the whole.” While Tim uses triangles and rhombi to complete the whole, Nick argues they need three other hexagons to represent the whole (familiar way of representing wholes). Tim tells Nick they need to represent the whole, but both realize it is impossible to use all the pieces, especially because the trapezoids are used as indicators of 1/12, placed on top of one hexagon (familiar ways of representing fractions). From the start (questions 1 & 2), they have been using pieces to represent the whole. Then, they overlay other pieces to represent their solution. We hypothesize this way of using the manipulative is familiar within this class (affordance). The limited amount of manipulative combined with the choice of fractions (variable) acts as a breaching element.

Nick suggests: “Let’s imagine there’re three more hexagons.” He suggests working with imaginary Pattern blocks. This is possible because there are physical Pattern blocks they can rely on as well. Tim says: “the third of twelve is…, the third of twelve is… four.” They conclude they need four trapezoids. Although they have a solution, they feel they must validate using the manipulative (affordance). Nick’s fingers point to the first two hexagons, then to two imaginary hexagons and so on. Tim convinces Nick they must represent the whole and “steals” some Pattern blocks left on the teacher’s desk. “It’s important not to mix them with our kit though,” Nick cautions. They complete the whole with three more hexagons, overlay four trapezoids and show their response to the teacher.

The teacher validates the answer but reminds them that they need to work only with their kit. The students feel they must start over. To validate their reasoning, they change the way of resolving (“representing the whole” strategy). Tim, therefore, proposes to “reduce the fraction.” He says: “Instead of four twelfths, we do two sixths… (thinks)… and a third.” He shows a third with the manipulatives. Using the manipulatives, he changes the whole as he “reduces” the fraction. According to him, 1/3 means they must use “three” hexagons as a whole. Nick says, “this is not one third, but think again saying: “it’s the same thing, we just reduced…” Both seem aware that something is not working but cannot go further from this proportional reasoning.

A researcher comes to ask about their solution. Nick tells her: “It's the two of them (showing two yellow hexagons overlaid by two trapezoids) but should be full of red (meaning with four trapezoids overlaid).” During their attempt to explain why their solution works, the researcher sees they struggle to represent the whole and make the three-thirds visible. The identification of the fraction with overlaid pieces, in that case, is their only way to act. She asks: “why are you keeping the red trapezoids on top?” She takes the two red trapezoids. She combines three pairs of hexagons with the pieces to show the three thirds and says “that makes 1/3, that 1/3 and that another third” (Figure 5). They are stunned. “Euh!… Well… yes!”, says Tim. “We did not succeed from the start,” adds Nick.

Figure 5: validation from the researcher

Discussion and conclusion

This analysis of students' action drifts us away from the belief that using manipulatives necessarily helps students (Ball, 1992). Tim and Nick are able to resolve the questions without any manipulatives. But using it makes them act differently. Thus, this illustration is coherent with previous observations that using manipulative is not a concrete version of doing mathematics without it, it is a completely different activity (Corriveau & Jeannotte, 2015). Moreover, we move from viewing manipulatives as an aid to facilitate the resolution of a task, to considering it as a constraint that stimulates new ways of doing and thinking. This is visible especially when Tom and Nick want to validate.

Through the lens of affordance, we see from the actions of Tim and Nick, that the use of Pattern blocks is bound to certain actions: representing the whole, usually with hexagons and representing the fraction by overlapping pieces, using the same partition (or pattern) for each part. Articulating the calculation and the validation with this manipulative, and showing the result, command this way of using it. We could interpret this use as a ritual from a commognitive perspective (Lavie, Stein & Sfard, 2019). However, in the progression of the three questions, we show how certain choices based on didactic variables create breaching elements that play an important role in students' activities. Even if Tim and Nick are able to resolve the questions by calculation, the introduction of manipulatives commands renewal of familiar ways of using it. They need to complete the whole using other pieces than hexagons, they deal with the impossibility to overlay pieces (using all the pieces to represent the whole) and even, in some other questions, they manage the impossibility to represent the whole. From a commognitive lens, the way the task is constituted acts as deritualization, a process that transforms a ritual into an exploration (Sfard, 2008). The students have no specification regarding the way in which the manipulatives must be used. They are the ones in charge of the endorsement. Mathematically, this task, and all the choices made around it, put the focus not only on one way to envision the concept of fraction (1/12 means there are 12 equal parts and a third means they are divided on three) but also put the focus on the equivalence of fractions (4/12 and 1/3) and on the process of validation. It emphasizes on rules that are necessary to communicate mathematically. Tim and Nick's activity indicates somehow that a solution and its validation must me "readable." It is as if oral explanations and calculations are not recognized as a way of communicating in mathematics for them. We hypothesize that this is an important aspect of the classroom culture. Finally, the way the manipulative is used nuances what is mathematically important when using it and what is not: e.g., the overlapping is a nice way to compare the fractions but is not necessary.

Acknowledgment

Thank you to Tim, Nick, their teacher. This study is supported by the Canadian Social Sciences and Humanities Research Council (430-2016-00332).

Multiplicative comparison of fractions: potentials and limits of commensuration meaning

Lalina Coulange[1], Aurélien Ovide[2] and Grégory Train[3]

University of Bordeaux, Lab-E3D, Bordeaux, France;

[1]lalina.coulange@u-bordeaux.fr; [2]aurelien.ovide@u-bordeaux.fr;[3]gregory.train@u-bordeaux.fr

We aim at examining the potentials of the commensuration meaning for teaching and learning fractions, in particular "multiplicative comparison relationships" between fractions. We focus on students' reasoning based on commensuration meaning by analyzing a variety of data collected through teaching experiments: on the one hand, old data from experiments conducted at the Michelet school by Brousseau in primary school in the eighties and on the other hand, recent experiments that we have conducted in a form of continuity with college students in a new context (one experiment designed by Brousseau for students of grade 5 and another we designed for students of grade 8). The results of our research highlight the potential of commensuration meaning to enable students to access to a broad conceptualization of multiplicative comparison relationships between fractions.

Keywords: Multiplicative comparison, fractions, commensuration

Introduction

Developing a deep understanding of fractions requires a conceptual understanding of different meanings of fractions and relationships between them (Clarke et al., 2008). In French primary school, fractions are studied as splitting the unit meaning. The French curriculum describes this meaning of fractions as follows: you split a unit by a natural number of equal parts and you take a number of those parts, potentially larger than the numbers of parts included in the unit. Brousseau's work (1987) highlights another original meaning of fraction, called commensuration. However, commensuration has not found its place in the French curriculum. In previous work, Chambris et al. (2021) and Coulange and Train (2021) have shown how splitting the unit meaning of fraction does not easily build multiplicative relations between quantities in primary school. Our goal is to examine the potential of the commensuration meaning for teaching and learning fractions, in particular "multiplicative comparison" (Greer, 1992) relationships between fractions. In this study, we focus on students' reasoning relying on multiplicative comparison relationships between different fractions with commensuration meaning.

Theoretical framework and methodology

Multiplicative comparison relationships, "flexible units" and fractions

In the domain of models of multiplication and division, Greer (1992) distinguished two main types of multiplicative word problems: equal group and multiplicative comparison. Relating to Greer's theoretical viewpoint about multiplicative field, we distinguish multiplicative comparison relationships between measures or numbers of units (seen as n more…than or n less…than) from inclusive relationships. Inclusive relationships between measures or numbers of units (seen as n times in) refer more to equal groups of objects considered in the context of measurement or counting. Such multiplicative comparisons seem necessary to develop a high-level conceptualization of magnitude

(Steffe & Olive, 2010; Thomson et al., 2014) relying on “flexible units” linked by multiplicative relationships to each other (Chambris, 2021; Chambris et al., 2021). Thus, they may provide a flexibility of reasoning about both measures and numbers in the field of arithmetic (Chambris, 2021).

Returning to our main subject, we assume that a broad conceptualization of fractions requires multiplicative comparisons, following a “fraction as comparer” approach (Freudenthal, 1983). Cortina et al. (2014) referring to Norton and Hackenberg (2010) also emphasizes the conception of fraction as “a size of an attribute, instead of as an actual piece of an object, or as a discrete element in a set (p.84)” in such an approach. From our point of view, this assumption is related to the distinction between “equal groups” and “multiplicative comparison” mentioned above.

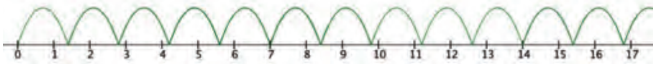
In our study, according to this theoretical background, we aim at examining the potential of commensuration (Brousseau, 2002) for teaching and learning multiplicative comparison between different fractions.

Commensuration meaning of fractions

Commensuration fraction meaning is distant from “splitting the unit” meaning that is usually considered in French curriculum. In the context of commensuration, $\frac{a}{b}$ is the relation between two physical quantities, such as b times the first quantity gives a times the second one. Classroom experiments related to teaching and learning this meaning of fraction were conducted in primary school (grade 5) during the eighties (Brousseau, 2002; Brousseau & Brousseau; 1987, Brousseau et al., 2014). In particular, Brousseau and Brousseau (1987) designed the “thickness of a sheet of paper” situation in which children had to find an optimal measurement strategy in situations of measuring something so thin that previously known techniques of direct measurement could not be applied. The situation involved measuring and comparing the thicknesses of various types of paper. The aim was to characterize the thickness of a sheet first by a pair of whole numbers (for example, 56 sheets – 8 mm) and then by a fraction (for example $\frac{8}{56}$ mm). Thus, the thickness of a sheet is $\frac{8}{56}$ mm means that 56 sheets of paper measure 8 mm. Building on this previous research work, we designed mathematical tasks based on the motion of bounds of robots along a number line intended to promote teaching and learning of the commensuration meaning with students in secondary school. These tasks contextualize commensuration: some robots make regular bounds on the number line, reaching a natural number of units in several bounds. The aim is to characterize the length of robot’s bound by a pair of whole numbers (for example 15 units and 7 bounds) and then by a fraction ($\frac{15}{7}$ units). The table below summarizes the two types of contextualization of commensuration which rely on two kinds of magnitude and measurement:

Table 1: Two types of contextualization of commensuration

Sheets of paper	Robot
Number of (regular) paper sheets: q sheets of paper	Number of (regular) bounds of a robot: q bounds

Measure of the thickness of a pile of (q) sheets measured in mm: p mm	Length reached on the number line measured in units (represented on the line): p units
Measure of the thickness of a sheet: $\frac{p}{q}$ mm but also $\frac{p\times a}{q\times a}$ mm, etc.	Length of the bound of a robot: $\frac{p}{q}$ units but also $\frac{p\times a}{q\times a}$ units, etc.
	


Methodology

Two types of data were used to study the potential of commensuration in the teaching and learning of multiplicative relationships between fractions.

On the one hand, the examination of old data relating to the engineering conceived by Brousseau (Brouseau & Brousseau, 1987) and experimented within COREM during the 1980s: all the sessions conducted during 1987 to implement the engineering in a class of 5th Grade (17 students) were the subject of a priori and a posteriori analyses (Artigue, 1988), based on all the videos of the sessions (archived in the VISA database) and the students' productions (archived and available for consultation at the "CRDM - Guy Brousseau).

On the other hand, building on this initial analysis, we designed and experimented with a resource based on a new context - that of fictitious robots and the study of the length of their bounds - a context that takes up the essential variables of the initial engineering proposed by Brousseau. In particular, our attention has been focused on tasks involving multiplicative comparison relationships between fractions. Experiments were conducted during 2021 in the 8th Grade (25 students) in accordance with the current mathematics curriculum. All the sessions were systematically video-recorded and the work produced by the students was collected in full.

Tasks of "multiplicative comparison" between fractions with commensuration

The background on the tasks under study

The examination of "old" data (Coulange et al., in press) of the teaching experiment of "sheets of paper" (Brousseau & Brousseau, 1987; Brousseau, 2002) emphasized some potential of commensuration as a means to build multiplicative comparison relationships between integers related to measures or of numbers of units. Indeed, in order to express the length of the thickness of a sheet of paper by equivalent fractions, students have to rely on such comparisons between thicknesses of a stack of paper sheets and between numbers of paper sheets. Our analyses of data related to the teaching experiment of "paper sheets" led us to consider that commensuration meaning could therefore offer strong potentialities related to the conceptualization of multiplicative comparison between fractions. Besides, the original sequence of "paper sheets" aimed at teaching such multiplicative comparison relationships (Brousseau & Brousseau, 1987). For this purpose, Brousseau designed mathematical tasks centered on the thickness of a cardboard sheet comprised of a given number of paper sheets. For example, (Figure 1, extracted from CRDM – Guy Brousseau) students had to answer the question: "A cardboard sheet is comprised of 5 paper sheets – the thickness of each paper sheet being $\frac{3}{25}$mm, what is the thickness of a cardboard sheet?"

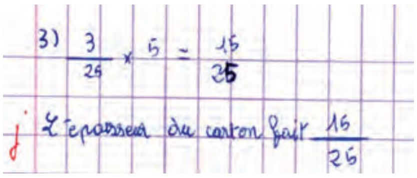


Figure 1: Student's work

We identified two kinds of possible reasoning supported by multiplicative comparisons:

- The thickness of a cardboard sheet is 5 times thicker than a paper sheet, so the pile of 25 cardboard sheets will be 5 times thicker than a pile of 25 paper sheets. Indeed, the thickness of a cardboard is: $\frac{3}{25}mm \times 5 = \frac{3\times 5}{25}mm = \frac{15}{25}mm.$

- The thickness of a cardboard sheet is 5 times thicker than a paper sheet, so we need 5 times less cardboard sheets than 25 paper sheets to obtain a pile of cardboard sheets which will have the same thickness of 3 mm. Indeed, the thickness of a cardboard is: $\frac{3}{25}mm \times 5 = \frac{3}{25:5}mm = \frac{3}{5}mm.$

Similar reasoning could also be conducted about dividing a fraction by a natural number to answer another type of questions: "The thickness of a cardboard sheet measures $\frac{7}{25}mm$. This cardboard sheet is made up of 8 similar paper sheets. What is the thickness of a cardboard sheet?"

Commensuration meaning of fractions may promote the emergence of these kinds of reasoning relying on multiplicative comparison between measurements or numbers of units. Analysis of "old" video data from the VISA video data base show that it is not so easy to promote such reasoning for students of grade 5. Students had difficulties in answering questions about the measurement of the thickness of a cardboard sheet. The teacher tried to help them by using an additive model: considering that the thickness of a cardboard sheet equals to the iterative addition[1] of the thicknesses of paper sheets. Referring to an additive model avowed students to solve the problem given the right answer. From our point of view, this may have moved them away from the two types of reasoning described above. In fact, the iterative addition model seems to be closer to an "equal groups"'s point of view (of objects as paper and cardboard sheets) than to a "multiplicative comparison"'s point of view (comparing the thicknesses of paper and cardboard sheets). Therefore, we aimed at investigating further the potential of commensuration meaning for the conceptualization of multiplicative comparison between different fractions through a new teaching experiment with older students. Thus, we designed new mathematical tasks related to commensuration and based on the motion of bounds of robots (see above) for students of grade 8. We experimented these mathematical tasks with a class of 25 students during the month of June 2021.

1 The thickness of a paper sheet being $\frac{a}{b}$ mm, the thickness of a cardboard comprised of n paper sheets equals to $\frac{a}{b}$ mm + $\frac{a}{b}$ mm + …. + $\frac{a}{b}$ mm + $\frac{a}{b}$ mm, n times.

A new experiment about commensuration and multiplicative comparison of fractions (grade 8)

In this new experiment, we have, on the one hand, taken up tasks close to those described above, involving the multiplication and division of a fraction by an integer. In order to permit the strong emergence of reasoning relating on commensuration meaning, we did not use, in a first step, the common notations of fractions but coded the length of the bound of a robot which reaches *a* units in *b* bounds by the couple (a u; b s)[2]. In a second step, the link between this notation and the usual notation of fractions was made. Such a choice allowed us to see a variety of reasonings, and not only reasonings based on "splitting the unit" meaning of fractions.

For example, the question asked to students was: "The robot A reaches 5 units in 12 bounds. The robot B makes bounds 4 times longer than those of the robot A. What is the length of a bound of the robot B?". The students' works below (Figure 2) show that they appear to have employed both types of reasoning mentioned above.

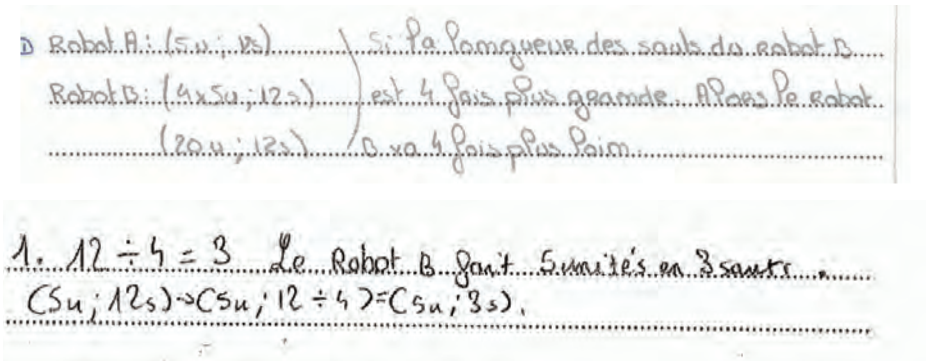

Figure 2: Two kinds of reasoning

The video data shows that students formulated these reasonings relying on multiplicative comparison between measurements and numbers of units. For example, to answer the question: "The robot A reaches 8 units in 21 bounds. The robot B makes bounds 14 times longer than bounds of the robot A. What is the length of a bound of the robot B?", one student spontaneously gave the correct answer:

Student: The robot A does 8 units in 21 bounds and the robot B make a bound 14 times longer than the length of the bound, of a bound of the robot A. So we have 8 times 14. It gives 112 units.

In addition, some of the wrong answers given by students in the class were able to be invalidated by themselves through interactions in the classroom. In the case of the episode below, a student was able to give the correct answer relying on multiplicative comparison, after a discussion with the teacher and another student.

Teacher: Why could it not be 21 times 14, actually?
Student 1: No because it is 21 bounds times 14 bounds. What I'm saying makes no sense.
Teacher: So why do you multiply the number of units by 14 and you don't multiply the number of bounds by 14. Is it correct?
Student 2: Because it is the length of a bound so it is the units which are multiplied and not the number of bounds.

---

[2] We made the assumption that we had used standard notation

Our analysis of this new teaching experiment confirms the potential of commensuration meaning to conceptualize multiplicative comparison of fractions, even though students sometimes partially state their own reasoning. For example, in the episode transcribed above, students did not formulate the argument of "with the same number of bounds" which remained implicit. However, these results led us to design more complex mathematical tasks addressed to students in the same class.

A new task: "composition of multiplicative comparison" between fractions with commensuration

Using the same experiment, students had to answer the following questions: "we consider the robot A and its bound (48u;9s) and the robot B and its bound (24u;18s). Which one of these two robots make the bigger bounds? Can you find a multiplicative relationship between the lengths of the two bounds?"

To answer the first question, we will not detail students' reasoning which appeared during the lessons (concerning the longest bound). Such reasoning has already been presented in Coulange and Train, (2021). Instead, we will focus on the second question centered on multiplicative comparison between fractions. This mathematical task is different from the tasks addressed to students before (and mentioned above). To answer the question, students must perform a multiplicative comparison between two given lengths of bounds of robots. A general description of the given mathematical task would be: "Giving two lengths of bounds, the length of the robot A (e u; f s) and the length of the robot B (g u; h s), the robot A reaching a distance n times greater than the distance reaches by robot B in m times less bounds (i.e., $e = n \times g$ and $h = m \times f$), find the multiplicative comparison relationship between these two lengths?". In the particular case of the tasks mentioned above, n=m. However, such a mathematical task requires reasoning based on composition of multiplicative comparison of relationships between measurements of distances (reached by robots) and numbers of bounds (made by robots). The robot A reaches a distance, n times greater than the one reached by the robot B, with m times less bounds than the number of bounds of the robot B (to reach the initial given distance related to this robot). So, the length of a bound of the robot A will be $n \ \times m$ longer than a bound of the robot B. In the particular case of the mathematical task addressed to students, it gives: a distance 2 times longer reached with 2 times less bounds mean bounds are 4 times longer.

Classroom experiments bring to light both difficulties to find the meaning of this composition of multiplicative relations but also levers to support the conceptualization of such compositions. For example, students seemed to mistake "a distance 2 times longer reached with 2 times less bounds" with the length of "a bound 2 times longer" $([m \times k\ u; n \times k\ b]$ and $[m\ u; n\ b] \times k)$. Such confusions may refer to previous tasks in which students had to find different designations of a same robot. Qualitative strategies of comparisons (for more details, see [Coulange & Train, 2021]) helped students to overcome such difficulties:

Teacher:	The robot A goes further than robot B? Is that true?
Student:	Yes.
Teacher:	And, concerning the number of bounds?
Student:	Smaller, but it goes further.
Teacher:	It goes further, it reaches a greater distance in fewer bounds? is that true?
Student:	Yes.

Concerning the composition of multiplicative comparison, the introduction of a third robot (reaching a distance two times greater than the distance reached by the robot B in the same number of bounds) allowed students to note that the length of robot A is not two times bigger than the length of robot B.

Teacher:	Robot A makes bounds two times larger than Robot B? I suggest you check it out! I want to find a robot C that makes bounds two times bigger than robot B. I would like to know if this robot is robot A […]
Teacher:	Is it robot A?
Students:	No!
Teacher:	It is not robot A. Is that true that Robot A makes bounds two times larger than robot B?
Student:	No.

According to these episodes, the didactical variable's choice, especially m=n (a distance 2 times longer reached with 2 times less bounds) seems not to be the best choice: it fostered the emergence of wrong answers given by students (the length of a bound of the robot A is 2 times larger than the length of a bound of the robot B). In the same time, the "third" robot introduced by the teacher to invalidate these first propositions played another function. It finally helped students to access the composition of the two multiplicative comparison relationships: they identified the length of a bound of this "third" robot as an intermediate measurement which is both two times longer than a bound of the robot B and two times less long than a bound of the robot A. Indeed, at the end of the session some students formulated the right answer taken up by the teacher:

Teacher:	The A makes bounds two times longer than C. […]
Student:	Two times this one (Robot C) which is two times this one (Robot B). […]

Conclusion

The findings highlight the potentials of commensuration meaning to access to a broad conceptualization of multiplicative comparison relationships between fractions. In our view, such multiplicative relationships are distinct from multiplicative inclusive relationships that could be constructed with an "equal groups" approach. Thus, the composition of multiplicative comparison relations as "*n* times more…than *m* times more…than" is more difficult to conceptualize than "*n* sets of *m* sets of". We assume that our new experiment did not allow all the students to easily access such conceptualization. However, this experiment shows that students, under teacher's guidance, finally mobilized such mathematical knowledge. We believe that these first results will lead us to improve the design of mathematical tasks devoted to the teaching and learning of multiplicative comparison relationships between fractions.

Investigation of Number Sense Strategies Used By 5th Grade Gifted Students in Turkey

Perihan Dinç Artut[1]and Zübeyde Er[2]

[1]Cukurova University Faculty of Education, Turkey

partut@cu.edu.tr

[2]Cukurova University Faculty of Education, Turkey

zbeyde-er@windowslive.com

The purpose of this research is to determine the strategies which 5th grade gifted students use in number sense problems. This study has been designed as a case study, which is one of the qualitative research designs. The sample of the study consisted of 21 fifth-grade students who were diagnosed as gifted in a centre of a southern city in Turkey. The number sense test was used as the data collection tool. This test consisted of 25 items, which were prepared in line with the five basic number sense components. The data obtained from the data collection tool were analysedthroughqualitative analysis methods. In addition, the students' opinions and answers to the questions were taken. The research findings presented that 25.90% of the students' solutions are number sense-based, 23.42% of them are partially number sense-based, and 43.61% of them are rule-based strategies.

Keywords: Number sense, Number sense components, Number sense strategies, Gifted students.

Introduction and Theoretical Framework

Number sense refers to a person's general understanding about numbers and operations in addition tohis ability and tendency to use this understanding to make mathematical judgments in flexible ways and to develop useful strategies for coping with numbers and operations. It reflects the tendency and ability to use numbers and quantitative methods as a tool for conveying, processing and interpreting information (McIntosh, Reys&Reys, 1992).

According to the standards of National Council of Teachers of Mathematics (NCTM,2000), students from pre-school to the end of the secondary education period must have understood numbers, the ways of representing numbers, the relationships between numbers and number systems, the meaning of operations and their interrelationships, and they must have been able to calculate smoothly and make appropriate estimations. On the other hand, it is emphasized that students must have developed the concept of number sensebased on these standards.Within the educational context, not every individual is the same and they have different learning rates, so there are individual differences among students. In this context, gifted students can be considered in one of the student groups that show individual differences.

Special talent is defined as a person's high level of performance in abstract thinking and reasoning skills and being above the normal intelligence age (Gagne, 2004). Renzulli (1978), on the other hand, stated that individuals with special talent have a high level of task awareness and creativity skills and they have academic skills above average.

Due to their different cognitive, personal and emotional characteristics compared to students with normal development, the question of how well gifted students have mastery of number sense strategies comes to mind. Foustana, Luwel, &Verschaffel (2017) stated that there are individual differences in the choice of strategy while solving the problems. In addition, stated that the choice of strategy depends on talent.In the related literature, there are some studies conducted about number sense with a group of gifted students, one of the group of students which show individual difference, (Doğan&Paydar, 2020;Tunalı, 2018; Wang, Halberda&Feigenson, 2017). Available resources were reviewed and no study investigating the strategies that are used by gifted fifth grade students in the number sense test was found. It becomes important to determine the number sense strategies they use when solving number sense problems of gifted students, a group of students with individual differences, since it produces significant results to be able to meet the educational needs of these individuals. Moreover, the study might have some contributions to create awareness about the importance of number sense of gifted and talented students in mathematics education.In this context, this study aimed to determine the strategies used by the fifth grade-gifted students while solving the number sense problems.

Method

Design of the Study

This study was designed as a case study, qualitative research designs. In case studies, generally more than one data collection methods are used. The purpose is to reach a rich variety of data that will confirm each other. In this study, the answers given by the students to the Number Sense Test (NST) were investigated as documents. In addition, the students' opinions and answers to the questions were takeninto account.

Participants

In Turkey, there are Science and Art Centres (SAC) in order to provide the most appropriate education and training environment for the gifted preschool, primary, secondary and high school individuals who have individual differences.Students who are diagnosed as gifted by standard tests receive education in line with their needs in Science and Art Centres outside of formal education hours.This research was conducted with 9 female and 12 male students, 21 in total, who were diagnosed as gifted and studying at fifth grade in the centre of a city in the southern part of Turkey. The research sample was determined on a voluntary basis among the students studying at the Science and Art Centre.

Data Collection Tool

The data collection tool consisted of some questions in the number sense scale adapted by Singh (2009) from McIntosh, Reys, Reys, Bana, and Farrell, (1997). Following the field experts' suggestions, some of the questions in the original form were excluded from NST, as they were not considered appropriate for the levels of the fifth grade students. Moreover, the views of a language specialist were taken for controlling the translated version of NST. In line with the advice given, some measurement units such as miles and gallons, which were not used in Turkey, was taken out. Then, the test was finalized. There are 5 components in the test as understanding the concept of number, using the multiple representations of numbers, understanding the effect of operations, using equivalent expressions, using calculation and counting strategies. Understanding number concepts of component is about understanding the value that the number represented and the size that the number indicated. They understand and use the numbers and relationships completely (Harç, 2010). For example, the skill of knowing that there are indefinite decimal number between 0.7 and 0.8 is a sign of this component. Using multiple representations is related to knowing different representations of the number or the value the number represented. Understanding the effect of operations is related to realize how the result can be affected when a number or the value of the operation is changed in an operation. Using equivalent expression is related to knowing the numbers in different expressions, that is, their equivalences. For example, understanding that two out of five can also be represented by an equivalence or understanding that 80 x 0.5 and 80:2 are equivalent symbolize this component (İymen, 2012). Using counting and computation strategies is related to knowing the result of the operation without using pen and pencil. The components of Number Sense Test (NST), the distribution of the questions about these components and some sample items are presented in Table 1.

Table 1:The components of Number Sense Test, the distribution of the questions about these components and some sample items

Components	Items	Sample Item
Understanding the concept of number	Number of Items: 6 Items: 1,6,11,16,21,25	Item 1:Is there a fraction between $\frac{2}{5}$ and $\frac{3}{5}$? If yes, how many?
Using multiple representation	Number of Items:5 Items:2, 7,12,17, 22	Item 7:  Some letters are given on the numerical axis. Please, make up a fraction of letters in which the numerator is about two times the denominator.
Understanding the effect of the operation	Number of Items:5 Items:3, 8,13,18,23	Item13: Circle the appropriate choice for the solution of 87 x 0.09. A) much bigger than 87 B)a little smaller than 87 C) a little bigger than 87 D) much bigger than 87
Using the equivalence representation	Number of Items:4 Items:4,9,14,19	Item 9: Which of the following operations' result is bigger? A) 145 x 4 B) 144 + 146 + 148 + 150
Using calculation and counting strategies	Number of Items:5 Items:5,10,15,20,24	Item 24:Circle the appropriate choice forthe result of [6 x 347] ÷ 43. A) About 30 B) About 50

		C) About 80 D) about 100
Total	25 items	

Data Collection and Analysis

The data of the research wereobtained by means of the interviews and document analysis technique. The students' answers on the number sense test were used as documents in this research. The interviews were conductedwith the same students in order to determine the way they thought while solving the questions in the number sense test. The NST wasadministered to each student individually. After the students finished answering the questions in the test, they were interviewed to find out the strategy they used while solving the questions. The interviews were recorded by a recorder after necessary permissions had been obtained from the students.

The data of the research was analyzed by making use of qualitative analysis methods. The audio recordings obtained from the interviews were transcribed and they were analyzed descriptively. Descriptive analysis is interpreting and summarizing the research data according to the themes which had been determined before (Yıldırım&Şimşek, 1999). Codes such as S1, S2, … were assigned to the students who were interviewed so as to keep their identities confidential. The strategies used while solving the number sense problems are *no answer(Unanswered) or explanation (Unanswered), an answer containing no explanation (Unexplained), rule-based strategy (RBS), number sense based strategy (NSBS) and partially number sense based strategy (PNSBS).* These strategies were explainedin below.

No answer or explanation (Unanswered): This category contains situations in which there are no answers or explanations,

An answer containing no explanation (Unexplained): This category contains answers without any explanation,

Rule-based strategy (RBS): This category contains finding the result by grounding on the operations or rules. For example; finding the result by equalizing denominators while adding two fractions with different denominators to each other,

Number sense based strategy (NSBS): This category contains understanding the numbers, knowing the relative size of numbers, using reference point, estimating the result and being able to evaluate its appropriateness, knowing the effect of numbers on operations (Şengül, 2013). For example; being able to judge that the fraction 4/7 is bigger than the fraction 2/5 without using any algorithms,

Partially number sense based strategy (PNSBS): This category contains situations in which both rule-based and number sense based strategies are used together. For example,using the points of 1 and 0.5 as reference points while comparing numbers. Feeling obliged to convert the number into a decimal number while deciding if the number 8/15 is bigger than 0.5 and doing this by using paper and pencil algorithm when needed (Şengül, 2013).

Findings

In this part, findings obtained from the research data and interpretations are presented.

The Five Components of the Numbers Sense Strategies

The strategies that 21 gifted students used for the problems about each number sense component were investigated and findings approached on the basis of components.525 answers that was used related to the strategies (25x21=525) were obtained from the students‟ solutions in the NST of 25 items.The distribution of the strategies that the students used in the answers to the questions in NST is presented in Table 2.

Table 2: The distribution concerning the strategies about the five the component theNCT

Components	Strategies	*F*	%
Understanding the concept of number	NSBS	30	23.80

	Unanswered	27	5.14
	Total	525	100

As seen in Table 2, according to the component of understanding the concept of number, 48.61% of the strategies that the students used in the answers to the items in NST are rule-based strategies..Moreover, some examples from the interviews with students and some sample answers to the items in the component of understanding the number concept are given below (Figure 1).

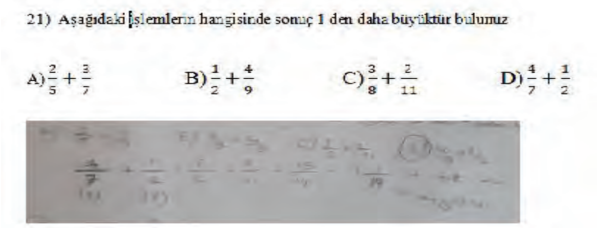

Figure 1:**Solution by using rule-based strategy**

Item 21 in NST is "In which of the following operations is the result bigger than 1? Please, find?". The explanation of the student who gave the answer in Figure 1 is as follows;*"I equalized the denominators as I did here. When I equalized the denominators, I reached the result in Choice D Choice D is bigger than 1 (S9)."*When the solution in Figure 1 and the opinions of the student are considered together, it can be said that the student used rule-based strategy. While S9 was doing addition in fractions, he solved the problem by grounding on the rules of equalizing the denominators. The explanation of S4 for the item 21 in NST is as follows; *"I considered the choices whether they were bigger or smaller than a half. Both fractions in choice A were smaller than a half so they were also smaller than 1. In choice B, there are two fractions. One of them is a half and the other one is smaller than a half. In choice C, both fractions are smaller than a half. In choice D, there is the addition of a fraction bigger than a half and a half so the number is bigger than 1 (S4)*". Thus, it can be interpreted that from the explanation of S4 that he used the number sense based strategy.

The findings about the strategies that are used in the problems of the component of using multiple representations are given in Table 2.Table 2 shows that 41.09% of the strategies that the students used in the answers to the items in NST are rule-based strategies. In addition, some excerpts from the interviews with students and some sample answers to the items in the component of using multiple representations are given below (Figure 2).

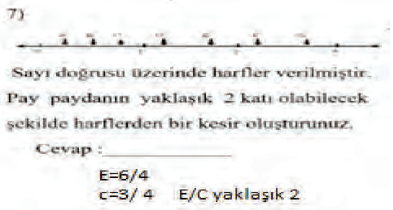

Figure 2: Solution by using rule-based strategy

Item 7 in NST is “Some letters are given on the numerical axis. Please, make up a fraction in which the numerator is about two times the denominator”. The explanation of the student who gave the answer in Figure 2 is as follows;*“I assigned values to the letters on the numerical axis. I assigned letter E as 6/4 and letter C as 3/4. I found out that the result would be about two times when I took the first fraction as it was, turned the second faction upside down and multiplied them (S15)”*.When the solution in Figure 2 and the opinions of the student are considered together, it can be interpreted that the student used rule-based strategy in his solution. The explanation of S7 about his answer for item 7 is as follows;*“As number G is bigger than 2 andnumber E is bigger than 1, I thought G/E would be about 2 (S7)”*. Thus, it can be interpreted S7 used number sense based strategy in his solution.

As seen in Table 2, according to the component of understanding the effect of the operation 44.76% of the strategies that the students used in the answers to the items in NST are number sense based strategies. According to the component of using equivalence representations 41.66% of the strategies that the students used in the answers to the items in NST are number sense based strategies. Also, according the component of using calculation and counting strategies 8.57% of the strategies that are used by the students in the answers to the items about using calculation and counting strategies in NST are number sense based strategies and 55.23% of them are rule-based strategies.

When Table 2 is considered, it is seen that 43.61% of the strategies that the students used while answering the items in NST are rule-based strategies. Table 2 presents that majority of the students used rule-based strategies while solving the problems in NST.

Conclusion andRecommendations

This study, in which it is aimed to determine the strategies that are used by fifth grade students in solving number sense problems, grounds on the findings received from 21 students.When all the solutions obtained from the students (without considering whether they are right or wrong) are considered, it is seen that 25.90% of the students' solutions are number sense-based, 23.42% of them are partially number sense-based, and 43.61% of them are rule-based strategies.

Er and Artut (2018), in the studythey conducted with 8thgrade students with normal developmentwith the same data collectiontool, stated that the students mostly (55, 57 %) used the rule-basedstrategy in their answers.Although the percentage of gifted individuals using rule-based strategies is high, it can be said that they prefer number sense-based strategies when compared to students with normal development.This may be due to the characteristics of gifted students.Tunalı (2018), in his study,found that the number sense levels ofgifted students were betterthan those with normal development.In addition, in his study, it was determined that gifted students preferred number sense strategies more, while students with normal development preferred rule-based approaches.In this context, it can be said that the results obtained from this study are parallel to the results obtained in Er and Artut (2018) andTunalı (2018).

When the importance of number senseis taken into consideration, the number of activities about the concept of number sense should be increased in the curriculum. Moreover, these activities should be administered in the lessons and gifted students should be encouraged to use their number senses.Furthermore, training should be given to gifted students to develop their mental calculation skills and prediction skills, so students' sense of number are developed.

Introduction

The importance of fostering number sense from the early years of learning has been highlighted by both universal references and normative frameworks for decades. However, despite this long history, no consensus has been reached on the definition of this object of study and how it should be measured and evaluated. This paper presents a revision of instruments dealing with number sense assessment.

Given that early numeracy skills are vital for later mathematics learning (Aunio, 2019; Jordan et al., 2009) it is necessary to have appropriate assessment tools that provide detailed information about children's performance and development (Purpura and Lonigan, 2015) and allow teachers to plan targeted instruction and interventions (Aunio, 2019).

Among the typology of existing instruments, Purpura et al. (2015) distinguish between those that perform discrete measures, assessing individual components and specific mathematical skills, versus those that perform broad content measures focusing on multiple mathematical components. Foegen et al. (2007) indicate that a tool covering a broader range of content might be a more suitable means of assessing early mathematical skills in children as these, particularly in the early years, develop as a sequence of connected concepts and skills (National Mathematics Advisory Panel, 2008).

The instruments studied in this paper are focused on the assessment of number sense, considering both early number sense (ENS) and mature number sense (MNS), according to the approach of Whitacre et al. (2020). ENS includes learned skills that involve explicit knowledge of numbers, such as number recognition abilities, counting, number pattern recognition, number comparison, performing arithmetic operations, measurement, and estimation concepts. For its part, MNS focuses on habits of mind and ways of behaving mathematically that are considered desirable, such as the flexible manipulation of numbers and operations or the ability to use numbers and quantitative methods as a means of communicating, processing, and interpreting information (McIntosh et al. 1992).

In this paper, we focus on these two components since we consider them to be of greatest interest in the field of mathematics education, precisely because they can be acquired and learned. Some of the instruments revised here are not specific to number sense, but address some of its dimensions within a broader assessment.

The instruments analyzed were found in documents obtained after searching the SCOPUS databases with the descriptors "tool" AND "numeracy" AND "primary education", "test" AND "mathema*" AND "primary education", "numeracy test" AND "primary education", and "number sense" AND evaluation. This search generated an initial sample of 187 articles. Subsequently, an abstract review was performed to select papers that focused on the use of instruments to measure number sense or related mathematical skills.

The analysis of these works leads us to highlight the existence of 10 instruments, among which there is a proliferation of those focused on the assessment of early number sense, mainly for ages between 3 and 8 years, while there are far fewer instruments for the assessment of the so-called mature number sense.

It is also observed that all the instruments analyzed approach the assessment of number sense from a quantitative perspective. However, given that there is consensus in considering number sense as something easily observable, it seems reasonable to address in future work instruments that attempt to assess number sense from a qualitative approach.

Multiplication as a matter of Grundvorstellungen, strategies and representations

Marei Fetzer[1] and Kerstin Tiedemann[2]

[1]Goethe University Frankfurt, Germany; fetzer@math.uni-frankfurt.de

[2]Bielefeld University, Germany; kerstin.tiedemann@uni-bielefeld.de

This paper is about the initial part of our research concerning the question of how to introduce multiplication in mathematics classes and how to support children's understanding of it. For that purpose, we developed a theoretical approach first which makes a distinction between basic ideas (*Grundvorstellungen*), strategies and representations of multiplication. On this basis, we are now able to investigate more closely how different aspects of the multiplication teaching fit together and which difficulties might arise in their interplay. In this paper, an example from a German mathematics textbook illustrates our theoretical reflections and distinctions.

Keywords: Multiplication, Grundvorstellungen, strategies, representations, textbooks.

Introduction

It is multiplication that, for primary school children, opens the door to larger whole numbers. In many countries, the action of repeated addition is commonly used to introduce multiplication. This initial approach often shapes the idea of multiplication and, thus, tends to become the dominant frame for interpreting multiplicative situations – for students as well as for primary teachers (Askew, 2018). However, relying exclusively on repeated addition proves to be critical for sustainable understanding of multiplication (Bakos & Sinclair, 2019; Askew, 2018). In relation to these findings, we plan a larger empirical study to have a closer look on the question of how multiplication is actually introduced in everyday classroom communication. But for now – and in this paper –, we focus on clarifying our theoretical perspective and, thus, differentiate between basic ideas in the sense of *Grundvorstellungen* (GVs), strategies and representations of multiplication. This way, we have become able to investigate more closely how different aspects of teaching multiplication fit together and which difficulties might potentially arise in their interplay.

Thus, in this paper, we present part of our theoretical framework and approach the following questions: 1) What are basic ideas of the mathematical concept of multiplication? 2) What are appropriate strategies for obtaining correct solutions to multiplication problems? 3) Which representations can help to teach and learn about those basic ideas and strategies?

We will present the example of a German textbook in order to illustrate the use of our theoretical reflections: What suggestions of handling the complex interaction of basic ideas, strategies and representations can be found in the textbooks?

On Grundvorstellungen

In order to be able to support children's understanding of multiplication, we have to ask what multiplication is all about: What does it actually mean to multiply? For our study, we follow vom

Hofe & Blum (2016, p. 226) and use the German term *Grundvorstellung* (GV; pural 'Grundvorstellungen'). Grundvorstellungen (GVs) characterize mathematical concepts and their applications to real-life situations. On a primarily normative level, they are descriptions of the relationship "between mathematical structures, individual-psychological processes, and subject-related contexts, or, in short: the relationships between mathematics, the individual, and reality." (ibid, p. 213). With regard to elementary school, the real contexts are, above all, everyday contexts of action. For the case of multiplication, then, the question is which everyday actions have an inherent multiplicative structure.

According to the GVs concept, three aspects can be distinguished: The *first* aspect is the "*constitution of meaning*" of a mathematical concept (ibid, p. 230). In our context, this means that children get to understand multiplication by linking the mathematical procedure to real-life contexts, situations, and actions. The *second* aspect is the "*generation of a corresponding mental representation*" (ibid, p. 230). In our context, this means that children approach multiplication by constructing mental representations which include exactly those aspects of the real-life context that are relevant from a mathematical perspective. The *third* aspect is the "*ability to apply*" the mathematical concept to real-life situations by recognizing a corresponding structure (ibid, p. 230). In our context, this means that children become able to apply the mathematical concept of multiplication to real-life contexts by recognizing multiplicative structures in the complexity of real-life situations.

We chose the GV concept for our research on multiplication for at least two reasons: *First*, the concept highlights that teachers (and mathematics educators) have to make decisions on a normative level: From an expert's point of view, which everyday actions have an inherent multiplicative structure and can be, for this reason, a suitable starting point for individual constitution of meaning? Thus, the GV concept focuses very clearly on the connection to real-life situations. *Second*, the GV concept allows us to differentiate between this normative level on the one hand and an empirical level on the other hand. Vom Hofe & Blum (ibid, p. 232) speak about a normative and a descriptive way of using the GV concept. When we use the concept in a descriptive way, we try to get as much information as possible about the mental representations that individual students *actuall*y have developed. Those mental representations might correspond to the intended ones more or less, but they are crucial when it comes to the actual processes of teaching and learning.

In the following, we will first use the GV concept in a normative way. Thus, we present two essential GVs of multiplication that can be found in the literature. Both of them ground on the activity of building units or – a bit shorter – of *unitizing* (Götze & Baiker, 2020; Lamon, 1994). This initial selection might need to be complemented and adapted in our ongoing research work.

Repeated addition

In Germany as in many other countries, repeated addition is the most common approach to introduce the basic idea of multiplication. Tasks then focus on *sequential situations* in which someone performs a specific *action* several times. An example from the German textbook "Zahlenbuch 2": A boy carries 3 books from a box behind him to a table in front and he does it exactly 7 times (figure 1, left). The boy says: "Always 3 books on a pile.". Two aspects are characteristic of the GV repeated addition: Someone bundles units and performs, one after another, a specific action on each of those units.

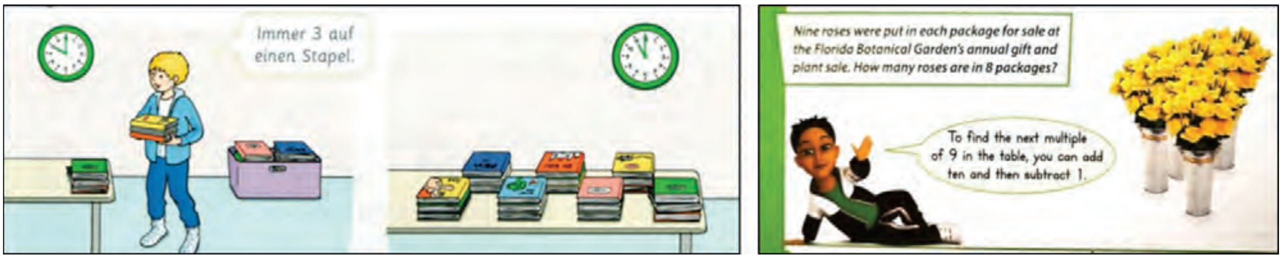

Figure 1: Dynamic and static situations

The story about carrying books from a box to a table can be told mathematically in two different ways. It can be described as a process of repeated addition (3+3+3+3+3+3+3) or, in order to shorten the story, as a process of multiplication (7·3). The different meanings of multiplicand and multiplier fit perfectly well to the real-life situation (3 books on each pile, carrying 7 piles one after another) (Götze & Baiker, 2020). Thus, multiplication is introduced as a 'shortcut' of a repeated addition. However, is multiplication really nothing more than a certain form of adding?

In other tasks, the chronological sequence is not highlighted that much. For example, nine roses were put in each package for sale at the "Florida Botanical Garden's annual gift and plant sale" (figure 1, right, from the US-American textbook "enVision Mathematics Grade 3"). This is a rather static situation; all activities are already completed. The only question that brings us to repeated addition is the question of the total number: "How many roses are in 8 packages?" In order to find an answer to that question, the boy suggests to add (and subtract) repeatedly: "To find the next multiple of 9 in the table, you can add ten and subtract 1." Thus, repeated addition is mainly presented as a *strategy* to obtain a correct solution.

In fact, there are mathematics educators that come up with doubts about the GV of repeated addition and its potential for understanding multiplication. For example, Nunes & Bryant (2009, p. 9) summarize: "Finally, it is assumed that, in spite of the procedural links between addition and multiplication, these two forms of reasoning are distinct enough to be considered as separate conceptual domains." Similarly, Bakos and Sinclair (2019) state, together with Akew (2018), that the exclusive reference to repeated addition implies "limiting access to opportunities through which functionally thinking can emerge" (Akew 2018, p.1). Since several years, this position is supported from different sides. First, there are empirical studies that report a correlation between the use of addition strategies and the underachievement on multiplication problems (Baroody, 1999; Park & Nunes, 2001). Second, studies focus on successful forms of teaching multiplication which do not introduce multiplication as a 'shortcut' of addition, but as a mathematical operation in its own right (Park & Nunes, 2001). Third, some researchers stress that the GV of repeated addition does not allow to recognize the *functional* relation between multiplicand and multiplier (Askew, 2018). This last reference leads us directly to the second GV.

One-to-many correspondence

The concept of one-to-many correspondence refers to the activity of comparing quantities in a certain way (Vergnaud, 1983). A first way of comparing quantities is to compare them additively. For example, Sara has 7 playing cards more than Jonathan has. There are two sets of cards and we can determine the difference between these two sets by adding: If Jonathan collects 7 additional playing cards, he will have as many cards as Sara. Thus, additive reasoning stems from the (mental) action of joining and placing sets in one-to-one correspondence. A second way of comparing quantities is to compare them multiplicatively (Sinclair & Bakos, 2019). For example, “Amy’s Mum is making 2 pots of tomato soup. She wants to put 3 tomatoes in each pot of soup. How many tomatoes does she need?” In this case, there are more than two quantities and these quantities are not compared additively. Instead, the action is rather putting two variables in one-to-many correspondence (Nunes & Bryant, 2009, p. 11). Two aspects are characteristic of the GV of one-to-many correspondence: Someone performs an action that keeps the ratio between two variables (tomatoes, pots) constant and that leads to bundled units – at least in the end.

It is noteworthy that the concrete action can actually be performed in one way or another. For example, Amy’s Mum can put one tomato in each pot until there are 3 tomatoes in both pots *or* she can always put 3 tomatoes at once in a pot. Both actions lead to the same result, to a constant ratio between tomatoes and pots. Thus, in the GV of one-to-many correspondence, the focus is put on relations between quantities. In other words, the basic idea of one-to-many correspondences puts particular emphasis on the relation between the multiplicand and the multiplier. Accordingly, this GV stresses the asymmetry of multiplication as well as repeated addition does.

The example of cooking tomato soup (with surprisingly few tomatoes) is taken from a study conducted by Park & Nunes (2001, p. 768). In this intervention study, the researchers compare two treatment conditions: teaching of multiplication through repeated addition and teaching through one-to-many correspondence. Both groups made significant progress from pre- to posttest. But, at posttest, the group taught by one-to-many correspondence performed significantly better than the repeated addition group in multiplicative problems even after controlling for level of performance at pretest (Park & Nunes, 2001, p. 770). On this basis, the researchers come to the conclusion that teaching of multiplication should not be grounded in repeated addition, but in one-to-many correspondence (ibid, p. 772). Further research results strengthen this position, namely those about children’s informal knowledge about multiplication. Several studies report that many children already start school with a remarkable understanding of one-to-many correspondence and that this informal knowledge seems to be quite resistant (Nunes & Bryant, 2009, p. 12, 21). Moreover, many children, who have not been taught about multiplication yet, quite successfully use correspondence strategies in order to solve multiplicative reasoning problems (Kouba, 1989; Carpenter et al., 1993).

On strategies

Independent of the focussed GV, it is another important aspect of teaching multiplication to provide strategies for children which allow them to obtain correct solutions to multiplication problems in a flexible and efficient way (Nunes & Bryant, 2009). However, strategies taught in mathematics classes seem to be different in different countries. To start with, we draw on the German perspective and refer to core strategies (Götze & Baiker, 2020).

Knowing by heart

From our perspective, knowing by heart is not actually a *calculating* strategy. Thus, you will not have to calculate anymore if you know the solution to a multiplication problem by heart. Still, it can serve as a very helpful “tool for solution” – for example as part of addition strategies as we will see in the next paragraph (Rathgeb-Schnierer & Green, 2013, p. 354). Knowing by heart is not necessarily linked to (any) Grundvorstellung of multiplication.

Repeated addition

Repeated addition was introduced as a GV above. Although some researchers argue that it is not really a separate idea of multiplication, it is understood as an appropriate strategy to solve multiplication problems anyway (Götze & Baiker, 2020).

One possibility to realize repeated addition is to add every single unit: $3+3+3+3+3+3+3 = 21$. Alternatively, you can start from a result that you know by heart and add or subtract the 'missing' units: $7 \cdot 3 = 15+3+3 = 21$. However, the concrete calculation process may look like, the "procedural links between addition and multiplication" become obvious (Nunes & Bryant, 2009, p. 9).

Changing order

Changing the order of the factors is a helpful strategy when solving multiplication tasks. This strategy is based on the mathematical structure of commutativity. Nevertheless, it is quite difficult to link this strategy to real-life contexts and, thereby, to the intended GVs. It is much easier, but takes longer to carry 7 times 3 books from a box to a table than it would be to carry 3 times 7 books. If Amy's Mum put 2 instead of 3 tomatoes in each pot and took 3 instead of 2 pots, the soup might still taste the same, but there would be more of dishwashing to do.

On representations

As we can see so far, the interplay of GVs and strategies might be rather difficult in detail. In this regard, it is particularly relevant that all of them require representations in order to be accessible to children in mathematics classes (Kuhnke, 2013). For this very reason, representations are the third part of our theoretical perspective.

Real-life or didactical

Kuhnke (2013, p. 42) differentiates between real-life and didactical representations. Real-life representations take up real-life contexts that children probably already know, whereas didactical representations are specially made for teaching purposes and, therefore, are strongly adapted to the intended mathematical structure. With a view to GVs, this distinction is important because real-life representations are much more helpful for linking the mathematical concept of multiplication to typical application situations that children might know from their everyday lives outside school.

Real-life: Picture sequences

Picture sequences are real-life representations. They are well-known and widespread representations of multiplication and usually consist of two or more pictures telling a story of repeated actions. Thus, this representation is closely connected to the GV and the strategy of repeated addition. As we see in the story of the boy and the books above, the story-line itself is reduced to a minimum. Thus, links to every experiences are supposed to be realized and, at the same time, processes of abstracting and seeing the mathematical aspect within that story are meant to be enabled.

Real-life or didactical: Unstructured and structured quantities

Pictures of structured or unstructured quantities might be either realized in real-life or in didactical representations. This way of representing multiplication is based on the discrimination of multiplicand and multiplier. In the case of unstructured items, the action of unitizing is highlighted. The one-to many correspondences may be visualized as well as the concept of repeated addition. Strategies supported by this way of representing are unitizing and repeated addition.

Mainly didactical: Rectangular arrangements

In Germany, rectangular arrangements as a particular form of structured quantities are quite common. They might be either real-life or didactical representations and support a close link between geometry and arithmetic. Rectangular arrangements especially enable the visualization of the commutative structure of multiplication. Such structured arrangements can represent both GVs: The focus can be on repeated addition or on one-to-many correspondences. Strategies supported by this way of representing are unitizing and counting units, repeated addition and changing order.

5. First insights: Textbooks

How is multiplication introduced in textbooks? Do representations align with certain GVs? What strategies are introduced and supported? In the following, we present an example from our textbook analyses in order to illustrate the use of our theoretical distinction between GVs, strategies, and representations as an analytic framework. Thus, we ask for 1) representations in order of their appearance and analyze on this basis 2) which GVs are addressed and 3) which strategies are supported.

In the German textbook „eins zwei drei Mathematik 2“ (one two three mathematics 2), the introduction of multiplication is to be found on pages 72-73.

Context: A common classroom.

Representations: Rectangular arrangements embedded in the classroom situation, didactical rectangular arrangement, pre-structured representations of quantities

Tasks: Talk about the picture, find multiplicative structures in your own classroom, talk about quantities and about amounts of units, write multiplication tasks according to the representations given, draw representations

Addressed GVs: repeated addition

Potentially supported strategies: knowing by heart, changing order, repeated addition

In this introduction, the focus is exclusively on the GV of repeated addition, although the given everyday situation of a classroom would support a much wider spectrum. Such pictures basically offer the opportunity to include unstructured quantities which require the process of unitizing and support the concept of one-to-many correspondences. Besides, the tasks reduce the potentially wide range of supported concepts. Accordingly, this textbook conceptualizes multiplication solely in the context of repeated addition. In particular, multiplication is reduced to a certain way of writing and speaking. It is understood as a ‘shortcut’ for addition.

The next pages 74-75 focus on rectangular arrangements.

Context: Children working in a (math) class room
Representations: rectangular arrangements (one embedded in a story line showing the sequence of progression, one row after the other is uncovered)
Tasks: write the addition and the multiplication problem, show the multiplication problem on the hundred board, draw the multiplication problem and write the matching addition problem.
Addressed GVs: repeated addition
Potentially supported strategies: knowing by heart, repeated addition

On these pages, the focus is put on rectangular arrangements. These didactical representations offer the opportunity to refer to the commutative structure of multiplication and to introduce the changing of order as an appropriate strategy to solve multiplication tasks. Interesting enough, this potential is not used. Instead, children should 'translate' between one type of representation (pictures of rectangular arrangements) and another (symbolic representations, multiplication and addition problems). Accordingly, there is a focus on the structure accomplished by a differentiation in rows and columns. Again, repeated addition is the only addressed GV and the only addressed strategy as well. The misleading idea of multiplication being a different way of writing additions is strengthened.

6. Discussion

There are at least two GVs of multiplication: repeated addition and one-to-many correspondences. Both rely on the basic mathematical activity of unitizing (Lamon, 1994). However, repeated addition is the dominant approach in many countries including Germany, Italy, Taiwan, the US and Canada. First (German) textbook analyses confirm that this way of introducing multiplication provides a good basis to repeated addition as a *strategy*. Nevertheless, we found *representations* that might be used for addressing a much wider range of multiplicative situations. We can think of comparing quantities multiplicatively, of stressing the functional relation between multiplicand and multiplier and, in this way, of focusing on one-to-many correspondences. But, as first analyses indicate, these potentials concerning the *Grundvorstellungen* don't seem to be exhausted in the textbooks. Instead, we found the introductions of multiplication being mainly restricted to the GV and the strategy of repeated addition. This is a surprising result, especially as many researchers agree on the GV of one-to-many correspondence as very promising for supporting children's understanding of multiplication and their performance on multiplication problems.

On the basis of these first results, we regard the theoretical discrimination of GVs, strategies and representations as helpful for our work on the question of how to introduce multiplication in a meaningful and consistent way. Thus, we resume that these elements do not always complement each other in a useful way, but can actually be in conflict.

How do we plan to proceed in our larger project? On the one hand, we want to find out how teachers are supported in their teaching of multiplication in different national contexts in order to prove, deepen and complete our findings from the textbook analyses. On the other hand, we are in process to do research in mathematical classrooms to get insight into the ways introduction of multiplication is empirically realized in everyday classrooms. We have identified remarkable challenges from a theoretical perspective. Thus, the question arises how teachers actually face these challenges of introducing multiplication. At the moment, we observe (German) mathematics classes of grade 2 in order to reconstruct empirically how teachers actually work with the offers of their textbooks and meet the challenge of introducing multiplication in class discussions. This way, we hope to contribute to the scientific discussion about competing approaches to multiplication.

Keywords: Flexibility in mental calculation, addition and subtraction, elementary arithmetic.

Introduction

Flexibility in mental calculation is a central goal of elementary mathematics education and there was an increasing research interest in children's approaches and flexible strategies in the last two decades (e.g. Green & Rathgeb-Schnierer, 2020). Empirical findings show that primary students rarely solve problems flexibly and adaptively, especially after learning standard written algorithm (e.g. Selter, 2001). Accordingly, students are often not capable to refer to number patterns and relationships as well as specific problem features for solving one or multi-digit problems flexibly (ibid.). Research results suggest that students' creative and flexible use and combination of different strategic means (Rathgeb-Schnierer & Green, 2013) decrease after introducing respective strategies as a sample solution in the classroom (Benz, 2005). Thus, specific approaches for learning arithmetic seem to have a negative impact on students' abilities in flexible mental calculation. On the other hand, studies show that students' flexible mental calculation can be supported by appropriate instructional approaches (e.g. Rechtsteiner & Rathgeb-Schnierer, 2017). For the development of perceiving and using number patterns and relationships as well as flexible mental calculation Schütte emphasizes the importance of the approach “Zahlenblickschulung" (2004, p. 142; see also Rechtsteiner & Rathgeb-Schnierer, 2017). In general, teaching approaches have a crucial impact on students' abilities in flexible and adaptive arithmetic. Although flexibility in mental calculation is consensually considered a relevant ability, the concept is not consistently defined and operationalized in different studies. Rechtsteiner-Merz (2013) has analyzed the existing approaches. In this study, we refer to the approach which connects the notion of flexibility to cognitive elements that sustain the solution process (e.g. Rathgeb-Schnierer & Green, 2013). Cognitive elements are defined in the context of this study according to Rathgeb-Schnierer & Green “as specific mental actions that sustain a solution process […]. These can be learned *procedures* (such as computing algorithms) or recognition of *number characteristics* (such as number patterns and relations)” (2019, p. 5, emphasis in original). In this vein, we define flexible mental calculation according to Rathgeb-Schnierer and Green: "Only if the tools of solution are linked in a dynamic way to problem characteristics, number patterns, and relationships would we consider as evidence of flexibility in mental calculation" (2013, p. 357).

Aim of the study

There are research projects that investigate flexibility in mental arithmetic with regard to the cognitive elements that sustain the solution process (e.g. Green & Rathgeb-Schnierer, 2020; Rechtsteiner & Rathgeb-Schnierer, 2017). However, conclusions about these cognitive elements cannot be drawn directly based on manifest characteristics, such as the obtained solution or the described methods of solution. Valid conclusions can only be derived from students' explanations and justifications. So far, no standardized instrument exists for capturing the cognitive elements objectively and reliably.

Furthermore, the existing instruments are not sufficiently validated. According to this, already published research results only allow limited generalizable conclusions. Our study pursues innovative approaches: It targets to develop and evaluate a standardized, semi-structured interview for second and third graders which allows capturing abilities in flexible mental calculation by revealing the cognitive elements that sustain the solution process. Therefore, we developed a semi-structured interview guideline regarding the quality criteria of objectivity, reliability, and validity. The interview contains activities of sorting problems (prompt: "Which problem is easy/hard for you?"), reasoning about sorting as well as comparing (prompt: "Which problem is easier for you?") and solving problems (e.g. Rathgeb-Schnierer & Green, 2013; Rechtsteiner & Rathgeb-Schnierer, 2017). For evaluation, we will conduct and videotape approx. 100 interviews with students from the end of second grade and beginning of third grade. Additionally, we survey other constructs, such as arithmetic skills and linguistic abilities. We aim to enhance existing methods to capture flexibility in mental calculation by providing an interview instrument with a different perspective that allows to be applied to a large sample. This interview offers new options regarding quantitative and qualitative analyses as well as triangulation analysis. We completed the pilot run of the semi-structured interview guideline with eleven second graders. Some of the interviews were also conducted by an assistant to see how well the semi-structured guideline worked.

Open-ended tasks as approach for learning arithmetic in heterogeneous elementary classrooms

Silke Friedrich[1] and Elisabeth Rathgeb-Schnierer[2]

Keywords: heterogeneity, open-ended tasks, equations

Introduction

This study explores a teaching approach for heterogeneous learning groups in mathematics instruction. In elementary school the diversity of students is a key challenge. Since elementary schools draw their student body from residential areas, students exhibit a wide range of abilities and achievement levels. In order to cope with heterogeneous learning groups, various approaches have been developed within mathematics education. In the German context, these approaches base on the concept of differentiation through open-ended tasks that allow multiple solutions on different achievement levels. This concept is specifically labeled as ‘natural differentiation’ (literally translated) (Scherer, 2013). This concept assumes that students work on differentiating open-ended tasks according to their learning and performance level. Whether this assumption is also confirmed in practice has not yet been systematically empirically tested. This is the aim of the presented research project. The study will compare the individual learning condition of students and the performance level when working on an open-ended task that allows multiple solutions (naturally differentiation).

Theoretical framework

The theoretical framework is the offer/take-up model (Angebots-Nutzungs-Modell) (Göbel & Helmke, 2010) developed by Helmke. This model describes the complex processes of teaching and learning and all influencing factors in a simplified way. To explain the effects of teaching and learning success, the model gives a compact overview of the most important variable clusters.

In this project we offer students an open-ended task. Open-ended tasks allow multiple solutions at different levels and thus provide learning opportunities for students with different levels of proficiency. The use of open-ended tasks that allow multiple solutions on different achievement levels represents an innovative approach of teaching and learning arithmetic in heterogeneous classes and inclusive education (Lindenskov & Lindhardt, 2020).

Aim of the study

The study aims to determine to what extent the use of an open-ended task depends on prior knowledge and other variables of learning condition. Our research question is: Do students process the open-ended task "Kombi-Gleichungen" (invention of equations with multiple operations) according to their prior knowledge and individual learning conditions?

Methodology

The sample includes 160 third graders from different heterogeneous classrooms. Firstly, we assessed the learning condition of the students by a questionnaire to analyze students' attitudes towards learning mathematics and a standardized test to measure the achievement level in mathematics. The chosen instruments allow to survey cognitive learning prerequisites as well as motivational and volitional learning prerequisites. Secondly, we conducted two math lessons and offered all students the open-ended task to invent equations in which the equal sign is relationally used (e.g., 2 + 7 – 3 = 10 – 4). This task allows multiple solutions, enables students to work at their individual performance level. The students' worksheets provide the database for our analysis. To assess the level of students' solution process, we use a category system (Friedrich & Rathgeb-Schnierer, 2020). Finally, we link level of the solution process to the learning prerequisites of the students.

Preliminary outcomes

After analyzing part of the data, it appears the highest processing level is characterized by invention of equations with different operations, multi-digit numbers, several calculation steps, and transitions with a systematic procedure. Inventing an equation system including two or even more complex equations is a characteristic of a high level of processing. All students were able to handle the open-ended task: Those who scored highly in the achievement test attempted to invent particularly complicated equations. Students with a low score invented many equations with few calculation steps.

The aRithmetic Discourse Profile as a tool for evaluating students' discourse according to the ritual to explorative continuum

Einat Heyd-Metzuyanim[1], Avital Elbaum-Cohen[1] and Michal Tabach[2]

[1]Technion - Israel Institute of Technology; einathm@technion.ac.il; avitalec.ntear@gmail.com

[2]Tel-Aviv University, Israel; tabachm@tauex.tau.ac.il

We propose a new tool – the aRithmetic Discourse Profile (RDP) for analyzing the arithmetic discourse of students, based on the commognitive theory. The tool maps students' discourse on a continuum between ritual and explorative participation. We apply the tool to the discourse of 12 7th grade students and exemplify the analysis on three tasks: one in addition of whole numbers, one in multiplication and one with fractions. Tasks were taken from regular curricular materials of elementary school mathematics. We discuss the affordances of the tool in relation to existing diagnostic tools.

Keywords: Arithmetic, discourse, assessment, commognition.

Introduction

Assessing students' mastery of arithmetic has multiple potential benefits. It can assist teachers in evaluating students' performance in relation to curricular expectations and provide researchers with measures of pre- and post- interventions. Two major forms of assessment currently exist for assessing students' arithmetic discourse. One is the common school-based exams (or standardized tests). The other are "diagnostical tools" usually used by educational psychologists to assess students' "arithmetic abilities" (or disabilities) (e.g. Chinn, 2020). School-based exams are effective for efficiently assessing students' outcomes. Diagnostic psychological tools are effective for identifying certain common deficits (such as problems with fact retrieval) (e.g. Dowker, 2012). However, both these types of tools do not provide a fine-grained profile of students' arithmetic knowledge and skills.

Previous commognitive studies (Ben-Yehuda, 2003; Ben-Yehuda et al., 2005) have started offering an alternative to the above two types of assessment, by proposing a form of "profiling" a students' arithmetic discourse, based on transcriptions of think-aloud interviews. However, these studies were quite preliminary in their conceptualization. Their categories were difficult to replicate and not sufficiently connected to a broad theory of learning. In the past two decades, the commognitive theory has evolved and sharpened its tools of analysis. One useful conceptualization that has come out of commognitive studies is that of the "ritual-exploration" dyad, which qualifies participation in discourses both according to development (learners starting from ritual and moving to explorations) (Lavie & Sfard, 2019) and according to achievements (learners experiencing difficulties performing more ritually than successful learners) (Heyd-Metzuyanim, 2015). Armed with these new conceptualizations our goal is to develop and test a tool for mapping students arithmetic discourse based on the continuum of ritual to explorative participation.

Theoretical Background

Commognition theorizes the learning of mathematics as a process whereby learners gradually become participants in the mathematical discourse. This process is characterized by movement from performance of ritual routines to explorative routines. Routines are pairs of *task* (what it is that the performer feels obliged to do) and *procedure* (the steps to achieve the goal). Ritual routines are aimed primarily at pleasing the masters of the discourse, usually teachers or parents. As such, they are mostly characterized by thoughtful imitation (Lavie et al., 2019). The learner attempts to repeat actions that she saw the expert perform in situations that she perceives as similar to the present task. As the learner gains experience with similar tasks, her routines gradually become more explorative (Sfard & Lavie, 2005). Explorative participation is characterized by flexible usage of different procedures to achieve a single task, and by the learner initiating these procedures to achieve her own goals. That is, the learner performs the routines to produce narratives about the world, not to please an external authority. Explorative participation is thus characterized by agentivity. In addition, explorative routines are *bonded*, that is, the output of each step serves as an input to the next step in the procedure. In contrast, ritual routines may often be unbonded since they are made up of steps imitated of others, without the performer being aware of how or why each step is bonded with the former ones.

In mathematics, routines are mostly concerned with producing narratives about mathematics objects. For example, the routine of multiplying 5×3 leads, eventually (after, for example, adding three to itself five times), to the narrative "5 times 3 is 15". Yet for such routines to be enacted with ease, learners need to *objectify* numbers. The process of objectification, according to commognition, is the main process that underlies what is often termed as "mathematical understanding". Within this process, learners come to view processes (such as counting or adding) as products. For example, the process of counting "one, two, three, four" eventually gets reified into an object ("four") that can be treated as existing on its own, regardless of the process of counting that led to it. The process of objectification, however, takes time, and ritual performers often treat the signifiers of mathematical objects (such as the digits of a number in the realm of tens) only *syntactically,* that is, without relation to the object that they are supposed to signify. The processes of objectification are never-ending in the learning of mathematics since mathematical discourses are hierarchical. Thus, for example, once the learner masters (or becomes explorative in) the discourse of natural numbers, they are expected to enter the discourse of fractions (or rationale numbers). Once this has been mastered, the expectations for participation are raised to the discourse of real numbers, algebra, etc.

School exams are ill-suited to examine the extent to which students perform explorative routines in a certain discourse, as they mostly give a picture of the final answer produced by the students' routines, not the procedure by which the answer was produced. Therefore, students may be identified as "successful" (or achieve highly on exams) in school mathematics, while many of their mathematical routines are still ritual (Heyd-Metzuyanim, 2015). Another problem with standard school assessment is that they can miss certain explorative routines that students who err in their final answers do perform. This is especially relevant to low achieving students (Ben-Yehuda et al., 2005; Heyd-Metzuyanim, 2013). To overcome these limitations, early commognitive research came up with a tool called "Arithmetic Discourse Profiling" (Ben-Yehuda, 2003). This tool, based on a form of cognitive interviewing, attempts to map the student's discourse in ways that highlight not just what the student does "wrong" (or non-canonically) but also (and more importantly) the actions the student does perform when attempting to solve mathematical tasks. In this work, we aim to extend the early attempts at profiling arithmetic discourse by using the more recent definitions and operationalizations of ritual vs. explorative routines. Our research question is: Based on tasks taken from elementary school curriculum, how can students' arithmetic discourse be characterized on the continuum between ritual and explorative participation?

Method

Our analytical tool was developed as a secondary data analysis, on data collected by the first author (Heyd-Metzuyanim, 2011). The data consists of arithmetic interviews conducted with 12 7th graders during 2008. The interviews were conducted as part of a larger study where the author taught the 12 students in three groups over a period of 5 months, in an out of school "course". The course was broadly defined as "mathematics enrichment" and the original study was aimed at examining interactions between emotional and cognitive aspects of learning. The students were placed in three groups (each of 4): Low achieving, middle-high achieving, and excelling. The excelling group consisted of 4 boys who came from an accelerated mathematics and science classroom (to which entrance was based on very high grades in elementary school mathematics and other subjects). Placement in the low and middle-high achieving group was based on reports coming from the school and parents of the students regarding their grades in elementary school mathematics and their achievements in the beginning of 7th grade.

All the interviews were conducted by the first author, in a one-on-one setting. Students were asked to think out loud as they solved the problems (Young, 2005). When they were not successful and asked for help, the interviewer attempted to scaffold the task, yet mostly she refrained from giving feedback on the correctness of the results. Interviews were videotaped with two cameras, one pointing at the student's face and one on his writing. Written artifacts were collected too.

The interview protocol was based on Ben-Yehuda's (2003) ADP protocol and consisted of 24 tasks (some very short) that had potential to illuminate various aspects of students' arithmetic discourse. For the present study, which goal was mainly to create analytical tools, we chose three tasks for analysis (the full protocol appears in (Heyd-Metzuyanim, 2011)). These tasks were (1) Add 96+7936 (if possible, "in your head") (2) Multiply 25×99 and (3) $\frac{2}{3}\times 9$. We chose these tasks as they covered a relatively large domain of arithmetic skills, including manipulating whole numbers and fractions.

Analysis: Analysis was done on full verbatim transcriptions of the interviews and proceeded in two steps. First, we divided each routine (task + procedure) into sub-routines (for example, adding 96+7935 often consisted of sub-routines such as adding 5+6, adding 11 to 8020, etc). Next, we determined whether the routine (or sub-routines) were ritual or explorative according to eight categories, taken from the literature on ritual and explorations. These are explained in Table 1.

Table 1 - Criteria of analysis for ritual-explorative routines

	Criterion	Analytical actions	Characteristics of an explorative routine	Characteristics of a ritual routine
1	Objectified /syntactic mediation.	Searching for evidence that the nouns signify numbers/quantities and	In whole numbers, relating to the place value of the numeral. In fractions: relating to different realizations of the fraction as the same, including fraction as	In whole numbers: relating to operations as signaling procedures on digits rather than on the whole number. In

		not just the signifier of the number	operator, part of whole, part of quantity, etc.	fractions, relating separately to the numerator and denominator.
2	Flexibility	Look for multiple procedures that are associated with the same task.	More than one procedure is associated with the main task OR a non-standard procedure is applied to the task.	Relying on only one procedure while showing rigidity and reluctance to use any other procedure.
3	Agency/External authority	Look for subjectifying discourse; examine verbs/pronouns and non-verbal signals that indicate the confidence.	Mathematizing with high confidence (no hesitations, question marks, no looking for approval). Spontaneously articulating mathematical narratives	Talking with question marks; Verbally or Non-verbally seeking approval from the interviewer; Relating to external authority for justification (e.g. "that's what I learned in school")
4	Focus on goal or on procedure	Look for verbs indicating doing (e.g. "I add") vs. being verbs indicating the result ("it is…");	Talking about the result, checking it, or explaining it spontaneously	Talking about the actions of the procedure. Ending the procedure without relating to the reasonableness of the result.
5	Bondedness	Examine the procedure; sub-procedures and the bonds between them.	Each sub-procedure feeds the next sub-procedure. The narrative of the result of sub-procedure N serves as the input of sub-procedure N+1.	There is a disconnect between a certain sub-procedure and its following one OR sub-procedures using different realizations are not treated as the same.

The final three characteristics were *Canonical procedures* that were coded as explorative if all the steps in the procedure aligned with standard mathematical procedures; *Canonical narratives* were coded as explorative if the end result of a procedure (e.g. the end result for the task "two thirds of 9" was "six") was canonical; and *Mediation* was coded as explorative if the procedure was fully initiated and enacted by the student, and ritual if some parts of it were mediated by the interviewer.

The first stages of constructing the coding criteria (exemplified in the findings section) were created by the first and third authors, through mutual agreement. After that, the second author was taught the coding scheme, blindly replicated it on 50% of the data, and created a coding manual.

After coding was complete, a "ritual/exploration" ratio was calculated for each student, on each of the tasks. The highest explorative ratio could be 0/8 (0 ritual, 8 explorative characteristics), whereas the most ritual performance could by 8/0. Notably some of the characteristics (agentivity, bondedness, canonical and non-canonical procedure/narrative) could be coded *both* as ritual and as explorative. This was necessary since we wanted to account for explorative elements of sub-routines. Thus ratios such as 7/3 or 5/6 were also possible. In general, ratios close to 1 showed "mixed" performance.

Findings

Table 2 - Ritual-Exploration ratios and relative placement of 12 students

Student	Achievement group	96+7935	25×99	$\frac{2}{3}\times 9$
Dana	Low	6/4	8/2	7/3
Hili	Low	7/2	Not attempted	Not attempted

Hila	Low	7/3	7/1	Not attempted
Naor	Low	2/6	8/3	4/5
Edna	Middle-high	8/3	6/7	Not attempted
Idit	Middle-high	0/7	6/5	7/4
Dan	Middle-high	1/7	7/6	2/6
Ziv	Middle-high	3/6	3/8	2/6
Ram	Excelling	0/6	0/8	1/7
Gabby	Excelling	0/7	0/8	1/7
Yoram	Excelling	0/7	0/8	0/7
Amir	Excelling	0/7	1/8	0/8

Table 2 summarizes the ritual/explorative ratios of the 12 students' (all pseudonymed) performance on the three tasks. Before we delve into the exemplification of how these ratios were determined, there are a few observations worth mentioning regarding this table.

Our first observation is that the ritual/exploration tool seems to capture a wide range of routine enactments, from those very high in exploration (0/8) to those almost only featuring ritual characteristics (8/2). Secondly, we see the low achieving group very high in ritual characteristics (or not attempting tasks at all); the moderate-high group is fluctuating widely, between 0 and 8; and the excelling group is quite consistent around the 0 – meaning high exploration. This lends validity to the tool as capturing features that reflect students' success in school mathematics. A third observation is that students can be inconsistent with respect to different tasks. For example, Dan's performance is explorative in the addition task, ritual in the multiplication task, and relatively explorative again in the fractions task. We do see, however, that in the excelling group these fluctuations do not exist.

Next, we demonstrate our analysis on two episodes from students' interviews, showing different types of routine enactment, associated with different ritual/explorative ratios.

Episode I: Hila, 96+7935 – Dominantly ritual performance

	What is said (what is done)	Writing
1	Hila: Ah, ninety-six plus seven, seven... seven thousand, seven thousand ninety and thirty, um, can I calculate?	96 + 7935 = 8021
2	Interviewer: Is there a way that you can do it in your head?	
3	Hila: I, um, it's so difficult for me, I-	
4	Interviewer: Try it	
5	Hila: OK. Ah, wow, three plus (..) nine, twelve. Um twelve, um twelve and five plus six is eleven. Eleven plus twelve, equals thirty-three (..), yes, ah no, twenty-three. So, it's eight thousand ninety and thirty, Ah no. Twenty three. OK.	
6	Interviewer: OK, look at the answer and tell me if it looks alright to you?	1 11 7935 + 96 8021
7	Hila: Oops.	
8	Interviewer: Wait, oops. Why oops? What's not good about it?	
9	Hila: 'cause I had to do plus	
10	Interviewer: And what did you do?	
11	Hila: Aah... (points at the paper) I didn't combine like... here the...	
12	Interviewer: Now do you want to do it vertically?	

13	Hila: (Writes). Eighty, three. Five – six, nine, yeah twelve, ten, yeah aah (erases) eighty, eighty (erases).	
14	Interviewer: And that’s a better way?	
15	Hila: Yes.	

We see in Hila’s performance 7 characteristics of ritual and 3 or explorative participation, thus her ritual/explorative ratio is 7/3. Following is the characteristics analysis: A. Non-objectified discourse. The digits in Hila’s discourse are treated as independent entities, to be combined and manipulated in some form, but not as indicative of a whole number or as place value (see line 5, where the digits are first added horizontally, and then line 13). B. Rigid performance: Hila sticks only to procedures of adding the digits separately. Even when asked to do it “out loud”, she tries (albeit unsuccessfully) to reconstruct some sort of procedure for adding the numbers digit by digit. C. External authority: Hila’s discourse is hesitant, and she relies on the interviewer to encourage her to try out the task to begin with [4], to monitor her answer [6, 8] and to suggest an alternative procedure [12]. D. Focus on procedure: Hila focuses only on the procedure (“I had to do plus” [9] “I didn’t combine” [11]). She does not check her answer showing no interest in the result. E. Canonical procedures: Some of the procedures Hila enacts are non-canonical (e.g. adding the sums of the unit digits and tens digits: 11+12). Other procedures are canonical (e.g. writing the “carry on” digits in the appropriate places in the vertical solution). Therefore, she got 1 on both “canonical” and “non-canonical” sides of the ritual/explorative table. F. Canonical narratives: Similar to E. some of Hila’s narratives are canonical (e.g. 5+6=11) while others are not (the overall sum is non-canonical). G. Mediation: Hila’s performance is mediated by several comments of the interviewer, especially the suggestion to “do it vertically” [12]. H. Bondedness: all of Hila’s sub-procedures feed one into the other. Therefore, she received a ‘1’ on the bonded criteria (explorative).

Episode II: Idit solving 25×99 - Example of mixed performance

1	Idit:	(Reads the task, sighs) I usually get messed up with such exercises
2	interviewer:	Is there something that you can do with the... ninety-nine? (..) That is very close to another number?
3	Idit:	A hundred (Interviewer: OK) You can round it (up) to like... (looks at Interviewer), no. First, I’ll round it to 25 times 100. Can I do (that)? (Interviewer: OK) Which turns out two thousand and five hundred (Interviewer: Umhmm) and then take off one. But (comments on failing on such exercises. Interviewer encourages her to try, nevertheless). So, it turns out a thousand… No (erases)… (writes 1049) wait, no (erases, mumbles, writes 2499.
4	interviewer:	Two thousand four hundred and ninety-nine
5	Idit:	that’s what seems most reasonable
6	Interviewer:	But do you think it’s correct? (Idit shrugs “I guess so” and smiles). If I tell you that this is 99. I tell you that this is 99 times (intrusion outside). If I tell you this as an exercise of 99 times 25 would it help?
7	Idit:	(giggles) No

Idit’s ritual/explorative ratio was determined as 6/5 for the following reasons: A. Objectified discourse: we only find indications of objectified discourse in Idit’s solution. She treats 25 times 100 as objects (“which turns out two thousand and five hundred” and “I’ll round *it* to 25 times 100” [3]). B. Rigid performance: Idit does not have an alternative procedure for multiplying 25×100 (e.g. by long multiplication), even though she is unhappy with the result [7] C. Both Agentivity and External authority: in some points, Idit makes independent choices and seeks no guidance (e.g. decides 1049 is an error and instead writes 2499). In other parts, she seeks approval from the interviewer (e.g. “Can I do that?” [3]) D. Focus on product. There are no indications that Idit is focused on the procedure and she does comment on the final product (“That’s what seems most reasonable” [5]) E. The overall procedure is non-canonical since she sames 25×99 with 25×100 -1 F. Canonical and non-canonical narratives: all the sub-narratives (25×100=2500; 2500-1=2499) are canonical however the overall narrative 25×99=2499 is non-canonical G. Mediation: Idit’s performance is mediated by the interviewer suggesting the similarity between 99 and 100 [2] H. Bondedness and non-bondedness: all of Idit’s sub-procedures are bonded, yet the overall procedure is not bonded to the overall task.

Discussion

In this study we asked how can students’ arithmetic discourse be characterized on the continuum between ritual and explorative participation? Our results indicate that the eight characteristics of ritual/explorative participation are useful for locating students on such a continuum. These characteristics are: Objectification, Flexibility, Agentivity, Focus on procedure/product, Canonical procedures, Canonical narratives, Mediation and Bondedness. We used these characteristics to construct a ritual/explorative ratio, where ratios close to 0 indicated high explorative performance, whereas ratios nearing 8/0 indicate ritual performance. Ratios around 1 indicate mixed performance, which mostly show parts of the sub-procedures are ritual while others are explorative.

The validity of this tool is stemming from three sources. First, we were able to achieve blind inter-rater reliability showing that our criteria of analysis were operational. Second, we found general coherence between the ratios and students school achievements (as indicated by placement into the achievement groups in the study, see table 1). Third, the ratios generally cohered with the first author’s experience with the students, gained through teaching them for five months.

Our findings generally support the commognitive theory of the development of students’ mathematical discourse in several respects. First, they show that students generally achieving higher (and thus, presumably more fluent in the arithmetic discourse) indeed perform more exploratively, while low achieving students (who have not mastered the discourse) perform ritually (Heyd-Metzuyanim, 2015). Second, we see from table 1 that students generally performed more exploratively in discourses that are primary (e.g. natural numbers) while in a newer discourse (fractions) the performance was more ritual. This is consonant with the theory that states higher level discourses are built upon primary discourses that are subsumed by them (Sfard, 2008). However, we also found some anomalies, such as a student whose performance on the multiplication task was ritual while his discourse on fractions was explorative. Future studies should look more into the question of whether these are anomalies that are characteristic of “transition” phases (such as at the level of beginning middle school) or whether they can be seen also in later stages of mathematical learning.

The study of course has several limitations, the main one of which is the relatively small number of participants. This is a limitation related to the high work-intensiveness of commognitive analysis and may be overcome in future studies by finding ways to make the analysis more efficient. Nevertheless, the method suggested in this study is the first form of quantifying mathematical performance according to the ritual-explorative continuum. As such, it opens up multiple avenues for further inquiry. For example, future studies can examine whether the pattern of "being around 1 ratio" in students who are identified as middle-high achieving repeats itself, while the pattern of "close to 0 ratio" is common in students identified as excelling. The latter question is especially important since we note that the curriculum mostly advances according to the assumption that students have mastered primary discourses. For example, middle-school curriculum is based on the assumption that students are explorative participants in the arithmetic discourse (Karsenty & Arcavi, 2003). Whether and how students "fill in" formerly learned discourses is an open question, which the tool proposed in this study may help to answer.

Counting strategies in a proficient grade 1 student: the case of Petra

Astrid Junker[1]

[1]Norwegian University of Science and Technology, Faculty of Teacher Education, Trondheim; astrid.junker@ntnu.no

A case study design was used to explore a foundational number-sense (FoNS) proficient student's strategy use in counting. The student, referred to as Petra, participated in a task-based semi-structured systematic counting interview. The interview was analysed qualitatively exploring part-whole reasoning in counting strategies in interrelation with FoNS, which was measured using a digital assessment. The interrelations were discussed as reflecting strands that Kilpatrick et al. (2001) found important for mathematical proficiency. Petra showed the ability to use combinations of one-to-one and relational strategies and high levels of adaptive reasoning and productive disposition. Petra also showed that a number-sense proficient student may be flexible in counting in the 0-10 range but not necessarily in the 10-20 range. Results are discussed as part-whole reasoning on the mental number line.

Keywords: Part-whole reasoning, mental number line, counting strategies, number sense, grade 1.

Introduction

Counting is a central to number sense, which is the ability to work flexibly with numbers and quantities predicting students' mathematical proficiency (Andrews & Sayers, 2015). Flexibility is essential in definitions of number sense. Developing mental representations of numbers and strategies represented on a mental number line enables flexible mental calculations, part-whole reasoning and relational strategies (Dehaene, 2011; Hunting, 2003; Rathgeb-Schnierer & Green, 2019).

Variation in counting and counting strategies is traditionally described in terms of Gelman and Gallistel's (1986) three how-to-count principles: the one-to-one principle of correspondence between numerals and items, the stable-order principle of numerals in any count, and the cardinal principle of the final counted item's numeral representing the number of items in the set. Students with mathematical difficulties are found to exhibit immature, inflexible and inefficient counting strategies and having problems shifting between strategies compared to proficient students (Gelman & Gallistel, 1986). Alternatively, or complementarily, variation in counting strategies can be considered as included in arithmetical problems as part-whole structures supporting relational strategies and part-whole reasoning (e.g. Hunting, 2003).

Mental flexibility is critical to the efficiency of mental strategies (Rathgeb-Schnierer & Green, 2019). Carpenter and his colleagues (e.g. Carpenter et al., 1996) has emphasised understanding students' thinking as a knowledge base for cognitively guided instruction promoting mathematical development. However, what mental processes contribute to mental flexibility? Kilpatrick et al. (2001) claimed that five interwoven and interdependent strands represent the flexible interrelations needed for mathematical proficiency. Extended knowledge of the continuum of number-sense proficiency and flexibility in counting is needed to develop characteristics of various proficiency, and improve the discovery and teaching of typical and atypical variations to support mathematical development in all students. The paper discuss flexibility as part-whole reasoning by exploring a grade 1 number-sense proficient student's systematic counting strategies considered in interrelation with foundational number sense (FoNS) concepts. The paper interprets interrelations to promote counting flexibility and raises the following research questions:

RQI: What strategies does a number-sense proficient grade 1 student use in counting?

RQII: How may strategy use be interrelated with part-whole reasoning on the mental number line?

The paper reports on data from a Ph.D. project studying 75 Norwegian grade 1 students' variations in counting and patterning strategies in relation to FoNS and verbal and nonverbal reasoning.

Theoretical framework

Andrews and Sayers' (2015) described systematic counting as being able to count forwards and backwards between 0 and 20, understanding ordinality and being able to start counting from an arbitrary starting point between 0 and 20. Systematic counting is integrated into Andrews and Sayers' (2015) FoNS definition and interrelates with the seven other components: number identification, number and quantity, quantity discrimination, representing numbers, estimation, arithmetic competence, and number patterns (Andrews & Sayers, 2015). Counting strategies develop from count-all one-to-one correspondence strategies to the more efficient retrieval strategies, such as count-on, which partly depend on one-to-one strategies and relational strategies. Finally, interrelations between counting and arithmetic emerge in the most abstract derived fact relational strategies based on commutativity and the inverse principle. Such mental representations enable part-whole reasoning about the relations between parts constituting the whole and decomposition of the whole into parts of the mental number line and efficient relational strategies (Dowker, 2014; Hunting, 2003).

Flexible counting strategies, conceptual understanding of numbers and the ability to count systematically have been found to depend on estimation abilities and the ability to compare small quantities without counting, also called subitising (Andrews & Sayers, 2015; Dehaene, 2011). Derived fact strategies might be a combination of counting and subitising (Dowker, 2014).

Understanding structures of patterns develops generalisations and promotes part-whole reasoning, which is critical for commutativity, number sense, algebra, and counting (Hunting, 2003). Counting repeating patterns (e.g. ABABAB, □ΔΔ□ΔΔ□ΔΔ) and growing patterns (e.g. 1 3 5, □ □□ □□□, ABAABAAAB) enable the use of both one-to-one building-up strategies and more advanced unit factor and scalar relational strategies, which consider a repeating unit or multiplicative relations between quantities in two or more measure spaces, but with different advanced levels.

Concrete counting operations with counting blocks or other manipulatives develop flexible and efficient mental counting and calculations (Rathgeb-Schnierer & Green, 2019). The mental number line enables the use of part-whole reasoning and is the cognitive system underlying number sense (Dehaene, 2011) serving mental representations of the ordinality, cardinality and magnitudes of numbers as well as the relations between numbers, thus enabling flexible operation with numbers.

Kilpatrick et al. (2001) holistically described flexibility as the following five strands that make up mathematical proficiency: (1) conceptual understanding interrelations between mathematical ideas and their mental representations, including knowledge of why and when mathematical ideas are important and useful, (2) strategic competence to formulate, represent and solve mathematical problems, (3) procedural fluency and knowing when procedures are appropriate, which is shown as flexible, accurate, and efficient procedures, (4) adaptive reasoning as the capacity to think logically about interrelations between concepts and situations, and (5) productive disposition involving the ability to see mathematics as useful and understanding that steady effort will pay off in combination with a view of oneself as an effective learner and doer of mathematics (Kilpatrick et al., 2001). The strands include students' attitudes and metacognition as it concerns knowledge and reflection on one's reasoning and problem-solving abilities.

Methods

A task-based semi-structured interview was designed to explore Petra's strategies for systematic counting: forwards and backwards in counting on 1s, 2s and 3s in the 0-20 range. Petra's counting and counting strategies were explored using a case study design (Yin, 2014).

Recruitment, sample, and case

Following informed parental consent, Petra, aged 5 years and 11 months, was purposefully chosen from the larger study sample as the student with the highest score on the digital number sense test of 75 grade 1 students. Petra is thus referred to as a number-sense proficient student.

Assessments and procedures

A task-based semi-structured counting interview was developed based on Andrews and Sayers' (2015) definition of systematic counting. A toy frog named Mr Minus asked ten questions to facilitate observation of Petra's counting strategies. Counting blocks were made available. If needed, Mr Minus modelled counting by jumping on a number line made of counting blocks. No time limits were given, the interview was video-recorded and lasted approximately 10 minutes. The author was Mr Minus's voice and initiated a dialogue by asking the following questions: (1) 'What number do we start counting at?' (2) 'How far is it possible to count?' (3) 'Is it possible to count backwards as well?' (4) 'Do we need to start counting at 1? Is it possible to count forwards from 7?' (5) 'Is it possible to count backwards from 9?' (6) 'Can we count from 20 to 0 too?' (7) 'I have heard some adults count in a weird way. They counted 2-4-6… Have you heard such counting? I am wondering how to continue to count if I am to continue to count the same way. Can you help me?' (8) 'Is it also possible to count backwards this way?' (9) 'I have heard some adults count in a weird way. They counted 1-3-5… Have you heard such counting? I am wondering how to continue to count if I am to continue to count the same way. Can you help me?' and (10) 'Is it also possible to count backwards this way?'. Mr Minus (test-administrator) gave verbal and nonverbal prompts if needed.

A digital FoNS assessment (Saksvik-Raanes & Solstad, in press) measured all FoNS components except for representing numbers, following Andrews and Sayers' (2015) number sense definition. Subitising was included as an eight component: (1) number identification, (2) systematic counting, (3) number and quantity, (4) quantity discrimination, (5) estimation, (6) arithmetic competence, (7) subitising, and (8) number patterns. Subitising tasks were timed.

In a 30-minute session, Petra dragged, dropped and organised objects on the screen or tapped the appropriate multiple-choice item to solve tasks. Figure 1 provides an example of each of the different task designs and the verbal instructions given in the systematic counting component tasks. Petra scored 62 out of 69 possible points.

Figure 1. The tree task design of the systematic counting component

A) Put the numbers in order, B) Place the star on the third star in the line, and C) Place the correct number into the box.

Analytical procedures

Petra's counting response and strategies in tasks 1 to 6 (see description in the "assessments and procedures" section) were coded and qualitatively analysed according to Andrews and Sayers' (2015) description of systematic counting and Gelman and Gallistel's (1986) how-to-count principles using NVivo. In addition, Petra's strategy use in tasks 7 to 10 was coded as one-to-one building-up/correspondence strategies, and as part-whole relational strategies depending on multiplicative relations between two or three units in counting. Number sense was measured using a digital assessment based on Andrews and Sayers' (2015) eight components of FoNS on an individual tablet. Petra's responses to the tasks in the digital FoNS assessment were scored dichotomously.

Petra's strategy use in relation to her FoNS was discussed to reflect part-whole reasoning on her mental number line, using Kilpatrick et al.'s (2001) strands of mathematical proficiency as guidelines.

Results and analyses

Semi-structured systematic counting interview

Mr Minus: What is the smallest number we can start to count from?
Petra: 1.
Mr Minus: How far is it possible to count?
Petra: Am I to count to hundred? 1-2-3-4-5-6-7-8-9-10-11-12-13-14-15-16-17-(…)-100.

At every -9 from 29 to 99, she prolonged pronunciation of the /i:/ vowel before the 10 transitions.

Petra: I also manage to count to hundred like this: 10-20-30-40-50-60-70-80-90-100. Now I counted only the tens.

Her thumb represented 10 and her index finger represented 20. No fingers were used for subsequent counting.

Mr Minus: Is it possible to start counting backwards?
Petra: I manage to count from hundred to eighty, I think. 99-98-97-96-95-94-93-92-91-80-89-88-87-86-85-84-83-82-81.

She prolonged the pronunciation of the vowels in 95 and 91 and quickly said 80 without self-correction.

Mr Minus: What comes next, after 81?
Petra: Seventy!

Petra finger-counted on her left hand and correspondently whispered every 10th number word from 10 in the additive direction for each finger, which was the opposite direction from the subtracting counting she had started using. She said 70 loudly and stopped counting.

Mr Minus:	Can we count from twenty to zero too?
Petra:	I do not think I know much about that! Sometimes I need to do like this.

She illustrated finger-counting corresponding to lip movements pronouncing 1-2-3-4-5.

Mr Minus:	That is okay if you need to.
Petra:	20-90-no-19-17-15-14-13-12-11-10-9-8-7-6-5-4-3-2-1-0.

Petra self-corrected 90 to 19. The three fist phonemes of Norwegian number words for 90 and 19 are identical and perhaps phonologically distracted her. After she said 19, she started finger-counting on her left thumb and whispered 1 before she said 10 while still holding up only her thumb, representing the 10th addend. As such, she combined a retrieval relational and a one-to-one strategy, as adjacent fingers one-by-one represented the consecutive addends while she whispered 11-12-13-14-15-16 before answering 17 loudly. She counted forwards from 10 and stopped when she saw there was one less finger on her hand than the number of fingers she remembered seeing on her hand from the preceding answer. Then she repeated her strategy of the thump representing 10. Because she whispered 11 without showing the index fingers before she whispered 11, she answered 15. She used the same strategy to find the subsequent answers, including 11. Petra stopped using her fingers when she continued to count down from 10 to 0.

Mr Minus:	High five! You made it! Is it possible to counting forwards from seven to twenty?
Petra:	I think so. That is almost what I already counted. 8-9-10-11-12-13-14-15-16-17-18-19-20. That was easy, you only start at eight.
Mr Minus:	Cool! Is it possible to start counting from 14 as well?
Petra:	14-15-16-17-18-19-20.
Mr Minus:	Is it so that we can count backwards from an arbitrary point as well, say from 9?
Petra:	9-8-7-6-5-4-3-2-1-0.
Mr Minus:	I have heard some adults count in a weird way. They counted 2-4-6… Have you heard that? I wonder how to count on from 6 if I were to continue counting the same way. Do you know?
Petra:	Yes, 1-2-3-4. And that’s only two! The next numbers are 8-10-12. And you know what? I also manage from three to nine.

Fingers one-to-one corresponded to the number words. Then she grouped two and two fingers on her left hand. She counted 3-6-9 while she showed one and one finger.

Mr Minus:	WOW! What is the next number when counting like that?
Petra:	12-15-18-20-23-26-29.

Petra one-to-one correspondently finger-counted and whispered numbers between 9 and 12. She continued to whisper-count with the same three fingers and said the number on the third finger loudly. Incorrect one-to-one correspondence made her answer 20 without self-correction.

Mr Minus:	You teach me lots of things! Is it possible to count backwards in the same way as you counted 2-4-6 forwards?
Petra:	Yes, I can try that. 10-8-6-4-2-0.
Mr Minus:	Okay. I have heard some adults count in a weird way. They counted 1-3-5… Have you heard that? I wonder how to count on from 5 if I am to continue counting the same way. Do you know?
Petra:	1-… Am I to do addition?

Mr Minus: I do not know. I just heard someone count that way. 1-3-5, and I do not understand what to say next if I am to continue in the same pattern.
Petra: 1-3-5…? 6?
Mr Minus: Maybe? I want to try something! I want to jump like they counted. 1-3-5… Now I jump once more. What am I to say when I land here? And here?

The interviewer lined up counting blocks, making a number line from 1-10. The frog jumped on every other block and said the number names corresponding to the number line position on which he landed on. The frog jumped on every other block and said the number names corresponding to the number line position on which he landed.

Petra: 7-10

This was Petra' answer for the two positions Mr Minus jumped on after 5.

Mr Minus: How did you do that?
Petra: I counted inside myself. I counted 2-4-6-8-10.

She correspondently pointed at the second, fourth, sixth, eight and tenth block.

Mr Minus: Okay. But I said 1-3-5 and you said seven was the next number. How did you know that?
Petra: I added two more.
Mr Minus: Okay, that was what happened! Is it possible to jump back and count in this way as well?
Petra: Do you mean 7-5-3?

She tapped her fingers on the table in the opposite downwards or subtractive direction.

Mr Minus: Yes! And now I think you showed me that it is possible!
Petra: I know how to make a rocket with my fingers! I do like this. Do you manage?

She ended the dialogue, making a rocket with both hands and laughed.

Foundational number sense (FoNS)

Petra mastered all number sense components in the digital assessment, expect for estimation and arithmetic. For numbers between 10 and 20, she showed difficulties estimating a number's position on the number line and doing arithmetical operations.

One-to-one and relational strategies

For tasks 1 to 6, Petra successfully used the required one-to-one strategy with correspondence between the number name and the counting procedure. Tasks 7 to 10 served as opportunities for part-whole reasoning about multiplicative relations between numbers and processes on the mental number line. Therefore, the tasks enabled the use of both one-to- one and relational strategies. As the results showed, Petra successfully and unsuccessfully used a combination of counting-all, counting-on and retrieval strategies. That is, both one-to-one and relational strategies. Success seemed to depend on the number range in which she counted. Petra did not use the one-to-one count-all strategy alone. Despite various success, she considered the appropriateness of more advanced relational strategies and showed emergent part-whole reasoning (Dowker, 2014). She used these strategies in combination with one-to-one backup strategies for support. The digital assessment also supported the assumption that she used relational fact retrieval strategies for numbers between 1 and 10 in forwards counting but used a combination of one-to-one and relational strategies in backwards counting above 10.

Discussion

Indications of conceptual understanding, procedural fluency, and strategic competence

Petra met some of Andrews and Sayers' (2015) systematic counting criteria. She counted correctly forwards to 100 and met their criteria of forwards counting from 0-20, but she did not meet the criteria of backwards counting from 20 to 0. She mastered forwards and backwards counting in patterns of 2s on even numbers in the 0–20 range but mastered only backwards counting on odd numbers in the 10–0 range. She successfully counted backwards from an arbitrary starting point between 10 and 0, but not between 20 and 10. There is compliance between Petra's counting, estimation, and arithmetic competence. Estimation is important for mentally representing the number line (Dehaene, 2011). Petra met the one-to-one principle of Gelman and Gallistel's (1986) in a count-all backup strategy but not in a combined backup and retrieval strategy counting-on from 10. The stable order principle was met in forwards counting in 1s and in patterns of 2s and 3s. She was challenged in backwards counting by 1s in the 20-10 range, omitting two numbers but not in the 10-0 range. The cardinal principle was confirmed in the number and quantity component of the digital FoNS assessment. Petra's strong subitising abilities may have played a role when her thumb represented 10 and when she reasoned in multiplicative relations, counted on 2s and explored counting on 3s.

Self-correction and efficient strategy use were implemented as procedural fluency. Self-correction occurred inconsistently. It is unknown whether incorrect counting from 99-80 resulted from number name or ordinality problems and a not fully established mental number line for the eighth or nineth 10 range, something her strategy use in the 20-10 range supports. If so, subtracting perhaps distracted her. These findings underline the interrelations between conceptual understanding and procedural fluency. Petra used efficient strategies, that is, when she counted to 100 by counting by 10s and when she counted in 2s and tried to count in 3s. Additionally, she showed a high level of strategic competence as she represented and solved problems verbally, explained her mental strategies and utilised manipulatives. The findings show the mutually supportive interrelations between strategic competence, conceptual understanding and procedural fluency (Kilpatrick et al., 2001).

Indications of metacognition through adaptive reasoning and productive disposition

Petra searched for similarities and differences or patterns in the counting and gave generalised explanations to show accountability of her strategy use in other situations. For example, she argued for transferring the use of the strategy, which made her master counting from 1 to 20 when she was asked to count-on from 7 to 20, and that she recognised relational patterns and explained she had to count by 2s to correctly continue the number sequence 2-4-6. Petra initiated, argued, explored, and demonstrated different ways and patterns of counting. For example, she counted by 10s to 100 and she tried to count by 3s after counting by 2s. Her interest in exploring unknown counting overcame her insecurity of succeeding or meeting an expectation of mastery without finger-counting.

Kilpatrick et al. (2001) claimed that knowledge about one's own thinking and ability to monitor one's own understanding and problem-solving contribute to strategic competence and adaptive reasoning, and is known as metacognition. Petra showed indications of a high metacognitive level. One is that she explained how she was strategically going to approach new tasks, which, according to Kilpatrick et al. (2001), reflected her motivation or productive disposition, which is important for learning.

Counting strategies as part-whole reasoning on the mental number line?

Exploring Petra's counting raises the question of whether and how mental number lines representing the different 10s interrelate and how to develop an understanding of the pattern regularity linking them. Petra seemed to have mental representations for the tens' group structure and the positioning system of -1 to -9 range. Still, ten-transitioning was challenging in backwards counting and in the 10-20 range. The phonological structure perhaps distracted her. Exploring and considering strategy use in an integrated approach of the area model part-whole reasoning and the linear model the mental number line and, as such, combined the mental map of numerosity and the mental number line needs further examination (Dehaene, 2011).

MS-Math – A design research project to support university students' fostering-competencies and primary school students' learning with the focus on perceiving, understanding, and using patterns and structures

Laura Korten

University of Muenster, Germany; laura.korten@uni-muenster.de

Keywords: mathematical patterns and structures, flexible calculation, fostering-competencies

Introduction

The poster presents the German project "MS-Math – Muster und Strukturen der Mathematik wahrnehmen, verstehen und nutzen lernen" ('Learning to perceive, understand and use patterns and structures in mathematics'). In this design research project, a support-program will be iteratively designed and implemented at the University of Muenster. It aims to provide diagnosis-guided support for primary school students with difficulties in learning mathematics. The support will be planned, realised and reflected by university students (student teachers). By doing this the university students will be stimulated to develop and improve their fostering-competencies at the same time.

Design and research interest

As the full name of the MS-Math project (see above) implies, the support-program focuses on patterns and structures in mathematics. For the area of arithmetic, this means that children get specifically supported in perceiving, understanding, and using number and problem relations for flexible calculation. Regarding this, a differentiation between 'inter-modal' problem relations (between problems) and 'intra-modal' problem relations (within problems) is defined in the project. MS-Math pursues the following three goals, which also reflect the design and research interest:

(1) Practice-oriented research – Gaining new research insights: In the project, in-depth insights of arithmetical learning processes of the supported children as well as of the supporting students regarding their fostering-competencies will be gained. The analysis of the learning processes and learning outcomes on both levels will contribute to a research-based specification of a fostering concept for primary school students with difficulties in learning mathematics. This concept has its focus on perceiving, understanding, and using arithmetical patterns and structures. The project also contributes to a deeper understanding about university students' development of fostering-competencies.

(2) Research-based design – Developing a university support-program in a research-based and practice-oriented manner: The university students are given the opportunity to develop and deepen fostering-competencies regarding support-oriented diagnosis & diagnosis-guided support in a case-based manner. The analysis of the learning processes and outcomes of the supported children and of the supporting university students (see (1)) will allow a research-based development and an empirical assessment of the support-program as a meaningful and rich learning environment for both, university students and primary school children.

(3) Research-based cooperation – Supporting teaching and learning at schools in Muenster: Teachers receive support in fostering children with difficulties in learning. The participating children receive weekly support based on their individual competencies and on latest research findings.

Theoretical background and design research methodology

Regarding primary school students' learning processes, with its outlined focus on perceiving, understanding, and using arithmetical patterns and structures, the project is following promising research findings (e.g. by Rechtsteiner-Merz & Rathgeb-Schnierer 2016; Verschaffel et al., 2009; Mulligan & Mitchelmore, 2013). On this basis the support gets planned, realized, and analysed. Regarding university student' fostering-competencies the approach of „professional noticing of children´s mathematical thinking" by Jacobs et al. (2010, p.172f.) is leading, to conceptualize three aspects: 1) attending to children´s strategies, 2) interpreting children´s understandings and 3) deciding to respond on the basis of children´s understanding (ebd., p.172ff.).

Following a design research approach, a support-program as a meaningful and rich learning environment for university and primary school students will be designed, tested, and improved by conducting design experiments in iterative design research cycles (Prediger et al., 2015). Each design experiment – a support session of two supporting university students and one supported child – gets video recorded. Their learning processes will be analysed using interpretative tools, which allow to gain new research insights (see (1)) and a research-based development of the support-program (see (2)).

First results: University students need specific criteria to be able to attend to children´s arithmetical strategies. Two criteria could be derived so far: Criterion of 'informativeness' and 'process reference'. The awareness and reflection of 'macro and micro cycles of diagnosis and support' helps them to respond more and more adaptively on the basis of children´s arithmetical understanding.

Categorization reliability of preservice elementary teachers' use of mental computation addition strategies on natural numbers using a written questionnaire

Anders Månsson[1]

[1]Oslo Metropolitan University, Faculty of Education and International Studies, Oslo, Norway; andersm@oslomet.no

Preservice elementary teachers' use of mental computation strategies in addition on two-digit natural numbers is analyzed using a written questionnaire. The inter-coder reliability of three researchers in their categorization of the preservice elementary teachers' explanations as mental computation strategies is investigated. The results show that the coders are to a large degree in agreement, strengthening the reliability of the method.

Keywords: Mental computation, addition, questionnaires, interrater reliability.

Introduction and theory

There exist variations in the definition of mental computation in the research literature, but a general trait among the definitions is calculating without using any equipment (Baranyai et al, 2019; Hartnett, 2007; Heirdsfield, 2011; Maclellan, 2001; Thompson, 1999). There are many advantages of becoming better at mental computation; for example, it improves number sense, it gives a better understanding of the place value system and elementary calculation rules, and it is often involved in everyday use of mathematics (Hope & Sherill, 1987; Maclellan, 2001; Thompson, 2010). Mental computation is part of the elementary curricular content globally, and in several countries there have in recent years been an increased focus on mental computation in teacher education (Hartnett, 2007).

Mental computation strategies are different ways that arithmetic problems are solved mentally (Hartnett, 2007; Threlfall, 2000). To do mental computation efficiently, one needs to be flexible, learn several different strategies, and know when to use which strategy (Rechtsteiner, 2019). Some strategies are more general, and others are more dependent on coincidences in the calculation. Thompson (2009) stresses the importance of teaching and using mental calculation strategies, since the traditional methods are generally not effective enough to improve students' numeracy proficiency. However, even though mental strategies are a desired focus for computational instruction in schools, Hartnett (2007) suggests that teachers have been slow to adopt such changes in their classrooms, and that a possible block to adopting this approach is the teachers' lack of knowledge about possible computation strategies. There is evidence to suggest that pupils are often not directly exposed to mental computation strategies in school, but rather are left to devise for themselves more or less efficient strategies (McIntosh et al, 1995). Many mental computation strategies are possible for pupils to discover on their own, but one cannot presume that all pupils will be able to do so (Murphy, 2004). Some pupils get stuck in unwieldly mental computation strategies, such as doing the standard algorithm mentally, and therefore need to learn more efficient strategies in an organized and systematic way (Heirdsfield & Cooper, 2004).

Mental computation strategies in connection to elementary pupils has been well researched, but less so in connection to preservice elementary teachers (PETs). Since PETs are the next generation of teachers, it is important that they know and master mental computation strategies. They need a strong foundation of the mathematics of mental computation including an ability to use efficient strategies of their own (Heirdsfield & Cooper, 2004; Thompson, 2009). It is therefore important to know the current knowledge and proficiency base of PETs on mental computation. Knowing which strategies PETs are aware of and use, gives valuable information for continuing professional development on how to address mental computation strategies in teacher education and related research, to improve teacher content knowledge on mental computation (Hartnett, 2007; Thompson, 2009; Valenta & Enge, 2013).

To investigate the mental computation strategy use of PETs, researchers need to categorize the PETs' current strategies. In research literature a common method to do this is through interviews, where one can ask the PETs follow up questions, an alternative that is not available in the same way for a written questionnaire. However, a written questionnaire is a more efficient tool than an interview when it comes to gathering larger sets of data in statistical investigations (Mastrothanasis et al, 2018).

There is not a single, consensus approach regarding how to categorize mental computation strategies (Whitacre, 2015). In this paper, I focus on strategy categorization using as a theoretical lens a comprehensive list of mental computation strategies on addition on two-digit natural numbers (Table 1). The list is the result of an exhaustive search of the mental computation strategies that occur in the literature. After each strategy is given a reference to where the definition can be found in the literature.

Table 1: Mental computation strategies for addition on two-digit natural numbers

Strategy	Definition	Source
1010 [ten-ten]	$46+23 \to 40+20=60 \to 6+3=9$ $\to 60+9=69$	(Beishuizen, 1993)
10s [1010 stepwise]	$45+39=\big((40+30)+5\big)+9$ $=(70+5)+9=75+9=84$	(Reys et al, 1995)
A10 [adding-on]	$35+29=(35+5)+24=40+24=64$	(Blöte et al, 2000)
AUTO [Automatic calculation]	Retrieve the answer automatically or from memory.	(Lucangeli et al, 2003)
B [balancing]	$89+24=(89+1)+(24-1)=90+23$ $=113$	(Heirdsfield & Cooper, 1997)
Counting	$3+5$: $4, 5, 6, 7, \underline{8}$	(McIntosh & Dole, 2005)
Doubles and near doubles	$6 + 7$: $6+6$ is 12, so it is one more.	(McIntosh & Dole, 2005)
N10 [stringing]	$46+23 \to 46+20=66 \to 66+3=69$	(Beishuizen, 1993)

N10C [stringing with compensation]	$52 + 79 \rightarrow 52 + 80 = 132 \rightarrow 132 - 1 = 131$	(Baranyai et al, 2019)
Round one or both addends to multiple of ten, then adjust	$79 + 26 \rightarrow 80 + 30 = 110 \rightarrow 110 - 1 - 4 = 105$	(Reys et al, 1995)
Round to multiples of five	$79 + 26 = (75 + 25) + 4 + 1 = 100 + 5 = 105$	(Reys et al, 1995)
SA [standard algorithm done mentally]	Mental image of pen and paper algorithm, placing numbers under each other, as on paper, and carrying out the operation, right to left.	(Heirdsfield, 2001)
u-1010 [1010 right to left]	$46 + 23 \rightarrow 6 + 3 = 9 \rightarrow 40 + 20 = 60 \rightarrow 60 + 9 = 69$	(Beishuizen, 1993)
u-N10 [N10 right to left]	$46 + 23 \rightarrow 46 + 3 = 49 \rightarrow 49 + 20 = 69$	(Beishuizen, 1993)
Using tens as the unit	$80 + 50 = 8$ tens $+ 5$ tens $= 13$ tens $= 130$	(McIntosh & Dole, 2005)

When categorizing there is the question of inter-coder reliability (Lange, 2011), that is if different researchers agree in their categorizations. Evaluating the inter-coder reliability is recommended as good practice in qualitative analysis, although this is a somewhat controversial topic in the qualitative research community, with some arguing that it is an inappropriate or unnecessary step within the goals of qualitative analysis (O'Connor & Joffe, 2020). Team coding is a good inter-coder reliability check (Miles & Huberman, 1994), and a standard way of doing this is using percentage agreement or Cohen's Kappa (Cohen, 1960).

Method

Purpose of article and research question

This paper is the first article in a planned series of articles where I utilize written questionnaires to conduct research into PETs' mental computation strategy use, making use of the comprehensive list of strategies in Table 1. In general, research articles categorizing students' and PETs' strategy use only draw on a subset of these strategies and different subsets in each article, thus limiting the degree of comparisons that can be done across the research literature. Before using the comprehensive list of strategies in Table 1 to categorize data from the PET questionnaires, I propose that it is important to first investigate the inter-coder reliability of researchers. (Some researchers may not think this is necessary in qualitative research, so alternatively the investigation can also be seen as out of curiosity or interest to understand how different teacher educator colleagues categorize the same data.) If different researchers' categorizations are in agreement that strengthens the reliability of the method. Therefore, a relevant and interesting research question is:

Using a written questionnaire and a comprehensive list of mental computation strategies occurring in the literature, how do different researchers differ in their categorizations of preservice elementary teachers' mental computation strategy use in addition on two-digit natural numbers?

To limit the scope of the investigation only addition on two-digit natural numbers is considered. If the categorizations are in agreement in this particular case, that increases the confidence in using written questionnaires to analyze PETs' mental computation strategy use in general.

Research participants

A written mental computation strategy questionnaire was in 2020 given to two different classes of PETs at a mid-sized university in Norway:

I. 31 second year PETs with 30 ECTS credits of university mathematics.
II. 15 third year PETs with a mix of 0, 30 or 60 ECTS credits of university mathematics.

Measures

The PETs' use of mental computation strategies was measured with a written questionnaire consisting of fifteen exercises on addition on two-digit natural numbers. Figure 1 shows the questionnaire instructions and how each exercise was presented to the PETs.

Important instructions! For every exercise do these steps in order:

1. **Calculate the exercise in your head**.
   - The calculation must be done solely in your head. You are **not** allowed to write anything on the paper.
   - If you do not know the answer after you have been thinking for a while, do not write anything and instead go to the next exercise.
2. **Write down the answer**.
3. **Explain mathematically how you were thinking.**

Exercise 1

$11 + 13 =$______

Explanation:______________________________

____

Figure 1: Questionnaire instructions together with the first exercise

The exercises were constructed by the author so that many different strategies would be used by the PETs:

1. $11 + 13$, **2.** $17 + 18$, **3.** $62 + 27$, **4.** $80 + 50$, **5.** $76 + 58$, **6.** $44 + 33$, **7.** $38 + 76$, **8.** $60 + 37$, **9.** $47 + 45$, **10.** $64 + 46$, **11.** $70 + 67$, **12.** $97 + 86$, **13.** $88 + 88$, **14.** $45 + 79$, **15.** $99 + 9$

The PETs' written explanations were categorized as mental computation strategies by three different researchers (of which one was the author) according to the list of strategy definitions given in Table 1. The explanations could also be categorized as "Other" (O) or as an "Unclear strategy" (US). In addition to being instructed to use the list of mental computation strategies, the researchers were directed to base their categorization solely on a PET's own written explanation (not speculating on how a PET was "really thinking" when calculating).

The categorization inter-coder reliability was measured by comparing (1) the percentage agreement (that is the proportion of the exercises that the coders agreed on) and (2) the average strategy distribution of the coders. Note that in (1) percentage agreement was chosen instead of Cohen's Kappa (Cohen, 1960), because the difference between them is negligible since there are many categories of strategies and the probability for random agreement when categorizing is thus small.

Data collection

The questionnaire was administered as part of a normal lecture in two classes (referred to here as Class I and Class II) at the university. The PETs' participation in the questionnaire was voluntary and anonymous. They were not informed beforehand that they would take a questionnaire, so they had no way of preparing for it. There was no time limit to the questionnaire.

The PETs' explanations in Class I were categorized as strategies by the author and another mathematics teacher educator (called instructor A). Both the author and instructor A are associate professors in mathematic didactics. The PETs' explanations in Class II were categorized by the author and another mathematics teacher educator (called instructor B). Instructor B is a university lecturer in mathematic didactics with several years of experience as an elementary school teacher.

Results

Class I categorized by author and instructor A

The author and instructor A were in agreement in $89.9\ \%$ and disagreement in $4.7\ \%$ of the $465(= 31 \times 15)$ exercises. In $5.4\ \%$ of the exercises their categorizations were overlapping (but not inclusion in set theory terms). One can conclude that the two persons categorizations are to a high degree in agreement, strengthening the reliability of the method.

Figures 1 & 2 show the averages of the 15 exercises for Class I as categorized by the author (Figure 1) and instructor A (Figure 2), where similar strategies have been grouped. (The strategies were consider separately when considering if categorizations were in agreement. Each strategy in the category Remaining have a small relative frequency ($\leq 1\ \%$).)

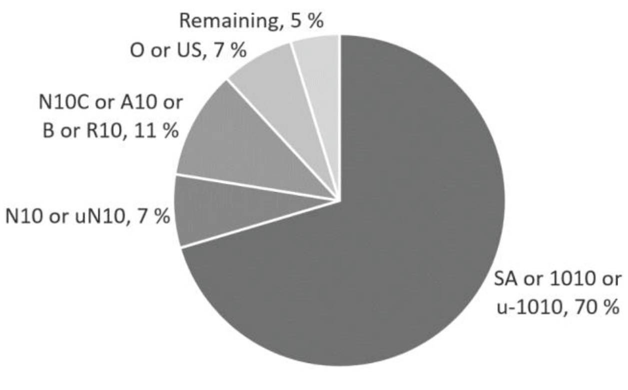

Figure 1: Class I categorized by author

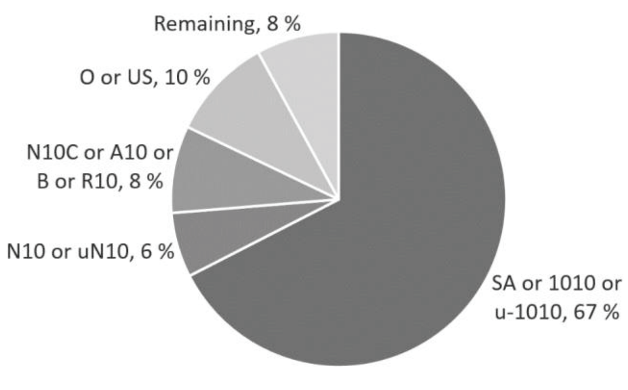

Figure 2: Class I categorized by instructor A

Generally seen the averages in Figures 1 & 2 reflect the relative frequencies in each of the 15 exercises. One exception is exercise 4 (that is $80 + 50$). Most of the PETs have calculated exercise 4 by adding $8 + 5$ and then attaching a zero. The author has categorized this strategy as "Other" (O) whereas instructor A categorized it as an "Unclear strategy" (US).

Class II categorized by author and instructor B

The author and instructor B were in agreement in 80.4 % and disagreement in 11.6 % of the $225(= 15 \times 15)$ exercises. In 8,0 % of the exercises the categorizations were overlapping (but not inclusion in set theory terms). Although the author's agreement with instructor B was somewhat smaller than with instructor A, the overall agreement of two categorizations is good also in this case.

The diagrams in Figures 3 & 4 show the averages of the 15 exercises for Class II as categorized by the author (Figure 3) and instructor B (Figure 4). The grouping of the categorizations is here the same as for Class I.

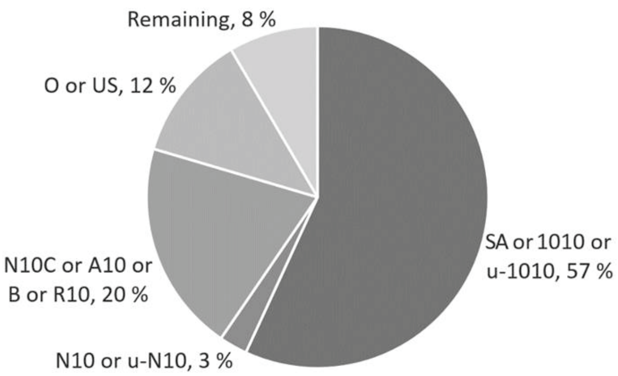

Figure 3: Class II categorized by author

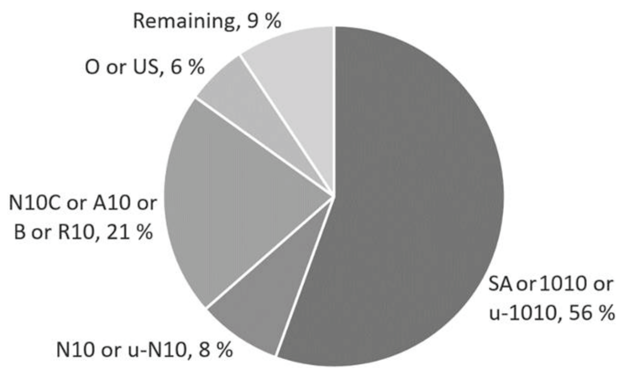

Figure 4: Class II categorized by instructor B

Discussions and conclusions

Exploring how different researchers categorize preservice elementary teachers' mental computation strategy use, utilizing the comprehensive list of strategies as a theoretical lens to analyze their work, is an important first step for me before moving into the all-important task of understanding more, in general, about PETs' strategy use. We have in this paper seen that, using a written questionnaire and a comprehensive list of mental computation strategies occurring in literature, there is good agreement between how three different researchers categorize PETs' explanations as mental computation strategies. This is a valuable result since it means that written questionnaires and the comprehensive list of strategies in table 1 can be used more reliably to analyze PETs' use of mental computation strategies.

Mental calculations with rational numbers: strategies' range and strategy selection

Ioannis Papadopoulos[1] and Michail Karakostas[2]

[1]*Aristotle University of Thessaloniki, Faculty of Education, Greece,* ypapadop@eled.auth.gr

[2]*University of Western Macedonia, Greece,* milakis123@gmail.com

In this paper primary and secondary school students are followed while they try to perform operations with rational numbers first mentally and then in paper-and-pencil. The same tasks were given to the participants of both groups. The findings give evidence that no matter the context (mental or written calculations) the dominance of the mental form of the written algorithm is unquestionable for both groups. Moreover, most of the student were not able to explain their decision to use the algorithm in their mental calculations. The students who were able to justify their choice claimed that their criterion was the accuracy, speed and easiness provided by the algorithm which creates a paradox since for all the items on the study the algorithm is the most time-consuming strategy.

Keywords: Mental calculations, rational numbers, written algorithm.

Introduction.

Mental calculations with rational numbers have been the focus of several studies (Caney & Watson, 2003; Rezat, 2011; Carvalho & Ponte, 2019). The ability to perform mentally such calculations is considered significant. According to the Principles and Standards of the NCTM (2000), "students should develop and adapt procedures for mental calculations and computational estimation with fractions, decimals, and integers" (p. 220). In the last CERME, Papadopoulos et al. (2019) highlighted the dominance of the use of mental form of the written algorithm as a way to calculate mentally the outcome of certain operations with rational numbers. The discussion that followed the presentation was fruitful and raised questions concerning the possible reason the participants choose this strategy, or whether they know alternative strategies and if yes why they do not use them. Moreover, the audience in the conference was wondering whether the results would be the same in case the students were asked to solve the same tasks in paper-and-pencil.

In this setting the current study attempts to give some answers to the above-mentioned concerns. So, the research questions are as follows:

(i) What is the range of the strategies employed by primary and secondary education students when they execute operations (first mentally and then in a written form) that involve rational numbers?

(ii) On what criterion do they choose their mental calculation strategy?

Theoretical background

Most of the studies on mental calculation focus on whole numbers and their four operations (Rezat, 2011). However, in recent years there is an ongoing interest on mental calculations with rational numbers examining issues such as the comparison of rational numbers (Yang et al., 2009) and the operations with them (Caney & Watson, 2003; Papadopoulos et al., 2019). Caney and Watson (2003) recorded the strategies the participants used while trying to calculate mentally. They ended with a series of different strategies: *'changing operation'* (e.g., subtraction to addition), *'changing representation'* (e.g., fractions to decimals and vice versa), *'use of equivalents', 'use of known facts'* (e.g., times table), *'repeated addition/multiplication'* (e.g., by doubling, halving), *'use of bridging'* (bridged to one/whole),*'working with parts of a second number'*(split the second number by place value or by parts), *'working from the left/right'*, *'using mental picture'*, *'using mental form of written algorithm'* and *'using memorized rules'*. They group these strategies in two main categories: instrumental and conceptual strategies. The first refer to strategies based on the use of procedural paths learned by rote. The second occurs when students make use of their knowledge on the specific set of numbers and operations in order to calculate mentally. Callingham and Watson (2004) found that in the realm of rational numbers it is easier to work mentally with fractions rather than with decimals or percentages and that division is more demanding compared to addition and subtraction (which holds equally for the set of whole numbers). Moreover, it seems that in the context of the addition and subtraction of decimal numbers the students preferred strategies they already used for mental calculations with whole numbers (Rezat, 2011). In their study on mental calculations with rational numbers by primary school students Carvalho and Ponte (2019) highlight two main findings: In their effort to work mentally the students (i) tend to use the strategy of 'changing representation' (from fractions to decimals), and (ii) 'use numerical relationships strategies supported by propositional representations' (p. 393). Another related issue is the ability of flexibility in mental calculations that has been raised by scholars such as Rathgeb-Schnierer and Green (2015) and the lack of which has been recorded not only for students but for teachers also (Lemonidis et al., 2018). Finally, Papadopoulos et al. (2019) who tried to record and compare strategies used by participants across all educational levels for the same tasks found that the mental form of the written algorithm dominated in the participants choices no matter the educational level (almost 43% for primary school students, 31% for secondary school students, 46% for University students from the Department of Primary Education and 59% for University students from the Mathematics and Engineering Departments). All the other strategies' percentages were close to 1%-2%. This raises the issue of how the solvers choose strategies in mental calculations. Indeed, the choice of the proper strategy is of critical importance. Threlfall (2000) described the process of choosing strategies as a series of certain steps: (i) prior analysis of the problem to recognize features that are associated to different possible strategies, (ii) decide which ones of these strategies are viable in terms of knowledge and skills, (iii) decide between the viable strategies the one that is (possibly) the easiest, and (iv) carry through the decision in practice. But as he admits 'neither children nor adults actually calculate in that way' (p. 84). The idea of teaching criteria for deciding in advance which strategy to use is rather not feasible and perhaps this explains why there are no suggestions in the relevant research literature for direct teaching on how to decide strategically the proper way of mental calculation (Threlfall, 2002). So, there is no proof on the way students choose to calculate mentally and this is why in this paper we chose to examine this issue. Threlfall (2002) claims that mental calculation strategies are not purposefully selected by the students, but they occur since the students are interested in finding the solution rather than the method. More precisely, he claims that "They are ways of thinking about mental calculations that do not describe the whole sequence to the solution, but concern just some of the steps, for example ways of beginning, ways of thinking about the numbers, and ways of relating the numbers to other knowledge" (p. 42).

Setting of the study

The total number of the participants was 127 students from primary and secondary education. More precisely there were 65 students from grades 5 and 6, and 62 students from grades 10, 11 and 12 in a rural area of Northern Greece.

Five tasks in total were given to the students (Fig. 1)

$\frac{3}{6}+\frac{4}{8}$	$4 \times \frac{6}{12}$	$1\frac{1}{2}-\frac{1}{4}$	$2\frac{5}{10} \times 2$	$8 : \frac{4}{8}$
Item 1	Item 2	Item 3	Item 4	Item 5

Figure 1: Tasks posed to the students

The tasks' design followed two principles. First, there are more than one ways to calculate each item. Second, all the items can be calculated in a fast and easy way if the solvers notice the quantities involved in each operation. Therefore, item 1 includes the sum of two halves and therefore the answer is 1. Item 2 is about four halves, therefore 2. In item 3 if the solver sees $\frac{1}{2}$ as $\frac{1}{4}+\frac{1}{4}$ it is easy then to get the result $1\frac{1}{4}$. For item 4 the result should be the double of 2.5, therefore 5. Finally, for item 5 the solver must think how many halves are needed to get 8. Therefore, the answer is 16. This small collection of items involves all the four operations and a variety of combination of numbers (fractions, whole numbers, mixed numbers).

The whole study consisted of a two-step process. Initially all the participants were interviewed individually. They were asked to solve the tasks one-by-one mentally vocalizing their thoughts while solving them. They were not allowed to make written calculations or to keep some notes. There was no time restriction, and they could skip tasks in case they felt they couldn't solve them. No feedback was provided to them during their effort. All interviews were recorded and transcribed.

For the second part, the students were invited to work individually on paper-and-pencil. Now they had to solve each item with as many different ways as they could. After completing the solutions for each item, the students had also to write down their answer for the question: Can you explain why from all these different ways of solving this item, did you choose this specific strategy for your mental calculation?

The transcribed protocols (first part) and the students' worksheets (second part) constituted our data. For the first part of the study the data were analyzed in two levels. First, the answers were categorized according to whether they were correct, incorrect, unanswered or not codable. Second, the correct answers were distributed to the different strategies of Caney and Watson (2003). It must be said however that not all the strategies appeared in the students' answers and that some new strategies emerged. For the second part, the data analysis took place at a qualitative level on the basis of content analysis following a more deductive sort of thematic analysis (Mayring, 2014). The data were coded independently by the authors and validity and reliability were established by comparing sets of independent results, clarifying codes and re-coding data until agreement.

Results and Discussion

Table 1 summarizes the distribution of the total number of answers (635 answers for the first part of mental calculation and 721 for the second part of written calculations) across the different strategies.

Table 1: Distribution of answers across different strategies for both parts of the study

	1. Written algorithm	2. Equivalent	3. Parts of a number	4. Change representation	5. Reduction
Mental calculation	**229/635 (36.06%)**	6/635 (0.94%)	5/635 (0.78%)	8/635 (1.25%)	4/635 (0.62%)
Written calculation	**296/721 (41.05%)**	26/721 (3.6%)	7/721 (0.97%)	20/721 (2.77%)	10/721 (1.38%)
	6. Algebraic	7.Combine	8. Incorrect	9.Unanswered	10.No-codable
Mental calculation	0/635 (0%)	7/635 (1.1%)	**263/635 (41.41%)**	**112/635 (17.64%)**	1/635 (0.15%)
Written calculation	2/721 (0.27%)	37/721 (5.13%)	**252/721 (34.95%)**	**68/721 (9.43%)**	3/721 (0.41%)

Examining the different strategies, it seems to be an overlapping between the use of *Equivalent* and use of *Reduction* since from the mathematical point of view it is the same. Reduction results always to equivalent fractions. We consider them different based on the wording of the participating students who treated them as such. It was the solver's aim as this was expressed verbally that made us to decide if the solution is associated with one strategy or another. Another new strategy is the 'algebraic' one (despite its limited presence) that was not included in the list of Caney and Watson (2003). An example of this approach collected from answers in item 1 is:

$$\frac{3}{6}+\frac{4}{8}=x \Rightarrow 48\cdot\frac{3}{6}+48\cdot\frac{4}{8}=48x \Rightarrow 8\cdot 3+6\cdot 4=48x \Rightarrow 48x=48 \Rightarrow x=1.$$

The category of 'combination' has been also added to include answers that combine more than one strategy at the same calculation. For example, in the following answer for item 5 the student combined the *Reduction* and *Written algorithm* strategies: $8\div\frac{4}{8}=8\div\frac{4\div 4}{8\div 4}=8\div\frac{1}{2}=8\cdot\frac{2}{1}=16$. For the same item, another response combined the *Equivalent* and *Change representation* strategies: $8\div\frac{4}{8}=8\div\frac{1}{2}=\frac{8}{0.5}=16$.

Two interesting observations can be made based on the arithmetical data of Table 1. The first is related with the range of the strategies employed by the participants in their mental and written calculations. It can be said that the results are more or less the same in both cases. Papadopoulos et al. (2019) highlighted the dominance of the mental form of the written algorithm in mental calculations with rational numbers. But it seems now that the situation is the same no matter the way of calculation (mental or written). Therefore, it is not the context of the calculation that promotes the use of the algorithm. The second observation is that almost the total number of the collected answers is around the triplet algorithm-incorrect-unanswered (almost 94% and 86% for the mental and written calculation respectively). This means that the main option for a correct answer is to use the algorithm. Otherwise, the most possible is to get an incorrect answer or skip the task.

The situation remains the same when the data from Table 1 are distributed across the two samples in Table 2. The algorithm percentages for primary education students for the mental and written calculations are 29.84% and 37.73% respectively. Interestingly no other strategies are employed by the primary school students except 2 answers using the ‘parts of numbers’ in the mental part of the study, and 2 cases in the written part (‘parts of numbers’ and ‘change representation). All the students (almost 100%) are gathered around the same triplet mentioned earlier. The secondary education students employed several strategies in their mental and written calculations. However, the frequency of these strategies is small compared with the use of the algorithm. So, in the mental part of the study 42,58% of the correct answers were based on the use of algorithm while only 28 out of 310 answers (9,03%) employed other strategies. The situation is improved in the written part of the study since the percentage of the correct answers that use other strategies (except from algorithm) is increased to 25,31% (100 out of 395 answers). But again the dominance of the algorithm (43.79%) is unquestioned.

Table 2: Distribution of strategies across the two samples for both parts of the study

	Mental calculation		Written calculation	
	Primary Education	Secondary Education	Primary Education	Secondary Education
Written Algorithm	**97 (29.84%)**	**132 (42.58%)**	**123 (37.73%)**	**173 (43.79%)**
Equivalent		6		26
Parts of number	2	3	1	6
Change represent		8	1	19
Reduction		4		10
Algebraically				2
Combination		7		37
Incorrect	**138 (42.46%)**	**125 (40.32%)**	**148 (45.39%)**	**104 (26.32%)**
Unanswered	**88 (27.07%)**	**24 (7.74%)**	**53 (16.25%)**	**15 (3.79%)**
Non-codable		1		3
TOTAL	325	310	326	395

An alternative way to organize the data for the written phase of the study is according to the number of different strategies per item employed by the participants (Table 3). From the 325 answers given by the primary school students (65 students × 5 items) 123 employed one strategy (i.e., the mental form of the written algorithm) and the rest of them but one did not employ any strategy. Only one student was able to use 2 different strategies for one item. The situation is slightly better for the secondary education students (62 × 5 = 310 answers). There was a small number of answers that employed 2, 3, and 4 strategies (49, 13, and 3 answers respectively). But again, the main characteristic is that the majority of the answers are around 0 and 1 strategies. So, our claim that it is not the context that imposed the use of the algorithmic approach is rather strengthened.

Table 3: Number of strategies for the same task

Number of different strategies	Primary Education	Secondary Education	TOTAL
0 strategies	**201 (61.84%)**	**122 (39.35%)**	**323**
1 Strategy	123 (37.84%)	123 (39.67%)	246
2 strategies	1	49	50
3 strategies		13	13
4 strategies		3	3
TOTAL	325	310	635

Therefore, almost half of the attempts represent lack of any strategy while in the case of the successful attempts almost 8 out of ten were based on the use of just one strategy, that is the use of the mental form of the written algorithm. So, the research question about the range of the strategies employed in these two different contexts can be answered in a rather clear manner: No matter the context, the students can merely use the algorithm in their calculations, or they are unable to respond successfully.

Table 4: Reason for choosing a strategy

Reason of choosing a strategy	Primary Education	Secondary Education	TOTAL
Easy / fast / efficient	7 (2.15%)	80 (25.8%)	87 (13.7%)
Teaching practice	1	2	3
Certainty	1	28 (9.03%)	29
Lack of another knowledge	8	5	13
I don’t know	308 (94.76%)	195 (62.90%)	503 (79.21%)
TOTAL	325	310	635

The second research question aims to reveal the criterion the students use to choose their mental calculation strategy. Our hope was to contribute to the issue raised by Threlfall (2002) that there is no proof on the way students choose to calculate mentally. The analysis of the collected answers resulted in five categories (Table 4). The students explained that they chose the specific approach in their mental calculation because (i) they think that this was the easier, faster, and more efficient way for the calculation, (ii) this is the way they were taught to calculate with rational numbers, (iii) they felt secure with the specific strategy, (iv) this was the only strategy they knew, and (v) they were unable to provide any explanation for their decision. For the primary school students what is impressive is the very small number of responses. In (only) 17 (out of 325) cases the students were able to explain the way they worked. This means that for almost 95 out of 100 cases they were not able either to justify their choice or to find any strategy that would serve their purpose (unanswered items). For those who were able to provide an explanation this was mainly the easiness/fastness/efficiency of the algorithmic approach. For the secondary education students, for almost 63 (out of 100) cases the students were unable to justify their choices. From those who gave explanations, again most of them justified their choice on the basis of the easiness/fastness/efficiency of the algorithmic approach. In comparison to the primary school students the only difference here was the increased number of answers (28 vs 1) referring to the issue of the certainty the students felt with using the specific strategy for mental calculations. Actually, focusing on the total sample what is evident is the students' inability to justify their choices. But what is especially interesting is a paradox that seems to appear after analysing all the responses. From Tables 1-3 it can be seen that the students exhibited an almost exclusive preference to the mental form of the written algorithm. This choice was later justified by them as the most easy, fast, and efficient way of calculating. Its efficiency is unquestionable. Indeed, the correct application of the algorithm guarantees the correct result. But it is interesting that they consider it easy and fast. For example, for item 1, the sum $\frac{3}{6}+\frac{4}{8}$ can be immediately (in an easy and fast way) be seen as the sum of two halves which is equal to 1. On the contrary, the participants preferred to make the fractions having the same denominator ($\frac{3}{6}+\frac{4}{8}=\frac{12}{24}+\frac{12}{24}$), to add them ($\frac{3}{6}+\frac{4}{8}=\frac{12}{24}+\frac{12}{24}=\frac{24}{24}$), to reduce the sum, to find 1 ($\frac{3}{6}+\frac{4}{8}=\frac{12}{24}+\frac{12}{24}=\frac{24}{24}=1$) and they considered this process as the most easy and fast.

Conclusions

The ability for mental calculations and the selection of the most suitable strategy for mental calculations are considered especially significant by the research community. In this paper we followed primary and secondary school students in their attempt to calculate (mentally and in paper-and-pencil) the same collection of tasks. It seems that the algorithm was the only option for primary school students no matter whether they calculated mentally or in paper-and-pencil. The secondary school students exhibited an ability to use alternative strategies, but the presence of these strategies was very small compared to the use of the algorithm. Most of the participants used just one strategy for their calculations in paper-and-pencil, which is indicative of limited flexibility (Heinze et al., 2009). Finally, most of the students justified their choice of the algorithmic approach considering it as being easy, fast, and efficient. From the mathematics point of view this creates a paradox since the use of algorithm provokes an increased cognitive load compared to many other mental approaches in calculating. The findings reveal some interesting aspects about mental calculations, but these findings cannot be generalized due to the relatively small number of participants. However, they deepen our understanding of the topic and challenge us for a future study to strengthen our arguments made here.

Using Concept Cartoons to support the number line as a vehicle for mathematical understanding

Maria Pericleous

University of Nicosia, School of Education, Cyprus; pericleous.m@unic.ac.cy

This contribution draws on a research study the aim of which was to investigate the number line as a vehicle for mathematical understanding in the naturalistic setting of the elementary classroom. This paper focuses on one aspect of this research; the use of Concept Cartoons as an educational tool to support the role of the number line as a tool for fostering the development of conceptual understanding. Evidence from whole class discussion and the pupils' own productions points to the role of Concept Cartoons in supporting pupils' sense making, the elaboration of informal strategies, and the development of more sophisticated ones.

Keywords: Concept Cartoons, number line, mental calculations, primary education.

Background.

The understanding of and ability to use the linear, mathematical number line constitutes an essential facet of pupils' mathematics education (Lemonidis, 2016). The number line representation plays an important role in facilitating pupils to develop flexibility in mental arithmetic as they actively construct mathematical meaning, number sense, and understandings of number relationships (Frykholm, 2010). The number line is not a simple representation. According to Herbst (1997), a number line is formed by the consecutive translation of a specified segment U, as a unit from zero that can be partitioned in an infinite number of ways. He suggests that the number line is a metaphor of the number system. The number line is also considered a geometrical model, involving a continuous interchange between a geometrical and an arithmetic representation (Gagatsis et al., 2003). Within the literature, two major types of number lines can be identified; the structured number line and the empty number line (Diezman et al., 2010). There is a large body of literature that discusses the number line and its crucial role in teaching and learning elementary mathematics (Beishuizen, 2010; Gravemeijer, 2020). Whilst generally effective, research findings often raise doubts about the usefulness of the number line as a didactical model (Van den Heuvel-Panhuizen, 2008). These studies point towards a coherent treatment of the number line throughout the years of compulsory education and presentation of the number line in the school official documentation in a developmentally appropriate manner, by focusing on the simultaneous presence of the geometric and the arithmetic conceptualization of number on the number line. It is acknowledged that it is superficial to simply recommend the use of the number line for the students' mathematical development or include it in curriculum materials and other recourses. If emphasis is given on the nature of the number line and its use as a representation of sophisticated ideas, then a conceptual way of teaching and learning is being encouraged, contributing to addressing students' difficulties (Van den Heuvel-Panhuizen, 2008). In promoting a non-threatening classroom culture that encourages all pupils to create, formulate, extend and express their mathematical understanding, and simultaneously provides the teacher an insight into the pupils' understanding, a didactical tool that can be utilised alongside the number line is Concept Cartoon.

Concept cartoons are cognitive drawings or visual engagements that use a cartoon-style design to present mathematical conversations inside speech bubbles (Dabell et al., 2008). The integrated written text is characterized by minimal use of written language, in order to be accessible by all pupils, regardless of their literacy skills. The cartoon characters are engaged in a dialogue or an argument presenting alternative statements, concepts or questions that are related to a central content-related topic. All alternative viewpoints presented by the cartoon characters have equal status and are grounded on research related with pupils' understanding in order to appear credible (Naylor & Keogh, 2013). Thus, the legitimized argument presented in the concept cartoon provides a comfortable and non-threatening environment inviting pupils to engage in and extent the characters' argument. Concept cartoons are considered a valuable learning and teaching tool that provides the pupils the opportunity to interpret and understand mathematical concepts (Naylor & Keogh, 2013). As the pupils' ideas are articulated by the cartoon characters, even reluctant or less confident pupils are encouraged to express their personal views as responses to the characters and justify their reasoning and thus, engage in the discussion (Sexton et al., 2009). Comparing and contrasting ideas facilitates learning and interpretation of knowledge, reveals and eliminates misconceptions (Dabell, 2008). Adding to the above, research studies with a focus on engaging pupils with concept cartoons, also argue that the use of concept cartoons has the potential of increasing levels of motivation, involvement and interest towards lessons and have a positive effect on mathematical achievement (Naylor & Keogh, 2013).

Keeping in mind the aforementioned, this paper focuses on Concept Cartoons, as an educational tool to support the number line as a vehicle for mathematical understanding. To be more precise, this paper examines how Concept Cartoons can be utilized in a Year 2 mathematics classroom to provide a fruitful context for appreciating the nature of the number line and its use as a representation of sophisticated ideas.

Method.

The results presented in this contribution form part of a broader study that constitutes an attempt to translate the idea of the number line as a vehicle for mathematical understanding in the naturalistic setting of the elementary classroom (Pericleous, 2022). To be more descriptive, this study sought to examine the use of the structured and empty number line as a tool to support and develop Year 2 and Year 3 pupils' sense making and calculation strategies specific to addition and subtraction in the number domain 0-1000. The study employed a design based research methodology (Cobb et al., 2003) that was informed by Realistic Mathematics Education and a socio-constructivist approach to teaching and learning (Gravemeijer, 2020). Thus, pupils' learning process was viewed from both the individual perspective and the social perspective. In this learning process, where pupils pass through various levels of understanding, models such as the number line function as a bridging device between informal to more formal mathematics, supporting a shift from a 'model' of pupils' informal solution strategies to a 'model for' mathematical reasoning (Gravemeijer, 2020). The study was conducted in a public primary school in Cyprus. The participants, as relevant for this paper, were 19 pupils (7-8 years old) of a wide range of abilities. The instructional sequences were conducted throughout a school year and were carried out as a part of the ordinary mathematics classroom with the teacher as the researcher and author of this paper. Starting from pupils' embodiment of the number line, and explicitly giving emphasis on the nature of the number line, the instructional approach was organized around number sequence and recognition, addition and subtraction in the domain from 1 through 100. The overall aim of the instructional approach was to create opportunities for the pupils to build connections or relations between representations of mathematical ideas, to have the freedom to come up with their own notations, find their own ways to decompose quantities and regroup/recombine them and express and discuss their ideas. In doing so, the pupils had the opportunity to understand the nature of the structured and empty number line before acting on them and modelling their solution strategies.

The data collection process as relevant to this paper included video data from the teaching sequences, the field notes from the teacher and pupils' written work. The overall process of analysis of the collected data drew upon progressive focusing and the constructs 'account-of' and 'accounting-for'. According to Stake (2004), progressive focusing is achieved in various stages; first observing, then further inquiry, beginning to focus on relevant issues, and then seeking to explain. The analysis of collected data started simultaneously with the data collection process, in order to further organise the instructional sequences. The data were treated both qualitatively and quantitatively, aiming at identifying pupils' thinking, strategies and procedures and their development. The ongoing analysis being conducted while the study was in progress led to a focus on several issues and events; accounts-of, which were then placed in a broader theoretical context by conducting a retrospective analysis (accounting-for). Creating the Concept Cartoons aimed at providing pupils the opportunity to appreciate the number line as a rich model that can have different manifestations, by giving them as much initiative as possible, and simultaneously reducing the leading role of the teacher. This paper focuses on Concept Cartoons that were employed as a way to support pupils' understanding of the number line and gain access to their calculation strategies. They present addition situations up to 100 without bridging. The pupils would explore a specific Concept Cartoon either individually or in small groups. After exploring a concept cartoon, pupils would draw a star next to the cartoon they felt more close to, as a way for the teacher to gain access to their thinking and understanding and adequately build on their existing knowledge. Classroom discussion would follow.

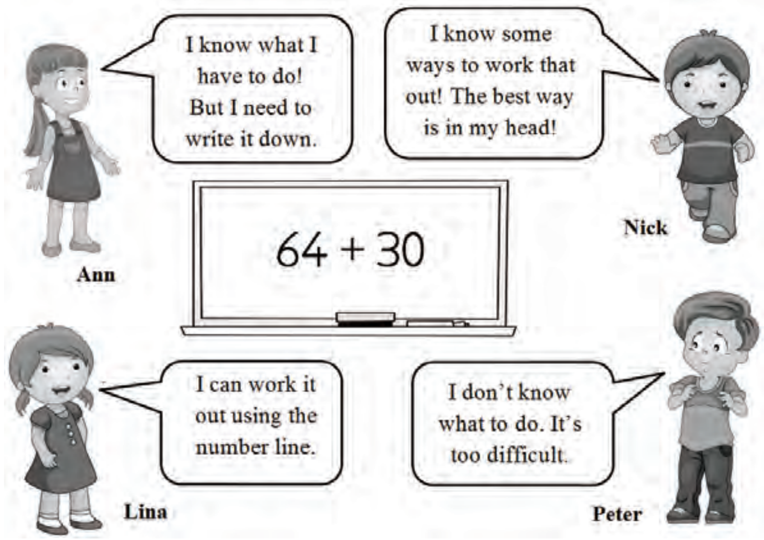

Figure 1: Gaining insight into the pupils' calculation strategies

Findings.

Supporting pupils' understanding of the number line.

There were instances where the Concept Cartoons were related with defining the structured and empty number line and developing key understandings underpinning the conventions considered to interpret, create and use number lines. For instance, in defining the structured number line, the Concept Cartoon was created by taking into consideration pupils' embodiment of the number line, requesting pupils' opinions regarding the cartoon characters' diagrams. The speech bubbles included two structured number lines (0-15, 0-30), a line with no marked numbers and a number line with no equal intervals between the marked numbers. All pupils drew a star on the structured number lines.

Student1: The child's *(cartoon character)* number line is wrong, because the numbers are at some parts very close to each other and at other places they are away from each other. They do not have the same distance from each other.

Student2: And the other one has no points for the numbers.

Student1: Yes.

Student3: It is a number line *(0-15)* because it begins from zero, the numbers have equal spaces from each other, and they are marked.

Student4: And the numbers are in order.

Student5: I agree. It is the same with the one that goes up to 30.

Teacher: Keeping in mind this discussion, how can we define the number line?

Student5: It is a straight line that has numbers that are placed in order; they are shown on the line with a mark and have the same distance from each other.

Student6: And it goes to infinity.

While, at first the pupils would refer to the perceptual features of the number line, progressively, they would make reference to order, continuity and the variety of numbers that could be represented on it. The discussion led to the conclusion that a number line shows the order of specific numbers, it includes points in equal intervals that show the place of the number and that the difference of a number to the next is constant. The classroom constructed a definition of the number line. This definition was often revisited throughout the year to support the development of a global perspective on the number system, by focusing on the unit interval and the partition of this interval.

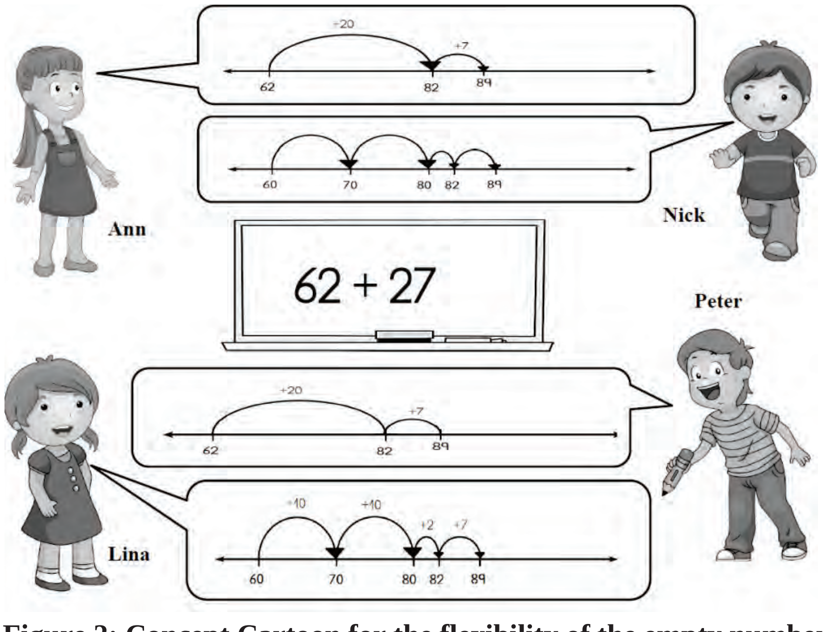

Figure 2: Concept Cartoon for the flexibility of the empty number line

Furthermore, Concept Cartoons were created so as to demonstrate the flexibility of the number line. For instance, the Concept Cartoon in Figure 2 was explored after the classroom was introduced to the empty number line as a tool to record one's thinking. By drawing upon the pupils' own informal strategies, Figure 2 provided the classroom the opportunity to discuss calculation strategies and the flexibility in the ways of recording results (for example including arrows or writing on top of the jumps made) and in the jumps made on the number line to solve a computation task. In this Concept Cartoon, the pupils' preferences were divided between the cartoon characters of Ann, Lina and Peter.

Student1: Ann and Peter added the tens and then the ones. They worked in the same way but Peter did not put the arrows.
Student2: Yes, but do we have to? It's addition, we know it from the plus sign.
Teacher: The empty number line gives us a lot of freedom in the ways of recording results.
Student2: Thus, we can decide what to do.
Teacher: Yes.

The pupils argued that it was more difficult to follow Nick's way of recording results because of the missing symbols above the jumps. The classroom established that the written symbols that accompany the jumps show the steps one follows to calculate the result, as well as possible errors. Furthermore, one pupil stated that even though he chose a cartoon character, his choice was related with the way of recording results and not with the calculation strategy presented by the cartoon character, explaining *"I would start from 60, add the tens and then the ones. It is easier this way"*. At this point, it should be noted that even pupils that struggled to model their calculation strategy on the empty number line, they understood the conventions used in interpreting the diagram, and thus, reading and identifying the strategy being modelled on the empty number line. Folllowing this Concept Cartoon, the pupils solved a calculation task, using their own strategies (see Figure 3).

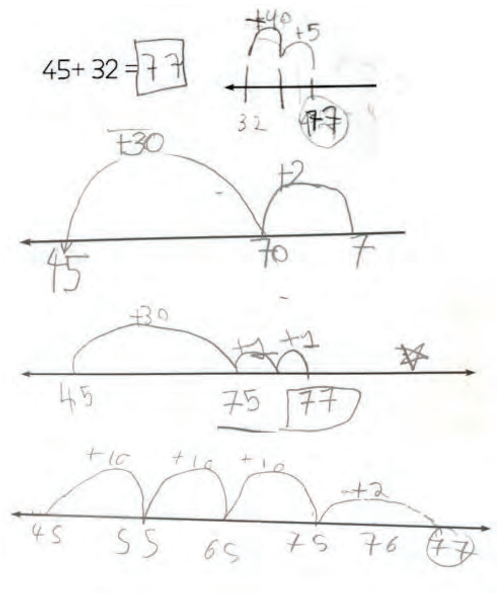

Figure 3: Pupils' calculation strategies

Gaining insight into pupils' calculation strategies.

Another type of Concept Cartoons created and employed in the classroom aimed at gaining insight into pupils' calculation strategies, as well as providing pupils with the opportunity to experience and develop a range of mental calculation strategies. Speech bubbles proposing various solution procedures encouraged pupils to identify the name of the character that best matched their personal strategy choice for calculating the result, and providing reasons for choosing the specific strategy.

For instance, in Figure 1, the Concept Cartoon was exploited as an introduction to the addition of two-digit numbers, where the second number is multiple of 10. The strategies used by the cartoon characters would enable the teacher to determine whether the pupils perceive the calculation as too hard, can solve the calculation in different ways, but recognise that a mental strategy is most efficient, would solve the calculation using auxiliary means, can remember a strategy, but would need to write it to perform the calculation (Sexton et al., 2009). The discussion led to a repertoire of proposed methods and procedures to calculate the result. According to the pupils the result could be calculated using arithmetic blocks, making jumps on a structured number line (counting by ones or tens), with a drawing (iconic representation of tens and ones, money model) or mentally. The pupils' mental reasoning strategy was to split 64 into tens and ones and processed separately. It was noticed that writing on paper to solve the calculation meant making a drawing and not a written calculation strategy. This can be explained by the fact that the pupils had not been introduced to written calculation strategies yet. This is also an indicator of pupils engaging in and extending the cartoon character’s argument. In addition, while no pupil perceived the calculation as difficult, the reliance on arithmetic blocks was evident, suggesting the need for the pupils to be provided with more opportunities to develop mental calculation strategies. Nonetheless, all pupils, using their preferred models, method and procedure reached the same result.

Adding to the above, in Figure 4, the methods used by the cartoon characters would enable the class to discuss various ways of computation as well as enable the teacher to determine the ways the pupils preferred to solve the calculation. The speech bubbles included splitting (Ann) where the numbers are divided by multiples of ten and units and processed separately when operations are carried out, stringing or compensation strategy (Nick) which refers to keeping the first number intact while splitting the second number into tens and ones, which are then added separately from the first number, the conventional paper and pencil algorithm (Lina) and arithmetic blocks (Peter). Even though the algorithm had not been introduced in the classroom, it was mentioned previously by some pupils, as knowledge they had acquired outside school. Thus, it was included in the Concept Cartoon, so as to be explicitly discussed, but without expecting pupils to use it as a way of working. Indeed, two pupils chose Lina. One pupil chose Peter, revealing that pupils would gradually rely less on models to solve a calculation task. The other pupils’ preferences were divided between Ann and Nick, with four pupils commenting that they did not need to write it down because they worked the calculation mentally. Figure 5 illustrates pupils’ calculation strategies when solving similar calculation tasks. Comparison of the pupils’ calculation strategies modelled on the empty number line that followed the exploration of Concept Cartoons presented in Figure 3 and 5 accordingly, also revealed that pupils’ strategies involved fewer steps.

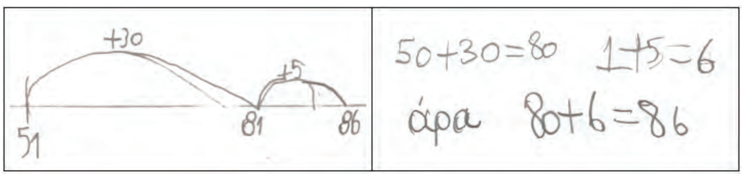

Figure 5: Pupil's calculation strategies

Discussion and Conclusion.

The purpose of this paper was to examine Concept Cartoons as an educational tool to support the number line as a vehicle for mathematical understanding. This study confirms findings from other research studies that Concept Cartoons act as an engaging and beneficial tool that supports pupils in interpreting and understanding concepts (Naylor & Keogh, 2013; Sexton et al., 2009). The Concept

Cartoons presented in this paper constitute an illustration of the attempt made to treat in a coherent way the number line by focusing on the simultaneous presence of the geometric and the arithmetic conceptualization of number on the number line, and fostering the transition from a model of pupils' informal solution strategies to a model for mathematical reasoning. Empirical evidence from the classroom indicates that Concept Cartoons created opportunities for the pupils to build connections and relations between representations of mathematical ideas, to have the freedom to come up with their own notations, as well as express and discuss their ideas, pointing to the usefulness of the number line as a didactical model (Van den Heuvel-Panhuizen, 2008). Initially, the Concept Cartoons provided the pupils with a platform from which, by drawing upon experience, they reached a definition, as suggested by Herbst (1997). Even though the instructional approach followed in this study was focused on positive whole numbers, the pupils' statements and work point to the number line being used as a metaphor to support thinking. Furthermore, by supporting pupils in defining and understanding the number line, the pupils were able to understand the conventions used in interpreting diagrams and thus, reading and identifying the strategy being modelled on the empty number line (see Figures 2 and 4). Adding to the above, findings from this study, also show, that the Concept Cartoons containing procedures in their bubbles (as a text or image), provoked discussion, reasoning and reflection regarding strategy choice and comparison of strategies, supporting pupils in developing mental calculation strategies (see Figures 3 and 5). As the Concept Cartoons were carefully designed by taking into account pupils' backgrounds, language literacy skills, as well as their level of mathematical understanding, pupils were kept motivated and engaged. This was also evident in the pupils' mathematical journal where they shared their thoughts stating for example *"I like concept cartoons because the characters are like us"*, *"The lesson is easier with the concept cartoons"*.

Concept Cartoons also proved a valuable instrument in providing the teacher with insight concerning pupils' understanding of the number line and the repertoire of strategies pupils use to perform an addition calculation. At this point it should be noted that this was not a straightforward process. For the effective use of the Concept Cartoons and supporting pupils' understanding of the number line and development of strategies and procedures, the classroom environment encouraged communication, exploration, discussion and reasoning. The social and sociomathematical norms negotiated and established in the classroom (Kilpatrick et al., 2001), offered pupils the freedom to develop, express and share their thinking. However, this does not tell the whole story. Concept Cartoons containing bubbles with proposed various results or with empty bubbles were also created and employed in the classroom both in addition and subtraction in the number domain 0-100. Through reflection and classroom discussion supported pupils progressing towards more elegant and higher-level strategies (Gravemeijer, 2020). Interpreting the number line, associating actions with it and communicating mathematical meaning may contribute towards a comprehensive picture of its conceptual structure and complete development of understanding of the number system. Additionally, employing Concept Cartoons alongside the number line in the teaching and learning process, points to the role of the teacher in taking into consideration their affordances, as well as the difficulties and limitations in their use depending on the mathematical content and the cognitive level of the pupil.

The number line is an important external representation in primary education and research has shown that performance in number line tasks correlates with general mathematical achievement. A promising tool for gaining insights into students' strategies—in number line and other tasks—is eye tracking. However, previous eye-tracking research has predominantly addressed students' use of strategies on an empty number line, whereas students' strategy uses and eye movements on the marked number line have hardly been explored. This paper presents an exploratory study that investigates student strategies in locating numbers on a marked number line. In this paper, we present students' strategies in naming and placing numbers on the number line as well as differences in the use of strategies between students with short and long response times, indicating the use of more or less efficient strategies.

Keywords: Number line tasks, eye tracking, strategies.

Introduction

It is of fundamental interest for mathematics education research to examine students' mathematical performance levels and their individual strategies when working on mathematical tasks to meet the individual needs of students (Anthony & Walshaw, 2009). The basis for many mathematical learning processes is laid in mathematics learning at primary level. Lacks in basic mathematical knowledge can lead to difficulties at secondary level (Moser Opitz et al., 2017). One essential aspect for learning mathematics is to develop the concept of numbers, which requires various aspects, including numbers in their ordinal aspect (Fuson, 1988). To build up and deepen an ordinal understanding of numbers, external representations with linear arrangement of numbers, such as the number line, are often used (Diezmann & Lowrie, 2007). Furthermore, number line tasks are "widely used to investigate mathematical learning and development" (Schneider et al., 2018, p. 1467) and students' number line estimation performance is of predictive nature for their mathematical development (Booth & Siegler, 2008). Therefore, it seems crucial to examine students' strategies in locating numbers on the number line. Previous research has indicated that eye tracking holds potential for the analysis of strategies in empty number line tasks (e.g., van't Noordende et al., 2016). In this paper, unlike previous ET studies, we investigate the use of strategies on the marked number line and show an exploratory first excerpt from a larger study.

Number line tasks

The number line is one of the essential external representations in mathematics education to address the ordinal number aspect (Diezmann & Lowrie, 2007). On the number line, numbers are arranged linearly and represented by their position in relation to other numbers (Schulz & Wartha, 2021). Students performance in number line estimation tasks correlates with broader mathematical competence (for a meta analysis, see Schneider et al., 2018). There are several types of number lines, for example, the marked number line or the empty number line. For the marked number line, there are different presentation options. The number line can be completely or only partially marked with hatch marks and labelled with numbers. Hatch marks can represent visual reference points, also without being numbered. Also, different ranges of numbers can be represented. Thus, on different scales the same marks and distances must be interpreted differently (Schulz & Wartha, 2021).

Often, the empty number line (where only beginning and endpoints are labelled) is used to study children's number sense. In studies using the empty number line, children are often asked to estimate the spatial position of numbers (e.g., van't Noordende et al., 2016). These studies indicate that children with mathematical difficulties (MD) show less precise estimations as compared to children without MD (Landerl et al., 2017). Further, eye-tracking studies have indicated that differences in the estimation of numbers between children with and without MD are related to the different use of strategies for estimating numbers (van der Weijden et al., 2018), that students with MD are less flexible in strategy use, and that student strategies may involve, for example, the use of reference points such as the given beginning, end- and midpoint (van't Noordende et al., 2016).

However, so far only little research has investigated students' strategies on the marked number line and previous works on the empty number line (e.g., Barth & Paladino, 2011) suggest that strategies may differ between the two representations—due to, for example, hatch marks, etc. Differences in strategy use on the marked number line may be related to a different use of reference points—as compared to the empty number line—and, furthermore, to the use of additional marks, which may be indications of counting strategies, as Diezmann and colleagues showed in an interview study (2010). This calls for studies investigating students' strategy use on the marked number line.

Eye tracking

Eye tracking (ET) is the technique to record a person's eye movements (Holmqvist et al., 2011). It has proven to provide insights into children's mental processes and their strategies when working on mathematical tasks—through domain-specific interpretations (Schindler & Lilienthal, 2019). There are some ET studies addressing number line tasks in the field of natural numbers—to investigate strategies in solving these tasks—both in adults (e.g., Sullivan et al., 2011; with MD, e.g., van der Weijden et al. 2018) and in children (e.g., Schneider et al., 2008; with MD, e.g., van't Noordende et al., 2016).

ET research has already addressed students' diversity with respect to their competence levels, for example, addressing children with and without MD. These ET studies use the empty number line with varying ranges of numbers (usually 0-100, e.g., Schneider et al., 2008; and 0-1000, e.g., Sullivan et al., 2011). Yet, little is known about how students deal with the marked number line and there are—to the best of our knowledge—no ET studies investigating the use of strategies in locating numbers in marked number lines tasks. As mentioned earlier, differences in students' locating of numbers on the number line could be due to different use of strategies. Therefore, it seems worthwhile to investigate students' strategies locating numbers on the marked number line.

We ask the following research question: *What strategies do students use in locating numbers on a marked number line, and how does students' strategy use differ?*

This study

Tasks and procedure

In this study, we used a number line with labelled beginning and endpoint and hatch marks—with distance between adjacent marks of a unit of 10. We used this type of number line, which is an intermediate form between a completely marked and an empty number line (Schulz & Wartha, 2021), to give students some help and orientation (steps of 10) but not to display all of the information (i.e., every single number) on the number line. We used two different task types. In the “number-to-position-task” (NP), we presented a symbolic number to the students and then asked them to place it on the number line. This task type is common in ET studies of number line tasks (e.g., Sullivan et al., 2011). In the other task type, the “position-to-number-task” (PN) (Figure 1), students were shown a position (red cross) on the number line and asked to name the number that corresponded to it. This task type avoids falsification of results due to possible motoric difficulties (Gomez et al., 2017).

Figure 1: Position-to-number-task

In individual sessions in a quiet room in their school, the students worked on the tasks. There were three items for each task format. Before the tasks, there was one practice task each (with number 10 each) to introduce the number line and get the students acquainted with the task format. In the NP, the numbers 70, 30, 90 (in that order) were to be placed on the number line. The numbers were presented in the upper left corner of the screen. The students were asked to read the number aloud to ensure they had perceived it correctly before the number line appeared. Then students were asked to point at the corresponding place, fixate it with their eyes, and let us know when they were done. In the PN, the position (red cross) of the numbers 80, 40, 60 (in that order) were shown and the students were asked to say what number was indicated. In between the tasks, the students were instructed to fixate a star in the upper left corner of the screen before the next task appeared, so that students’ gazes started from the same place. The students received no response as to whether their answers were correct. Verbal answers were recorded through an audio-recorder.

Participants and eye tracker

A total number of 186 German fifth graders (165 students of a comprehensive school, 21 students of a special school for learning difficulties) worked on the tasks. We chose fifth graders since at the end of primary school (i.e., grade 4), students may still have difficulties with the number line (Rodriguez et al., 2001). From the entire group of participants, ten students each were selected for the NP and PN tasks (mean age: 10.11 years) based on response times in the respective task type: To get insights into a diverse set of strategies, we included five students (both tasks: three students from special school and two students from comprehensive school) whose response times were particularly long (LRT-group), and five (from comprehensive school; except for NP: one student from special school) with particularly short response times (SRT-group). This choice was made since long and short response times typically reflect different strategies (e.g., Schindler et al., 2019). Additionally, we analyzed only trials where students solved the tasks successfully, to rule out that the students just guessed.

The students’ eye movements were recorded with the remote eye tracker Tobii Pro X3-120 (120 Hz, binocular, infrared). This eye tracker is attached to the bottom frame of a monitor and therefore very unobtrusive. The average accuracy for the students in this study was 0.7°. Tasks were presented on a 24” Full HD computer screen. The distance of the students to the screen was about 50 cm.

Data and data analysis

We used response times and videos, which were provided by Tobii Pro Lab software. The existing ET studies on number line tasks examine fixations. In our study, however, we use gaze-overlaid videos (where student gazes are augmented through a dot wandering around)—like, for example, Schindler and Lilienthal (2019) did. These videos are unfiltered and contain all captured information, that is, all eye movements are considered (not only fixations), which is advantageous when studying strategies. Analysis of these data has already proven to be useful in identifying children’s strategies in other mathematical domains and tasks (for quantity recognition, see e.g., Schindler et al., 2019). We analyzed the gaze-overlaid videos in an inductive manner based on Mayring’s (2014) qualitative content analysis: For each task, the eye movements were first looked at, described, interpreted, and then paraphrased. In a subsequent strategy finding process, commonalities between the eye movements of the students were sought, categories of strategies were found and each assigned with corresponding descriptions. Finally, the strategies used by the students in the two groups (with long and short response times) were compared qualitatively.

Results

In the following, we will pursue the research question: *What strategies do students use in locating numbers on a marked number line, and how does students’ strategy use differ?* We will do so by elaborating on the strategies used by the LRT-group and the SRT-group respectively. For visualizing gaze patterns, we use gaze plots, although we used gaze-overlaid videos for the data analysis.

Position-to-number-task

Task 80: The five students of the SRT-group showed an orientation to the end of the number line (100), this means they used counting from 100 backwards to the red cross (80) (Figure 2).

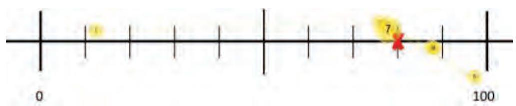

Figure 2: Gaze plot SRT-group—identifying 80 on the number line (PN)

The students of the LRT-group mainly used counting from the beginning of the number line forward and were partially additionally oriented to the whole number line (i.e., gazes were at beginning and endpoint) (Figure 3, left). One student also showed an orientation of 100 backwards after first appearing to want to count from the beginning (Figure 3, right).

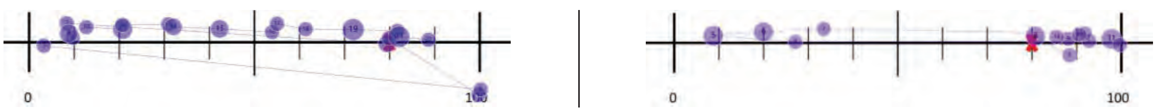

Figure 3: Gaze plots LRT-group—identifying 80 on the number line (PN)

Task 40: The students of the SRT-group named the number without looking at reference points (i.e., direct identification), or oriented themselves to the middle (50) of the number line (Figure 4).

Figure 4: Gaze plot SRT-group—identifying 40 on the number line (PN)

The LRT-group students mainly used counting from the beginning of the number line forward (Figure 5, left). One student additionally used the middle of the number line as orientation (Figure 5, right).

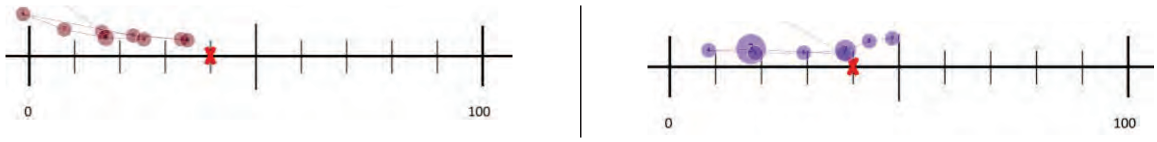

Figure 5: Gaze plots LRT-group—identifying 40 on the number line (PN)

Task 60: Both groups predominantly used the middle of the number line as orientation (Figure 6, left), while the students in the LRT-group partly also paid attention to the entire number line (i.e., beginning and endpoint) (Figure 6, right).

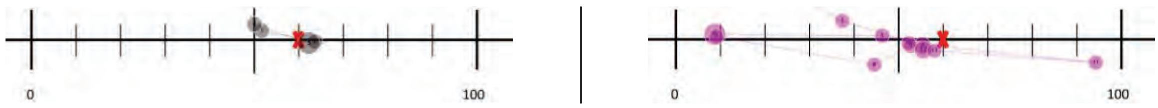

Figure 6: Gaze plots—identifying 60 on the number line (PN)

In sum, we found that students with long response times predominantly used counting procedures, which are time-consuming—especially from 0 forward for high numbers—or a combined use of reference points (e.g., beginning and endpoint). In contrast, students with short response times tended to use more efficient strategies such as looking directly at the red cross or the nearest reference point.

Number-to-position-task

Task 70: In this task, there was predominantly an orientation to the endpoint (100) for the SRT-group. Two examples of orientation to the endpoint are shown in Figure 7: from 100 stepwise (counting) to 70 (left) and from 100 directly to 70 (right).

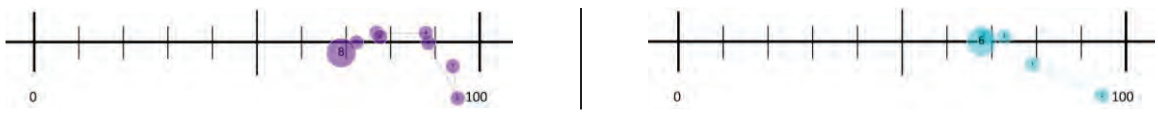

Figure 7: Gaze plots SRT-group—placing 70 on the number line (NP)

The orientation to 100 was also frequently evident in the LRT-group, but here students sometimes additionally showed an orientation to the midpoint (50) (Figure 8, left). One student of the LRT-group used counting from 0 forward (Figure 8, right).

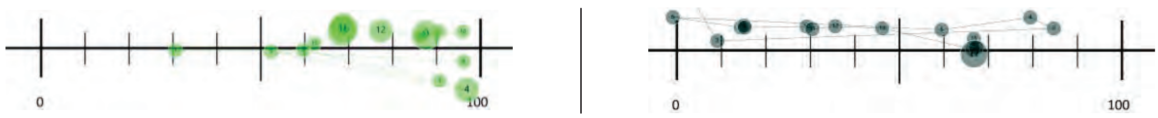

Figure 8: Gaze plots LRT-group—placing 70 on the number line (NP)

Task 30: The students of the SRT-group either counted from the beginning (Figure 9, left) or used no reference points (Figure 9, right).

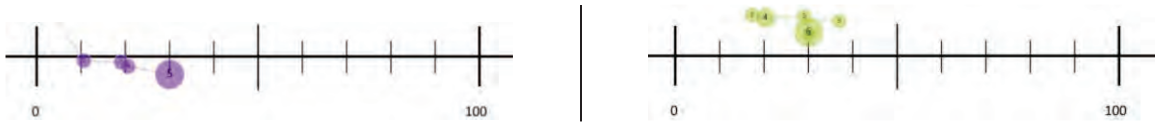

Figure 9: Gaze plots SRT-group—placing 30 on the number line (NP)

One student of the students of the LRT-group counted from the beginning but additionally had many gazes at the end of the number line (Figure 10, left). Another one was more oriented towards the middle (50) and counted backwards (Figure 10, right).

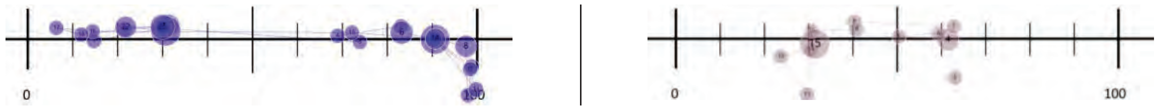

Figure 10: Gaze plots LRT-group—placing 30 on the number line (NP)

Task 90: Here, the strategy use was similar for the two groups. The placing of the number happened either directly (Figure 11, left) or in orientation to the endpoint (Figure 11, right).

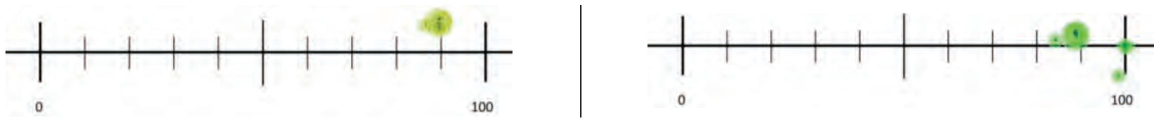

Figure 11: Gaze plots—placing 90 on the number line (NP)

In sum, for the first two tasks of the NP, students who had short response times appeared to use more efficient strategies than students with long response times, such as using a near reference point only. In contrast, in the group of students with long response times, for example, combination of strategies (reference points) or counting from the beginning (time-consuming for high numbers) occurred.

Discussion

Our study revealed different strategies for tasks on the marked number line—indicated by the students' eye movements. We found that the students appeared to use different reference points (beginning, midpoint, or endpoint) and that they partially combined reference points. We found counting strategies starting from different reference points and we also found strategies of direct orientation starting from different reference points or without looking at any reference point. Furthermore, our analyses indicate differences in the use of strategies between students who had long response times (LRT) and those with short response times (SRT). For the naming of numbers on the number line (PN), there were apparent differences between the two groups: The LRT-group used time-consuming counting procedures along the number line and the combined use of reference points. They used the relation of given marks (Schulz & Wartha, 2021), for example, that the number 40 is next to the number 50, the marked midpoint, less often than students with shorter response times. SRT-group students had almost exclusive gazes at the marked place and the nearest reference point. Students with longer response times used less efficient strategies. This is in line with previous ET research (e.g., Schindler et al., 2019), including studies on the empty number line, which showed differences in the efficiency of different students' use of strategies (e.g., van't Noordende et al., 2016). Beyond that, for placing numbers on the number line (NP), similar differences in the use of strategies were found. However, these differences in the use of strategies only showed for two out of three tasks. This could be due to the chosen number of the third task—90 is close to 100 and probably therefore, there was little variation in this task.

Our insights relate to the results found by Rodriguez et al. (2001) that students in the transition from primary to secondary level may still have difficulties with the number line. This implies that naming and placing numbers on the number line partially needs to be supported at the beginning of secondary school—even in the range up to 100. With respect to the whole sample, future studies should explore the tasks on the marked number line further to see if the results found here are transferable and if the trends of our exploratory study can be found in larger samples. Looking at more students, might show a greater variation of strategies. It would also be interesting to investigate if there are differences between children with and without MD in their strategy use to locate numbers on the marked number line—as shown for the empty number line (e.g., van't Noordende et al., 2016). We believe that our exploratory study contributes to gain fine-grained insights into students' strategies when working on number line tasks—an important tool for the development of the number concept and its ordinal aspect (Diezmann & Lowrie, 2007). Gaining such insights is an important step for being able to address students' individual needs in this mathematical content (Anthony & Walshaw, 2009).

Teachers’ perspectives on number and addition in year one: application of FoNS framework in interview analyses

Pernille Bødtker Sunde[1] and Judy Sayers[2]

This study investigates Danish teachers’ perspectives on teaching and learning number and addition in year one through analyses of semi-structured interviews with six year one teachers. The teachers’ perspectives are analysed through an established year one framework for number sense: Foundational Number Sense (FoNS). The analysis indicates that the FoNS framework is a useful tool to identify factors that teachers privilege, but important foundational factors, estimation, quantity discrimination and number patterns were only superficially discussed by the teachers in their interviews.

Keywords: Foundational Number Sense, teacher perspectives, simple addition, year one students.

Introduction

Learning and teaching of arithmetic has been a major topic for educational research for decades (Nunes et al., 2016) and the importance of students’ arithmetic competence for mathematical development in general is widely acknowledged. Thus, numerical and arithmetic competence has been linked to development of mathematics achievement and difficulties (e.g. Feigenson et al., 2013; Geary et al., 2013; Ostad, 1997). Teaching of arithmetic in primary school relies on the implementation of key knowledge to set up strong foundations for a successful development of arithmetic competence, e.g. adaptive flexibility, strategies for mental calculation, and number knowledge. Therefore, it is important to get insight into teachers’ perspectives on the teaching of number and arithmetic in the early years of school, where number and basic arithmetic is the primary focus, and research suggests is a crucial stage in children’s development of number competencies.

In this paper, we explore six Danish teachers’ perspectives on the teaching and learning of number and addition and analyse whether this is aligned with the FoNS framework.

Numerical and arithmetic competence

Development of arithmetic competence rely on several components of numerical competence or number sense (Desoete & Grégoire, 2006; Fuson & Burghardt, 2003), for example: symbolic knowledge and number words (e.g. Chu et al., 2015), mapping symbols to quantity (e.g. Geary, 2013), basic counting skills (e.g. Jordan et al., 2009), number comparison skills (e.g. De Smedt et al., 2013), estimation skills (e.g. Booth & Siegler, 2008; Gilmore et al., 2007), and knowledge of base-ten number structure (Laski et al., 2014). The individual components of number sense are all important for further mathematical development, however, the links between them are essential for students’ development (Gersten et al., 2005).

Recently, Andrews and Sayers (2015) proposed a framework for identifying students’ opportunities to acquire foundational number sense, FoNS, and demonstrated its strength when analysing lessons and textbooks in different cultural contexts (Andrews & Sayers, 2015; Löwenhielm et al., 2019;

Sayers & Andrews, 2015). The framework is derived from an extensive literature study and comprises eight categories of FoNS (for a thorough description see Andrews and Sayers, 2015): 1) Number recognition, 2) Systematic counting, 3) Relationship between number and quantity, 4) Quantity discrimination, 5) Different representations of number, 6) Estimation, 7) Simple arithmetic competence, and 8) Awareness of number patterns. Each of these categories has been shown to play an important role in students' development in mathematics (Andrews & Sayers, 2015).

The current study

This study investigates six Danish year one teachers' perspectives on the teaching and learning of number and addition in year one through analyses of semi-structured interviews. The aim of the study is to analyse whether teachers' perspectives are aligned with established mathematical knowledge of numerical and arithmetic competence. Our research questions are: 1) Can the FoNS framework be applied to teacher interviews effectively? 2) Can the FoNS framework inform us what teachers privilege when discussing their lessons on number and arithmetic?

Methodology and Methods

Drawing on exploratory Case study methodology (Yin, 2013), this small qualitative study is based on semi-structured interviews and lesson observations with six Danish year one teachers. The teachers' utterances related to different aspects of the teaching and learning of number and addition were analysed and categorised using the FoNS framework (Andrews & Sayers, 2015).

The selection of participants ensured an equal number of male and female teachers, and a cross section of professional experience (2-24 yrs.) and age (30-49 yrs.). The teachers were informed about the project both in writing and at an introductory meeting prior to the interviews took place. By the end of the project, the teachers were offered to read and approve the transcripts of the interview. None of the teachers took advantage of this offer. Pseudonyms have been used throughout.

Teacher interviews

In accordance with an exploratory Case study investigation a series of open ended interview questions were used to elicit teachers' perspectives on what they emphasise in the teaching on number. Each interview lasted between 45 and 60 minutes, and the interview focused on the teachers' perspectives on teaching and learning of arithmetic in year one. The semi-structured interview was guided by questions related to the teacher's plans for and reflections on a specific observed lesson on number and arithmetic as well as general questions on the teaching and learning of number and arithmetic (addition and subtraction) in year one. The questions on the observed lesson was related to planning of the lesson: "Why did you choose these specific activities?", carrying out the lesson: "How did you experience the lesson? Did it proceed as you had expected?", Progression: "How will you follow up on this lesson? What will be the next step?", and characteristics of a 'good activity': "what is a good activity and what makes it good? What do the students learn in these activities?".

General questions about learning were asked specifically about teaching addition, for example: "how do you introduce the students to addition" and "what aspects do you emphasize?", prerequisites for learning addition: "What is the prerequisites for learning addition, how do you ensure the students have the prerequisites?", and "Are there aspects of learning addition the students' find especially difficult?", Furthermore, questions were asked about children's progression in teaching addition, for example: "How do you see the progression in teaching addition?" and "What do you expect your students to know or be able to work on by the end of year one?".

Throughout the interview, if the teacher primarily referred to practical aspects, e.g. "a good activity is easy to explain for the students" or "the lesson went well because many students participated in the activity", the teachers were asked additional questions related to the mathematics of the activities and lesson, e.g. "what aspects of number and addition do you think the students learn through that (particular) activity?". According to Bryman (2016), this was to ensure teachers had an opportunity to reflect on the aspects of mathematics that were of interest in this project. Only utterances with mathematical content related to number and arithmetic were categorised in the analysis.

To analyse how six teachers, describe their approaches to their lessons we transcribed the interviews using NVivo. Excerpts presented here were all translated into English, a process that included transforming Danish idioms into equivalent English expressions without losing the speaker's intended meaning (Brinkmann & Kvale, 2015). We have chosen to scrutinise these teachers' utterances to identify what components of number sense they privileged over others in their teaching of number and addition. In so doing we used a deductive approach (Bryman, 2016; Yin, 2013) where the first author read each transcript repeatedly, to determine which FoNS components were addressed. To minimize the need for translating the interviews, the second author then read the collective excerpts of the different categories to ensure consistent categorisation. In the following, we present the results of our application of the FoNS framework to the interviews.

Results

In the following we provide examples of utterances by teachers that were mapped directly to each of the FoNS categories. However, a statement or description of an activity can contain several FoNS categories and is then assigned to all relevant categories.

FoNS categories in the interviews

Number recognition: Knowing number symbols and number names were emphasised by all teachers but explicated very differently. The teachers expressed very different levels of necessary knowledge for the students. One teacher, Else, said that the students "need to know the numbers, their value and be able to write and read them, and recognise them". Frida exemplifies by saying "they should know what twelve looks like". Allan specifies a number range: "the students need to learn the numbers to 100" and Dan explicated that the students do not have to know the number name as long as they "can write it" although he also emphasised knowing the names of the tens. Knowing the names of the tens was also mentioned by Carl as a help to find the number names of two-digit numbers. Bettina, talking about the base ten number system, explained how she focused on "enhancing the students' competencies of naming number". Naming two-digit numbers are something that many students find difficult because of the Danish number names. Carl mentioned this and explains how he addressed this in activities where the students "have to find the number 13 or 17 so they practise finding the correct symbol for the correct number name".

Systematic counting: Counting skills are addressed by all teachers. Dan said that “they need to know the number sequence” and Carl stated “Early maths is mostly about counting”. Else said, when asked what she thought should be the focus in year 0 (a preschool class) she said “it’s important that they just count and count and count”. All the teachers provided many examples of counting procedures, often performed by the use of manipulatives or other representations e.g. a number line. The number line was mentioned by all the teachers in relation to activities of ordering numbers or “find the number” and when performing counting procedures. However, Carl and Else were the only teachers directly referring to knowledge of “the number before and after”. All teachers referred to skip counting, often by ten. Skip counting was used together with references to times tables and the teachers thus referred to “knowing the ten times table” when they taught the students to count in tens in order to find the name of a two-digit number.

Number and quantity: The relationship between number and quantity was addressed by four of the teachers but with different levels of articulation. Allan emphasised that “they need to recognise that quantity and number kind of go together”. Bettina said “the students need to understand the symbols and the naming of quantity”. Carl, elaborating on “the translation between number and quantity”, underlined that “they need to understand quantity; the symbol 4 equals four things”. Likewise, Else emphasised the understanding of the relationship between number and quantity. “They need to have an idea of what value is and what is worth more (…) so many dots or centicubes, what is the size and quantity of that”.

Quantity discrimination: Comparing quantity was addressed very briefly by only two teachers and only in a single statement from each. Else described an activity where students construct two-digit numbers by combining two playing cards, write the number and compare with the next number they construct. She reflects: “I don’t know if they just write some numbers or if they actually understand which is bigger and which is smaller”. Allan also addressed comparing numbers in relation to doing addition and comparing possible results: ”seeing this result is one bigger and this is one smaller than the other”.

Representations of number: All teachers mentioned several different representations of numbers, both concrete materials like money, centicubes and fingers, but also partitioning in tens and ones, friends of ten and the number line. In two of the classes all students had a tablet, and the two teachers also mentioned and app, Number Pieces, where students can represent numbers using ones, tens etc. and partition numbers.

Estimation was only mentioned by one teacher, Else. She very briefly referred to estimation of quantity by mentioning an activity of “how many in the jar”. This is an activity, where the students have different containers with an unknown number of items. The students then guess how many items are in the container and afterwards they count the exact number of items. However, she did not explicitly use the expression estimation or to estimate.

Simple arithmetic: Given the teaching and learning of number and arithmetic in year one was the focus of the interviews, simple arithmetic was mentioned by all teachers. However, the teachers differed substantially with regard to their focus on different calculation methods and strategies, the number range, bridging ten and level of fluency with single digit addition.

Number patterns: Several teachers talked about knowing the sequence of numbers (categorised as systematic counting), but only two explicitly referred to putting in correct order. Else referred to a specific evaluation activity where the students have to put some number cards in the correct order. Carl described an equivalent activity where students are given a number card and then has to line up according to the number sequence.

Summarising Results

The FoNS categories were well presented in the teachers' responses to questions. Table 1 provides an overview of how the categories are distributed over the six teachers' interviews.

Table 1: Overview of the categories of Foundational Number Sense (Andrews & Sayers, 2015) and their presence in the interviews with the six teachers indicated by X. A: Allan, B: Bettina, C: Carl, D: Dan, E: Else and F: Frida.

Category	A	B	C	D	E	F
Number recognition	X	X	X	X	X	X
Systematic counting	X	X	X	X	X	X
Number and quantity	X	X	X	X	X	
Quantity discrimination	X				X	
Different representations	X	X	X	X	X	X
Estimation					X	
Simple arithmetic competence	X	X	X	X	X	X
Number patterns			X		X	

Discussion

The aim of this paper was to investigate whether teachers' perspectives are aligned with the FoNS framework in year one. The discussion provides insights into how year one teachers in six Danish schools perceive key teaching and learning number and arithmetic attributes, but also how a simple framework can be used to identify these.

The analysis of the interviews revealed that all components of FoNS were addressed explicitly or implicitly in the interviews, but not equally by all teachers. A single teacher, Else, addressed all eight categories, whereas the teacher Frida only addressed four. The remaining four teachers addressed five or six of the categories. However, what is perhaps more important is to what extent the different components of FoNS were addressed by the teachers.

Although all teachers explicitly emphasized number symbols and number names (Chu et al., 2015) as the most important aspects of "knowing number" not all teachers mentioned quantity and creating the link between symbols and quantity (Geary, 2013). However, all teachers mentioned the importance and relevance of using manipulatives, which implicitly provides learning opportunities for students to create the link between number and quantity, and other number representations. Counting skills (Jordan et al., 2009) was explicitly mentioned by all teachers. Thus, some of the basic components of FoNS and prerequisites for doing arithmetic is explicitly or implicitly part of the teachers' perspectives on the teaching and learning of number in year one.

Three of the components found to be of special importance in the early years, quantity discrimination (De Smedt et al., 2013), estimation (Booth & Siegler, 2008; Gersten et al., 2005; Gilmore et al., 2007) and number patterns (Gersten et al., 2005), was only addressed implicitly by one (estimation) or two teachers (quantity discrimination and number patterns), and in all cases these categories was only addressed superficially and implicitly by the teachers. These findings resonate with a cross-cultural study by Sayers and Andrews (2015) on the opportunities to learn different aspects of FoNS in different activities observed in six different European classrooms. Across countries, they found no episodes where teachers encouraged students to estimate and only 2 of 18 episodes where a single teacher introduced quantity discrimination.

Although estimation is considered to be one of the most important mathematical competences along with proportional reasoning and problem solving (Sriraman & Knott, 2009) it is remarkably absent in both classrooms (Andrews & Sayers, 2015; Sayers et al., 2016), textbooks (Sayers et al., 2021), and curricula (Andrews et al., 2021; Sunde et al., 2021). In this study we have shown that teachers do not explicate estimation or estimation related activities as an important part of their year one teaching.

With regard to the application of the FoNS framework to teacher interviews we found it successful on two key points: 1) The framework provided an easy to use categorisation of components of number sense known to be of importance for further development in mathematics (Andrews & Sayers, 2015). 2) The use of the framework also highlighted the differences in the number sense components the different teachers addressed.

In conclusion, the findings indicate that teachers are cognisant of a wide range of the important foundations for developing FoNS and arithmetic competence. However, it is also apparent that three crucial aspects, quantity discrimination, estimation skills and number patterns, were only mentioned implicitly by one or two teachers in the interviews.

We have shown that the FoNS framework is easy to apply in analysing teacher interviews, and can successfully reveal patterns of teachers' perspectives on the learning of number in year one. The analysis shows the differences between teachers with respect to the number of FoNS categories and it highlights the underrepresented categories.

This study cannot provide insight in how teachers actually teach. The analysis can only give an indication of what teachers emphasise in their classroom practice. A teacher's description of an activity cannot provide the full picture of the complete range of FoNS categories that the activity would cover when actually performed by the teacher in interaction with students in the classroom. Thus, the actual learning opportunities for the students might be richer than the interview would suggest. However, it would be reasonable to expect that what the teachers emphasise in the interviews is what they would also emphasise during teaching. Further research on video observations will show to what extend the findings of the lack of awareness on quantity discrimination, number patterns and estimation skills are accentuated in the actual teaching and learning in the classroom.

Informal strategies of students with autism spectrum disorder in solving Cartesian product problems

Steven Van Vaerenbergh[1], Irene Polo-Blanco[2], Lara González-de Cos[3] and Juncal Goñi-Cervera[4]

University of Cantabria, Department of Mathematics, Statistics and Computing, Spain; steven.vanvaerenbergh@unican.es[1]; irene.polo@unican.es[2]; lara.gonzalezdecos@unican.es[3]; juncal.goni@unican.es[4]

The present work focuses on arithmetic word problem solving and explores the strategies used by 26 students diagnosed with autism spectrum disorder when solving multiplicative Cartesian product problems. The students solved two outfit problems involving small and large numbers, respectively. The success in both problems was low. We found a variety of correct strategies, predominantly operation strategies. Most incorrect strategies were based on additive relations with modelling. We detail the difficulties observed during the problem-solving process, and implications for teaching students diagnosed with the disorder are drawn.

Keywords: Primary education, combinatorial thinking, cartesian product problems, solution strategies, autism spectrum disorder.

Introduction

Combinatorics constitutes a significant component of the mathematics curriculum, building on a rich structure of principles that underlie several other areas, such as counting, numeration, computation and probability. While developing their combinatorial thinking skills, children learn key mathematical skills such as constructing meaningful representations, reasoning mathematically, and generalizing mathematical concepts (English, 1991, 2005).

An important process in the development of combinatorial thinking skills is the acquisition of combinatorial strategies. A standard task to help children acquire these strategies is the Cartesian product problem (English, 1991), which consists in finding all possible combinations of two items, taken out of two different sets of items. Mulligan and Mitchelmore (1997) found that children in grades 2 and 3 used three main intuitive strategies for solving different types of problems with multiplicative structure, and all three are encountered among the correct resolutions of Cartesian product problems. These strategies are: i) direct modeling with counting strategies (when concrete manipulatives or drawings are used to model the problem situation, and objects are counted with no obvious reference to the multiplicative structure); ii) counting strategies (when the same actions are performed as in the previous level, but without the use of manipulatives); and iii) operation strategies (when multiplications are used). Several studies have shown that children develop these strategies intuitively, and that they acquire increasingly more sophisticated strategies for this type of problem, depending on age and experience (English, 1991; Maher & Martino, 1996). Mulligan and Mitchelmore (1997) note, though, that the Cartesian product problems are considered very difficult by the children, and most of the responses obtained in their study were incorrect. Furthermore, the majority of these incorrect responses were based on applying an inappropriate additive strategy, in which the numbers were added instead of multiplied. The prevalence of this incorrect strategy in the resolution of Cartesian product problems is confirmed by Nesher (1992), for students in grades 3 to

6, and by Ivars and Fernández (2016), for students in grades 1 to 6. The latter study additionally performs a more detailed analysis of the incorrect responses, identifying strategies such as one-to-one combinations (when elements are combined one to one without repetition) and nonsensical strategies (which include blank responses).

The focus of our research is on students with autism spectrum disorder (ASD). This disorder is characterized by deficits in social development, communication, and restrictive and repetitive behaviors or interests (American Psychiatric Association, 2013). These characteristics may lead to poor problem-solving capabilities, in particular since they often result in low reading comprehension and difficulties in thinking ahead or planning tasks. In order to improve problem-solving capabilities in ASD students, adapted instruction is required. To that end, there has been a growing interest in researching mathematical learning in this group (Bullen et al., 2020; Polo-Blanco et al., in press a; Polo-Blanco et al., in press b) and, in particular, in the strategies they employ when solving mathematical problems (Polo-Blanco et al., 2019, 2021). This research is especially relevant since students with ASD are increasingly incorporated into mainstream educational settings at all levels of education (Roberts & Webster, 2020).

The literature on probabilistic thinking, in particular combinatorial thinking, in students with ASD is very scarce. To our knowledge, only the work by López-Mojica, e.g. (2013), analyzes the resolution of combinatorial tasks in one student with ASD. The author highlights the need to explore combinatorial activities in order to introduce the idea of probability (López Mojica, 2013). At the same time, the importance of combinatorial thinking in students in general is clear, as emphasized by several authors (e.g., Eizenberg & Zaslavsky, 2004; English, 1991, 2005): First, as mentioned before, it allows them to acquire the mathematical skills that are present in the educational curricula. Second, people use basic principles of combinatorics in many everyday situations, for instance by enumerating all possible ways an event can occur, which is key to making informed decisions (Yee, 2009). Combinatorics therefore develops skills needed in daily life, and we consider this aspect to be especially relevant for ASD students, whom it helps to be more autonomous in their adult life.

For these reasons, in this paper we set out to investigate the strategies used by students with an ASD diagnosis when solving Cartesian product problems. In particular, we study the strategies they use when solving two “outfit problems”, which require a multiplication to obtain all possible combinations. Based on the results in previous studies with students of typical development, we anticipate that the students with ASD will also experience difficulties in the task, and that they will use basic strategies in their resolution.

Our research questions are:

- What strategies do students with ASD employ to solve multiplicative Cartesian product problems?
- What are the main difficulties they encounter during the process of solving Cartesian product problems?

Methodology

We conducted an exploratory and descriptive investigation (Yin, 2017) in which we detailed the solving strategies of 26 students with ASD, as well as the main difficulties identified, when solving combination problems with multiplicative structure.

Participants

The participants were 26 students aged 6 to 12 years (23 males and 3 females), diagnosed with ASD according to DSM-5 (American Psychiatric Association, 2013), with minimum IQ of 70 on the WISC-V (Wechsler, 2014), and minimum equivalent mathematical age of 5.5 years. All of them were attending primary education in 19 ordinary schools in Cantabria (Spain). The mean chronological age of participants at the time was 9.35 years, with a standard deviation of 2.06. The mean IQ of the participants was 89.88, with a standard deviation of 11.77.

Data collection instrument

Based on Mulligan and Mitchelmore (1997), we designed a questionnaire with 16 multiplication and division problems of the types: equal groups, multiplicative comparison and Cartesian product. Of these 16 problems, students first solved 8 problems involving small numbers. Then, the students who had provided the correct solution for a problem were asked to solve the corresponding large-number problem. In this study we analyze the two Cartesian product problems that required a multiplication for their resolution, one with small numbers and one with large numbers. These problems are:

- Outfits Problem, Small (OPS): I have 3 shirts of different colors and 4 different pairs of pants. If I wear one shirt and one pair of pants each time, in how many ways can I dress?
- Outfits Problem, Large (OPL): I have 8 shirts of different colors and 3 different pairs of pants. If I wear one shirt and one pair of pants each time, in how many ways can I dress?

The students solved these problems individually, in one session of approximately 25 minutes and in a classroom free of distractions, with only the interviewer and the student present. Before starting to solve the problems, the interviewer explained what the test consisted of, and made sure that he or she understood the statements, reading them with him or her in cases where the student was confused. The student was told that he or she could write, use manipulatives (interlocking blocks) or answer orally. All sessions were videotaped, and the solutions were transcribed for later analysis. The students' strategies were coded by the fourth author. An experienced mathematics education teacher, who was blind to the hypotheses of the study, recoded 30% of the students' strategies. The mean interobserver reliability for strategy categorization was 94%, calculated as the number of agreements divided by the number of agreements plus disagreements and multiplied by 100.

Analysis categories

We adhered to the following system for classifying the strategies used to solve multiplicative structure problems (Ivars & Fernández, 2016; Mulligan & Mitchelmore, 1997): incorrect strategies (level 0), direct modeling with counting (level 1), counting (level 2) and operation strategies (level 3). The incorrect strategies (level 0) considered were inappropriate additive relationships, one-to-one combinations, and given number (when one of the numbers in the problem is given as the answer).

Results

Table 1 shows the strategies followed by the students on the Cartesian product problems with small numbers, OPS. Eight out of the 26 students followed correct resolution strategies, the most frequent one being operations based (six students). Two students (S7 and S15) represented this strategy symbolically in the form of a horizontal algorithm, while another two (S13 and S26) expressed the multiplication verbally ("Three times four"). The last two students (S32 and S35) started by manipulating cubes and then gave the answer, one verbally and the other symbolically. In Figure 1, we can see that S32 used the orange and purple blocks to create structures of different heights, representing respectively the three T-shirts and the four pants. He then selected an orange structure and hit it against each of the purple ones, saying aloud the numbers "*one*" till "*four*". Finally, he said "*four times three*" and wrote the number 12 as the solution. S35 joined four blocks and then another three, and wrote the number "7", as we can see in Figure 1. He then corrected "*ah, but it asks you how many ways... Seven is the total*". He wrote the multiplication in the form of a vertical algorithm as the result and said, "*Twelve ways. I think 12 ways*", and he crossed out the number seven he wrote earlier.

Table 1: Strategies followed for the OPS problem

Correct strategies			Incorrect strategies (level 0)			
Direct modeling with counting (level 1)	Counting (level 2)	Operation strategies (level 3)	Inappropriate additive relationships	One-to-one combinations	Given number	Other
S10	S19	S7, S13, S15, S26, S32, S35	S3, S4, S11, S12, S16, S17, S20, S21, S24, S25, S27, S31	S8, S29	S28, S34	S14, S30

One student (S10) demonstrated a matching strategy that he expressed through drawings of all possible combinations of shirts with pants. As shown in Figure 1, he assigned a number to each shirt and pair of pants, and used the symbol "+" to express the pairing. After finishing the drawing, S10 counted the pairs obtained and provided the answer.

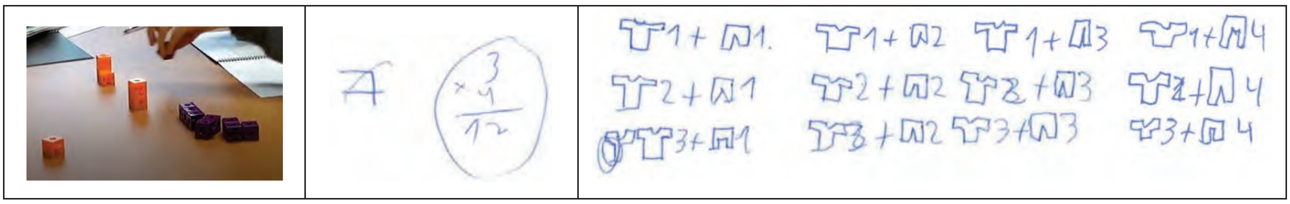

Figure 1: Examples of correct solution strategies, by S32 (left), S35 (middle), and S10 (right)

Another student (S19) used a correct counting strategy, although he made a calculation error when executing it. In particular, his strategy consisted in the repeated addition of the same number ("*four*"). He performed mental calculation to keep track of the running total, while using his fingers to represent the amount of times he had added this number. Eventually, however, he got confused and raised an additional, fourth finger, answering: "*I would say sixteen*".

The most often encountered incorrect solution strategy for the OPS problem was the application of inappropriate additive relations (12 students). In this case, the students added the quantities given in the statement instead of multiplying them, obtaining “7” as a result. Out of them, five students responded verbally: three stated this orally and two (S17 and S31) simply wrote the result without further explanation. In Figure 2, we can see that two students responded by expressing the sum symbolically, one in the form of a vertical algorithm (S16) and one in the form of a horizontal algorithm (S20). One student (S3) used drawings to help him perform the additive strategy. After reading the problem, he drew a boy wearing pants and a T-shirt, and an additional two T-shirts and three pairs of pants around it. Interestingly, one of the T-shirts resembled very much the one he was wearing at the moment, and from his remarks he was imagining these were his clothes: *“Okay, I always wear this one... ah, no, only on one day I wear this one*”. Finally, he said “*It would be one plus one equals two*”, and concluded “*seven*”, which he wrote down as the result. Another student (S4) used cubes to calculate the result, as we can see in Figure 2. He picked up three cubes with one hand and placed them on the problem sheet, and then put four more cubes, concluding that there were “*seven*” different shapes.

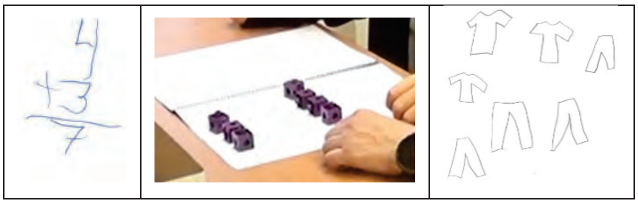

Figure 2: Examples of incorrect solution strategies, by S16 (left), S4 (middle), and S12 (right)

Three students (S11, S12 and S27) tried multiple representations to solve the problem. S11 initially took three red marbles with his left hand and four orange blocks with his right hand, said *“seven”*, and wrote the number “7”. He argued to the interviewer that this was the result by saying, “*Because I added the t-shirts [shows his right hand with four orange blocks] and also the pants and in total it would give... [starts singing, playing with the chips]*.” S12 initially answered, “*Three and four*, *seven.”* After the interviewer asked him what that “seven” was, S12 began to draw the 3 shirts and the 4 pants, as we can see in Figure 2. After the interviewer insisted “*how many ways can I dress?”* S12 repeated, “*Seven”*. S27 made arguments apparently unrelated to the task and first said that the answer was “14”, writing down “14 and 30” and finally ended up saying that it was “7”:

S27: I got it, seven.
Interviewer: And how do you know it's seven?
S27: The first one you put the shirt on, then socks and pants and lastly combing our hair and brushing our teeth. Okay? That's it.
Interviewer: So you... you count seven things that you do. But why do you know it's seven?
S27: Because I do, because three plus four is seven.

Two students (S8 and S29) performed an incorrect one-to-one combination strategy, by matching each garment from one set with one from the other set, without repetition. Both students expressed this verbally. For instance, S29 wrote “*three ways”* and argued *“because there are four pants, I can only use three because... [he thinks] because I have one pair of pants left over*”.

Two of the students (S28 and S34) responded a number already given in the statement. S28 verbally expressed that the solution was “*three*”, and argued that “*because he had heard it*”. S34 answered several times as a result “*many*”, and, after the interviewer requested that he specify how many, he said “*three or four*”, which are the number of shirts and pants given in the statement, respectively.

One student (S14) performed a strategy that could not be identified as any of the previous. After reading the problem, S14 said “*Three, four... Ouch! Let's see...*” and wrote the number “5”, and argued: “*Three, four, five*”. We interpret that he provided “5” as the answer because it was the next number in the numerical sequence. A final case of a strategy classified as “other” is that of S30, who drew a picture of a boy wearing a tracksuit, copying some letters from his own jacket. Although the interviewer insisted that he continue, S30 was tired and distracted and did not answer anything else.

All students who obtained a correct answer in the OPS problem went on to solve the large-number multiplication problem, OPL. These students, seven in total, again used a correct strategy to solve this second problem, as summarized in Table 2. Specifically, most of them used operation strategies (5 students), which three of them (S7, S15 and S32) represented symbolically in the form of a horizontal algorithm, and the other two (S13 and S26) expressed verbally. For instance, S26 read the problem and said “*I think I am going to multiply eight by three*”, and then wrote “24” as a result.

Table 2: Strategies followed for the OPL problem

Correct strategies		
Direct modeling with counting (level 1)	Counting (level 2)	Operation strategies (level 3)
S10, S35		S7, S13, S15, S26, S32

Student S10 repeated the matching strategy he had applied successfully in the OPS problem, drawing all possible combinations of shirts and pants. This time, he represented them by the letters “C” (from “*camiseta*”, in Spanish) and “P” (from “*pantalones*”) accompanied by numbers, as shown in Figure 3. When finished drawing, he counted the pairs obtained and provided the answer.

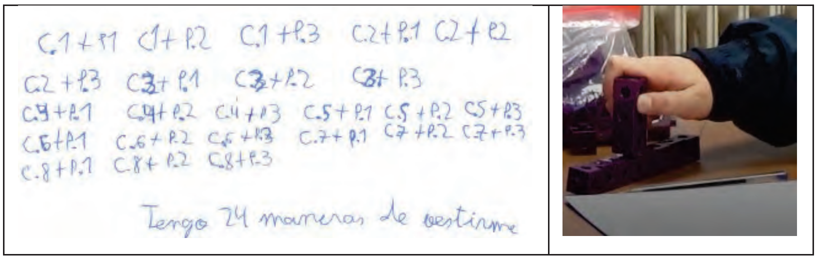

Figure 3: Examples of correct solution strategies for OPL, by S10 (left) and S35 (right)

Finally, student S35 used a modeling strategy with a manipulative type of representation making use of blocks. He first joined eight blocks, and then another three blocks, after which he combined both groups forming an inverted “T”, as we can see in Figure 3. Following this, he touched each of the blocks in the row of eight and repeated this step three times. He then said “Twenty-four”.

Interviewer:	Okay, how did you know?
S35:	By counting per pair of pants how many shirts there are.
Interviewer:	And what did you count?
S35:	Well I counted [touching the blocks in the row where there are eight]: one, two, three, four, five, six, seven, eight [counts the row again] nine, ten, eleven,...
Interviewer:	Okay okay.

Discussion and conclusion

This work contributes to the area of problem solving in students with ASD. Specifically, we have analyzed the strategies used by students with ASD when solving Cartesian product problems that involve multiplications. Most of the students failed to solve the problems correctly, and a variety of strategies were found in the analysis of their solutions. The most frequently used correct approach consisted of operation strategies based on internalized calculations. In line with the results found in the literature for students of typical development (e.g., Ivars & Fernández, 2016), the most frequent incorrect strategy was the use of additive relations, carried out on many occasions through modeling.

The results show significant difficulties in understanding the problems, confirming previous studies on problem solving in ASD students (Polo-Blanco et al., 2019), which could be related to the language difficulties characteristic of the disorder. In order to facilitate the understanding of Cartesian product problem solving, the problems could be contextualized to topics familiar to the student, in line with previous work (Polo-Blanco et al., 2021). In addition, basic modeling strategies could help the student understand the situation and the combinations posed in the problem. In order to move from modeling and counting strategies to operation strategies, it is advisable to adapt the instruction to the needs observed, and to start from the strategy used by the student. For instance, if the student uses a table to list the combinations, it may be useful to help them see that the number of combinations coincides with the result of the multiplication. In general, teaching methodologies adapted to the characteristics of ASD students should be designed for the resolution of these problems (Polo-Blanco et al., in press a), for instance, by including self-instruction lists with the support of visual guides.

The results of this work allow us to further explore the elements that hinder the learning of students with ASD, in order to offer effective instructions to achieve an improvement in academic performance and, ultimately, a greater autonomy and quality of life in adulthood.

Make practice more productive – Introducing productive practice

Sze Man Yeung and Taro Fujita

University of Exeter, Graduate School of Education, UK; sy381@exeter.ac.uk, t.fujita@exeter.ac.uk

Keywords: Procedural learning, productive practice, mathematical thinking.

Repositioning the role of practice in mathematics learning

There is a growing concern about effectively carrying out practices for enhancing the students' procedural fluency (Codding et al., 2011). Nonetheless, the function of practices is often inadvertently reduced to a way of mechanical skill training. It is believed that the didactic potential of practices is far more than this. Wittmann and Müller (2017) carefully categorise three types of practice that give us a clear purpose of doing practice: Introductory practice, Basic practice, and Productive practice. Introductory practice helps students to familiarise themselves with the new knowledge; Basic practice focuses on the small set of skills which should be mastered automatically; Productive practice integrates the practice of skills with the training of higher-order skills (e.g., exploration and explanation of patterns, problem-solving) (Wittmann, 2019). These three types of practice have their own unique functions in the learning process, so they are important and irreplaceable.

This study aims on investigating how the learning environments of productive practices can be embedded into the daily lessons as a part of the curriculum for basic skills and higher-order skills training. The aim of this poster is to introduce and provide some examples of productive practice.

Productive practice

Wittmann (2019) emphasises that productive practices are mathematically rich and well-structured small tasks, which provide unique opportunities for exploring and explaining the mathematical patterns while encouraging students to have plenty of basic skill practice. Two examples of productive practices (Wittmann & Müller, 2017) are shown below:

Schöne Päckchen (Pretty Packages)

Pretty Packages (Figure 1) are deliberately arranged in columns with flexible addends that either ascend or descend. While students are having plenty of practice time on addition, they also have the chance to explore the patterns and understand the concept of particular arithmetic laws (in this case, the associative law). They can make use of what they discovered and solve the questions effectively.

12+15=?	12+15=?	12+15=?
12+16=?	13+16=?	13+14=?
12+17=?	14+17=?	14+13=?
12+18=?	15+18=?	15+12=?
:	:	:

Figure 1: Schöne Päckchen (Pretty Packages)

Number pyramid

Number pyramid is commonly used in school for practising addition and subtraction and itself is based on Pascal's triangle, which is a source of rich mathematical properties in mathematics. It can become a good example of productive practice because the numbers in the bricks can be arranged deliberately to create different circumstances for exploring. For example, set A in Figure 2 with the number in the right bottom one increases by 1 and set B in Figure 2 with the number in the middle one increases by 1 create different effects to brick A. During the process of dealing with the actual numbers and finishing a collection of additional exercises, students can observe how the pattern of the given numbers at the bottom might affect the later answers and explain it mathematically. Students are not expected to explain the pattern in terms of algebraic expression, but they can have an important pre-algebra experience.

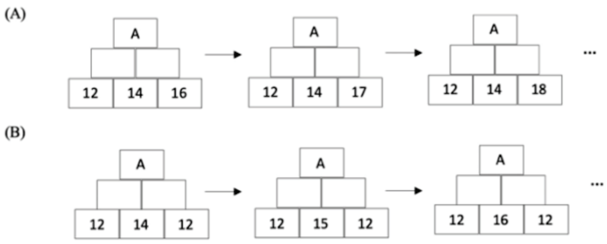

Figure 2: The bottom bricks of number pyramids are intentionally arranged

A problem-solving task with various solutions can be created by arranging the number pyramid in another way (Figure 3). While practising the arithmetic, students also have a chance to enhance their problem-solving skills through the process of observing, conjecturing, justifying, and reasoning.

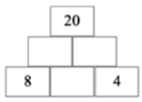

Figure 3: Productive practice which nurtures problem-solving skills

What's next?

Productive practices are not some separated tasks for specific problem-solving skills; instead, they are well-designed packages of learning environment which are fully merged with the curriculum. They can prompt deep procedural learning, meanwhile create opportunities for students to understand phenomena in a mathematical way and enhance their high order thinking skills. To evaluate and further develop the design of the learning environment with the use of productive practices, a design research study of using number pyramids in grade 2 classroom will be conducted. In the study, the lessons will be observed and some of the students will be invited for interviews afterwards; thereby analysing their mathematical thinking process while doing productive practices.

Solving multiplicative structure problems with fractions in Primary School: Prior strategies to a teaching experiment

Cristina Zorrilla, Pedro Ivars, Ceneida Fernández and Salvador Llinares

University of Alicante, Spain;

cristina.zorrilla@ua.es, pere.ivars@ua.es, ceneida.fernandez@ua.es, sllinares@ua.es

In this paper, we present the study in progress that is being carried out to examine characteristics of the transition from natural to rational numbers when Primary School students solve multiplicative structure problems. A teaching experiment has been designed, including a pre-test, an instruction, and a post-test. In these pages, we focus on the first two phases of this teaching experiment and the beginning of phase three with a preliminary analysis of the pre-test. Results show the levels of success and strategies that students use when they solve multiplicative structure problems before participating in the instruction.

Keywords: Numbers, fractions, multiplication, division, elementary education.

Introduction

In the 80s and early 90s, a line of research focused on students' difficulties in solving multiplicative structure problems (e.g., De Corte et al., 1988; Fischbein et al., 1985; Levain, 1992) emerged. This research showed that although solving multiplicative structure problems involves reasoning about the structure of the problems independently of the number set involved, primary and secondary school students had difficulties solving multiplicative structure problems when natural numbers were replaced with rational numbers (e.g., Fischbein et al., 1985).

In light of these results, there was a need to provide mental strategies to students to counteract these difficulties (Fischbein et al., 1985) and present the different structure problems, systematically alternating natural and rational numbers as numerical sets (Levain, 1992). De Corte et al. (1988) analysed whether 11-12-year-old students had other informal strategies, different from the algorithm, and to what extent these led them to the correct answer. For this purpose, they designed a test with problems with natural and rational numbers, including eight multiplication problems with an asymmetrical structure. This test was solved twice: once with a multiple-choice format, which required the choice of the appropriate arithmetic operation among six options; and once with a free-response format, which required the use of any strategy that provided an answer to the problem. They found that sixth-grade students were more successful in solving multiplication problems as free-response tasks than multiple-choice tasks, where the correct strategy was reduced to the algorithm. However, as far as we know, there is no research focused on how primary school students progress from natural to rational numbers when they solve multiplicative structure problems, although students' difficulties in solving these problems with rational numbers persist (Zorrilla et al., in press).

This study examines characteristics of the transition from natural to rational numbers in primary school students when they solve multiplicative structure problems. For this purpose, we design a teaching experiment (Stylianides & Stylianides, 2013) that theoretically focuses on teaching with variation and on developing students' relational thinking during instruction. This methodological approach distinguishes three stages (Cobb & Gravemeijer, 2008; Gravemeijer & Prediger, 2019): preparation (the design of a teaching module), implementation, and analysis. In this paper, we present the design of the teaching module that consists of a pre-test, instruction and a post-test, a description of the implementation, and a preliminary analysis focused on the pre-test. With the pre-test analysis, we can answer the research questions: What are the levels of success of sixth-grade Primary School students (11-12-years-old) when they solve multiplicative structure problems with natural and rational numbers before the instruction? Furthermore, which strategies do sixth-grade Primary School students use to solve them?

Conceptual framework

Teaching with variation

Learning is related to developing a particular way of seeing (Marton & Pang, 2006): discerning. Students must discern the object of learning, which implies discerning the critical features. To discern each critical feature, students must experience variation in one of its dimensions while other features remain invariant (Marton & Pang, 2006).

Teaching with variation is an approach widely shared by Chinese teachers (Cai & Nie, 2007), being even imperceptible within Chinese culture (Sun, 2011). In contrast, in Occident, imperceptibility is not associated with its popularity but with its unfamiliarity (Sun, 2011). This teaching with "indigenous" variation is called *Bianshi* teaching in Chinese, whose translation would be "changing form" in English (Sun, 2011; 2019). *Bianshi* practice is not only an approach in mathematics education (Sun, 2011) but also it is an efficient way of working on problem-solving (Cai & Nie, 2007). *Bianshi* variation practice incorporates three types of widespread activities (e.g., Cai & Nie, 2007; Sun, 2019):

- One problem, multiple changes (OPMC). Presenting an initial problem and, once it is solved, presenting and solving variations of the initial problem.
- One problem, multiple solutions (OPMS). Presenting a problem and providing the opportunity to solve it using different strategies to promote flexible ways of thinking in choosing/designing a strategy to solve the problem.
- Multiple problems, one solution (MPOS). Using the same strategy to solve a set of problems of identical structure.

Student participation in these *Bianshi* activities promotes meaningful connections (Cai & Nie, 2007; Sun, 2011; 2013). Furthermore, *Bianshi* activity allows students to develop a confident attitude towards unfamiliar problems, advance problem-solving skills and obtain flexible thinking (Cai & Nie, 2007). The latter benefit could be closely related to developing relational thinking strategies, which we discuss below.

Relational thinking: Strategies for multiplicative structure problems

In this study, we focused on the isomorphism of measures problems (Vergnaud, 1997), whose structure is a proportion between two measure spaces (M1 and M2), each containing two quantities. In these problems, one of the quantities is reduced to 1, so three types of problems arise depending on which of the other three quantities is the unknown (Greer, 1992): multiplication, where the unknown is the total quantity; partitive division, where the unknown is the quantity per group; and quotitive division, where the unknown is the number of groups.

Relational thinking involves using the fundamental properties of operations and equality (Empson & Levi, 2011). Multiplicative structure problems involving fractions support the emergence of relational thinking about operations as students begin to find their own more efficient strategies, relating operations and quantities and representing and structuring their thinking (Empson et al., 2011).

Empson and Levi (2011) identified different strategies that students produce with multiplicative structure problems. The strategies develop from a basic way of thinking (*direct modeling* and *repeated addition*) to more sophisticated ways of thinking (*grouping and combining strategies* and *multiplicative strategies*):

- Direct modeling. Students represent all the quantities by drawing. Then, they count, add or subtract until they get the answer.
- Repeated addition. In this strategy, students also count, add or subtract; however, unlike direct modeling, they take mathematical symbols to represent mathematical relationships.
- Grouping and combining strategies. Unlike the previous strategies, students only represent quantities that they consider necessary. They start grouping quantities until they reach what Empson and Levi (2011, p. 57) call "friendlier amounts", usually natural numbers, which they then work with.
- Multiplicative strategies. Students show multiplicative thinking through the formation of groupings, but which, unlike the previous strategy, are linked multiplicatively.

The latter two strategies show a greater understanding of the relationships between quantities, as students begin to simplify their computations. Below, in Table 1, we show these strategies by solving a quotitive division problem.

Table 1: Children's strategies for a quotitive division problem

Children's strategies for multiplicative structure problems	Problem: My mother has made 2 litres of orange juice. If she has distributed it in $\frac{1}{4}$ litre glasses, how many glasses has she filled?
Direct modeling	
Repeated addition	$\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}+\frac{1}{4}=\frac{8}{4}=2$ She has filled 8 glasses
Grouping and combining strategies	$\frac{1}{4}+\frac{1}{4}=\frac{2}{4}$ litres → 2 glasses $\frac{2}{4}+\frac{2}{4}=\frac{4}{4}$ litres → 4 glasses $1+1=2$ litres → 8 glasses
Multiplicative strategies	4 groups of $\frac{1}{4}$ is 1. There are 2 ones in 2, so there are 2 times 4 or 8 groups of $\frac{1}{4}$ in 2 so she has filled 8 glasses

Method

We have designed a teaching experiment that consists of three stages (Cobb & Gravemeijer, 2008; Gravemeijer & Prediger, 2019): preparation, implementation, and analysis. The first phase consisted of the design of a teaching module. First, we defined the learning objective: favouring the transition from natural numbers to fractions in solving multiplicative structure problems using relational thinking strategies (Empson & Levi, 2011), and the use of teaching with variation (e.g., Sun, 2011). The teaching module consisted of eight sessions of 50 minutes approximately: a pre-test (one session), the instruction (six sessions) and a post-test (one session). The instruction is based on the three types of *Bianshi* activities and the development of the different strategies introduced above:

- OPMC. Each session starts with an initial problem, and variations are made according to a feature, while other features remain unchanged. For instance, in Figure 1, the initial problem has the total quantity as unknown (multiplication problem), while the variations have as unknown the quantity per group (partitive division problem) or the number of groups (quotitive division problem). All other characteristics remain unchanged (for instance, the number used). Another example of variation is shown in Figure 2. The quantities of the initial problem are natural numbers, while the following problems vary according to the quantities considered (natural numbers, N; unit fractions, UF; non-unit proper fractions, PF; and improper fractions, IF). All other characteristics remain unchanged.
- OPMS. Students can solve the problems using different strategies (students could use the strategies described above to solve the problems from Figures 1 and 2). The instructor (one of the researchers) guides them in progressing from basic to more sophisticated strategies.
- MPOS. The problems and their variations allow students to use the same strategy as they are problems with the same structure.

The pre-test and post-test were designed to analyse changes in both the students' levels of success and the strategies used by them in solving multiplication, partitive division and quotitive division problems with natural numbers and fractions. Both tests had three problems of each typology.

In the second phase, we implemented the teaching module with three different groups of primary school students (a total of 61 6^{th} graders, 11-12 years old). The students solved the pre-test and post-test individually during the first and the last session of the teaching module. During the instruction, first, students worked in small groups, solving three problems in each session and then, the different strategies used were discussed with the whole class. Data collection is necessary to document students' reasoning' progress and their evolution during the teaching module (Cobb & Gravemeijer, 2008; Cobb et al., 2016). Therefore, all sessions were videotaped, we collected students' worksheets during all the sessions and students' discussions in small groups were also voice recorded.

Currently, we are at the beginning of phase 3, analysing the data collected. The research data are primary school students answers to the pre-test and post-test, the videos and audio transcriptions of the sessions and students' worksheets collected during the instruction. In this study, we present a preliminary analysis of the students' answers to the pre-test to explore the levels of success and the strategies that sixth-grade Primary School students' use when solving multiplicative structure problems with natural and rational numbers before participating in the instruction. This gives us information about the starting point in our instruction, and later it will allow us to identify changes along with the teaching module and the post-test to identify characteristics of the transition from natural to rational numbers in primary school students.

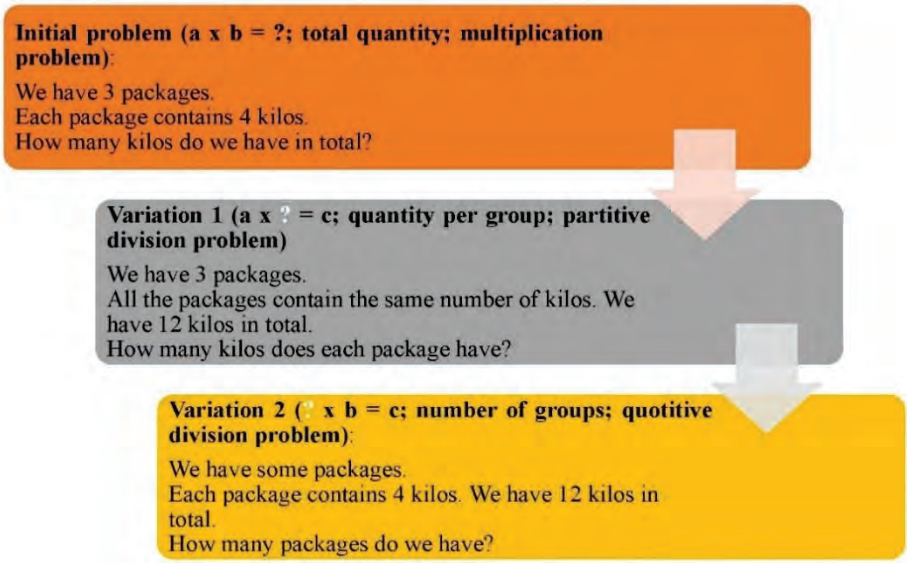

Figure 1: An example of variation: the unknown quantity as a critical feature

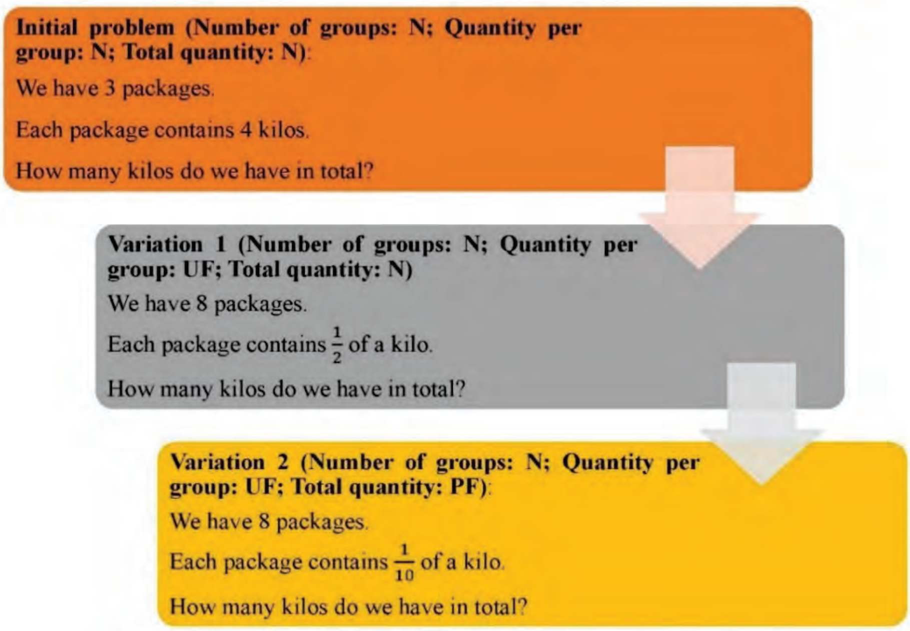

Figure 2: An example of variation: the quantity used (N, UF, PF, IF) as a critical feature

Pre-test analysis

The analysis is being carried out in two phases. In the first phase, students' success levels in each problem were analysed. In the second phase, we focused on students' strategies. To illustrate the analysis process, we will use a quotitive division problem from the pre-test. The problem is: *My mother has made 2 litres of orange juice. If she has distributed it in* $\frac{1}{4}$ *litre glasses, how many glasses has she filled?*

Phase 1. Analysis of students' success levels

Each problem is codified as "1", whether the procedure is correct (independently of computation errors), or as "0", whether the procedure is incorrect (Table 2) to obtain students' success levels.

Table 2: Example of success level analysis

Student answer	Code	Description
$\frac{1}{4} \times 2 = \frac{2}{4}$	0	The student uses a multiplication algorithm correctly but incorrectly according to the problem statement
Ha llenado 8 vasos 2 litros = 2000 ml $\frac{1}{4}$ litro = 250 ml 2000 ÷ 250 = 8 vasos	1	The student converts the number of litres to millilitres and uses the division algorithm correctly to get the number of glasses she has filled

Phase 2. Analysis of students' strategies

Secondly, the analysis focuses on the strategies used by the students. Currently, four researchers are analysing a sample of different problems to generate descriptors of the strategies used in each problem. We have begun to discuss the similarities and differences in the strategies used by the students. Below are some examples of the strategies that have emerged during this first approach to the analysis process.

In Figure 3, to solve the problem, the student (P52) graphically represents the total quantity (two litres) in two jugs which he/she divides into fourths (which is the amount of juice in a glass). To give the result, the student counts the number of $\frac{1}{4}$ he/she has drawn and answers, "she has filled 8 glasses".

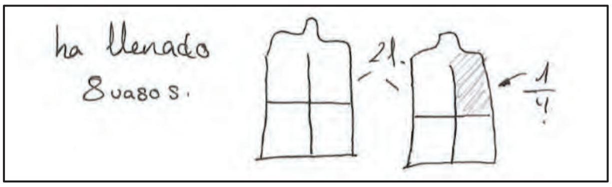

Figure 3: Strategy based on a graphical representation (P52)

In Figure 4, the student (P58) does not need to represent the quantities graphically and makes groupings. First, the student identifies that four times $\frac{1}{4}$ is a litre of juice. As the total quantity is two litres, to obtain the answer he/she doubles the number of glasses he/she fills with one litre, obtaining eight glasses. In Figure 5, the student (P12) converts two litres into 2000 millilitres and $\frac{1}{4}$ litre into 250 millilitres to divide with natural numbers.

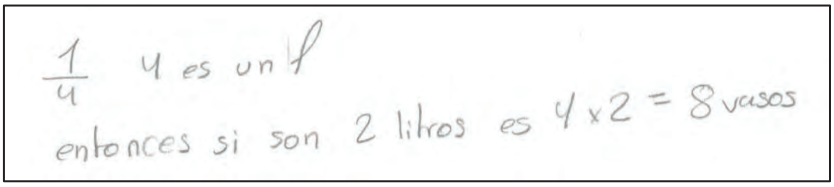

Figure 4: Strategy based on groupings (P58)

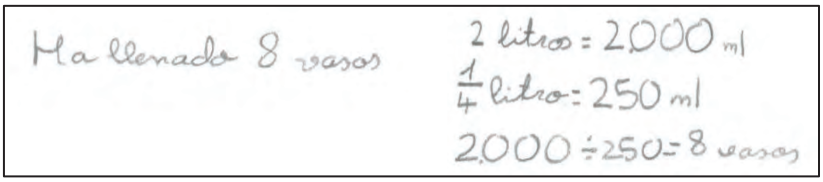

Figure 5: Strategy based on a conversion to natural numbers (P12)

First results and conclusions

We have identified different levels of success according to the numerical set used and the type of problem solved. On the one hand, concerning the numerical set, 94% of the participants correctly solved problems with natural numbers while 46% correctly solved problems with fractions. On the other hand, according to the type of problem, results of the pre-test showed that 68.3% of the participants correctly solved the multiplication problems, 52.5% the partitive division problems and 65% the quotitive division problems.

Regarding the strategies, although we are in the process of analysis, the descriptors of strategies identified are closely related to the general categories identified by Empson and Levi (2011; e.g., drawing-based strategies such as *direct modeling* or grouping-based strategies such as *grouping and combining strategies*). Furthermore, we have identified incorrect strategies which suggest the need for teachers to focus students' attention on the invariance of the structure of the problem regardless of the numerical set involved. Our results provide details regarding the participants' starting point prior to the instruction and will allow us to identify changes along the teaching module to identify characteristics of the transition from natural to rational numbers.

The Working Group

In CERME12, the Thematic Working Group 3, 'Algebraic Thinking', continued its work from previous CERME conferences. We had a total of 27 papers and three posters with a total of 39 people in the group. Participants represented countries from Europe and other continents: Canada, Cyprus, Denmark, Finland, France, Germany, Greece, Hungary, Italy, Norway, Spain, Sweden, The Netherlands, United Kingdom, and the United States of America. The papers loosely centred around six themes. These were: Generalisation and Pattern, Structure, Equations and Variables, Theoretical, Functional Thinking, and Algebraic Thinking. We discuss each of these themes below.

Generalisation and Pattern

Generalisation is a key aspect of algebraic thinking and there were a number of papers which looked at how students might be helped in developing their generalisation skills further. Figural patterns continue to feature as a significant research tool to explore students' generalization skills, although perhaps less common during this conference than the last. Mazza et al. looked at Grade 10 students as they considered proofs related to figurative patterns. Students were presented with 'visual proofs' and asked to justify theorems based upon those pictures. They found that there was a close match between the way in which students described the figural patterns in terms of mathematical properties and their explanations of the theorems. Goñi-Cervera et al. used a well-known growth pattern involving chairs placed around a certain number of tables. Their particular focus was students with autism spectrum disorder (AS) compared with students they describe as 'typically-developing' (TD). Although there was more success gained by TD students, it was found that the most frequent strategies for both groups were the same. Lócska and Kovács found that generalisation and reasoning strategies were supported by an intervention with 7th grade Hungarian students. This intervention used numerical tricks based around the array of numbers in a month found in calendars. Reinhardtsen and Carlsen's study involved students approaching introductory algebra through a calculational perspective. They found that teaching norms of emphasising procedures and products remained and that students could evaluate letters but struggled to use them to express generalisation and structure. Kilhamn reported a case study where computer programming was used when working with pattern generalizations. Tinkering with the code sparked students' curiosity in new ways, and when the computer did all the arithmetic, the students were free to look for pattern and structure.

Structure

A key aspect of algebra which was prominent in the previous CERME was that of structure. The continuum between operational and structural thinking was present in a number of papers. Lenz's study offered situations which included boxes with unknown or indeterminant numbers of marbles in boxes. She looked at kindergarten and elementary school children's approaches to establishing relationships within the continuum of number-orientated and structure-orientated approaches. The need to break away from concrete representation and perceive the variable as a thought object was argued. Unteregge's study involved slightly older children in Grade 4 and looked at the way they justified equalities within the result-orientated and structure-orientated continuum. It was found that students with a clear understanding of equality used different rationales across this range and could easily switch between them. Sencindiver (see Wladis et al. with Sencinder underlined) presented a paper concerning college students doing an algebra course, also using a framework of operational and structural thinking. Students were asked to justify algebraic transformations of expressions; an analysis of their attempts was conducted in terms of the students' understanding of equivalence, substitution, and substitution equivalence. Wladis et al. (paper with Wladis underlined) also used the operation and structural continuum but along with another dimension of extracted vs. stipulated to look at college students' thinking about equivalence. They found that this two-dimensional framework was useful to analyse students' definitions of equivalence. Their finding was that although students noticed 'sameness', they struggled with articulating a more standard definition of equivalence. Vlachos investigated students' understanding of what constituted a set. The sample included students from Grades 6, 9 and 12. Various prevalent misconceptions were identified. Grade 12 students did considerably better but there was no significant difference found between Grade 6 and Grade 9 students.

Equations and Variables

Dealing with equations is a standard part of the algebra curriculum. Roos and Kempen looked at the bar model as a pedagogical tool to assist with solving algebraic equations. Their study involved two cycles with low attaining Grade 10 students followed by Grade 8 students. They found that there was a need for students to develop conceptual understanding of which operations were illustrated within the model, rather than focusing on the numbers involved. López Centella et al. studied Grade 5 students to see whether they could relate a given algebraic equation to five different contextual situations. They found that the students had different forms of justification depending upon the contextual situation, and that the students were able to infer mathematical truths which had not been explicitly taught to them. Korntreff and Prediger's study involved Grade 7 and 8 students. They focused on the variable which appears within certain algebraic activities. Variables can play the role of 'generalizers' or unknowns. Their teaching experiment showed that students could construct both meanings for a variable, but only some students were able to distinguish explicitly the distinction between the two. They also found that the meaning students had of a variable was related to the algebraic activity within which the variable was used. Tondorf and Prediger studied Grade 5 students who were asked to justify the transformation from one arithmetic expression to another, both of which could be represented by the same geometric image. When making sense of the transformation of an expression, many students linked this with the geometric representation. They concluded that the dynamic transformation of a graphical representation could be used ahead of the dynamic transformation of symbolic expressions.

Theoretical

There were a number of papers which were based around theoretical arguments or developing models related to the teaching and learning of mathematics. Eriksson carried out a literature review on algebraic thinking related to students of 5-12 years old. She considered three perspectives in respect to teaching approaches which were based upon whether arithmetic thinking or algebraic thinking was developed first or whether they were developed at the same time. It was found that more research is needed on the perspective of developing algebraic thinking before arithmetic thinking. Weigand et al. came from the German tradition of *Grundvorstellungen*, which they translated as Basic Mental Models. They compared four different models for an equation and explored the relationship between these models and solving equations, particularly in relation to the use of technology. Three other papers used a similar framework to each other in their studies. Strømskag and Chevallard analysed textbooks from different countries, along with other publications from influential authors. They found that the evolution of curricula related to the notion of functions has seen a decline in algebra being taught as a modelling tool, and the reduced inclusion of parameters in algebraic equations. Hällback et al. analysed the algebra content of two Swedish upper secondary programmes and found that the programme for vocational education and training was more focused on *know-how* aspects rather than *know-why*. In contrast, the programme for higher educational preparation was more evenly balanced between these two aspects. Finally, Tonnesen constructed a praxeological reference model to develop a diagnostic test tool. This was used to examine students' technical and theoretical knowledge of basic algebra.

Functional thinking

Functional thinking is a significant aspect of algebraic thinking. Frey et al. interviewed 35 educational experts across five countries about their views of what constitutes functional thinking. In their preliminary results from two German interviewees and one interviewee from the Netherlands, it was found that there were different views across those experts. Sterner's study involved contextual growth patterns being presented to Grade 1 students and found that graphical representation, along with well-thought-through terminology, was significant in developing students' reasoning about recursive and also covariational relationships. Pittalis et al. focused more widely on algebraic thinking. They proposed and empirically validated a framework describing algebraic thinking abilities of Grade 3 students. Functional thinking, along with two other abilities, were found to form an index of those students' capacity to respond to algebraic tasks.

Algebraic thinking

Algebraic thinking is, of course, the focus of our Thematic Working Group. In that sense this is a theme which pervades all the papers. There are papers, though, where this is a more explicit focus. Radford presented his own conception of what constitutes algebraic thinking before then going on to analyse Grade 3 students' engagement in tasks presented in concrete and iconic semiotic systems. He found that the students generated two key algebraic ideas: that of 'removing' (from both sides) and 'separating' (effectively reducing the coefficient of the unknow to 1). Bräuer's study also avoided use of symbolic language by using the image of balance scales to support learning of linear equation systems, involving multiple unknowns, with Grade 3 and 4 students. It was found that the students could use algebraic strategies in an informal way without the need for an explicit intervention programme. Akinwunmi and Steinweg made a distinction between focusing on patterns and focusing on structure in their study with Grade 3 and 4 students. They argued that awareness of structure was important for students to engage in reasoning about patterns and made a case for the importance of material representations to help develop more structural arguments. Chimoni (Pitta-Pantazi et al.) presented a paper where they also made the case that seeing structure is important in early algebraic thinking. They found that students who solved arithmetical tasks using algebraic strategies were also able to solve algebraic tasks. They concluded that generalised arithmetic abilities underpin manipulation of algebraic expressions. Lastly, Fred et al. saw algebraic thinking as a resource or tool for action. They argued that explicit connections should be made between algebraic thinking and ways in which algebra plays a role in addressing challenges such as sustainability and climate change. In their analysis of two major research review books, they found that most of the 'powerful algebraic ideas' had a logical or psychological focus.

Discussions and further directions for TWG3

There was much discussion about the relationship between arithmetic thinking and algebraic thinking. Sometimes these were mentioned as a transition from one to the other. If that were to be the case, then is there a type of continuum between the two or is there an abrupt shift from one to the other? What constitutes the beginning of algebraic thinking? Alternatively, are these seem as running in parallel with each other, or are they actually more separate than sometimes imagined? For example, algebraic thinking can exist within a non-arithmetic context. We feel the link between these two is an important area for future work, perhaps considering the idea of *advanced arithmetic thinking* (which looks forward from arithmetic, rather than *pre-algebra*, which looks back from algebra). We also noted that terms, such as arithmetic thinking, functional thinking, relational thinking, and algebraic thinking were used without them always being defined. Different ways in which such terms are used can result in quite different analysis and conclusions being drawn from studies. The use of representations/models was a feature in a number of papers, and we felt that more work could be focused on how the abstraction process might involve gradual moving away from the use of representations/models. Algebra was often presented as a desired endpoint within some empirical studies, and we felt that more research could be done around the way in which algebra can be used, such as a modelling tool. We were aware of some important areas which were not represented so much in the papers and posters at this CERME. This included the use of technology. Also, there was no reference to the aesthetic aspect of algebraic activity. This is far from a dry area of mathematics and can bring many insights and Aha! moments which have an affective impact. We are aware that some papers may be presented within other TWGs in relation to both these aspects, but we feel that research around both these would be a very welcome addition to the next CERME in this thematic working group. Lastly, we noted the relative lack of discussion about the role of teacher interactions with students whilst involved with algebraic activities. Often focus was on the tasks presented to students but the way in which tasks are introduced and the nature of the teacher-student interactions which follow can be just as, or even more, significant as the tasks themselves.

Analysis of children's generalisations with a focus on patterns and with a focus on structures

Kathrin Akinwunmi[1] and Anna Susanne Steinweg[2]

[1]TU Dortmund University, Germany; kathrin.akinwunmi@tu-dortmund.de

[2]University of Bamberg, Germany; anna.steinweg@uni-bamberg.de

Generalisation processes belong to the core of algebraic thinking. The development of these processes begins as early as the primary school classroom, when children describe and reason about mathematical patterns. Our theoretical framework includes a distinction between patterns and structures. The focus on structures is important for children to engage in reasoning about patterns rather than just describing them on the surface. In an exploratory study with 45 third and fourth graders, we use an epistemological perspective to examine how this distinction is reflected in children's generalisations. The results create awareness of the algebraic quality of justifications.

Keywords: Early algebra, generalisation, description, explanation.

Introduction

Algebraic thinking can evolve around a wide range of mathematical topics. Blanton's research group addresses equations, generalised arithmetic, and function (Blanton et al., 2019). Twohill (2020) collapses the first two into one branch. In line with various researchers, we regard arithmetic as a starting point and interpret arithmetic tasks as potentially algebraic (Malara & Navarra, 2003; Britt & Irwin, 2008; Steinweg, 2017). This potential can emerge as early as arithmetic lessons in primary school if the underlying mathematical structure is focused on. Kieran et al. (2017) indicate structure as "one of the central pillars in the development of early algebraic thinking" (p. 423). The relation between structure and pattern, therefore, is essential and focussed on in the first part of the theory.

Structural thinking in the outlined sense expects generalisations which can be characterised as "seeing the general in the particular" (Mason & Pimm, 1984). The process of generalisation includes a certain shift of attention (Mason, 1989) from calculating given examples to thinking about the objects and their properties and relations (Mason et al, 2009). This paper provides a suggestion for a more in-depth analysis of generalisation processes and gives insight into a pilot study.

Theoretical framework

First, we provide an overview of key ideas of algebra arising from arithmetic and thereby clarify the difference we assume between mathematical structures and patterns. Taking a closer look at generalisations, this distinction leads to two categories of generalisations. Finally, the research questions of the study presented here are outlined.

Our research is embedded in a specific perspective on the relationship between *patterns* and *structures* (Steinweg et al., 2018). In line with Schifter (2018) and Mason et al. (2009) *structure* is defined by the mathematical properties and relations. In primary school arithmetic four realms of objects with specific properties can be identified and ordered in key ideas. The earlier used key ideas of algebraic thinking (Steinweg, 2017; Steinweg et al., 2018) have been fundamentally revised and enhanced based on theoretical and empirical findings. We consider properties and relations of numbers, operations, equations, and functions as key ideas (Figure 1).

Each key idea holds very specific mathematical structure to be explored, even though the realms are interwoven, e.g., equations require operations and numbers. The properties that are explored in one key idea differ from the ones that are focused on and explored in another. The focus of attention enables different generalisations of specific structural aspects. For example, working on the key idea of operations requires specially tailored tasks and questions that allow to recognise commutativity, distributivity, et cetera.

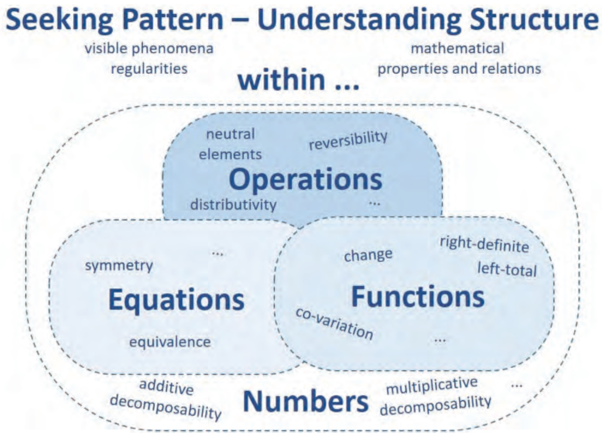

Figure 1: Key ideas of algebraic thinking

The mathematical cores of the objects associated with the key ideas are the abstract *structures*. Understanding structures and reasoning with these properties requires advanced relational or structural knowledge (Schwarzkopf et al., 2018) in the sense of profound background information. Access to mathematical structures is not easily gained and should be mediated. *Patterns* can literally function as mediators and thus as door openers to the respective mathematical background. The abstract mathematical structure can be made accessible and particularly visible in patterns and, vice versa, the mathematical structure reveals itself in patterns (Figure 2).

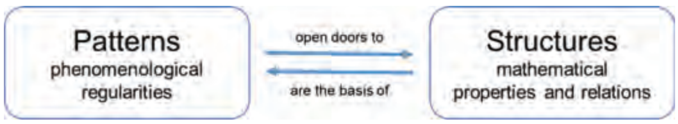

Figure 2: The distinction and relation of patterns and structures

Patterns offer perceptible regularities in visible phenomena (Schwarzkopf et al., 2018; Mulligan & Mitchelmore, 2009). Seeking for pattern is the first step to find the door behind the scenes. Pattern as representations hold information about the underlying structure (Küchemann, 2020). The visibility of pattern can be realised in various representations, i.e., tables, graphs, number sentences, and so forth.

Pattern tasks that aim for understanding structure allow for four different activities summarized as ReCoDE (Recognise-Continue-Describe-Explain) (Steinweg, 2019). Descriptions and explanations of a certain pattern require expressions, which can be verbal or symbolic. Even when the use of variables is not available or not yet developed, research documents various effective linguistic means such as referring to examples, phrasing conditional sentences, quasi-variables (Akinwunmi, 2012; Bastable & Schifter, 2008; Cooper & Warren, 2011; Schliemann et al., 2007).

Children’s reactions to given patterns may include both descriptive and explanatory parts. More importantly, *generalisations* may occur in both parts. Strømskag (2011) provides theoretical foundation for regarding algebra as generalisation of patterns. Blanton et al. (2019) differentiate between four types of thinking: generalise, represent generalisations, justify generalisations, reason with generalisations. Although this distinction enables teachers to focus on different aspects of generalisations activities, these four aspects are not disjunctive. For example, representations may support justification, or justification may include reasoning with the newly gained objects (properties, relations). Mason et al. (2009) identifies a disposition to think structural and to integrate the structural ideas into one’s mathematical thinking. Therefore, there is an opportunity to open the doors to the abstract mathematics behind a pattern, to realise structures by exploring patterns. “Generalization of a phenomenon involves the analysis of visible instances of the phenomenon, and the application of conclusions to cases that are not observable” (Twohill, 2018, p. 216). The step through the pattern door into the mathematical realm –towards mathematical thinking and away from given examples– does not emerge automatically.

In our view, *generalisations* in *descriptions* generally focus on the visible regularities, i.e., the patterns. *Explanations* provide the possibility to focus on the structure behind a pattern. However, this possibility is not automatically perceived by every child. Explanations justify certain regularities and may refer either to patterns or to structures.

Our research project addresses qualitative analysis of children’s responses, considering the outlined distinction between patterns and structures. The analysis categorises:

- *generalisations* which focus on the *pattern*, i.e., on the visible regularities, and
- *generalisations* which focus on the *structure*, i.e., on the mathematical properties or relations.

Furthermore, the *means of generalisations* in both categories are studied on. The processes of generalisation –starting from local findings and combining them into more general arguments– appear to be linguistically similar at first. Some national studies document that children –without further impulses of the teacher– typically recognize regularities only on the surface of the given patterns and justify their findings with empirical knowledge without looking beyond the pattern (Häsel-Weide, 2016; Link, 2012). However, a closer look at the two categories reveals that the objects of generalisation, and thus the awareness, differs substantially. Accordingly, the distinction between pattern and structure as two kinds of context of reference (Steinbring, 2005) may shed light on different –if any– forms of generalisations.

Finally, the in-depth analysis can be beneficial to the classroom interaction and provide adequate and helpful ideas to facilitate approaches to mathematical structures. Supporting children's development of algebraic thinking depends on deliberate attention of the teachers. The teachers need awareness of the given references in explanations and should invoke appropriate impulses and further questions.

According to this research desideratum described above, we addressed the following research questions:

- Which focus of generalisation can be identified in children’s explanations in pattern tasks?
- Which impulses do support the development of generalisations that focus on structure?

Methodology and Design

In this paper we present results from an interview study with 45 participating 3^{rd} to 4^{th} grade primary school children. The one-on-one interviews are conducted in separated rooms at the school, video-taped and transcribed. The content focuses on patterns based on the properties of operations.

In the first part of the interviews the participants are confronted with patterns in symbolic representation (e.g., left side of Figure 3; task type A). The arithmetic context is deliberately no challenge to calculate for 3^{rd} and 4^{th} graders, as the study focuses on generalisations. These kind of pattern tasks are common in German textbooks. Children are, therefore, used to the typical classroom questions to continue and describe the pattern.

In the second part, a special impulse is designed: A picture showing a child using counters in a common material (field of 20) to solve the second task of the given pattern (the right side of Figure 3 shows a simplified version of the picture which is presented to the pupils; task type B). Counters are on the table throughout the interview. The aim is that the change of representation from symbolic to iconic stimulates the children to change the focus of generalisations.

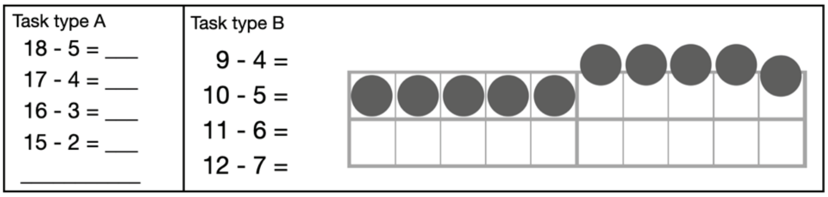

Figure 3: Task sheets on exploring the constant difference

The qualitative analysis of the data follows the interaction analysis according to Steinbring (2005). Following this method in children's interaction and verbal responses mediation processes between the given *signs/symbols* to be interpreted and the *reference contexts* that the children use for interpretation are identified. The revealed mediation in turn provides information about the children's so called epistemological basis of mathematical knowledge, i.e., the *concepts*. The triadic relationship, usually represented in a triangle (cf. Fig. 4–6), thus allows the re-construction of the child's focus in the generalisation process in order to answer the raised research question.

Results and Discussion

Due to place restrictions, only a summary of the overall findings of the qualitative analysis of all 45 cases can be given at the end of this section. The in-depth analysis is exemplarily set out in two cases, Katie and Nicole. These cases are chosen because they exemplify two substantially different arguments used in the generalisation processes.

Katie is asked to explain the pattern (task type A) and then to justify the constant result. Like all the participating children in our study, Katie generalises the symbolic patterns in the first part of the interview by describing the variation of the numbers separately.

Katie: Here, the numbers are getting smaller and here they are also getting smaller. […] For plus [addition tasks] these would have to get bigger. For minus [subtraction tasks] it is also getting smaller, because otherwise it wouldn't work.

Katie refers to the given numbers as if minuends and subtrahends were separate sequences ['here' and 'here']. In the further comment, she describes the increase and decrease for all addition or subtraction tasks in a more general term. The use of the subjunctive indicates the process of abstraction away from given (numerical) examples towards general statements. Katie gives evidence to her generalisation referring to (classroom) pattern experiences and, therefore, empirical knowledge (Schwarzkopf et al., 2018). Hence, her justification does not yet include a structural argument. Using the epistemological triangle (Steinbring, 2005), Katie's generalisation process, her interpretation of the signs mediated through a reference context, can be expressed as follows (Figure 4):

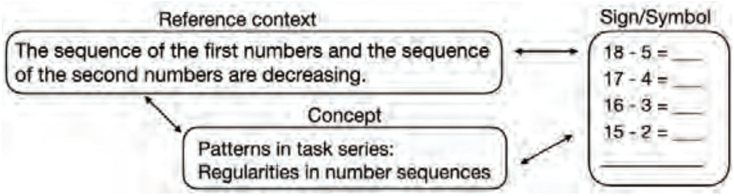

Figure 4: Katie's interpretation of the task series

Given the iconic impulse in the second part (task type B), Katie immediately decides to reconstruct the tasks using counters and lines up 9 counters in front of her.

Katie: So, 9 minus 4. 1, 2, 3, 4 (counts aloud while removing 4 counters successively) is 5. Now we have one more here (takes another counter from the material box and fills the line up to 10 counters), because now it's 10 (points to the task sheet), but in return we are allowed to take away one more (removes 5 counters). Again it's 5.
(Fills up the line to 10 counters.) Now again we take one more (adds one counter from the material box to the line) and we are allowed to take away one more. 2, 3, 4, 5, 6 (counts aloud while removing 6 counters then regarding the remaining counters). And therefore, the result is always the same.

Working with the counters, Katie's arguments change fundamentally. It is the change of representation that creates a new interpretive challenge that leads Katie to consider and generalise the effects of her actions. She now focuses on the effect of changing both numbers simultaneously and she reasons, that 'in return' to add one more (increasing the minuend), one is allowed to also take away one more (increasing the subtrahend). This expression focuses on the reversibility of addition and subtraction and the context of reference in her generalisation is, therefore, now one of the important properties of those operations. Her reasoning with structural knowledge exceeds the numerical examples and includes a valid argument for an indeterminate 'we'. She intends not only to convince the interview partner, but points to a general validity. Her conclusion ['therefore'] holds universally ['always']. The difference in arguments in her generalisation process is also visible in the epistemological triangle (Figure 5).

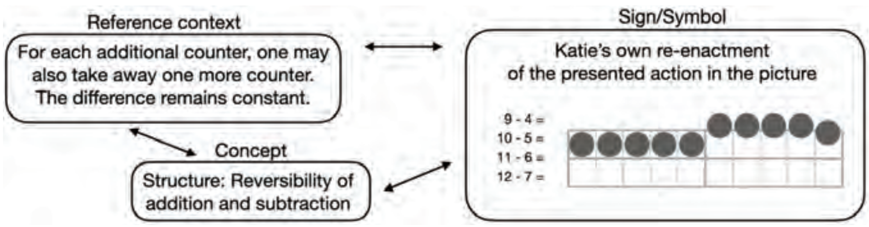

Figure 5: Katie's interpretation of her own re-enactment of the action in the picture

In the second case, Nicole's reaction in the first part of the interview is very similar to Katie's reaction and is therefore not presented here. In the second part (task type B) her reasoning is quite different from Katie’s, although she also decides to use counters to explain why the result remains constant.

Nicole: Now if you had five minus three (puts 5 blue counters in a first row and 3 red counters in a second row without one-to-one correspondence), that would be 2 and that is the starting task. And if you then remove this one here (takes away one from the blue counters) and this (takes away one from the red counters), then immediately you see, that both are getting smaller. And for minus it has to be smaller on each side (looks up thoughtfully as she speaks), so that the result stays the same.

The analysis of Nicole’s argument shows some generalisations with the focus on patterns. First, she presents a self-selected task 5 – 3 that is not part of the task sheet. She describes the regularities of the pattern in a general way using some general expressions ["both" and "each side"]. Nicole is convinced that the simultaneous decrease of the two numbers will always lead to the same results. Her generalisation refers to known empirical facts [‘it has to be’] without giving evidence, why this rule holds. In her justification, she does not focus on the properties of the operations. It can neither clearly be said, whether she interprets the space of the missing counters in the second row as the difference of the two amounts, nor does she express the effect (the shift) on the space by decreasing minuend and subtrahend simultaneously. Moreover, she does not mention the reversibility of the two operations. Instead, she refers to her existing empirical knowledge to justify the pattern, as illustrated in Figure 6. The lack of reference to the properties of the operations in the given explanation in this second case gives no discernible indication that Nicole understands the underlying structure that generates the pattern.

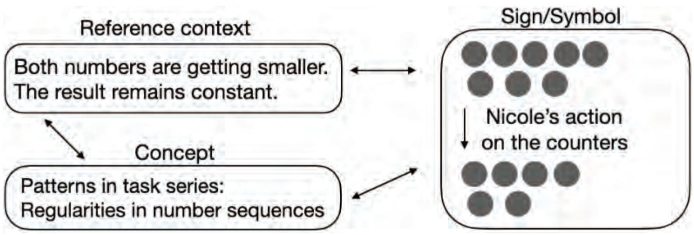

Figure 6: Nicole’s interpretation of her own action on the counters

Through such analyses as exemplified above, insights could be gained into the generalisation processes of the 45 participating children, some of which we will summarize here:

- Both foci of generalisation processes with the focus on patterns and with the focus on structure were identified in the interviews but not in equal proportions during both interview sections (with task type A and B).
- In the first encounter (task type A) none of the children focused on the properties (of the operations) that are the structural basis for the emergence of the pattern. Instead, they used generalisations of patterns by referring to empirical knowledge (classroom experiences or known facts) or they used one discovered regularity in the pattern to justify another (see Nicole’s case).

- In the second part of the interview (task type B), the iconic impulse and the counters initiated reasoning processes in which almost all children started to focus on structure, i.e., the properties of operations (see Katie's case as an example).

Closing Remarks

Working on pattern tasks is an established approach to algebraic thinking in primary school. The distinction between *patterns* as visible regularities and *structures* as abstract properties and relations that generate the patterns provides opportunities for deeper analysis of children's reactions to pattern tasks.

In our view, it is useful to distinguish between these generalisations theoretically as well as empirically. Researchers and even more teachers need to be aware of both kinds of arguments in order to provide appropriate follow-up-questions or stimuli –such as changing representations– to help children access the mathematical background behind patterns.

> Teachers who are themselves explicitly aware of structural relationships, who are aware of perceiving situations as instances of properties (rather than as surprising and unique events), are in a position to promote similar awareness in their learners (Mason et al., 2009, p. 29).

To identify children's understanding of structure is a complex endeavour. With the theoretical framework and the methodology presented in this paper we contribute a possible approach to deeper analysis of generalisations in algebraic thinking processes and provide some exemplary insights. In particular, generalisation processes with the focus on structure can be identified as references to properties of mathematical objects.

Generalisations do not necessarily imply or include structural justifications. The context of reference provides information about the concept focused on and the depth of a generalisation. The focus on patterns can pave the way to the underlying structures, i.e., the mathematical background. Sticking to the surface of patterns only and teacher's acceptance (or expectation) of solely generalisations of patterns hinders deeper understanding and ultimately algebraic argumentations.

This study also shed light on the impulses which support the development of generalisations that focus on structure. It became apparent that, paradoxically, symbolic representations of tasks entice children to remain on the surface of the pattern and stick to concrete (numerical) examples, meanwhile iconic or material-based representations provide the opportunity to find more structural arguments. Therefore, representations and processes of representing play a crucial role for generalisations with the focus on structure. However, they are not a sufficient criterion for structural arguments as can be seen in Nicole's case.

The qualitative results of our study are of course limited to first indications but also pave way for further studies. They are only a first step, and further studies on the other key aspects of algebraic thinking (numbers, equalities, and functions) or different age groups could be conducted.

Dealing with multiple unknowns and their relationships using the balance scales model at primary school age

Michelle Bräuer

Martin-Luther-University Halle-Wittenberg, Germany; michelle.braeuer@paedagogik.uni-halle.de

The present study design focuses on primary school students' abilities in early algebraic thinking, using a task format with balance scales, which intends to provide a material-supported introduction to dealing with linear equation systems with multiple unknowns and their relationships. This offers an approach not demanding formal symbolic language, i.e. without the use of letters. In this paper, first insights from case studies on students' approaches are presented.

Keywords: Algebraic thinking, unknowns, linear equations, balance model, relational thinking.

Introduction

This article focuses on how primary school students aged 9–11 years old (grade 3 to 4) deal with linear equation systems as well as how they use and describe the contained relationships between multiple unknowns, as a core of algebraic thinking. To circumvent the well-known difficulties of learning algebra in later grades (e.g., Kieran, 2004), a task format was developed, which consists of iconic representations of balance scales and colored geometric shapes. This omits, for example, the equal sign and formal symbolic language in the form of letter variables. The aim of the study is to investigate how students use and describe relationships between multiple unknowns in linear equation systems. The ongoing study takes place before the introduction to algebra in the classroom context as well as without a previous teaching program. Therefore, the research questions are the following: *To what extent do primary school students show different approaches and strategies for dealing with multiple unknowns, as a core of algebraic thinking, in linear equation systems represented as multiple balance scales? How do the children use and describe the relationships between the unknowns represented in the tasks?*

Theoretical framework

Early algebraic thinking

So far, there is no unified definition of early algebraic thinking. Kieran, for instance, made the following definitional attempt:

> "Algebraic thinking in the early grades involves the development of ways of thinking within activities for which letter-symbolic algebra can be used as a tool but which are not exclusive to algebra and which could be engaged in without using any letter-symbolic algebra at all, such as, analyzing relationships between quantities, noticing structure, studying change, generalizing, problem solving, modeling, justifying, proving and predicting" (2004, p. 149).

Furthermore, to conceptualize early algebraic thinking from a multidimensional perspective, the following components of algebraic thinking in early grades can be cited: *Handling operations (as objects) and their inverses; establishing relationships between numbers, sets, and relations* *(relational thinking); generalizing; dealing with changes; dealing with unknowns; using symbolic representations* (Fritzlar, 2011, pp. 37–38).

Starting from this characterization of algebraic thinking this paper focuses primarily on the component “Dealing with unknowns”, which is particularly important and means the handling and analysis of known and unknown quantities as well as establishing relationships and structures between them (e.g., equivalence transformations). In addition to this aspect by dealing with unknown and known quantities, students have to operate on the unknowns which comes along with an analytically thinking where logical deductions are to be made, without necessarily using letters. This characterization of algebra’s analytic nature distinguishes algebraic from arithmetic thinking (e.g., Radford, 2015).

Balance scales model

The balance model is “one of the most popular didactic artefacts used to teach the solution of linear equations” (Lins, 1992, p. 208) which also underlies many studies in algebraic thinking. Previous studies have shown that even students in the early grades can solve linear equations where the unknowns can occur on both sides of the equation (e.g., Brizuela & Schliemann, 2004). To enable students to deal with linear equations and develop an understanding of equality, the balance model is often used in early grades because it “can assist students in providing a language base for solving problems'' (Otten et al., 2019, p. 2). Otten et al. (2019) found in an intervention study with fifth-graders using embodied learning environments that the balance model can promote students’ ability to solve linear equations, to further illustrate equivalent transformations using conventional algebraic equation solving strategies (restructuring, simplification, isolation by elimination and substitution) in an informal way. Regarding the fifth-grade students’ algebraic reasoning, Otten (2020) investigated different types of representation and states that algebraic reasoning was better developed by the balance model than by informal linear equations. Warren and Cooper (2005) conducted an interview study with third-grade students supported by a teaching program with the aim to investigate the extent to which students can solve tasks with an unknown using a concrete physical balance scale model. They found out that this expands the understanding of equality and equal sign to a more comprehensive relational perspective.

While previous studies are usually associated with a teaching program, the following study will forego this to be able to analyze the students’ approaches and capabilities of algebraic reasoning. Previous studies investigated just one linear equation with often only one unknown, thus focusing on just determining the unknowns or moving to a formal symbolic language rather than, as in this case here, on the process itself as well as dealing with multiple unknowns and their relationships. In relation to the component “Dealing with unknowns”, this means that relations between unknowns must be established and used and operating with the unknowns as known mathematical objects is necessary. Moreover, not only the unknown should be determined, but the relationships between the multiple unknowns are in the focus. Furthermore, it can be assumed that the presence of multiple unknowns leads to a more complex task structure, and structure of relations to be established, so that early algebraic thinking can be investigated particularly well in such situations, since arithmetic-based procedures seem less obvious. The aim of the present study is firstly to investigate how students work on tasks with two or more linear equations represented by drawn two-plate balance scales, secondly which relationships between unknowns were constructed and used, and thirdly how they deal with the unknowns (in the sense of equivalence transformation). Thereby students' reasoning regarding algebraic strategies solving systems of informal linear equations should be analyzed. In addition, first impressions and, above all, the potentials of the developed research approach, are to be highlighted to show to what extent the study design allows an investigation of early algebraic thinking at all and makes a reconstruction of this possible and worthwhile.

Methodological approach

To be able to reconstruct the approaches as well as students' description of their procedures regarding algebraic ways of thinking in as much detail as possible, an ongoing interview study of my PhD project is currently being conducted. This study focuses on the mathematics education before the introduction of linear equations and algebra in general, therefore students of different grades of primary school in Germany were selected for the thirty-to-forty-five-minute interviews.

The assignment is to work on the tasks and to explain and justify how the students proceed and think about, in which everything can be used that is on the table (paper, pens and laying material designed analogously to the tasks presented below). The "Thinking-aloud" Method is also used to try to gain insight into the students' ways of thinking, so that they are also encouraged to verbalize these ways of thinking and proceeding. This also results in the role of the interviewer, who is only to encourage, with as few inquiries as possible, that the procedure and the considerations are verbalized by the students.

To investigate the approaches for dealing with linear equation systems containing multiple unknowns in terms of algebraic thinking in primary school age, the following task design was developed. Based on the number of unknowns (in the form of geometric shapes of different colors) and the underlying task structure, different types of balance scale tasks emerged. In Figure 1, we can see an introductory task, firstly supporting students to become familiar with the task format and secondly, if necessary, to avoid misconceptions due to less existing experience with this type of scale from everyday life, and the task types. This will now be explained in more detail.

The number of unknowns per se remains constant within the four described task types A to D. The task structure can involve scales and relationships between unknowns, for both the given and the asked scale pans. They contain each either one unknown per scale pan (unmixed) or partially multiple unknowns per scale pan (mixed). Students are asked to construct and formulate a relation between two unknowns (unmixed) or a requested new relation between multiple unknowns to one unknown (mixed).

In task type A each given scale pan contains only one unknown. Students are asked – illustrated by a third scale – to construct another relation between two unknowns (unmixed–unmixed). The specifications of the given scale pans in task type B are like task type A, however the last scale asks for a relation between multiple unknowns (e.g., a triangle and a red square) on the one side to one unknown on the other side (unmixed–mixed). The task structure is changed in task type C because the given scale pans are partly each based on one or more unknowns and students are asked for a relation between two unknowns (mixed–unmixed). For task type D, the one or more given scale pans contain multiple unknowns and a relation between multiple unknowns is asked (mixed–mixed).

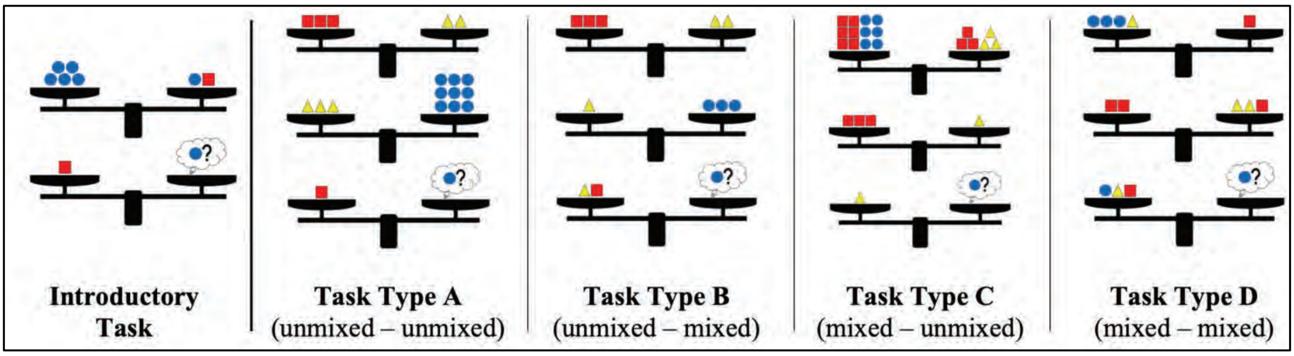

Figure 1: Overview of examples of the task types used in this study[1]

Likewise, the task types can be extended with respect to more unknowns like four (e.g., additional green pentagons). Tasks on this have also been worked on by this age group but are not considered in this paper. Within the task types, further distinctions can be made with respect to difficulty-increasing factors (e.g., whether substitution is possible), but these are not examined in this paper.

The individual interviews, consisting of tasks of all task types (see above), were audiovisually recorded, transcribed, and afterwards analyzed using the qualitative content analysis according to Kuckartz (2018). The categories for analysis were obtained inductively from this data material, as well as deductively based on theoretical considerations, for example regarding the algebraic strategies for solving systems of linear equations.

First results

Within this paper, the task types A, C and D (see tasks worked on in Figure 1) are considered, because the most different approaches can be expected here. Subsequently, to show a beginning spectrum of different approaches in terms of strategies and use of materials etc., which is supported due to the good verbalization ability of the students, I refer to the three case studies of Caspar, John (both at the end of fourth grade) and Lenny (at the end of third grade) and their answers.

Insight into the approaches for task type A and use of material

In the processing of this task example Caspar uses the material (Figure 2). He represents the second scale of the task sheet (step 1), counts the circles and then removes three circles on the right side and one triangle on the left side of the scale (step 2). He apparently recognized that three circles correspond to a triangle, which is challenging, because this relation is not explicitly given. Caspar replaces the two remaining triangles with three squares in the next step (step 3). He has thus recognized that the left side of the second scale corresponds to the right side of the first scale. Then Caspar replaces one square and two circles. Based on the now two laid squares on the one hand and

[1] These given examples of task types, related to examples with three unknowns (blue circles, red squares, and yellow triangles), will be referred to when presenting the results of the case studies.

the four laid circles on the other hand, he can determine that one square corresponds to two circles (step 4). At this point, for example, Caspar logically deduced, a characteristic of algebraic thinking.

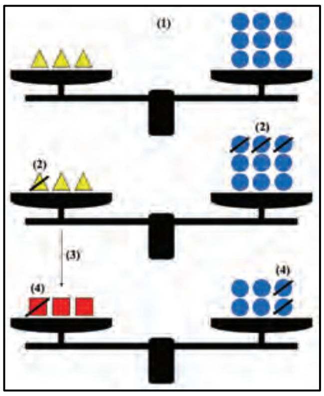

Figure 2: Caspar's use of material in example task of task type A[2]

After Caspar was able to determine the solution with the help of the material, he explained his approach as follows:

Caspar: Because (…) I took away three here [points to the circles, as indicated by the second scale in Figure 2] so that this is as heavy as two [points to the triangles (second scale)].

Interviewer: Yes.

Caspar: And then I had six here [points to the circles on the right side (second scale)] and three here [points to the triangles on the left (first scale)] and then I had taken away one here [points to the square (third scale)] and then I had taken away four here [points to the four circles on the right side (third scale)] and then one here [points to the square on the left side (third scale)]. Then I had four here and two here [points to both sides (third scale)] and then I had taken away one more [points to left side] and here again two [points to right side] and then I had one to two.

The assumption described above about Caspar's approach is confirmed by his explanations. He thus used an explicitly represented relation to replace one unknown with another unknown, making use of substitution, and constructed two non-explicitly represented relations (e.g., the two triangles he is pointing are equivalent to six circles) and used them to simplify. While Caspar proceeds step by step using the material to remove elements of the same value on both sides, John verbalizes some steps, so that the recognized and apparently used relations only become implicitly clear. The description of John's procedure shows that he clearly refers to the calculation he performs when verbalizing it. John interchanges the dividend and divisor:

John: Ah, one square is two circles, because three squares are two triangles and three triangles are nine circles and if you still, so three divided by nine is three and, if you subtract one of those three (..) so from the triangles, (…) that would actually be two circles one. Yes, two circles are one square.

Lenny solves the task and verbalizes his procedure in a highly abbreviated computational description:

Lenny: Two.

Interviewer: Explain why.

---

[2] The strokes visualize the laying away of the figures using the material.

Lenny: That‘s nine and that’s three. Because nine divided by three is three [points to the second scale of the task sheet (Figure 1)]. Two times three is six [points to the first scale]. Six divided by three is two. One equals two circles [points to the third scale].

In contrast to Caspar, Lenny presumably does not simplify, but uses the non-explicit relation that one triangle corresponds to three circles in his procedure by determining how many circles correspond to the two triangles on the right scale pan of the first scale, as well as the three squares on the left and then the relation between the one square and the circles he is looking for.

Insight into the approaches for task type C

Caspar, using the relationship between the triangle and squares on the second scale, replaced the squares with triangles on the upper scale, which points to the substitution strategy. Based on the understanding of the balance of the upper scale, i.e., matching the elements on the two scales, Caspar can correctly determine that one triangle corresponds to three circles (left side of Figure 3).

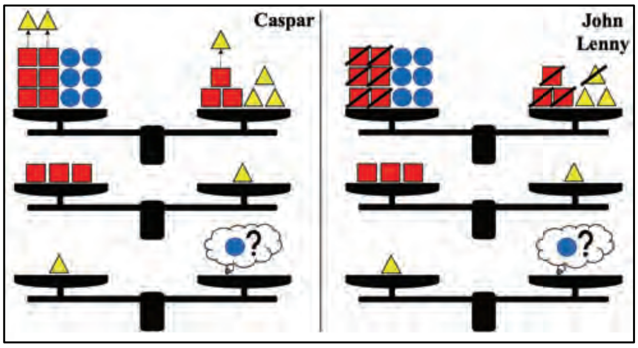

Figure 3: Approaches of Caspar, John & Lenny for the example task of task type C

John and Lenny each describe the same procedure, but in reversed order of the following steps: In one step, three squares on each side of the upper scale equalize with each other, and in another step, a triangle on the right side equalizes with three squares on the left side of the upper scale. In doing so, both John and Lenny explicitly recognize and use the relationships and choose ‘‘balancing’’ (as so named by John) as an isolation strategy, in contrast to Caspar, for completing the task, by removing elements with same value on both sides (right side of Figure 3):

John: (38 sec pause) With the one triangle we already balance the one half, that is three squares [points to three squares of the left side of the first scale]. With the other triangle with the three squares [points to the squares on the right side of the first scale] we balance the second row of squares on the left side and then there are two triangles left for a total of six circles. Therefore, the two triangles weigh exactly as much as six circles, so one triangle weighs exactly as much as three circles.

Lenny’s description also makes it clear that he is aware that the balance must meanwhile continue to exist:

Lenny: I cross those off [cross out the three squares on the right side of the first scale on the task sheet] and cross those off [cross out three of the six squares on the left side].
Interviewer: Ok.
Lenny: But they are one here [points to triangles]. If you cross out one of them [cross out a triangle on the right side], you cross out these again [cross out the three remaining squares on the left side] and now you know pretty much how many these are [points to the six circles], namely exactly as many as these [points to the two remaining triangles].

Interviewer: Ah.

Lenny: Because... namely those remain [circles the triangles on the right] and those remain [circles the circles on the left], because they must weigh the same, otherwise the scale would not be in the balance. So (..) three.

Insight into the approaches for task type D

If we look at the individual processing steps of the three children, there are no differences. The three children refer to the second scale first (Figure 1). While John and Lenny continue working in the next step from the relationship that one triangle corresponds to half a square, John names this relationship incorrectly at the beginning (see the following transcript), Caspar uses the reverse relationship, namely that one square corresponds to two triangles. Based on this consideration, the next step concerning the left side of the first scale turns out to be obviously more difficult for John and Lenny. While Lenny starts from the triangles as one half and the three circles as the other half of the square on the right side, John relates circle and triangle inversely, so that one circle corresponds to one third of the triangle. Verbalizing this relationship is especially difficult for John and the editing process is much longer than Caspar's:

John: So two triangles are half a square (..) because here are two squares [points to the left side of the second scale] and there [points to the right side] are two triangles and one square and that is balanced. (20 sec pause) And three circles are also as heavy as half a square. (8 sec pause) So a circle is as heavy as a third of a square. (17 sec pause) That's why there must be at least six circles here [points to the right side of the last scale] (5 sec pause) and in addition there are three and one, so there are a total of seven, no, ten circles here.

Caspar: I cross off this and that [points to one square each on both sides of the second scale], two yellow triangles are as heavy as one red square. (13 sec pause) They are [points to the circles of upper scale] like a yellow triangle. [8 sec pause, takes a pen and starts a tally sheet next to the last scale]. I think you need ten circles, because a square is as heavy as six circles, because three circles are as heavy as a yellow and two triangles are as heavy as a red square. [5 sec pause] So a triangle is as heavy as three circles and a blue circle is as heavy as one blue circle and that's now ten circles [points to thought bubble on task sheet].

Conclusions

It should be taken for granted that, based on the case studies presented, only initial conclusions can be drawn, which do not aim to make generalizable statements. First, it has been shown that it seems possible that the children are able to cope with the developed task format of the balance scales, as well as with the material provided with it. The solving processes can be made accessible by means of study design (also through possible independent use of material) and subsequently described in a differentiated manner. Already the few case studies could reveal that a diversity of approaches between and within the tasks can be identified, but needs to be investigated in further research, so only a first insight can be given here. This wide variety of approaches could be shown within the processing of one task, for example, Caspar making use of substitution and John and Lenny of isolation strategy in task example of task type C. The approaches and reasoning of the presented students show that they often logically deduce and use algebraic strategies in an informal way even without an intervention program – a characteristic of thinking algebraically.

Possible changes of students' approaches working on the different tasks can also be analyzed. This becomes clear in the case of Caspar, for example, who worked with and without materials, but also used different strategies for working on the linear equation systems (see above). In addition, it was shown that the children of the presented study without having passed a special teaching program, in principle, can deal with multiple unknowns, recognize, and describe the associated relationships between the unknowns. Such a handling would hardly be realizable at this age level with a formal representation in the form of linear equation systems with letter variables.

The qualitative interview study will continue, and further research will also investigate difficulty-increasing factors, which, in addition to the number of unknowns etc., may influence task difficulty, approaches and the success by solving the tasks as well as the possible transfer of these results to other task types and the implementation in the classroom context.

Teaching algebraic thinking within early algebra – a literature review

Helena Eriksson

Dalarna University, Sweden; hei@du.se

There is a lack of overview regarding previous empirical studies within the early algebra research field. Consequently, the aim of this study is to propose one way to organise how algebraic thinking can be operationalised when teaching students five to twelve years old. The study is conducted as a literature review. The results show six categories of operationalising algebraic thinking with these young students. These categories can briefly be organised as three traditions: (1) arithmetic thinking tradition developing arithmetic thinking first, (2) developing arithmetic and algebra at the same time, or (3) algebraic thinking tradition developing algebraic thinking first. This method of organisation highlights one tradition of algebraic thinking where more research is needed - the tradition in which algebraic thinking is developed first. This tradition, as stated in the results, includes the category algebraic work.

Keywords: Early algebra, algebraic thinking, literature review, primary school students.

Introduction

In the early algebra research field, authors attempt to explain student opportunities to explore and discern mathematical relations, patterns and arithmetical structures through processes of noting, conjecturing, generalising, representing, justifying and communicating (Kieran et al., 2016). Early algebra is then manifested using symbols other than numbers only including geometrical figures, verbal and written language and gestures (Kaput, 2008; Kieran, 2004, 2018; Kieran et al., 2016). One problem within this research field is the age of the students and which level of the school system that is referred to as "early". In the literature included in this review, early algebra can refer to the youngest students' work on structures in mathematics, the introduction of algebra in secondary school or intermediate algebra, for example, as preparation for college-level mathematics (Katz, 2007). This broad focus on the level of schooling makes it difficult to navigate this field of research. Additionally, early algebra focusing only on the youngest students has been operationalised in different ways in different empirical studies (Blanton & Kaput, 2011; Kieran, 2004). Parts of this research concerns issues about how algebraic thinking should best be introduced to the youngest students. Hodgen, Oldenburg, and Strömskag (2018) argue, in a discussion on the last twenty years of developing research in mathematics education, that there is a need of an overview of this large number of different empirical studies regarding early algebra. Thus, it is difficult to navigate in this research field. The aim of this paper is to propose a method of categorising research regarding the teaching traditions of, or for, algebraic thinking in the age group five to twelve years old. The research question guiding the literature review is: According to which different traditions can algebraic thinking be operationalised within early algebra for students five to twelve years old?

Early algebra research and ways of operationalising algebraic thinking

This section briefly highlights different traditions of operationalising student algebraic thinking.

Research on algebraic thinking within early algebra concerns student actions related to ways of doing, thinking and talking about algebra (Hodgen, Oldenburg & Strömskag, 2019). This research also includes ways of operationalising algebra in teaching (Hodgen, Oldenburg & Strömskag, 2019). Kaput (2008) suggests two core aspects of algebraic thinking that may briefly be described as: (1) algebra as generalisations and expressions of the generalisations, and (2) algebra as guided actions on symbols within conventional symbol systems. Kaput (2008) further describes three strands of an embodiment of these core aspects: algebra as the study of structures, algebra as the study of functions, relations and statements, and algebra as the application of modelling languages. Kieran (2004) has proposed that algebraic thinking is connected to three interrelated activities for teaching school algebra broadly described as: (1) generational activities, for example forming equations, (2) transformational activities, for example rule-based operations, and (3) meta-level activities, as for example problem-solving in which algebra can be used as a tool. Further, Radford (2014) describes three ways of manifesting algebraic thinking as; (1) factual algebraic thinking, when students use their daily life language, (2) contextual algebraic thinking, when the symbols and language the students use are related to the specific context or situation, and (3) symbolic algebraic thinking, when the students use formal algebraic symbols. Davydov (2008) provides a fourth way of describing algebraic thinking related to the youngest students that is theoretically grounded on the idea that algebraic thinking develops if students can work with, and reflect on, arithmetical generalisations and that the youngest students are able to carry out such generalisations. Davydov (2008) argues that the young students should be introduced to algebraic work from the very beginning of their schooling and that students need to jointly take part in the work of identifying mathematical problems, choosing tools to work with, developing models to reflect on solutions and mathematical concepts, and lastly reflecting on whether the models developed are general and will work when solving other types of mathematical problems. The suggested tools when constructing these models include most algebraic symbols and geometrical figures (Schmittau, 2003).

Concerning the youngest students in the school system, van Oers (2001) describes three different traditions of mathematics teaching: (1) arithmetic thinking first – an arithmetic tradition in which teaching focuses on operations with numerical examples, (2) arithmetic and algebra at the same time – a problem-solving tradition in which teaching focuses on arithmetic and algebra as methods for solving tasks, or (3) algebraic thinking first – a tradition of algebraic thinking in which teaching challenges the students to identify mathematical problems and focus on what tools to use when solving these problems. In this third tradition van Oers (2001) suggest algebra to be used as a tool when teaching the youngest students.

Methods

This systematic literature review was conducted using the keywords; early algebra and algebraic thinking in the *Education Resource Information Centre (ERIC)* database. Early algebra was searched on 12 March 2018 and yielded 206 articles, algebraic thinking was searched on 26 October 2018, and yielded 331 articles. Fifty-one articles were identified in both searches. One observation due to the date of the search is that any articles of a later date can be deductively organised into the categories described below.

While reading the titles and the abstracts of the 486 articles, a process of elimination was conducted in two steps. In a first reading, 274 articles were taken for further analyses including studies of students five to twelve years old. In a second reading, still based on the titles and the abstracts, 147 articles focusing on operationalising algebraic thinking in teaching were selected for further analyses. Articles concerning teachers or teacher students and articles about, for example, students with less ability in mathematics not focusing on teaching were omitted. They were omitted because these studies focused on how the participants understood algebra not on how to operationalise algebraic thinking. In total 147 articles were included in the extended analyses.

The next step in the analyses was to identify the descriptions of student opportunities to think algebraically. This was achieved by constructing thematic categories regarding operationalising algebraic thinking in early algebra according to the analysis question; Who is doing what with what tools and with what aim? (Eriksson & Eriksson, 2021). Here, the categories were inductively identified related to in which way the teaching of algebraic thinking was described in the studies. And finally, the categories found in this step of the analyses were interpreted and grouped into more overall traditions inspired by van Oers' (2001) suggestions concerning different traditions for mathematics teaching; (1) as an arithmetic thinking tradition or arithmetic first (2) as a tradition of arithmetic and algebra at the same time or (3) as an algebraic thinking tradition or algebra first.

Results

The results of the literature review are presented in Table 1. This table includes a presentation of the six categories regarding operationalising algebraic thinking within early algebra.

Table 1:

The traditions, categories, and teaching examples given in the articles

Tradition	Category	Examples of focus in teaching
1. Arithmetic thinking tradition (arithmetic first)	1.a) Algebraized elementary mathematics	47-18+18=47
	1.b) Pre-algebra	Numerical answers to unknowns
2. Algebra and arithmetic at the same time	2.a) Early algebraization	Operating with unknowns, equalities
	2.b) Arithmetico-algebraic thinking	Relationships between different tools and notations
	2.c) Emergent algebraic thinking	Geometrical patterns
3. Algebraic thinking tradition (algebra first)	3.a) Algebraic work	Structures between concepts jointly reflected using algebra, geometrical figures and language

1. Arithmetic thinking tradition

Category 1.a) is termed algebraized elementary mathematics and is related to the *arithmetic thinking* tradition. In this category, algebraic thinking is built on details manifested as arithmetic (Britt & Irwin, 2008; Lins & Kaput, 2004). Algebraic thinking could be developed by making structures visible using arithmetical examples. As one example, a statement such as 47+18-18=47 visualises that whatever is added and then subtracted entails that the original number does not change (Lins & Kaput, 2004). To summarize this category: algebraic thinking is related to the idea that algebra is about generalisations that can, or need to be, developed from arithmetical examples (Britt & Irwin, 2008; Lins & Kaput, 2004). Thus, algebra is introduced after the students have developed their arithmetic abilities.

The category 1.b) includes studies presented as pre-algebra. These studies describe teaching that aims to prepare for algebraic teaching grounded in arithmetic (e.g., Carraher & Schliemann, 2007). Arithmetic is thus seen as operations with numbers, separated from algebra that is about generalisations. The teaching of pre-algebra in these studies is proposed to be positioned after arithmetic but before teaching algebra. The students are, for example, supposed to work with (1) counting, grouping and sorting artefacts, (2) numbers and numbers of objects, (3) comparisons of quantities and values, (4) organisation of sequences and (5) sums, differences, quotas, and products of quantities and values. To summarize this category: the focus is on numerical values, thus the arithmetic aspect of mathematics.

2. Algebra and arithmetic at the same time

Category 2.a), related to the *algebra and arithmetic at the same time* tradition and is termed early algebraization (Blanton & Kaput, 2011; Kieran, 2004). Early algebraization is based on the idea that arithmetic can be more than counting and by-heart knowledge (Blanton & Kaput, 2011; Kieran, 2004). The teaching described often focuses on student opportunities to analyse relationships between quantities, identify structures, generalise, solve problems, model, argue, prove and predict (Blanton & Kaput, 2011; Kieran, 2004). The studies representing this category state that the differences between arithmetic and algebra are not completely distinct, but the differences can be presented according to what is specific for algebra, thus: a focus on relationships, not counting numerically, a focus on operations and their inverses, a focus on the process of problem-solving, not only the answer, a focus on symbols such as numbers and letters and a focus on the meaning of the equals sign (Kieran, 2004). To summarize this category: algebra is used to analyse arithmetical relationships beyond numerical answers using numerical symbols.

In the category 2.b), teaching is focused on an arithmetico-algebraic way of thinking. The teaching within these studies describes, for example, a modelling process focusing on both arithmetic and algebra (Hitt et al., 2016; Pittalis, 2018). This type of teaching is categorised by student actions related to arithmetic, visible arithmetic processes, their transformations to algebra and their inverses. Students are supposed to develop arithmetic and algebra at the same time, consequently teaching focuses on relationships between different notations, tools and student actions (Hitt et al., 2016). To summarize this category: the studies identify points of contact between arithmetic and algebra instead of describing differences.

Category 2.c) is termed emergent algebraic thinking and is suggested by, for example, Radford (2000, 2014) and Zazkis and Liljedahl (2002). Research interest concerns teaching focused on student ability to generalise and to then symbolise generalisations, thus students are allowed to express generalisations verbally using gestures and symbols without any requirement for students to note generalisations in a purely correct algebraic manner. Emergent algebraic thinking can thus be developed without using common mathematical nomenclature. The studies included are based on student opportunities to work algebraically by, for example, representing solutions to mathematical problems verbally, by using written language, drawings, symbols, models and gestures. These actions form the observable data used to analyse the algebraic thinking developed in teaching (Roth & Radford, 2011). Problems are often manifested by geometrical pattern development. To summarize this category: emergent algebraic thinking focuses on different symbols, verbal language and gestures to operationalise algebraic thinking.

3. Algebraic thinking tradition

The final category 3.a), and the only category that is related to the *algebraic thinking* tradition, is termed algebraic work in which researchers often refer to the El'konin-Davydov Curriculum (Kozulin, 2003; Schmittau, 2003; Sophian, 2002; Venenciano & Dougherty, 2014). Here, teaching the youngest students begins with measuring and comparing quantities related to lengths, volumes, areas, weights and numerical values. These quantities are often noted using algebraic symbols and geometrical length segments. This type of teaching is operationalised as collective analyses of mathematical concepts, their derivation from measurement and their representation by schematic models. Relationships between quantities are identified by the students in collective problem situations. For example, a whole class may collaborate together with a teacher to develop models that visualise how a relationship noted as $A = B + C$ can also be represented as $C = A – B$ or $B = A – B$. In order to be able to discuss such statements, the students and the teacher often use length segment models and algebraic symbols as in Figure 1.

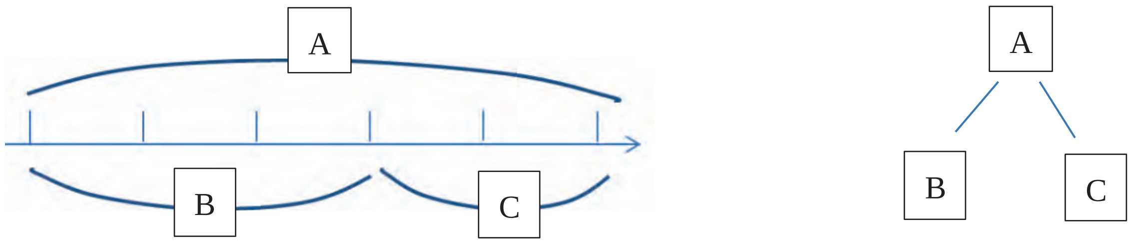

Figure 1: The relationship A = B + C as it is presented in Davydov (2008)

Here, Algebra is used as a tool to discuss general structures of mathematical concepts (van Oers, 2001). The relationships depicted in Figure 1 can be used by students as a means for reflection on the essence of mathematics as scientific knowledge of quantity and relationships. In a next step students can compare quantities that are almost the same, quantities that do not differ significantly and thus need to be measured to be compared. Students may also compare quantities of lengths to quantities of weights to discuss if they are possible to compare. A third task may be to compare quantities of, for example, volume in containers of different shapes. Students then must identify that an intermediary unit is necessary in order to compare the different quantities. Such tasks can be designed without using numerical examples. The sets of progressively more difficult problems are not organised with different content but as problems in which previous solution methods are inadequate but give guidance. Students are supposed to identify the need for new methods, tools and conceptual knowledge. Increasingly difficult and complex problems are designed for the students to solve (e.g., Schmittau, 2003). It is proposed that this algebraic way of teaching is introduced to students from about five years old. The studies categorised as algebraic work under the *algebraic thinking* tradition often focus on student agency, their opportunities to initiate and take part in discussions on mathematical content and reflect on structures and relations. Summarising this category, the students begin with algebra before arithmetic in joint activities.

Discussion

As the results above describe, the research field concerning early algebra is multifaceted in how algebraic thinking can be operationalised in teaching. Researchers in the literature review argue that it is not easy to obtain an overview of what algebra is and what arithmetic is when describing teaching in the different types of teaching traditions. This is managed here by categorising different teaching according to how algebraic thinking is operationalised. However, the same researchers argue that it is important to grasp differences and similarities between these two contents in order to better understand what is in focus and what is possible for the students to distinguish (Radford, 2000; Kieran, 2004, 2018). In this overview, these categories have been organised as; beginning with arithmetic and then introducing algebra, working with arithmetic and algebra at the same time and beginning with algebra to develop algebraic thinking as well as arithmetic thinking. Some concluding remarks are given in relation to the first and the third tradition.

In the arithmetic thinking tradition, arithmetic abilities are supposed to be developed before the students are expected to develop algebraic thinking. Within this tradition, algebra is usually introduced in middle school when the students have worked with arithmetic for a while and supposedly have developed basic arithmetic abilities. Even though these studies are included in the research field of early algebra, it is thus not the youngest students who are referred to in the research literature. This teaching tradition empowers students to communicate generalisations by using numerical examples as in, for example, pre-algebra (Carraher & Schliemann, 2007) and algebraized elementary mathematics (Lins & Kaput, 2004). According to Kaput's (2008) description of algebraic thinking, this teaching can be understood in relation to generalised arithmetic, but less in relation to syntactical, guided manipulations of symbols. Based on Kieran (2016) and Kieran et al. (2018), this kind of teaching tradition can be understood as generalisation activities despite the symbols used being numerical. However, referring to Radford's (2014) descriptions regarding manifestations of algebraic thinking, it is doubtful whether this is to be considered as algebraic thinking when the content is related to numerical values only.

In contrast to the arithmetic thinking tradition, the algebraic thinking tradition emphasis that algebraic thinking needs to be developed first in order to develop arithmetic thinking. Here algebraic thinking is operationalised in the earliest grades in elementary and primary school. Algebraic structures and relationships are worked with as a foundation for arithmetical work (Davydov, 2008; Schmittau, 2003; Sophian, 2002). The development of mathematical abilities using algebraic symbols and line segments is suggested as a means in a collective, problem-solving activity (Kozulin, 2003; Schmittau, 2003; Sophian, 2002; Venenciano & Dougherty, 2014). Teaching should focus on relationships between mathematical concepts and structures within arithmetic such as relationships between quantities (Schmittau, 2003). One important difference between this *algebraic thinking* tradition and the *arithmetic thinking* tradition is the idea that theoretical knowledge is developed by ascending from the abstract to the concrete (Davydov, 2008). In order to enable this process among the youngest students as well, algebraic symbols and algebraic ways of thinking are essential in the algebraic tradition. Comparing this way of operationalising algebraic thinking to Kaput's (2008) three strands, this can be seen as: a) algebra as the study of structure and systems abstracted from computation, b) algebra as the study of relationships and structures and c) algebra as collective modelling. Referring to Kieran (2004), the *algebra first* tradition is focusing generalisation work in which students and a teacher jointly construct equations and reflect on structures as they identify problems and explore mathematical tools.

The result of this literature review indicates that there is a lack of studies within the third tradition - starting with algebra. This gap is also identified by Coles (2021) in a discussion in Educational Studies in Mathematics, in which he states that ”[t]he manner in which symbols arise from activity within Davydov’s work potentially offers huge advantages in multi-lingual classrooms, and I would see this as a rich area of future research” (p. 475). Consequently, this review confirms Coles’ (2021) argument that more studies in this field are necessary, specifically studies that could expand our knowledge of the *algebraic thinking* tradition.

Powerful algebraic ideas: Early algebraic thinking and active citizenship

Jenny Fred, Paola Valero and Hendrik Van Steenbrugge

Stockholm University, Sweden; jenny.fred@su.se, paola.valero@su.se, hendrik.van-steenbrugge@su.se

How can powerful algebraic ideas be understood for the combined purpose of developing students' emergent algebraic thinking and fostering future active citizens? To address this question, we have examined two major research review books on early algebra to investigate the interpretations of "powerful algebraic ideas" that are present in the books as a whole. Skovsmose and Valero's (2008) four interpretations of powerful mathematical ideas (which focus on the logical, psychological, cultural, and sociological power of mathematics) were used. We show that in the books and book chapters there is a dominance of the logical and psychological interpretations of the power of algebraic. Furthermore, the cultural and sociological interpretations appear connected to algebraic thinking as a resource or tool for action in "society". Advancing new possibilities of expanding the ways in which early algebraic thinking is made powerful for students is a challenge to research.

Keywords: Early algebra, algebraic thinking, powerful algebraic ideas, socio-political perspective.

A socio-political perspective on early algebra?

In the last decades, early algebra research has stressed the importance of students' introduction to algebraic practices in the lower grades to support students' emergent algebraic thinking (e.g. Kaput, 2008; Radford, 2014). Such an early introduction lays the ground for further algebraic thinking. Since algebra has a special position in mathematics, through its applicability in other areas and for its role in supporting general reasoning, conclusions, and proofs, an early introduction to algebraic practices and thinking is considered a foundation for realizing the intentions of the mathematics curriculum with respect to students' overall mathematical learning (Cai & Knuth, 2011). Simultaneously, interest on the socio-political dimensions of mathematics education has grown among researchers and practitioners (Gutiérrez, 2013; Planas & Valero, 2016). A socio-political approach to mathematics education considers the development of mathematical thinking and learning as an aim tightly connected with the overall societal intention of providing students with tools to become active citizens. In other words, mathematics education should offer clear opportunities to deploy mathematical thinking to consider and act on the problems and concerns of students as members of a society (e.g., Skovsmose, 1994). When bringing these two lines of research together, one could think that the aim of developing students' algebraic thinking is not only to advance the learning of further mathematics, but also more explicitly to empower children's critical reflection and democratic participation in communities of peers and in society (Hauge & Barwell, 2017). As it appears from the analysis of the basic works in our study, more often than not this combined aim is not so clearly articulated in research. Thus, bringing together students' emergent algebraic thinking and fostering future active citizens becomes a relevant challenge to advance a socio-political research work on early school algebra.

This paper has the intention of examining the way in which the aims of early algebra are expressed in research. Identifying how such aims are articulated is a first step in finding ways to connect them with the intentions of empowering students as future citizens, and in opening possibilities for new design of curricula and pedagogies that promote algebraic thinking.

We took inspiration in Skovsmose and Valero (2008), who reviewed how research in mathematics education views mathematics as being powerful and learning mathematics as empowering students and giving them access to participation in society and democracy. They reviewed research with three questions in mind: a) What is the understanding of "power" present in research? b) What is the source of the power of mathematical ideas? and c) What are the consequences of that power? As a result, they identified four distinct interpretations of the notion of "powerful mathematical ideas" that are present in the field. Mathematics and mathematics education are powerful in a *logical* sense when the focus is on the internal characteristics of mathematics. The learning of mathematics is then justified "for the sake of the internal characteristics of mathematics" (Skovsmose & Valero, 2008, p.15). Powerful mathematics education is powerful in a *psychological* sense when the focus is on the individual's possibility of acquiring mathematical knowledge. Powerful mathematical ideas are then defined in relation to the mental operations involved in the learning of mathematics, rather than the internal logics of algebra. Mathematics education is powerful in a *cultural* sense when the focus is on students' interpretations of their life possibilities in a context and reflects a situated learner's perspective, addressing students' background, but also their foreground, or how students perceive themselves as mathematicians in their future live. Mathematics education is powerful in a *sociological* sense when considering mathematics as a central tool for larger social action and organization. Powerful mathematical ideas, then, are "defined in relation to the extent to which they are used as a resource for action in society" (Skovsmose & Valero, 2008, p. 21).

In our case, these four interpretations invited us to inquire in which ways democratic access to early algebraic thinking can be considered as powerful for the purpose of connecting the development of algebraic thinking with the intention of education for an active citizenship. The question we want to discuss in this paper is: How can we understand powerful algebraic ideas for the combined purpose of developing students' emergent algebraic thinking and fostering future active citizens?

Methodology

To answer this question, we examined two major research review books in the field of early algebra (Cai & Knuth, 2011; Kieran, 2018) to investigate the interpretations of "powerful algebraic ideas" in the books as a whole. This process was done in three steps. First, an analytic tool was created (Table 1) where Skovsmose and Valero's (2008) three questions (a) What is the understanding of "power" present in research? b) What is the source of the power of mathematical ideas? c) What are the consequences of that power?) helped guiding the description of each interpretation. Second, we performed an exercise of *researching research* (Pais & Valero, 2012) on the two books to identify statements present in the texts related to each of the four interpretations. This was done by scanning for keywords associated to each interpretation, identifying excerpts that expressed these ideas, and articulating the overall sense of powerful algebraic ideas present in the books. In researching research as an analytical approach, we were not interested in pointing the particular author of an idea. Rather, we identified the regularities of what is being said about powerful algebraic ideas. Therefore, the excerpts that illustrate the interpretations are coded “C&K” and “K” plus the page number to point the source of the citations in Cai and Knuth (2011) and Kieran (2018) respectively.

Table 1: Summarised view of Skovsmose and Valero’s (2008) Powerful mathematical ideas…

Logically speaking…	**Psychologically speaking…**
Mathematics is seen as objects. The focus is on understanding mathematical concepts and doing mathematics for the sake of the internal characteristics of mathematics. The goal is to establish mathematical knowledge, its ways of working and to provide new insight into a different set of concepts. Being able to make abstractions is essential. Mathematics empowers through peoples’ enculturation in it.	Mathematics is conceived primarily as a learning process. The focus is on capturing and facilitating the developmental nature of mathematical thinking towards higher levels of abstraction and formalization. The mathematical power is situated in its developmental potentialities.
Culturally speaking…	**Sociologically speaking…**
Mathematics is seen as a tool to relate to people’s context and life conditions, for making decisions, participating in different practices, and envisioning future life possibilities. Mathematics is powerful as it allows the understanding and transformation of who learners can become.	Mathematics is seen as a descriptive and prescriptive resource and tool for action that formats society. Mathematics is powerful as it allows planning and decision making as an integrated part of technological actions. It also allows to recognize the harms that mathematics, as a resource in technological action, can create.

Powerful algebraic ideas

Table 2 shows the approximate distribution of excerpts in the texts. From this distribution, it is clear that most of the terms appear in connection with the logical and psychological focus.

Table 2: Distribution of number of excerpts

Interpretation	Keywords	Nr. of excerpts
Logically speaking...	abstraction, concept, generalization, mathematical structures, origin	More than 200
Psychologically speaking…	argumentation, mathematical thinking, mediating tools, modelling, reflection,	More than 100
Culturally speaking…	critical decisions, culturally, family, student´s background, student´s foreground	Less than 20
Sociologically speaking…	agency, empowerment, citizenship, critical thinking, critical reflection, democratic, real, society	Less than 10

In what follows we characterize the four different interpretations of powerful algebraic ideas as they appear in the two books. We acknowledge that even though we try to keep the four interpretations as distinct perspectives and emphases, they are not strict, clear-cut categories. Rather there are fine lines of distinction and similarity between them. Therefore, we tried to capture what can be foregrounded within each interpretation.

… Logically speaking

Algebraic ideas are presented in the books as powerful logically speaking when stress is placed on the features of algebra such as abstraction, mathematical structures and generalization. This dimension of powerful algebraic ideas connects to the multiple perspectives one needs to understand concepts and by linking these concepts to one another. For example, generalizing is described as powerful in relation to processes of identifying mathematical structures and relationships in mathematical situations. Seeing and describing mathematical structures and relationships are also seen as powerful in relation to constructing meaning. For example, understanding the "multiple meanings of variables and the ability to employ variables to express mathematical relationships or situations" (K, p. 144) are also expressed in terms of powerful algebraic ideas. The power of thinking algebraically is described as empowering students to analyse relationships, to notice structures, to generalize, to problem-solve, to model, to justify, to prove, and to predict (K, p. 408). Furthermore, "structure in terms of an agreed list of properties" is seen as a powerful algebraic idea when using them as axioms for deducing other properties (K, p. 287). In sum, the power in this category is strongly related to the internal logics of algebra.

… Psychologically speaking

From a psychological point of view, powerful algebraic ideas seem primarily to be defined in relation to what students can grasp and give meaning to in the learning processes of algebra. For example, symbolic notions are emphasized as tools in relation to students' thinking regarding generalizations and relationships between variables: "in particular, to recognizing the varying nature of variables" (K, p. 276). The algebraic symbols are also emphasized as powerful to describe and reason with overall mathematical ideas (C&K, p. 19). Schematizing, discovering patterns, "to imagine and to express, to specialize and to generalize, to conjecture and to convince" is also mentioned in terms of being powerful algebraic ideas (K, p. 334). This in relation to recognise "situations as instances of a class of similar situations, which constitute a person's example space" (K, p 334). "Observing examples to find regularities, noticing structure and relationships, forming conjectures about the observations, and then proving and concluding general statements" was also mentioned in terms of being powerful (K, p. 356). Mental models are mentioned as ways of thinking about abstract concepts (e.g., balance for equivalence) and/or represent abstract concepts (e.g., physical balances, balance diagrams, balance language, equations as balance). Transforming processes, the recognition of mathematical ideas and the use of mathematical strategies and analytical tools were mentioned (C&K, p. 332). Abilities such as meaningful symbolic reasoning are seen as powerful because they prepare for the abstraction of more advanced concepts and thinking in later grades. (C&K, p. 14). In contrast to powerful mathematical ideas in a logical sense, mathematical ideas are powerful because they relate primarily to students' *learning* of algebra rather than to a predominant focus on the internal characteristics of algebra.

… Culturally speaking

We interpret this dimension as emphasizing informal notions of algebraic concepts where language plays an important role. Competencies as to going from informal notions to more formal ways of mathematical thinking are emphasized (K, p. 29). Algebra is described as a cluster of modelling languages both in and out of mathematics (C&K, p. 492). The importance of tasks for students' lives is also emphasized for students to engage and participate (C&K, p. 430). Argumentation competences is attributed a crucial role (C&K, p. 469) even though algebraic thinking not always is mentioned directly; rather, activities with a special focus on argumentation. Further, is algebraic thinking highlighted as creating marginalization of students in schools and society as well as "a gateway to academic and economic success" and in that sense is algebra seen as valuable for the students. Culturally speaking powerful algebraic ideas recognize the *situated perspective* of learning algebra and the culturally loaded meaning associated to learning algebra.

… Sociologically speaking

The role of algebraic thinking is sometimes backgrounded, and sometimes it is foregrounded. Furthermore, "the use of symbols (letters) to express relationships (to model) and thereby to resolve problems" are mentioned in terms of powerful algebraic ideas (C&K, p. 561). "Real" problems are used as starting points where transforming processes, reorganizing mathematical ideas, schematizing, discovering relations and patterns, symbolizing, using analytic tools, and refining existing models are deployed as tools for students to have agency over their life situations and to critically scrutinize their environment interpreted as powerful algebraic ideas (C&K, 2011 p. 332). Students' abilities to make sense of data is mentioned, this in relation to whether and how different quantities relate to each other. In relation to this seem tables, graphs, and the use of symbols to work as tools or models to invite the students to describe and reason about mathematics ideas (C&K, 2011 p. 19). Algebraic reasoning is also highlighted, this in terms of being a powerful algebraic idea (K, p.380). In some excerpts is algebraic thinking expressed powerful in relation to work as a "fluid domain of thinking", "habit of mind" and as a particular resource to be used and integrated in every topic (C&K, p.18).

Discussion and conclusions

As described earlier on, we set us the task of discussing how to understand powerful algebraic ideas for the combined purpose of developing students' emergent algebraic thinking and fostering future active citizens. That is, we try to move early algebra education towards a practice at intersection of fostering future democratic citizens and the emergence of algebraic thinking for future mathematical learning. The main result, in screening two major research review books, is that there is a dominance of the logical and psychological interpretations of "powerful algebraic ideas". This result resonates with Skovsmose and Valero (2008) who, for the general field of mathematics education, could see a large number of publications adhering to these two interpretations of power. To keep assuming that the logical and psychological interpretations will lead to an empowerment of students may be problematic. As we know, the connection between mathematical knowledge and competence and relevant problems that people face in their lives does not happen "naturally" (Hauge & Barwell, 2017). As society gets more complex and children face the challenges of sustainability and climate change, it becomes necessary to make explicit connections between algebraic capacities/thinking and the ways in which algebra plays a role in addressing such shaky situations.

Our analysis of powerful algebraic ideas culturally and sociologically speaking can guide us in the attempt to enlarge the idea of algebraic practices where students are involved in more socially relevant issues, as for example climate change and sustainability, and where algebraic thinking becomes a resource or a tool for concrete critical thinking and action. One way of inviting students to be involved in this kind of activities is to work with models of situations that go beyond so called realistic or semi-real references for a controlled problem. For example, we can challenge students to read or model "reality" and then by raising certain questions/issues implicit make algebraic thinking becoming an analytical tool in the exploration of those models. Further, asking questions/making statements that invite the students to becoming aware of models' potential of visualizing only certain "things" and leaving other things unnoticed and invite them to reflect on what kind of consequences that may have. In this kind of work, algebraic thinking can become a language tool/resource as well as an analytical resource/tool (see also Blanton 2008). Another way of inviting students to this kind of work is in relation to technological action, where algebraic thinking can work both as a tool to create technological solutions as well as enable the students to detect that all things that are created with mathematics are not all good. Thinking in this direction, the contextualization becomes crucial, this in the establishment of an arena where algebraic thinking can operate both as a source of power but at the same time inviting students to critical examinations of mathematics itself. This implies a need to uncover the contextualization of a certain structure and at the same time creating another kind of need for algebraic thinking.

The remaining question is then, which could be new possibilities to build those kinds of arenas with the combined aim for early algebraic thinking? We believe that as a community of researchers, we could embrace the challenge of designing algebraic practices that place algebraic thinking in a larger context. In contrast to the usual work with problems and contexts tailored for algebra, we see that *wicked problems* (Block et al., 2018; Hauge & Barwell, 2017; Jurdak, 2016; Rittel & Webbers, 1973; Steffensen, 2021) can be a fruitful idea to both empowering the contextualization as well as creating another kind of need for algebraic thinking. Wicked problems can help us bridging the gap between school algebra and more socially relevant issues (e.g., Jurdak, 2016; Steffensen, 2021). Wicked problems can be described as complex problems with no definite formulation of what the problem and its solution actually is. Then the problem-formulations are vague and involve different interests and/or perspectives which encourage to negotiate disagreements that open up for different framing of the problem. Thus, if we want to go beyond providing students with tools to solve problems encountered in real life and instead invite the students to work as mathematicians handling conflicting stakes, complexity, decisions, and uncertainty, exploring algebraic activity to address wicked problem can be rewarding.

Neither of the above, however, comes without challenges. There is a risk that the students' either disregard mathematical (in this case algebraic) aspects or disregard socio-political aspects or disassociate them. Our further research intends to explore this further by imagining wicked problems in an iterative and collaborative process including pre-service teachers, teachers, researchers, and teacher educators, where we also stage these imagined wicked problems with 6–9-year-old students.

Acknowledgment

This paper reports on research conducted within the graduate school *Relevancing mathematics and science education* (RelMaS), funded by the Swedish National Research Council.

What is *functional thinking*? Theoretical considerations and first results of an international interview study

Kerstin Frey[1], Ute Sproesser[1] and Michiel Veldhuis[2]

[1]Ludwigsburg University of Education, Germany; kerstin.frey@ph-ludwigsburg.de, ute.sproesser@ph-ludwigsburg.de

[2]iPabo University of Applied Sciences, Amsterdam, the Netherlands; m.veldhuis@ipabo.nl

In this paper, we present the first results from the Erasmus+ project FunThink which focuses on enhancing functional thinking from primary to upper secondary school. In an international interview study (in Cyprus, Germany, Netherlands, Poland, and Slovakia) we investigated 35 educational experts' views on what they consider functional thinking to be. From each country between six and nine experts were interviewed. We analyze these semi-structured interviews using qualitative content analysis, with both deductive and inductive categories, related to different conceptualizations of functions, mathematization, activities supporting functional thinking, and cognitive aspects related to functions. These analyses are currently underway; therefore, we present our theoretical background, our coding scheme which is under construction, and excerpts of three interviews in this proposal.

Keywords: Functional thinking, expert interviews, empirical study.

Introduction

Functional thinking is required when relating two or more quantities, e.g., when understanding scientific laws such as the dependency between speed, distance, and time or when modelling something we read about in every newspaper such as the spread of a virus. Hence, it is not only a key element of (school) mathematics but also relevant for other disciplines and everyday situations (e.g. Selden & Selden, 1992; Vollrath, 1989). However, there is no consensus in the international literature on what exactly encompasses functional thinking and, hence, educators might also understand this notion differently, with different implications for teaching practice. This paper presents first findings of the Erasmus+ project *FunThink- Enhancing functional thinking from primary to upper secondary school*. The overarching goal of this project is to improve the teaching and learning of functional thinking across all school grades. As a basis for further steps in the project, the project members, inter alia, conducted a corresponding literature review, charted national curricular situations, and interviewed mathematics education experts[1] in order to portray their individual perspectives on functional thinking. Altogether, the interview study was conducted in five countries, yet, in this paper only interview excerpts from Germany and the Netherlands are presented regarding the question *what educational experts consider functional thinking to be*. To relate these empirical insights to relevant theoretical considerations on functional thinking, we present in the following section the corresponding theoretical background.

[1] Further partners in the interview study are Martina Geisen, Veronika Hubeňáková, Monika Krišáková, Edyta Nowińska, Marios Pittalis, and Miroslawa Sajka.

Theoretical background

Based on the concept of function which reaches back to Bernoulli (1667 – 1748, Büchter & Henn, 2010), the notion of functional thinking was introduced over 100 years ago during the reforms of Meran in 1905. At that time, functional thinking was understood as conceptual interpretation of the mathematical object of function and was considered a “guiding category for teaching mathematics in order to concentrate, unify and structure different areas of mathematics taught in schools” (Krüger, 2019, p. 35). Since then, it has developed in different ways in the international context which led to a variation in definitions. In the following, we present three main strands in the understanding of functional thinking.

First of all, functional thinking can be seen as a major component of algebraic thinking (Warren & Cooper, 2005). More precisely, Pittalis et al. (2020) describe functional thinking “as the process of building, describing, and reasoning with and about functions” (p. 632) and relate this rather broad definition to Blanton and Kaput (2011), Stephens et al. (2017), and others.

The definitions by Markworth (2012) and Smith (2008) rather focus on the aspects of representation and generalization of functional thinking. They see functional thinking as a type of

> […] representational thinking that focuses on the relationship between two (or more) varying quantities, specifically the kinds of thinking that lead from specific relationships (individual incidences) to generalizations of that relationship across instances. (Smith, 2008, p. 143)

Besides those two strands, Cañadas et al. (2016) describe functional thinking in a general sense composed of topics, methods, and relationships concerning functions. Moreover, these authors show examples that fit into the two previously outlined strands: Functional thinking includes functional relationships between quantities, the generalization, and representation, which all support the understanding of function behavior (Blanton & Kaput, 2011). Moreover, it is linked to the ideas of change, more explicitly to qualitative and quantitative change, the relationship between changes and the ability to use these relationships for solving problems (Warren & Cooper, 2005).

These three definitions illustrate that there is no clear consensus about what functional thinking entails. Although they appear disparate, they do share the idea that functional thinking involves reasoning about the relationship between quantities. Considering that, one could ask how functional thinking can be developed by learners and how teachers can support this process. Functional thinking cannot be learned as an independent topic but has to be considered in close connection to the concept of function (cf. Vollrath, 1989). With this regard, the literature describes four perspectives on functions that play an important role when dealing with concrete function tasks or preliminary activities. These so-called *function aspects* include characteristics of functions and can form a basis for the design and implementation of tasks in mathematics education. In the international context, usually four main aspects of functions are distinguished: input-output, covariation, correspondence, and mathematical object (e.g. Doorman et al., 2012; Pittalis et al., 2020).

Function as an input-output assignment stresses the operational and computational character of the function concept; in this sense, it is not necessary to be aware of the causal relation between the in- and output (Pittalis et al., 2020). It is for example relevant when dealing with patterns and structures:

within a sequence of values, *recursive patterning* describes the existing variation and indicates how a next element can be determined if the previous element or a number of elements is provided (Stephens et al., 2017).

The aspect of covariation emphasizes the simultaneous variation of two quantities, often a dependent and an independent variable, and relates to Thompson and Carlson (2017). In their work, they offer a definition of a function with a focus on covariational reasoning:

> A function, covariationally, is a conception of two quantities varying simultaneously such that there is an invariant relationship between their values that has the property that, in the person's conception, every value of one quantity determines exactly one value of the other. (p. 436)

This definition highlights the connection of two variables and their interdependency without using the terms dependent and independent variable. Similarly, Confrey and Smith (1995) describe the covariational approach as comprehending, analyzing, and manipulating the relation between two changing quantities. The change in one quantity appears if a change in the related quantity occurs.

The view on a function as a correspondence relation focuses on the relation of the independent and dependent variable and on how this relation can be represented (Smith, 2008). In more formal definitions of functions this view is expressed as ordered pairs:

> […] a *function* from a set S to a set T is a rule that assigns to each element x of set S a unique element of set T. The set S is called the *domain* of the function. If f is the name of the function, then the unique element in T corresponding to an element x in S is denoted $f(x)$ […] and is called *image* of x. The set $\{f(x) \mid x \in S\}$ is called the *range* of the function. (Yandl, 1991, p. 72)

To conclude, the fourth aspect focuses on a function as a mathematical object with its own specific representations and properties which can be dealt with. This perspective is needed to compare a function with another function or with another mathematical object. Higher-order processes like differentiation or concatenation require this view of a function (Lichti & Roth, 2019).

Different to the international context, in Germany, only three aspects are commonly discussed. The aspect of input-output assignment is omitted as a separate aspect. It is rather included in the other aspects. For example, using a function machine where something is put in, which then results in an output relates to the aspect of correspondence due to the direct assignment. Moreover, considering the covariation between inputs and outputs can help finding the underlying rule. At the same time, the input-output assignment can refer to the object aspect if the calculation does not happen within a function but with the whole function (e.g. addition of two functions) which then results in a new output. This difference in the distinction of the aspects of functions might be due to country-related particularities or the historical development as in Germany the notion of functional thinking is clearly associated to Vollrath (1989) who only distinguishes these three aspects of functions.

The set of four aspects can be considered to show an increasing level of sophistication. Studies report a gradual development from a process view which is similar to the input-output-assignment aspect to a more structural view which can be compared to the function as a mathematical object aspect (Sfard, 1991). Activities with a focus on input-output assignment are often already included in primary school (e.g., Leinhardt et al., 1990; Lichti & Roth, 2019; Pittalis et al., 2020; Stephens et al., 2017).

Studies show that young students are able to reach sophisticated ways of reasoning with functions, or algebraically, if rich tasks are provided accompanied by fitting instruction (e.g., Blanton et al., 2015; Stephens et al., 2016; Stephens et al., 2017). The implementation of the three other aspects often follows later in the curricula, whereas the object aspect appears to be the most abstract one.

As stated above, functional thinking is closely intertwined with the concept of function and cannot be considered on its own. The topic of function has been found to cause difficulties for many secondary school students (Sproesser et al., 2020). Reasons for these difficulties might be found in the abstract character of functions which makes the concept only accessible through modelling in representations and focusing on the changes between such representations (cf. Duval, 2006). Tables, algebraic expressions, graphs, and verbal descriptions are the most common representations used in school. Each of these types of representation has advantages and disadvantages depending on the specific situation and task at hand. A flexible use of representation and changes between representations, can support students' learning and understanding of functions and therefore of functional thinking (e.g. Adu-Gyamfi, 2007).

Returning to what was stated at the beginning, functional thinking is considered a key aspect in mathematics and relates to many other disciplines, and everyday life. It is present in many situations even if we are not aware of it. The second part of this paper, which describes excerpts of an international interview study, provides insight into how international educational experts see functional thinking. This is particularly important in how they frame the development of students' functional thinking. Similarities and differences to the above-mentioned definitions of functional thinking will become visible from our analysis of the interviews.

Research question and methodology

The interview study was carried out in order to collect views and experiences of educational experts on functional thinking and to get insight of which elements described in the literature are particularly relevant for them. The research question for the main study is: *what do educational experts in Cyprus, Germany, the Netherlands, Poland, and Slovakia consider functional thinking to be?* In this paper, only exemplary results from Germany and the Netherlands are presented.

Sample

Experts of mathematics education in all five partner countries (Netherlands, Poland, Cyprus, Slovakia, and Germany) were informally approached by project members to participate in this study. The interviewees ranged from professionals for mathematics education from primary to tertiary education working at universities to experienced mathematics teachers for primary and secondary schools and curriculum developers. They were chosen in order to gather views from different professional perspectives but all were considered as experts referring to functional thinking in their embeddings. Between six and nine interviews were conducted in each partner country which led to a total of 35 interviews. In this paper, only excerpts from two interviews in Germany and one interview in the Netherlands are presented. A more detailed description of these three interviewees can be found in the results and discussion section.

Procedure and interview guideline

Prior to the interviews, a semi-structured interview guideline was created to answer, inter alia, the questions of what the experts understand by functional thinking and how it can be addressed in the classroom. Further questions included what students should learn to develop functional thinking in the interviewee's opinion and what exemplary tasks could look like. Moreover, some information was gathered about the interviewees' professional background. The interviews took place virtually or in person depending on the current situation (mostly related to COVID-19 restrictions) in each country. A recording, video tape (together with corresponding transcripts) or a detailed protocol of each interview was used for the analysis. The analysis is currently still in progress. The analysis methodology we use is qualitative content analysis according to Mayring (2014). This is used for building a coding scheme with inductive and deductive categories.

Coding scheme

As our coding scheme is currently under development, we only refer to the main categories we are working with. In a first step, we code educators' ideas in the perspective on functional thinking they referred to. Here, the four aspects of considering functions (input-output, covariation, correspondence, mathematical object) play the main role. Secondly, we code how functions are used for mathematization described by educators, which can take place inside (from informal to more formal mathematics, i.e., vertical mathematization) and outside (modelling a meaningful situation with mathematical tools, i.e., horizontal mathematization) of mathematics. In a third step, we code the activities educators described which they thought could support or require functional thinking. This especially addresses patterning and dealing with representations. Finally, we code semantic and syntactic elements and concepts related to functions and functional thinking, other related fields and counterexamples. As these codes are still under construction, in the following, we only show a first sketch of the analysis of interview excerpts.

Results and discussion

The first interviewee from Germany (G1) works at the transition from university to licensed teachers (a part-time seminary, where graduated college students gain their teaching license) with a focus in mathematics education. Interviewee G1 answered the question of what he considers functional thinking to be in the following way:

> Functional thinking [..] is everything that has to do with the dependence of two quantities, of two variables. […] It is so the upper goal, the upper principle, so on the one hand the one variable has a value, that affects the value of another variable that dependents on it. It would so rather be the static side, so the allocation, then also the change, if one variable changes, what consequences does it have for the other variable. Yes, and the third would be so basically the course that you can conclude, the overall picture of the dependency. […] It already goes in the direction of the idea of using mental representations of mathematical concepts (*Grundvorstellungen*), but above these basic ideas stands the consciousness of dependence and everything that is around it or what is subordinate, the calculating that must actually, that leans on this principle. […]

The description of functional thinking by interviewee G1 is rather broad and highlights the dependency of two variables. Concerning his perspective on functions, the aspects of covariation, correspondence, and mathematical object are clearly mentioned and described as basic ideas. According to the interviewee, everything that follows, like calculations, can be derived from these principles. Due to the prominence of the aspects according to Vollrath (1989) in Germany, it is not surprising that the aspect of input-output assignment is not mentioned.

Another German interviewee (G2), a teacher from primary school (Grade 1-4), answered the same question. The interviewee is a longtime teacher who initially studied education for primary and lower secondary school with a focus in general studies, German, and mathematics. Besides the degree in education, the interviewee also has a postgraduate degree in pedagogy.

> […] what do they actually want with that in elementary school? […] it's about relationships for me in functional thinking, so not just functions according to the motto of a value is assigned to another value, but about relationships, about the discovery of relationships, and then again a bit of the science lesson plays into it for me, which then says laws of nature, you can make discoveries, you can observe them, you can explore them, you can measure something, math comes into it again […].

Interviewee G2 is rather general in her definition of functional thinking. G2 sees functional thinking in a wider sense than just related to functions. The focus is on relationships and connection to real life. The elements of discovery, observing, exploring, and measuring of relationships show this close connection to the real world. G2's description of functions indicates the aspect of correspondence. Later in the interview, as example, she mentions collections of tasks with continuous elements where students can recognize patterns (*starke Päckchen*) as an activity for addressing functional thinking which includes elements of the input-output assignment. In general, G2 seems less aware of the aspects of functions and functional thinking. In contrast to G1, G2 only mentions some aspects and does not address them explicitly.

An interviewee from the Netherlands (N1) has been a teacher for 16 years, mainly in the upper primary school grades (Grade 5 and 6). When asked about her definition of functional thinking, she mentioned "that must be about relating mathematics to a context and its utility." This is related to our code on horizontal mathematization (modelling extra-mathematical situations with mathematical tools), which is rather well established in the Netherlands, due to the implementation of realistic mathematics education. When prompted by the interviewer that functions could also be interpreted in a more mathematical sense, she referred to patterning tasks in the early grades of primary school, doing rows of calculations and observing what remains fixed and what changes, graphing activities, and summarized all these as "reasoning about relations." In this she clearly related to the covariational view of functional thinking while describing useful activities for eliciting it. Interestingly, she connected this reasoning about relations also to an attitude that students should develop in society, seeing relations, experimenting, encountering obstacles, and systematically try to deal with them.

These first excerpts indicate a clear difference in views between experts. Functional thinking is mostly understood in a way that is somewhat similar to one of or a mixture of the definitions mentioned in the theoretical background. Yet, the descriptions provided by the interviewees are less detailed and some lack a complete description of all aspects of functions and functional thinking. The detailed analysis which is to follow will provide more insights, from all the partner countries, into the extant conceptualizations of functional thinking in practice.

This paper focuses on algebraic learning and explores the strategies followed by 17 students with Autism Spectrum Disorder and 17 typically-developing students to solve a generalization task in a functional thinking context. We design and administer a questionnaire with different questions about specific (consecutive and non-consecutive) cases and the general case. Success in the proposed task was higher in the group of typically-developing students. Different strategies were encountered, predominantly (1) modeling with drawing and (2) operations, with neither group having much success obtaining the general term. We discuss the implications for teaching students with autism.

Keywords: Autism spectrum disorder, functional thinking, generalization, primary education, strategies.

Introduction

In the context of mathematics education in Spain, the official primary school curriculum establishes the requirement for students to successfully solve situations involving both numbers and their relationships (BOE, 2014). Along these lines, the early algebra presented is intended to introduce algebraic thinking in levels before secondary school (Blanton et al., 2015).

Some studies on functional thinking have focused on studying the strategies shown by students when solving generalization tasks that involve functional relationships. For example, Blanton and Kaput (2004) noted differences between the various strategies used depending on the age of the participants. In Early Childhood Education, students used counting and addition strategies, while some fifth graders managed to establish multiplicative patterns through words and symbols. Cañadas and Fuentes (2015) also studied the strategies shown when solving a functional relationship and concluded that the six- and seven-year-old students participating in their study responded by using strategies such as counting with drawings, direct answer, associating elements in groups and others.

Although the official curriculum in Spain is standardized and intends for all students to achieve the same goals by the end of the primary school, the reality is that classrooms are increasingly heterogeneous in terms of their students' characteristics. This diversity of students includes those with Autism Spectrum Disorder (ASD), which is a developmental neurobiological disorder that manifests itself during the first years of life and lasts throughout the entire life cycle. Its main symptoms are: (a) persistent deficits in social interaction and communication and (b) restrictive and repetitive patterns of behavior, interests or activities (APA, 2013). In addition, people with ASD may exhibit resistance to change, a tendency to maintain routines, deficits in executive functions, and difficulties in understanding spoken and figurative language, and in inferring the mental states of other people (Ozonoff & Schetter, 2007).

Students with ASD are increasingly enrolled in mainstream schools alongside their typically-developing (TD) peers (Barnett & Cleary, 2019). Some of the deficits of the disorder, such as those in executive functions or verbal comprehension, may interfere with learning, particularly in learning mathematical concepts (e.g., Chen et al., 2019; Polo-Blanco et al., 2019; in press). Specifically, deficits in abstract reasoning may limit the ability to generalize (Minshew & Goldstein, 2002; Ozonoff & Schetter). Although there are studies that analyze the understanding of pre-algebraic functional tasks by TD students (Cañadas & Fuentes, 2015; Morales et al., 2018), there are few analogues for ASD students (Barnett & Cleary, 2019; Goñi-Cervera et al., 2021; Polo-Blanco et al., under review).

Considering the above, we expect that students with ASD will rely often on basic strategies like the use of modeling with manipulatives when solving a task in a functional context, and that they will show difficulties when generalizing the functional relationship.

Objectives

This study is part of a larger one whose main objective is to describe the mathematical abilities of students with ASD and their relationship with cognitive variables, such as executive functions. This work focuses on algebraic learning and explores the strategies employed by TD and ASD students to solve a generalization task in a functional thinking context in order to observe similarities and differences between the two groups of students in terms of the strategy use, and to describe possible difficulties in the ASD group.

Methodology

This research of an exploratory nature (Yin, 2017) relied on cases and controls, and compared the solution strategies of students with ASD matched with their TD controls when solving a task that involves the functional relationship $f(x) = 2x + 2$.

Participants

The participants were 34 students in grades 1 through 4 (6 to 9 years old) from 12 schools in Cantabria (Spain). Of these, 17 had ASD diagnosis and 17 were TD at the time of the study. The students were paired: each ASD with each TD control from the same school and grade as his/her ASD student pair. An inclusion criterion for participants from both groups was to have IQ equal to or greater than 70 as measured by WISC-V. Ten of the participants were enrolled in 1st grade (A1, A2, A3, A4, A5, and their respective TD pairs T1, T2, T3, T4 and T5), two (A6 and T6) in 2nd grade, six (A7, A8, A9, T7, T8, T9) in 3rd grade and 16 (A10, A11, A12, A13, A14, A15, A16, A17, T10, T11, T12, T13, T14, T15, T16 and T17) in 4th grade. The arithmetic mean and standard deviation of the IQs for the ASD group were 87.35 and 10.22, and 103 and 13.12 for the TD group.

The participants with ASD were recruited in different ways, by advertising the project through social media, the press, associations, guidance staff in schools and hospitals. Once an ASD participant was recruited, a TD student from the same school and class to act as a control was sought via family members or the school's guidance staff.

Information gathering tool

A task used in Carraher et al. (2008) and Merino et al. (2013) whose structure involves the function $f(x) = 2x + 2$ was adapted and implemented. The adaptation consisted of using simple language, helping the students read the statement and guiding their work. The task began by presenting, as an example, a square table with four people around it and two square tables together with six people (Figure 1). They were then asked how many people could be seated if 3, 4, and 5 tables (consecutive terms) were joined, if 8, 18, and 100 tables (non-consecutive terms) were joined, and if any number of tables (general term) were joined. The task was given to the students in printed form so they could solve it individually in writing, or both in writing and orally, and they had manipulatives (blocks) that they could use if they wanted.

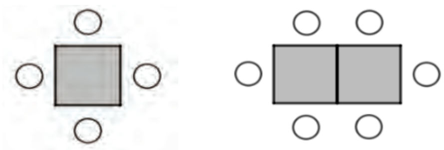

Figure 1: Introduction of the task with people arranged at one and two tables

The students answered the task individually in a classroom free of distractions, with only the interviewer present. Prior to this task, the students had solved three other tasks with the same interviewer in a previous session. First, the interviewer created a climate of trust with the students, letting them play with the blocks or drawing. If the student was not comfortable, the session was postponed. The solution process was videotaped and transcribed for later analysis. Both the written and oral responses were analyzed.

Analysis categories

Based on the strategies defined by Morales et al. (2018), the following categories of answers were established: (a) no answer: if the student does not provide a response, either verbal or written, or does not know the answer; (b) direct answer: if the student provides an answer that is difficult to justify or has no apparent relation to the task; (c) given number: if the student provides as an answer the number given in the statement; (d) modeling with manipulatives and counting: if the student models the situation using the available manipulatives; (e) modeling with drawing and counting: if the student models the situation using drawings; (f) counting: if the student performs the same actions as in modeling, but without using manipulatives or drawings; and (g) operations: if the student performs additive or multiplicative calculations orally or in writing.

Results

Next, and to simplify, we show the frequency of the strategies used by the participants in those questions that involve consecutive, non-consecutive and general terms (see Table 1). The results show how often a certain strategy is used by ASD and TD students. The numbers in parentheses indicate the number of right answers. The column "students" shows the number of students who used this strategy at least once.

Table 1: Frequency of Strategies and Success in Solving the Task f(x) = 2x + 2

	Autism spectrum disorder students				Typically-developing students			
	Case							
Strategy	Consecutive	Non-consecutive	General	Students	Consecutive	Non-consecutive	General	Students
No answer	0(0)	8(0)	4(0)	5	0(0)	8(0)	2(0)	4
Direct answer	9(2)	7(1)	6(0)	10	0(0)	1(0)	0(0)	1
Given number	3(0)	3(0)	1(0)	1	0(0)	2(0)	0(0)	2
Modeling with manipulatives and counting	0(0)	0(0)	0(0)	0	6(3)	4(1)	2(0)	4
Modeling with drawing and counting	15(12)	7(2)	2(0)	6	21(17)	14(7)	3(0)	9
Counting without manipulatives	3(3)	2(0)	0(0)	1	0(0)	0(0)	1(0)	1
Operations	21(0)	24(0)	4(0)	11	24(6)	22(5)	9(1)	14
Total number of strategies	51 (17)	51 (3)	17 (0)		51 (26)	51 (13)	17 (1)	

In what follows, the strategies are exemplified, focusing on the two most frequent in both groups. We also show some examples concerning other less frequent strategies.

As Table 1 shows, the *operations* strategy was the most frequent, in both groups of participants with ASD (49 occasions among all the sections) and the TD students (55 occasions among all the sections). However, no student with ASD used this strategy successfully, compared to three 4th-grade TD students (T10, T12, and T15) who correctly answered twelve times.

The students with ASD who used the *operations* strategy chose, for the most part, additive operations. For example, A1 exhibited the strategy by using an incorrect additive operation, answering for 100 tables: "200. Because 100 + 100 is 200". Student A8 also used an incorrect additive strategy, answering all the sections of the task by adding six to the number of tables given. Among the ASD students, only A13 resorted to multiplication (for example, for 18 tables, he multiplied 10 by 18 and for the general term, answered: "you have to multiply it by 10"). Two other students with ASD used multiplicative reasoning, although without explicitly stating the multiplicative operation. For example, A15 answered for the general term, "I counted by twos", and A11 used expressions such as "four times four" or "you add ten times four".

In turn, 14 TD students used the *operations* strategy. They proposed correct and incorrect additive operations. For example, T12 responded correctly to the consecutive terms, looking at his previous answer and adding two. On the contrary, T1 used an incorrect strategy, because when asked "How many people can be seated if 100 tables are joined?" he described being unable to draw the 100 tables and referred to how "3 + 2" people sit at each table. A transcript of the conversation between the interviewer and the student (Figure 2) is provided below:

Interviewer: What if we have 100 tables?

Student T1: Well… two and three. Two and three and two and three and two and three

Interviewer: How would we put that?

Student T1: We have to put: three, two, three, two, three, two, three, two… in all of them. […]

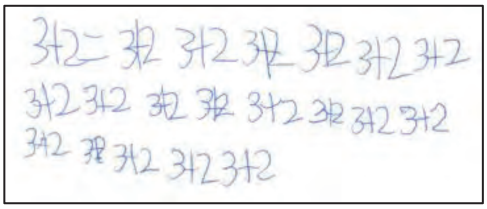

Figure 2: Operations Strategy for 100 Tables (T1)

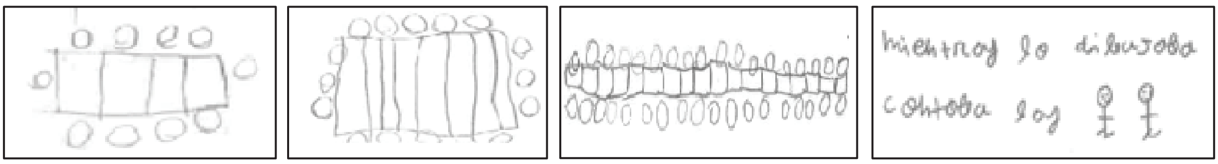
Among the 14 TD students who used *operations*, 10 of them used some multiplication throughout all the sections, and of these, 7 used multiplications exclusively. Thus, T10 used a multiplicative operations strategy by reasoning "you have to multiply the number of tables by 2 and then add 2 for those at the ends", when asked for the general term.

The *modeling with drawing and counting* strategy was the second most frequent strategy, both for ASD (24 times) and TD (38 times) students. In addition, this strategy was the one that led to the most correct answers, especially in the consecutive cases.

Figure 3 (a and b) shows the solution for four and eight tables given by student A7. The first solution is correct, while the second is incorrect, as it places more guests than there should be at the ends. Figure 3 (c and d) shows the solution for 18 tables and the general term for student T7. The solution for 18 tables is incorrect, as he forgot to draw the people at the ends. The solution of the general term shows that T7 determined the number of people by drawing and counting them.



While drawing, I counted the

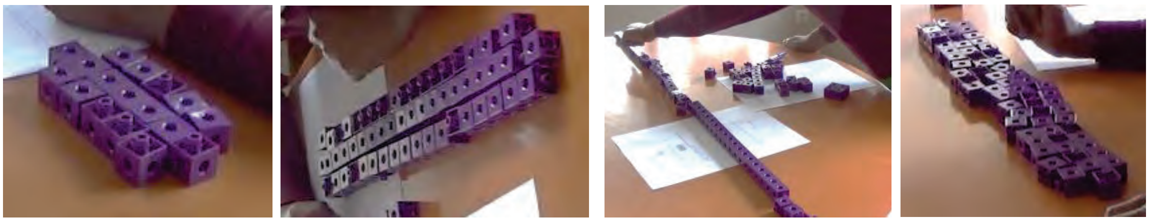
(a) (b) (c) (d)

Figure 3: Modeling Strategy with Drawing

Other less frequent strategies

The remaining strategies were less frequent in the two groups of students. For example, on up to 12 occasions, four TD students used the *modeling with manipulatives and counting* strategy, which was not used by any student with ASD. Student T16 used the blocks made available during the task, modeling the situation for the different numbers of tables. The modeling was correct for 3, 4, 5, 8 and 18 tables (Figure 4, a and b), and incomplete due to insufficient blocks for 100 tables (Figure 4, c).

In addition, T16 also used blocks, particularizing to represent "any number of tables" and respond to the general term (Figure 4, d). He said: “counting these pieces... The middle thing was the tables and those who are here next door were the people”.



(a) (b) (c) (d)

Figure 4: Modeling with manipulatives strategy for 5, 18, 100 tables and general term (T16)

Another infrequent strategy in ASD students was *counting without manipulatives*. Two students (A1 and T4) used a counting strategy for some questions. Thus, to determine how many people could be seated if 4 tables were joined, A1 swayed to the right and left, and each time his body tilted to one side, he counted one. Each time his body titled to the middle he said “a gap here” meaning it was a table and no one sits in a table. He said: “one, a gap here, two, a gap here, three, a gap here…". Student T4 also employed a counting strategy by responding to the general term by writing "using the tables and counting them".

Regarding the *direct answer* strategy, it was only used by one TD student and for just one question, while 13 students with ASD gave these answers on 22 occasions. After being unable to draw 100 tables, T4 replied: “A thousand… I don't know. Or 50 or so... A thousand".

In the group of students with ASD, an example of the *given number* strategy was provided by student A12, who did not justify his answer to the problem in any section. However, his answers show a relationship p = t, where p is the number of people and t the number of tables. His answers for the terms t = 3, 4, 5, 8, 18, and 100 were 3, 4, 5, 8, 18, and 100, respectively. In addition, for the general term he wrote the number zero. This could be related to the absence of a specific number of tables or people in the statement. Students T6 and T16 also responded with the same number of tables to the question that involved 100 tables.

Conclusions

With this exploratory study, we are contributing to the start of an investigation comparing algebraic thinking in both TD and ASD students in primary education. Success in the proposed task was higher in the TD group, although it was accessible to some of the students with ASD.

In both groups of students, the predominant strategies were *modeling with drawing and counting* and *operations*. The task increased in difficulty as the number of tables rose, with the question involving the general term proving very difficult. Contrary to what we expected, *modeling with manipulatives* was not used by any student with ASD. One reason that could explain this is that the material provided (blocks) was not adequate to represent the situation. Given the type of literal thinking common in ASD students (Happé, 1995), they may have had difficulty imagining that the blocks represented the tables and people around them. However, they did not show difficulties in implementing the modeling strategy through drawings. The frequent use of a *direct answer* strategy among students with ASD and given that in most cases it did not lead them to the correct answer, could be associated with a poor understanding of the task. The preference in ASD students for following additive strategies agrees with previous studies carried out with TD students and enrolled in lower grades (Blanton and Kaput, 2004). In addition, the choice of strategies based on drawings agrees with previous research involving 5- and 6-year-old TD students (Cañadas & Fuentes, 2015) and it is in line with other works about problem solving by ASD students (Polo-Blanco et al., 2019).

As a future line of research, the sample could be expanded to delve into possible differences within the group with ASD, and to see if subgroups of normal-performing and low-performing students are identified, in line with previous work (Chen et al. 2019). The aim of this study is to enhance the research on mathematical learning in students with ASD. In particular, this study serves as an aid to those teachers who work with ASD students enrolled in mainstream classrooms who follow the official curriculum, alongside their TD peers.

A praxeological comparison of algebra content in vocational and academic preparatory programmes in Sweden

Matilda Hällback, Kajsa Bråting and Olov Viirman

Uppsala University, Sweden; matilda.hallback@edu.uu.se, kajsa.brating@edu.uu.se, olov.viirman@edu.uu.se

We compare the algebra content in the Swedish upper secondary syllabi for higher educational preparatory (HEP) and vocational educational and training (VET) programmes. The study is theoretically embedded in the Anthropological Theory of the Didactic (ATD), where praxeology is used as an analytical tool. The results reveal that the algebra content in the VET programmes is more focused on praxis ('know-how') aspects compared to the HEP programmes, in which the balance between praxis and logos ('know-why') aspects is more even. We discuss the results in view of students' opportunities to develop algebraic knowledge within the framework of the given syllabi.

Keywords: Algebra, ATD, praxeology, syllabus.

In 2011, Swedish upper secondary school underwent a major reform, with the implementation of new curriculum documents and school organisational structures (Swedish National Agency for Education, 2011). An essential consequence of this was a stronger separation between vocational educational and training (VET) and higher educational preparatory (HEP) programmes (Lindberg & Grevholm, 2013), which has raised questions regarding social justice and purposes of education (Nylund et al., 2017). As part of the reform, three alignments in mathematics were introduced: for vocational, social science-oriented, and natural science-oriented programmes. Before 2011, all students, regardless of programme, took the same first course in mathematics. In this paper, we look more closely at the mathematical content in the syllabi for the three alignments in the 2011 curriculum, particularly the algebra content in the first two courses for each alignment.[1]

Algebra is often referred to as a gatekeeper, not only to more advanced studies in mathematics and science (Blanton et al., 2015) but also to participating in society and gaining full access to civil rights (Moses & Cobb, 2001). At the same time, algebra appears to be a problematic topic for students in several countries (Hemmi et al., 2021). One reason for this may be that algebra has traditionally not been introduced until secondary school, creating a gap between arithmetic and algebra (Linchevski & Herscovics, 1996). However, in recent decades, research has repeatedly shown that students benefit from being gradually introduced to algebra already from the earliest grades (Blanton et al., 2015). These findings have slowly made their way into the educational system (Hemmi et al., 2021).

In Sweden, algebra has been a difficult topic for students to manage for many years (Hemmi et al., 2021). In the international evaluation TIMSS (Trends in International Mathematics and Science Study), Swedish students' results in algebra have been below international average since the 1960s (Bråting, 2021). Research has revealed that generalised arithmetic is virtually absent in the last three Swedish curricula for compulsory school (Bråting, 2021), and Swedish students have trouble understanding the different roles of variables (Kilhamn, 2014) as well as using the relational property

[1] Since the analyses conducted in this paper, small revisions have been made to the syllabi. The analyses in this paper are based on the syllabi that were valid until 30 June 2021.

of the equal sign (Madej, 2021). However, this research, like most of the recent Swedish research on algebra learning, was conducted at compulsory school level. Research on algebra learning at upper secondary level in Sweden is lacking, particularly since the 2011 reform. One exception is Gustafsson's (2019) thesis on upper secondary students' difficulties with algebra, revealing that students still struggle to understand the different roles of variables and the invisible multiplication sign in expressions such as 4x (see also Hewitt, 2012).

This study is part of a larger project exploring socioeconomic aspects of the didactic transposition of algebra in Sweden. In the present study, the focus is on the transposition of algebra from scholarly produced knowledge to the educational system (Chevallard, 2006). Hence, the study is theoretically embedded in the Anthropological Theory of the Didactic (ATD), where praxeology is used as an analytical tool. The aim is to unpack differences in how algebraic content is formulated in the syllabi for VET and HEP programmes, and to discuss how these differences may affect students' opportunities to learn algebra. In forthcoming studies, the focus will shift towards aspects regarding social justice and purposes of education. We pose the following research question: *From a praxeological perspective, what characterises the algebra content in syllabi for VET and HEP programmes and what are the main differences?*

A praxeological perspective on school algebra

The Anthropological Theory of the Didactic (ATD) is particularly useful for studying teaching content, such as school algebra, from an institutional perspective. It acknowledges that humans and human activity are involved in the teaching and learning process, that syllabi do not appear ex nihilo, and that the process is an "exogeneous production" (Bosch & Gascón, 2006: p. 54). In other words, the process is "something generated outside school that is moved […] to school out of a social need of education and diffusion" (ibid.). Within the ATD, this process is expressed in terms of the *didactic transposition*, which describes how (mathematical) knowledge is transposed between different institutions (Figure 1). The outcomes of the teaching and learning process depend on the humans involved in it – starting with scholars developing and determining the content at one end, and ending with the students' learned knowledge on the other (Bosch & Gascón, 2006). From this perspective, it is thus possible as a researcher to study a content from an unbiased position. In this study, we are interested in investigating the transposition of algebra from 'Scholarly knowledge' to 'Knowledge to be taught' (Figure 1). This corresponds to the algebra content developed by professional mathematicians, selected by the educational system, and transferred into so-called school algebra (Bråting, 2021; Hemmi et al., 2021; Kilhamn, 2014).

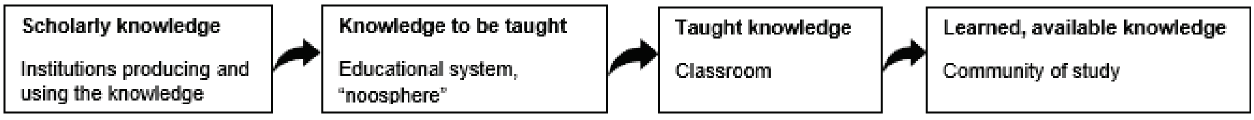

Figure 1: The didactic transposition from Bosch and Gascón (2006, p. 56)

To describe mathematical (indeed, any human) activity, ATD employs the notion of *praxeology* (Bosch & Gascón, 2006). Any praxeology is divided into two blocks: praxis ('know-how') and logos ('know-why'). The praxis block thus contains the practical part and consists of types of *tasks*, (mathematical) tasks or exercises to be done, and *techniques*, the method(s) connected to the type of task. The second block, logos, consisting of *technology* and *theory*, refers to human thinking and reasoning and is the 'explaining' part of the praxeology (Chevallard, 2006) (see Figure 2). The suffix -*logy* in technology indicates that this is a discourse on a given technique. This discourse is expected to justify the technique as a valid way of not only solving a particular type of task but also of clarifying the logic behind it. Theory can therefore be explained as an overarching theory or a set of underlying principles that justifies the technology (e.g. Chevallard, 2006).

PRAXIS	TASK
	TECHNIQUE
LOGOS	TECHNOLOGY
	THEORY

Figure 2: A model of the praxeology concept (Chevallard, 2006)

School algebra has been studied from an ATD perspective for many years. Summarising findings from such research, Bosch (2015) describes a situation in which a formal approach to algebra predominates, to the detriment of a functional view. In today's secondary schools, Bosch claims, algebra is largely identified with equation solving, and 'the language of algebra' is reduced to a formal structure whereby students are asked to manipulate algebraic expressions with little regard for what they represent. In contrast to this, she outlines a view of school algebra building on ATD principles, where it is instead interpreted as "a *process of algebraization* of already existing mathematical praxeologies" (ibid., p. 61, emph. in original). In other words, instead of being yet another piece of mathematical content, algebra appears as a general tool for modelling any school mathematical praxeology.

Method, material, and procedure

In this study, we have conducted a praxeological analysis of the syllabi for the first two mathematics courses in the national curriculum for upper secondary level in Sweden, Lgy11[2]. We view curriculum documents as indicative of the transposition from scholarly knowledge to knowledge to be taught (Figure 1); through this analysis we have been able to discern nuances in the written language and unpack implicit meanings behind the formulations in the syllabi, thus contributing knowledge of the transposition processes behind the algebra content in the upper secondary curriculum.

The first two mathematics courses in Lgy11 each have three alignments: a, b, and c, aimed at vocational (VET), social sciences-oriented (HEP), and natural sciences-oriented (HEP) programmes, respectively. In vocational programmes, Course 1a is compulsory and 2a is optional. In social sciences-oriented programmes, 1b and 2b are compulsory and 3b is optional (compulsory in economy). In natural sciences-oriented programmes, 1c, 2c, and 3c are generally compulsory, while 4 and 5 are optional (4 is compulsory in some programmes). The subject plan starts with an introduction to the subject and a formulation of aims. The syllabus for each course (1a, 1b, 1c etc.) consists of core content and knowledge requirements based on mathematical competencies. In this study, the sole focus of the analysis has been on the core content. This is organised in categories

[2] In the rest of the paper, we will use the abbreviation Lgy11 (Läroplan för gymnasieskolan [Syllabus for the upper secondary school], Swedish National Agency for Education, 2012).

written in bullet points, which constitute our unit of analysis. Before beginning the analysis, we extracted the algebra content from the core content, using Blanton et al.'s (2015) so-called big ideas of algebra consisting of I) variables, II) equivalence, expressions, equations, and inequalities, III) generalised arithmetic, IV) proportional reasoning, and V) functional thinking. The units of analysis containing algebra content were then classified in praxeological terms. Here it should be pointed out that Swedish school syllabi contain no explicitly formulated tasks, meaning that this part of the praxis block did not appear in the analysis.

In the classification, we made use of what we have called 'determining words'; that is, words that carry information on how the core content can be interpreted praxeologically. For instance, the core content in Course 1a regarding problem solving is formulated: "Strategies for mathematical problem solving including the use of digital media and tools" (Swedish National Agency for Education, 2012, p. 5). The word 'strategies' indicates an emphasis on different methods, which we interpret as *technique* (praxis). As another example, in the core content of Course 3b in the category 'Algebra', we find: "The concepts of polynomial and rational expressions, and generalisation of the laws of arithmetic for dealing with these concepts" (ibid., p. 27). The term 'concept' suggests that the teaching situation should offer a wider perspective on polynomials and rational expressions, i.e. to learn *why* they work. In learning a mathematical concept, definitions and underlying principles are conceivably offered, which we interpret as *theory* (logos). Contrastingly, the term 'generalisation' suggests drawing on established rules to justify new algebraic rules, and we have interpreted this as indicative of *technology* (logos).

Following the classification, the pieces of algebra content were sorted into tables with one column for each alignment. To help identify patterns in the content of the different courses and to recognise differences and similarities between the alignments, as a last step the praxeological 'determining words' were picked out and placed in a new summarising table. The analysis was done by the first author, but was discussed and reviewed by all authors throughout the process.

Results

We begin by presenting the results of the analysis of algebra content in all three alignments in the core content categories "Understanding of numbers, arithmetic, and algebra" and "Relationships and change". In order to be as transparent as possible, we provide the tables used in our analysis for Course 1 in both categories. Due to lack of space, the tables connected to Course 2 are not shown. In the following tables, green, purple, and yellow mark technique, technology and theory, respectively.

Table 1: The category 'Understanding of numbers, arithmetic, and algebra' in Course 1

Ma1a (VET)	Ma1b (HEP, social sciences)	Ma1c (HEP, natural sciences)
Handling algebraic expressions and formulae relevant in subjects typical of a programme, […]	Handling algebraic expressions and formulae relevant to subjects typical of programmes.	Generalisation of the rules of arithmetic to handle algebraic expressions.
	The concept of linear inequality.	The concept of linear inequality.
[…] as well as methods for solving linear equations.	Algebraic and graphical methods for solving linear equations and inequalities and exponential equations.	Algebraic and graphical methods for solving linear equations and inequalities and exponential equations.

As Table 1 shows, in the first category in Course 1 alignment *a* merely contains determining words indicating a focus on technique (praxis), whereas alignment *b* also contains wordings indicative of theory (logos). Words interpreted as indicative of technology (logos) were only found in alignment *c*. Furthermore, it is notable that the term 'generalised arithmetic' (technology) only occurs in alignment *c* (top right in Table 1) and that inequalities are only referred to in the HEP alignments.

Overall, Course 2 contains more algebraic topics in this category than Course 1 does. Some of the content focusing on praxis aspects is exactly the same in all three alignments, for instance certain methods for solving equations. However, the way linear equations are described differs between the alignments: While alignment *a* contains the phrase "use of linear equations in problem solving situations", in alignments *b* and *c* it is formulated as "the concept of linear equations". A similar distinction appears regarding logarithms: While alignment *c* introduces the *concept* of logarithms (theory), in alignment *b* the concept of logarithms is connected with *solving* exponential equations (technology). In alignment *a*, logarithms are not included at all.

Table 2: The category 'Relationships and change' in Course 1

Ma1a	Ma1b	Ma1c
The concepts of ratio and proportionality in reasoning, calculations, measurements, and constructions.		
Differences between linear and exponential processes.	The concept of a function, domain, and range of a definition, and also properties of linear functions and exponential functions.	The concept of a function, domain, and range of a definition, and also properties of linear functions and exponential functions.
	Representations of functions, e.g. in the form of words, shapes, functional expressions, tables, and graphs.	Representations of functions in the form of words, functional expressions, tables, and graphs.
	Differences between the concepts of equation, algebraic expression, and function.	Differences between the concepts of equation, algebraic expression, and function.

In the category "Relationships and change", wordings suggest a greater emphasis on logos compared to the previous one. This holds for both Courses 1 and 2, and for all three alignments. In Course 1, phrases indicative of technique (praxis) are only found in alignment *a* (in connection with ratio and proportionality; see top left in Table 2), while technology appears in all three alignments, either in the form of concepts in connection to specific techniques (in alignment *a*) or specific aspects of concepts, such as properties of or representations of functions (alignments *b* and *c*). Furthermore, in Course 1, a focus on theory can only be found in alignments *b* and *c*, in connection with the function concept. However, here it is important to emphasise that in alignment *a*, functions are not introduced until Course 2. The syllabus for Course 2a describes the function concept in almost the same way as in alignments *a* and *b*, except that "applications of functions" are added in Course 2a, indicating an emphasis on praxis. Finally, it is worth mentioning that in Course 2 the content regarding graph construction is phrased identically in all three alignments.

In Table 3 we have compiled all determining words found in the syllabi, and ordered them according to whether they are indicative of technique, technology, or theory. As the analysis revealed only small differences between the *b* and *c* alignments, in the table we have merged the two into the same column. In conclusion, Table 3 indicates that the praxeological organisation of the algebra content of the first two courses in the VET and HEP alignments differs in focus. The VET praxeology has a strong emphasis on praxis, while logos, in particular theory, is largely absent. The HEP praxeology, on the other hand, is more even in its emphases, with a fairly strong theoretical component.

Table 3: A compilation of the determining words that indicate technique, technology, or theory

	Ma1a	**Ma2a**	**Ma1bc**	**Ma2bc**
Technique	Methods Handling Strategies Calculations Solution of Construction Measurements	Methods Handling Strategies Use of Solving Construction Applications	Methods Handling Solving	Methods Handling Solving Construction Applying
Technology	 Reasoning Differences	Representations Reasoning Properties	Representations Properties	 Reasoning Properties
Theory	The concept	The concept Differences between concepts	The concept Differences between concepts Motivation Generalisation	The concept Differences between concepts Motivation Extension

Discussion

In response to our research question, through a praxeological analysis of the mathematics syllabi for the first two courses in the Swedish national curriculum for upper secondary school, we have concluded that the praxeological organisation of the algebra content in the VET alignment emphasises praxis (techniques), whereas the praxeological organisation in the HEP alignments is more evenly balanced between the praxis and logos blocks. However, although theory and technology (logos) are emphasised more in the HEP alignments, they are typically not connected to particular techniques. Indeed, connections between techniques and technologies are rarely explicit in the syllabi. The content regarding ratio and proportionality in Course 1a, generalisation of arithmetic laws in Course 1c, and complex numbers in Courses 2b and 2c are the only pieces of core content with formulations of technologies supporting techniques in the same core content. This lack of connection between technique and technology, as well as the limited role of theory in alignment *a*, makes it difficult to view the praxeologies outlined by the syllabi as complete, even allowing for the lack of explicit task formulations.

One of our main findings was that the praxeological organisation of school algebra in VET programmes syllabi emphasises several techniques, with little or no technology or theory justifying them. This resonates with the formal and technical approach that Bosch (2015) claims is characteristic of school algebra internationally: The 'language of algebra' is reduced to different techniques of equation solving and manipulation of algebraic expressions. It is not *per se* a problem that praxis is more emphasised in the VET programmes syllabi; given that the overall purpose of VET programmes is to act as preparational for the various future vocations, a more practical focus is needed. However, what is problematic is the inadequate connection between techniques and technologies in the core content. As technologies serve to justify the given techniques (see Figure 2), one apprehension regarding this – which is supported by Bosch's (2015) description of school algebra – is that the techniques are turned into mere 'recipes' for solving given tasks, without being grounded in knowledge of the underlying concepts. Such knowledge might, for instance, enable students to select the most efficient technique for solving a particular task. In the core content for HEP programmes, on the other hand, we saw more formulations that were only connected to the logos block (mostly theory), but with little or no connection to particular techniques.

As Gustafsson (2019), Madej (2021) and Hewitt (2012) have already stressed, students have difficulty understanding the meaning of different algebraic representations, such as the meaning of the equal sign and variables. From this study, we know that the algebraic knowledge to be taught at upper secondary level has a fairly insufficient organisation of praxis and logos, regardless of alignment. While it might be possible to build teaching situations merely around logos or praxis aspects of a concept, for a praxeology to hold and make sense, both aspects are needed, as "[praxis] entails logos, which in turn backs up praxis" (Chevallard, 2006, p. 3). Thus, one might ask whether the insufficient organisation observed in this study is connected to students' understanding of different algebraic representations, and whether the differences detected between alignments persist throughout the didactic transposition. Hence, as this small study focused only on formulations in the syllabi and not on students' knowledge, textbook content, or teaching situations, our next step is to examine how textbooks and teachers emphasise and organise algebra praxeologically. These forthcoming studies will also help us to dig more deeply into questions regarding social justice and purposes of education (Lindberg & Grevholm, 2013; Nylund et al., 2017).

Tinkering in algebra – the case of John

Cecilia Kilhamn[1]

[1]Gothenburg University, Sweden; Cecilia.kilhamn@gu.se

Finding a general rule for a figural pattern is a common type of task in early algebra, intended to enhance the ability to express generalization. In light of the incorporation of programming in school mathematics, this paper reports on one teacher's experience of using tinkering as a didactic strategy for patterning tasks, in comparison with a traditional approach. The discussion centers around possible benefits of integrating programming and algebra. An affordance of working with a computer program was that the general expression became relevant for the students and changed from being the end point of a patterning task to function as the starting point for mathematical tinkering.

Keywords: Algebra, figural patterns, computational thinking, programming, tinkering.

Introduction

The current world-wide incorporation of programming in school curricula (Brown et al., 2014; Mannila et al., 2014) raises questions of how these new ideas and technologies could enhance mathematics education. In Sweden, as in many other countries, *programming* has been included in the mathematics syllabus (Bocconi et al., 2018). Uniquely for Sweden, programming has also specifically been connected to algebra, although it is not a well-defined concept in the curriculum documents (Kilhamn & Bråting, 2019; Swedish National Agency of Education, 2018). Programming could be broadly interpreted as a pedagogical tool for developing students' digital competence and computational thinking, or in a narrow sense as a set of computer coding activities. Many Swedish teachers struggle to understand and shape what programming in school mathematics is and what it might be in relation to mathematics education (Kilhamn et al., 2021; Misfeldt et al., 2019). In this paper programming is seen in the broad sense, defining computational thinking (CT) in line with Aho (2012) as "the thought processes involved in formulating problems so their solutions can be represented as computational steps and algorithms" (p. 832). The aim of this paper is to contribute to a discussion about how algebra learning could benefit from programming activities and computational thinking practices such as tinkering. By describing a teacher's experience of a lesson on figural patterns based on tinkering with code, the paper seeks to induce a discussion in the spirit of Gadanidis et al. (2017), who write that "We need many more cases of what *might be* in mathematics and CT integration to better understand the role CT affordances might play in disrupting and improving mathematics education" (p. 94).

Figural patterns

Algebra is sometimes described as the study of structure, where algebraic thinking emphasizes relations and structure over processes. Hewitt (2019) defines algebraic structure as a combination of recognizable parts and recognizable patterns connecting the parts. Structure is important to discern in order to describe generalizations across and between specific instances. Patterning tasks, i.e. working with figural patterns, can be used to enhance students' sense of structure (Hewitt, 2019), and to promote students' understanding of functional relationships (Friel & Markworth, 2009). In this paper, figural patterns are seen as a way into generalization.

A traditional teaching trajectory for patterning tasks starts with a figural pattern where the first three figures are visually exposed. The students are then asked to find the number corresponding to the next figure, then perhaps to figure number 7, then 10, then 20, then 100. Typically, students insert the numbers in a table to find a functional relationship between a figure number and the total number of elements in the figure, and finally write a general expression for figure *n*.

This teaching trajectory has been widely reported in research literature (e.g. Blanton et al, 2015; Kieran, 2018). Some researchers stress the importance of drawing (Friel & Markworth, 2009) or using words and gestures (Radford, 2014) before symbolizing. However, sometimes the teaching trajectory quickly moves away from the visual figures into a table of values, where a total number of elements for each figure is calculated and students are asked to look for patterns in the table. Hewitt (2019) describes the danger of students losing touch with the context of the figural pattern by spending time calculating and looking at the table of values created from the figures. In order to see structure, he suggests students should stay focused on the figures and avoid doing the arithmetic, since the total number hides the structure that reveals the generalization. He argues that “learners should never do any arithmetic, just write down the arithmetic they would do”(ibid, p 563). El Mouhayar (2018) showed that students who focused on numbers were more likely to take a recursive approach, going from one figure to the next, whereas Strømskag (2015) found that students who stayed within the figural context more often found a general expression

In contrast to the traditional learning trajectory for figural patterns, a more challenging problem could be to present a pattern and ask for the figure number of a large number of parts. One such problem about a matchstick figure, taken from TIMSS07, was used in a study of problem solving in small groups (Kilhamn, 2012). When the study was presented at a conference in Cambridge, participants in the audience criticized the problem, advocating instead the traditional step-by-step instruction described above, claiming it to be the ‘right way to teach patterns’. The reaction pinpointed the fact that this type of instruction is a well-established didactic strategy. However, as the case of John presented below will show, it may not always be the most prosperous strategy.

Computational thinking and tinkering

Computational thinking (CT) is a fairly new concept in educational research, first introduced by Papert in 1996. The term involves the kind of thinking skills needed to understand and capitalize on digital technology, and practices used by programmers. In recent years, researchers in computational science as well as mathematics education have attempted to define CT or create frameworks that describe it (e.g. Aho, 2012; Grover & Pea 2013; Kotsopoulos et al., 2017). One of several commonly accepted elements of CT is pattern generalization (Grover & Pea, 2013), which is also an important ingredient in algebraic thinking. In this paper we will focus on the practice of tinkering brought up more or less explicitly in all CT frameworks.

Dictionaries often define tinkering as the act of improving something by making changes to it, and a tinkerer as a person who enjoys experimenting with and repairing machines. In a CT perspective, tinkering experiences promote engagement in changes and modifications of existing objects (Kotsopoulos et al., 2017). Brennan and Resnick (2012) describe several CT practices such as testing, debugging, reusing and remixing, that could be seen as aspects of tinkering. Tinkering involves exploration, modification and reflection, it is about trying, adjusting and trying again. Fundamentally, it builds on learning from failures, turning mistakes into triumphs in the spirit of Thomas Edison, who is said to have uttered “I have not failed, I have just found 10 000 ways that won’t work”.[1] In mathematics education, tinkering could mean to explore a mathematical idea or mathematical relationship by making small and purposeful changes and reflecting on these. It is not the same as a guess-and-check problem solving strategy, since the main objective when tinkering is not to find a correct answer but to explore and change something already present. In a description of a teaching intervention in a Grade 6-7 algebra class, Boaler and Sengupta-Irving (2016) used the term *mathematical tinkering* to describe how the students played around with a problem and its solution, going beyond the problem at hand to explore the effect of small changes, challenging themselves to make the problem harder.

Method

The case study presented here emerged from a larger set of data collected when studying the transposition of knowledge that followed the recent inclusion of programming into school mathematics in Sweden (Bråting et al., 2021). A research question for the larger study was: *What opportunities, challenges and pitfalls related to the learning of algebra can be identified in the didactical choices teachers make when implementing programming in mathematics?* Interviews were initially made with 20 teachers identified as early adopters (Kilhamn et al., 2021). They were all enthusiastic about the challenge, had some previous experience in teaching programming, and many were responsible for implementation of digital technology in their schools. The audio recorded interviews took approximately 30 minutes and were semi-structured around questions that had been supplied in advance. Following four background questions the interview guide included the following topics: What is the role of programming in mathematics? Where do you find inspiration and ideas? Can you give an example of a good programming activity that you have tried? What programming concepts are important to bring up in mathematics?

Many of the teachers described programming activities with little connection to mathematics, and when there was a mathematics content, it was most commonly geometry, arithmetic or probability. One teacher was different in that he said he tried to incorporate some Python programming into every topic, in almost every lesson. When asked to describe a good lesson he chose an algebra lesson. He claimed that the incorporation of programming had changed his teaching and created better learning opportunities for his students. His story is reported here as the case of John.

The case of John

The interview with John was made in October 2019. John had by then been teaching mathematics, science and technology in grades 7-9 for over 25 years. In 2017 he was appointed head teacher with a specific responsibility to coach his colleagues in the use of digital tools and programming, mainly in technology. In mathematics he used an interactive whiteboard, but struggled to find ways to engage students in programming activities that were compatible with the mathematics curriculum. In 2018,

[1] https://www.goodreads.com/author/quotes/3091287.Thomas_A_Edison

when programming was officially included in the mathematics curriculum, he started to use the net-based platform Google Collaboratory, coding in Python. John described a lesson about figural patterns in Grade 7 (students' age 13), claiming that it was the first time ever that his students truly engaged in finding a general expression for a pattern. When he started working with these students two months earlier, they had no previous coding experience through school. Every student in his classroom has a personal laptop, so he can use the platform both in class and for homework, where he can see what the students do, give personal feedback and pick up student solutions for whole class discussions. John's ambition is to get students into the habit of using Python code every lesson so that they become accustomed to programming, learning syntax through experience more than direct teaching. John stood out from the other early adopters in that he included programming in almost every content topic, rather than making it a topic in itself. He said he did not teach programming per se, but he told his students to use programming, treating it as a mathematical tool. Typically, he would give them an example code to tinker with and modify. In addition to the interview, python codes as well as written reflections that John shared with his colleagues were collected.

The lesson

Below, the lesson is described in three parts and analysed in relation to aspects that were in some way different from the traditional teaching trajectory on figural patterns described above.

Part 1: Introducing the general expression

During the previous lesson, the class had worked with a figural pattern where a number of markers in a figural arrangement increased by three for each figure, starting with five. They had explored and discussed what features of the pattern were important in order to find a general expression: change and starting number. Together they now wrote the following basic code in Python, which everyone copied into their personal computer and tried out.

```
figure_number = int(input("What figure do you want the number of markers for? "))
number_markers = figure_number*3 + 2
print("Figure number ", figure_number , "has ", number_markers, "markers")
```

The code gives a sequence of instructions that computes and prints the figure number and its corresponding number of markers. John expressed that he did not expect all students to comprehend the code in detail, but for this part of the lesson it was enough to copy the code and run it to confirm that it worked for that pattern. John wrote the following reflection: "Many students found this difficult and did not seem to see the benefit of this program. The next step is to get the students to program."

Part 2: Transferring to other patterns

In contrast to a standard lesson where the general expression for the pattern comes at the end, the programming activity used the general expression as the starting point for exploration through tinkering. After introducing the above piece of code, the students worked with similar figural patterns presented as tasks in their textbook, all visual configurations of growing patterns with linear solutions. The students were encouraged to make use of the code they had produced but with access to sticks and markers if they needed. All students chose to work with the code. When they knew that one pattern was described by `figure_number*3+2` they could start to tinker with the expression to explore the effect of small changes. A further challenge came when the question was posed the other way around, for example “what figure number would need 64 sticks?” The code did not produce the answer and needed to be modified. John explained:

> “Then I showed the class how to modify this code so that instead of asking for a certain figure it prints the first 50 figures with the number of sticks in. And then you can see that: ‘Well there are 55 sticks in figure number 17’. And this – when they suddenly saw – they had it all there! It was like ‘wow’ they could do anything, all information was there in this table that was printed.”

In this section of the lesson the power of the computer was put to use, so that patterns could be investigated using larger numbers and more data without having to do all the calculations. The students discussed large numbers and compared different outputs. The most confident students started to think about what needed to be changed in the code to get the inverse operation instead.

Part 3: Homework assignment

Finally, John assigned the following task as homework:

Make a program that calculates the number of white squares in the following pattern. The program should ask what figure you want to know the number of white squares for, and then show you the result. If you want, you can modify and improve the program.

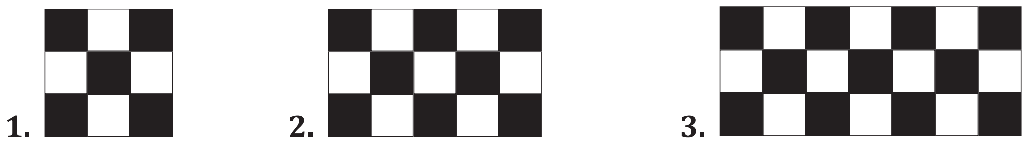

Figure 1: Figural pattern used for homework: the first three figures.

All students managed to solve the task although the pattern on surface value looked quite different from previous patterns. Many explained that they had copied the original code and tinkered with it until they got the correct result when they ran it (`figure_number*3+1`), checking with the given Figures 1–3. Some modified the code, adding features. Some came up with quite different solutions, with more or less efficient codes. Others came up with creative expansions, such as making a loop that kept asking for another figure number or commands that could handle an invalid input.

In the interview, John expressed that his students better understood the importance of finding the formula for a pattern because it is used in the program. It was the first time he saw that students found the general expression useful. In traditional patterning tasks many students would do the arithmetic for the first three figures and perhaps a few more, but they would lose interest before they got to the general expression, not seeing the point of finding it. Now they were dazzled with what the computer could do once they inserted the expression and were curious to see what happened with the numbers produced when small changes were made. It was, John noted, easier for them to relate to the figure *n*, because it was there, in the program, with the descriptive name `figure_number`.

Discussion

The case of John brought out several possible affordances of introducing programming when dealing with figural patterns. One was that students, as suggested by Hewitt (2019), could explore the pattern without doing a lot of arithmetic. In fact, the power of using a computer code to do the arithmetic enabled students to look for patterns in larger numbers and to find structure in a table with many more entries. Iteratively moving back and forth between the code, the printed output and the original pattern figures enhanced students' focus on structural aspects of the pattern while downplaying arithmetic procedures. However, according to John, the main benefit had a more psychological character addressing the fact that students found the general expression relevant and useful as a way to communicate with the computer. Instead of being the end point of the task, as in traditional patterning tasks, the expression became a starting point, something to tinker with that sparked curiosity. Furthermore, the expression became more visible and made more sense when the variable was represented by a descriptive word, not as the abstract letter *n*. This could potentially be a useful intermediate step before dealing with variables in symbolic algebra, well worth further investigation.

Tinkering proved to be a valuable practice for these students when looking for a general expression for a pattern. The algebraic question "What is the general expression for the *n*th figure of the pattern?" changed into a computational question "What do we need to change in the command given to the computer so that it describes or generates the pattern?", leading up to questions about the effects of different changes made in the code. While this is in line with how Aho (2012) defines CT, it also uncovers opportunities for students to rise to yet another level of generalisation that further develops their algebraic thinking, namely that very different patterns can be described by the same or a similar algebraic expression. Tinkering, or what Brennan and Resnick (2012) describes as reusing and remixing predefined code, empowered students to see similarities between patterns with quite different surface features.

Another benefit was the opportunity of expansion, providing more challenge for students who needed it. Many of the students in John's class started posing new questions, such as what to do if the input is invalid or how to write the code so that the figure number is the output when the total number is the input. Furthermore, it would be possible to tackle the pattern the other way round by asking students to change the expression in the code slightly and then try to create a pattern to match the new expression and the numbers printed when the program was run.

The various affordances of programming in John's algebra lesson suggest that we should be open to the use of programming is school mathematics. Further design research with lessons like this would therefore be valuable. However, a teaching approach that involves tinkering with code is only possible when the teachers' coding proficiency is high, otherwise the work is bound to get stuck on syntax issues. This case study describes a teacher with many years of experience and good programming skills, which is not always the case. Much work is still needed to help teachers develop necessary programming competence (Kilhamn et al., 2021; Misfeldt et al., 2019), but in the meantime teachers could embrace a tinkering approach to teaching and start using mathematical tinkering, in the sense of Boaler & Sengupta-Irving (2016), for mathematics in general and patterning tasks in particular.

Why not let the lesson start with an intricate algebraic expression, perhaps graphically represented using dynamic software, and then explore what happens when small changes are made?

Students' ideas about variables as generalizers and unknowns: Design Research calling for more explicit comparisons of purposes

Stefan Korntreff [1] and Susanne Prediger [1,2]

[1] TU Dortmund University, Germany, [2] IPN Leibniz Institute for Science and Mathematics Education, Kiel/Berlin, Germany; stefan.korntreff@math.tu-dortmund.de,

prediger@math.tu-dortmund.de

Students' challenges with variables are well documented. Although instructional approaches have been developed to support students' conceptual understanding of variables as generalizers, many students confound variables as generalizers (e.g. in generalization activities) with a second meaning, variables as unknowns (e.g. in equation solving activities). In our design research project, we developed a teaching learning arrangement in which both meanings could be constructed. The design experiments reveal first qualitative evidence that students were able to construct both meanings, but only some students developed explicit awareness of the distinctions of meanings. This calls for more explicit comparison activities with a focus on different algebraic activities and their underlying epistemic purposes, as well as the development of a meaning-related language in which students can express both meanings.

Keywords: Variables as generalizers, variables as unknowns, variation principle, learning from comparison, design research.

Theoretical background

Learning from comparison has proven effective in many contexts for raising awareness of critical differences (Alfieri et al., 2013). In our design research study, we use this design principle to increase students' awareness about critical differences between meanings of the variable (Usiskin, 1988; Malisani & Spagnolo, 2009). The research question for this paper is: *Which ideas do students articulate about variables as generalizers and as unknowns and how do they compare the conceptions?* The qualitative case of a larger design research study reveals that not only local meanings, but also underlying epistemic purposes need to be compared. We outline the theoretical background, the design principle and the methodological framework, before unfolding the case of two students.

Variables as generalizers and unknowns

The concept of variable lies at the heart of most algebraic activities, yet various studies reveal many students' difficulties with understanding variables in all their meanings (e.g., Malisani & Spagnolo, 2009; Küchemann, 1981). Whereas the meaning of *variables as unknowns* (a fixed set of hidden numbers that have to be disclosed, e.g. in equation solving activities) seem to be constructed more easily (Küchemann, 1981), the meaning of the *variable as a generalizer* reveals a critical obstacle in many students' understanding of the variable (Bardini et al., 2005; Malisani & Spagnolo, 2009). The conception of the *variable as generalizer* draws its relevance from generalization activities, in which the variable is used to express general relationships without any further specification of the numbers for which they apply (Usiskin, 1988).

Although various instructional approaches were established to enhance students' conceptual understanding of the variable as generalizer, students still tend to confound the two conceptions of variable as unknown and as generalizer, even after going through these approaches (Bardini et al., 2005; Prediger & Krägeloh, 2016). At least three reasons can be identified for these confoundations of conceptions: *First*, variables as generalizers and as unknowns share crucial similarities on the surface. Both represent numbers, both are signified by letters, and the same syntactical operations can be performed with them during algebraic transformations. A *second* reason for these confoundations was identified in the unprecise language by which students express their ideas about variables (Prediger & Krägeloh, 2016). Generalization activities require certain phrases to *think* and express generalizations (see Table 1). Hence, to allow students to grasp relevant differences in meanings, contrasting relevant phrases might be useful. *Third*, students do not seem to be aware about the different natures of the algebraic activities in which they are used. They naïvely assume that all variables are used in problem solving activities, in which a variable denotes a hidden number, which has to be disclosed by solving an equation and, thus, assign this meaning also to variables in generalization activities. As Bardini et al. (2005) showed, many of these students impose the meaning of unknowns to the generalization activities by interpreting them as a "*temporally indeterminate number* whose fate is to become determinate at a certain point" (p. 129, emphasis in original). That means, students use variables in activities, which require a generalizer, but act as if they were disclosing unknowns.

Table 1 summarizes similarities and differences of the two conceptions that are potentially overlooked by students. Other authors (Usiskin, 1988; Bardini et al., 2005; Prediger & Krägeloh, 2016) have already identified the surface level, the meanings and the algebraic activities as crucial for students' understanding. Additionally, the underlying epistemic purpose (i.e., what kind of knowledge gain is intended by its use) became apparent during our empirical analysis. Thus, the last row serves as an advance organizer for the later analytical outcomes.

Table 1: Similarities and differences of variables as generalizers and unknowns (of increasing depth)

	Variable as generalizer	**Variable as unknown**
Similarities on surface level	Both represent numbers Both are signified by letters and are object of equal syntactical operations	
Differences in meanings in examples (Küchemann, 1981)	Variable stands for all possible numbers of a relevant domain (e.g., in equality 3 (x+5) = 3x + 15)	Variable usually stands for a (concrete set of) hidden number of a relevant domain (e.g., in equation 3x+5 = 13)
Meaning-related phrases for expressing the meaning (Prediger & Krägeloh, 2016)	An arbitrary number, always a different number, the number always changes, …	The number we are looking for, number is already fixed
Differences in underlying purposes		

Algebraic activity (Usiskin, 1988)	Generalization activities in which variable is used to express general relationships	Problem solving activities in which variable is used as a hidden number that needs to be disclosed
Epistemic purposes (Usiskin, 1988, Bardini et al., 2005)	One wants to express that no further determination of an algebraic statement is needed – there is nothing more to know	One wants to express that something is not yet known, but shall be known in the future

Design Principles: Creating Rich Experiences and Learning from Comparison

The presented research is embedded in a larger design research project (Gravemeijer & Cobb, 2006) that aims at designing a teaching-learning arrangement to enhance students' conceptual understanding of variables as generalizers and as unknowns and at developing an empirically grounded local instruction theory. Here, we focus on sequences in which student explicate the meanings and the purpose of variables, first in rich experiences with generalization and problem solving activities, and later in reflective sequences by the design principle of learning from comparison.

Learning from comparison has proven to be effective in different domains for increasing students' conceptual and procedural knowledge and awareness (cf. meta-analysis by Alfieri et al., 2013). When comparing different uses of a concept or procedure, students have been shown to detect relevant structural features, and to learn to distinguish them from irrelevant surface features (ibid.). In algebra education, learning from comparison proved effective for increasing students' flexibility with different solutions procedures, in particular the Chinese Bianshi tradition also applied it for conceptual learning, e.g. for geometry concepts (Guo & Pang, 2011). Here, we adapt it for our purpose of raising students' awareness for the difference in meanings between generalizer and unknown.

This adaptation is not self-evident as conceptual differences of the generalizer and the unknown seem to lie especially deep, because their meanings ground in different underlying purposes which seem to be confounded by the students (Table 1). Thus, the differences of these two meanings of variables cannot be reduced to pointing out relevant definitional features and contrasting them. In addition, language challenges can be expected in the design experiments (Prediger & Krägeloh, 2016).

Methodological framework of the design research study

Design experiments as method of data gathering

In this paper, we focus on snapshots of students' ideas when *learning from comparison about variables as generalizers and unknowns* in a first design of a teaching-learning arrangement that engages students in generalization activities as well as informal equation solving activities. The data was gathered in design experiments in an online setting, taught by the first author of this paper. For each of the six pairs of students (n = 12) with varying mathematical prior knowledge, usually 4-5 sessions were conducted. In total, 33 hours of video were recorded and partly transcribed. This paper focuses on the case of two girls from a German-speaking school for higher tracked students: Anna (Grade 7) was a high achieving student who had not encountered variables signified by letters in her formal education before. Nora (Grade 8) already worked with variables in various algebraic problems (transforming expressions etc.), but Nora's teacher considered her in need to refresh and deepen her understanding of variables.

Methods of data analysis

For the qualitative analysis of students' ideas about the variable as generalizer and unknown, the transcripts were segmented and situations were selected in which students explicitly related the two meanings of variables to another. Then, we applied an open coding procedure to code students' utterances with respect to their ideas about main differences and similarities, starting from codes in Table 1. The last line of Table 1 emerged during this coding procedure.

Empirical insights into students' ideas about generalizers and unknowns

Anna and Nora's understanding of the variable as generalizer

In the first three design experiment sessions (of 90 minutes each), Anna and Nora receive rich possibilities to engage in generalization activities in the context of an e-scooter rental (0.15 € per minute riding time, 1 € to unlock the scooter). The students conduct repeated calculations in the table in Figure 1 and discover that variables can represent all relevant numbers. In Session 1 after filling the table, the teacher asks for an explanation:

Date of e-scooter ride	Driving time (in minutes)	Costs for pure driving time (in Euro)	Expression for complete costs (incl. 1 € unlock)	Total price (in Euro)
May, 16	20	20 x 0.15	20 x 0.15 + 1	4.00 €
May, 19	12	12 x 0.15	12 x 0.15 + 1	2.80 €
May, 24	27	27 x 0.15	27 x 0.15 + 1	5.05 €
May, 25	18	18 x 0.15	18 x 0.15 + 1	3.70 €
General	x	x x 0.15	x x 0.15 + 1	Not calculatable

Figure 1: Table for re-inventing variables as generalizers in e-scooter context

1.601 Teacher: Um, now we have written *x* there suddenly. What does the *x* mean in this calculation? Can you explain that?
1.602 Nora: Um, that is an *x*-arbitrary number.
1.603 Teacher: Mhm, and what does that mean, "*x*-arbitrary number"?
1.604 Nora: Uh, that every number can stand there.
1.605 Teacher: Mhm, very nice. Anna, any extensions?
1.606 Anna: Yes, *x*-arbitrary just means that only this one number in this calculation, which is represented by this letter x, though, can be every number. This number, 0.15 or 15 Cent, they are not changeable, they stay always. Only *x* is changeable […].

Nora describes the meaning of the variable as generalizer by "*x*-arbitrary number" and "every number", which does not necessarily guarantee that she has firmly grasped the idea of a variable as an indeterminate generalizer for generalizing expressions (as the analysis of comparable cases in Prediger & Krägeloh (2016) reveals). In Turn 1.606, Anna compares the changeable nature of *x* with the unchangeable nature of constants and thereby implies that the variable represents different numbers. Later on, Nora also expresses her understanding by describing that different driving times influence the total cost of the ride:

1.649 Nora: […] if one drives 10 minutes now, then it is cheaper, as if one drives 20 minutes.

Anna and Nora's understanding of the epistemic purpose of the generalizer

Even if both girls have built a solid understanding of the meaning of the variable as generalizer, their ideas substantially differ when asked to explain the purpose of describing situations with variables:

2.029 Teacher: So, why do we do that, writing down such a general expression [with variables]?
2.030 Anna: Yeah, to represent, not so much to know a total price in Euro. Rather, for representation. Okay, um, this information here, the 0.15 and the 1, these are fixed numbers which stay like this in every calculation, but the *x*, this is the changeable, variable number.
[…]
2.034 Nora: I don't know. Maybe if one calculates this mentally, and then one forgets it, one has to start from the beginning. And here, one has written it down?
[…]
2.039 Teacher: But what is the advantage if I […] remember this expression [*points at* $33 \times 0.15+1$] or this one [*points at* $x \times 0.15+1$]? So, what is the difference?
2.040 Nora: Uh, that for the one below [*refers to* $x \times 0.15+1$] we don't know how long he was driving, and then, we actually don't have to calculate it.
2.041 Teacher: […] Anna, any extensions?
2.042 Anna: Yeah, then one just has to look: Okay, I know for sure that the 0.15 and the 1 stay. Thus, I only have to look which information *x* has been in this calculation. And this would be 19, for example. Then I only have to look: Okay, 19, and then I can calculate again.

In Turn 2.030, Anna describes the purpose of using variables (represented by letters) from a representation perspective: Variables represented by letters allow to differentiate between changeable and constant numbers in a series of similar calculations. Nora, in contrast, points out in Turn 2.034, that algebraic expressions with letters give relief to one's memory capacity. Anna takes up this idea in Turn 2.042 and further develops it into explaining the purpose typical for formulas: Algebraic expressions establish a general sequence of calculations, which guarantees the determination of a number depending on another number. Thus, Anna articulates a purpose that is typical for a "calculator's mind" (Radford, 1996, p. 50): one formula can substitute many similar calculations. In sum, Anna assigns two purposes to variables as generalizers: (a) It signifies the changeable numbers and therefore distinguishes them (visually) from constants, and (b) it allows to establish a formula, which reduces complexity for the evaluation of new numbers.

For Nora, Turn 2.034 does not yet provide evidence that she also thought about Anna's purpose (b) or simply referred to the general idea that written language allows to relief memory capacity. However, in Session 3, after extensive work in a spreadsheet environment, she gives the following answer when asked to describe the use of the variable in algebraic expressions:

3.752 Nora: So that we can use the formula for every single number and immediately know how much the solution is.

Thus, at latest the work in the spreadsheet environment allowed Nora to establish the perspective of the calculator's mind and to express Anna's purpose (b). Yet, there might be a crucial difference between Anna and Nora concerning the *epistemic purpose* (i.e. the intended knowledge gain) with which they use the variable. For Nora, the immediate knowledge of a solution seems to be the main intention to establish a formula using variables. Thus, she ascribes an epistemic purpose to generalizers that is more typical for unknowns, namely that the variable needs to be known in the future (Bardini et al., 2005). In contrast, Anna explicitly articulates in Turn 2.022 that the calculation of "a total price in Euro" is not the main goal. Anna's idea (a) allows her to see that the algebraic expression has a function beyond quick calculation and the reduction of complexity, namely to contrast changing quantities from constants. This suggests that Anna is aware of the crucial epistemic purpose of the variable as generalizer, namely to see the variable not just as a temporal misfortune that needs to be overcome at a certain point (Bardini et al., 2005), but as something that has a value in its own right.

We infer that for these students (and also other students in our design experiments) the understanding of generalizers needs to be expressed also by the underlying epistemic purposes for the use of variables. Therefore, epistemic purposes can reveal subtle but important differences in students' ideas.

Nora's struggle to compare the generalizer and the unknown

In Session 4 of the design experiment series, Nora and Anna are engaged in problem solving activities in which they had to find unknown numbers. For example, they find the unknown price per minute x by informally solving the formal equation $x \times 11+1 = 3.20$ that identified two descriptions of the total cost of an e-scooter ride, namely one as a general algebraic expression and the other as a concrete price. Nora manages to interpret both sides of the equation as the total cost of the ride and she also describes the differences of these two descriptions as follows: "one is the total costs in a calculation and the other is the sum of the total costs" (Turn 4.133). Yet, when the teacher points out a difference between x in the general expression $x \times 11+1$ and in the equation $x \times 11+1 = 3.20$, Nora struggles:

4.136	Teacher:	[…] If I only have the expression [*writes* $x \times 11+1$], Nora, and it stands for the total costs, does it always result in 3.20?
4.137	Nora:	Um, no, because the x, it can be replaced by any arbitrary number.
4.138	Teacher:	Okay, very nice. And here, what is it like [*points at equation* $x \times 11+1 = 3.20$]? What does x stand for, here?
4.139	Nora:	Um, what [what do you mean]?
4.140	Teacher:	Okay, does this x still stand for all numbers, somehow arbitrary numbers, like you have said before?
4.141	Nora:	Yes? [*hesitant, asking*].

Afterwards the teacher checks again if Nora really believes that x in the equation $x \times 11+1 = 3.20$ still represents any arbitrary number, and Nora again confirms this. It seems that Nora struggles to give the letter x a different meaning than that of an arbitrary number, even though she has profound experiences with tasks on disclosing unknowns from her previous classroom experiences and from the task just solved. For example, she found one concrete number that solves the equation, interpreted this number correctly as the driving price per minute, and, furthermore, in Turn 4.137 explicitly stated that the expression $x \times 11+1$ does not always equal 3.20. Hence, for Nora it is not at all obvious that letters need to be reinterpreted in certain algebraic situations.

A possible explanation for Nora's struggle to reinterpret the letter is that she acts like the students observed by Bardini et al. (2005) and understands it as a temporal generalizer that eventually needs to be disclosed (e.g., by transforming the equation to get a solution). Hence, for Nora the determination of an unknown number is part of the *epistemic purpose* that she connects with letters that represent any arbitrary number. If this explanation of Nora's struggle is accurate, it shows that she could profoundly profit from a more explicit comparison of the generalizer

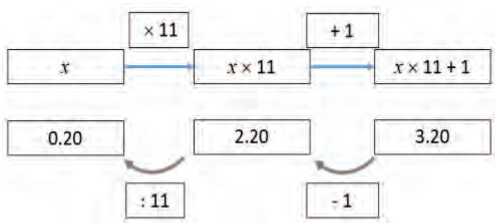

Figure 2: Working backwards for informally solving x × 11 + 1 = 3.20

and the unknown, not only comparing their meanings, but also their purposes, attached to their use in generational and problem solving activities.

Anna's intuitive comparison of the epistemic purposes of generalizer and unknown

In Session 5 of the design experiment series, Nora and Anna are again engaged in informal equation solving activities in which they have to find unknown numbers by undoing, i.e. working backwards in arrow schemes (Figure 2). During a discussion about how the arrow scheme has to be interpreted, Anna provides exactly the comparison of epistemic purposes that Nora needed:

5.101 Anna: If I had to describe this by and large, these are two different cases. One is someone who may have to do this calculation several times, because he is somewhat like a salesman or something and has different prices per minute [*x represents the price per minute in the expression* $x \times 11+1$] […]. Then of course such a calculation [$x \times 11+1$] is a good idea, because one can then simply always insert the x, right? So, whether it is 0.1, or 0.2 or 0.3.
And the other one is someone who might want to know exactly, uh how - why am I paying 3.20 now? So, he calculates backwards again, looks, uh, what price is coming from where, how is it put together?

In this remarkable statement, Anna describes the upper and the lower part of the arrow scheme as two different cases which represent different meanings of the variable. She explicitly compares the different epistemic purposes of the generalizer and the unknown: For the generalizer, she refers to the calculational ease that comes along with a formula – her purpose (b). Moreover, she enriches it by a meaningful story in which a general expression by means of variable is a "good idea" in itself. Hence, it is quite likely that Anna again uses the variable with the epistemic purpose typical for the generalizer. For the unknown, in contrast, Anna constructs a scenario where someone wants to know a certain unknown quantity. Thus, she explicates the typical epistemic purpose of the unknown.

Discussion and Outlook

In this paper, we investigated which ideas students articulate about variables as generalizers and unknowns before and when being prompted to explicit comparisons. As the presented case study indicates, prompting students to compare the different conceptions of variables seems to be a fruitful approach to explore and develop students' ideas about variables. In the case of Nora, for example, such a comparison-prompt revealed her difficulties in switching from one conception to another. The analysis revealed that Nora's difficulties with confounding meanings might be explained by a misunderstanding located in the purpose that she attributes to the variable as generalizer: Her understanding of the generalizer still used the epistemic purpose of the unknown, namely that variables are only temporally indeterminate and shall be disclosed in the future (Bardini et al., 2005).

From these observations (in the case of Nora and other students in our sample), we infer that the level of comparison should be deepened: *not just the meaning* of generalizer and unknown need to be compared to gain an elaborate and distinctive understanding of these two conceptions, but also the different *underlying epistemic purposes of their use in two different algebraic activities* (what resonates with the epistemological analysis by Usiskin, 1988). The case of Anna showed that some students intuitively compare the epistemic purposes by themselves. Interestingly, Anna embedded such comparisons in everyday scenarios that made the different algebraic activities and the underlying purposes accessible for her. Since the explication of epistemic purposes proved to enhance the students' deep understanding of the conceptions of variables, we will incorporate this focus of comparison in future design experiment cycles.

In sum, this case study underlines and explicates the diagnosis of Bardini et al. (2005) that students' understanding of the meaning of variable depends on their deep lying ideas about the algebraic activities in which the variable is used, and we add an explicit awareness of the epistemic purpose of this use. Therefore, it seems that a reflection on the purpose of different meanings of variables and, thus, a comparison of different algebraic activities as presented by Usiskin (1988) could also be promising to foster students' understanding of variable.

Norwegian and Swedish student teachers’ explanations of the solution of a linear equation: A qualitative approach

Niclas Larson

University of Agder, Norway; niclas.larson@uia.no

Keywords: Linear equation, explanation, student teacher.

The purpose of this study is to explore how student teachers explain the solution to a linear equation. Previous analyses with a quantitative approach have reported what aspects the participants included in their explanations (Larson & Larsson, 2021), applying a set of low inference codes developed by constant comparison (Andrews & Larson, 2019). This report focuses qualitative aspects in these explanations. The participants were 146 Norwegian and 161 Swedish student teachers for compulsory school. They were given a correct but deficit three step solution to a linear equation:

$x + 5 = 4x – 1$; $5 = 3x – 1$; $6 = 3x$; $2 = x$

The participants were invited to explain the solution to a fictive friend, who was absent when the topic was introduced to the class. The analytic tool (Andrews & Larson, 2019) included codes of how the operations in the solution were explained, and ‘explanatory codes’ identifying e.g. if the student teacher clarified that the purpose of solving an equation is to find the value of *x*, and that you in the solving process want to separate unknowns from knowns. The quantitative analyses showed that less than half of the participants clarified that the purpose of solving an equation is to find the value of *x* (the code ‘conceptual objective’), while a majority explained that you want to separate unknowns from knowns in the solving procedure (‘procedural objective’). Even though previous reports revealed relevant results, including differences between the two countries (Larson & Larsson, 2021), quantitative analyses produce only rough descriptions of the participants’ replies. If a script was coded as ‘conceptual objective’, there might still be differences in how this was expressed. Identifying such differences requires a qualitative approach, where the wording that yielded a specific code is scrutinised. The purpose of this report is to highlight some initial results from this qualitative analysis.

Conceptual objective

This code deals with the purpose of solving an equation, that is to find the value of *x*. Since the task was to explain how to solve the current equation, it is a strength if the purpose of the solution was stated early in the reply. One good example is a script that was well organised in bullet points. The first point said: “When you want to solve an equation, you want to find the value of *x*.” This immediately enlightened the purpose of the solving process for the fictive friend or a potential student. Two other examples were: “In the task above we want to find the answer to *x*. That is what number *x* is.” and “Here, we have to find out which *x*-value makes the equation work out and the values of each side to become equal.” Despite the wording in the former excerpt might not be the best, it still explains that the purpose is to find the value of *x*. That is also true for the latter, which in addition mentions the balance property of an equation.

The excerpt “*x* is a variable we want to find out.” includes the notion of variable. It might, however, be unclear because it does not explain what it means to ‘find out a variable’. This also applies to the student teacher who as first sentence wrote “What is sought is the symbol ‘*x*’.”, and later in the script wrote “To get *x* …”. These excerpts deal with the purpose of solving an equation, but the descriptions are imprecise and might not help a student who does not already know what it means to ‘get *x*’.

An example of lower quality is where the ‘conceptual objective’ first is mentioned in the last assertion, after several operational steps: “We do <u>not</u> wish to be left with $3x = 6$, we wish to be left with how much $\underline{x}$ is. That is $x = 2$.” Despite this is a fair explanation of the last step, the reply does not provide the fictive friend an initial information of the purpose of all the operational steps.

Procedural objective

This will be illustrated by just one example. The first sentence said: “Collect all *x* on one side.” The following assertions were numbered. Point 1 began with: “Move the *x* which is easiest to move (the one that stands alone).” In addition to handling the separation of unknowns and knowns, this assertion also touched how this should be accomplished. Point 2 began: “Collect all detached numbers on one side.” And point 3 said: “To get *x* alone, divide both sides by the number in front of $x \rightarrow 3$.” Overall, this is a thorough description of the procedure in the solution, that is to separate unknowns from knowns. Several scripts included only the third point from the example above. In spite all these scripts were coded as ‘procedural objective’, providing this description at the end only is an explanation of lower quality than the one providing the idea of separating unknowns from knowns in each step of its explanation.

Finally, there were excerpts mentioning both the ‘conceptual’ and the ‘procedural’ objective, as the one starting “Equations mean to find out what the unknown is, that is *x*. We do this by getting *x* to stand alone on one side of the equals sign.” Although the language has some shortcomings, this explanation early highlights both the purpose and the process of the solution, which is likely to be beneficial for the student.

Summary and implications

This paper suggests it is important as well *what* is included in the explanation of the solution, as *where* in the solution it appears. It highlights, that before the operational steps you should stress that the purpose of solving an equation is to find the value of *x*, and to do that you want to separate unknown terms from known. That will justify the operational steps and is hence likely to be beneficial for the learner. This means the results presented might be useful for teachers, and in teacher education.

Relational thinking with indefinite quantities - case studies from elementary school children

Denise Lenz

University of Halle, Germany; denise.lenz@paedagogik.uni-halle.de

Early algebra is becoming more and more important in research of mathematics education. Relational thinking and variables are emphasized as essential sub-areas of algebraic thinking. The article provides an insight into kindergarten and elementary school children's abilities to establish relationships between quantities. The children's approaches can be described in a continuum between number-oriented and structure-oriented approaches. The influence of indefinite quantities can be shown by comparing three case studies.

Keywords: Elementary school mathematics, early algebra, relational thinking, variable, task design.

Introduction

The present study is about early algebra, which importance is steadily increasing for mathematics teaching in elementary schools (e.g. Kieran, 2018; Cai & Knuth, 2011). Studies show that an algebraization of mathematics lessons in elementary school is beneficial for itself as well as for later algebra learning (e.g. Mason, 2008; Kaput, 2008). Compared to arithmetic thinking, algebraic thinking is characterized by a structural rather than an operational view of mathematical objects (Steinweg, 2013; Kieran, 2004). Kieran (2004) named the consideration of relational aspects of operations instead of their computation as an essential way of thinking in early algebra. Likewise, comparing mathematical expressions and a relational understanding of the equal sign plays an essential role in early algebraic thinking. The creation of relationships between mathematical expressions defines algebra and can be described in particular in the aspect of relational thinking, which forms the theoretical framework of the present study.

Theoretical framework

Relational thinking is to be regarded as a sub-area of early algebra and can be defined as follows:

> "Sentences have to be considered as wholes instead of as processes to do step by step. When students analyze expressions, they compare elements on one side of the equal sign to elements on the other side of the equal sign or they look for relations between elements on one side of the equation" (Molina & Ambrose, 2008; p.64).

Fostering relational thinking with the help of equations is a possibility and has already been studied (e.g. Carpenter et al., 2003; Molina et al., 2005; Molina et al., 2008). Nonetheless, non-formal representations can also be used to establish relationships between elements (Schliemann et al., 2007). They offer the advantage of granting access to younger children as well and thus capturing pre-school starting points for mathematical learning. Furthermore, problems of the formal representation are avoided. This includes the relational understanding of equal signs, which can be seen as a prerequisite for using relational thinking with regard to equations (cf. Molina et al., 2005).

In addition to relational thinking, dealing with variables is an essential aspect of algebraic thinking. In principle, three aspects of variables can be identified: variables as unknowns (e.g. $5 + x = 8$), variables as indeterminate like in functional relationships or as a general number, for example to describe the laws of calculation (e.g. Freudenthal, 1983). The influence of various variables on relational thinking is illustrated by a study by Stephens and Wang (2008). They showed that the inclusion of multiple variables supports the use of relational thinking. Secondary school students had to put numbers in the boxes of the equation $18 + \square = 20 + \square$, establishing relationships between two indeterminate values. Compared to placeholder problems with only one unknown, these equations could stimulate students to think relationally rather than using operational solutions.

Relational thinking as the creation of relationships between mathematical expressions - be it equations, operations or relationships in factual relationships - is of great importance in early algebra. In particular, the connection between variable concepts and the use of the relationships between mathematical elements is challenging and requires further investigation, particularly with regard to young children of preschool and elementary school age. Therefore, the research questions examined in this article are the following: *How do elementary school children establish relationships between known, unknown and indefinite quantities that are represented by real material? What influence does the different use of known, unknown and indefinite quantities have on the use of relational ways of thinking?*

Method

The aim of the study is an exploratory recording of the abilities of preschool and elementary school children to think relationally[1]. As Stephens and Wang's (2008) studies have shown, the use of multiple variables within equations is helpful in stimulating relational thinking. With regard to the age group of kindergarten and elementary school children, a design was chosen in which equations with known and unknown quantities were represented with the help of material. Based on Melzig (2013), tasks were created in which boxes and marbles represent known and unknown quantities. Melzig showed that boxes open up a first access to a sustainable understanding of variables. The non-formal task design with real material (boxes and marbles) should also enable preschool children to show their relational thinking and can serve as a starting point for developing sustainable ideas about variables. Various equations with one or more variables have been translated into an arrangement of different colored boxes and single lying marbles. A story was told: two children play with marbles, some of which they keep in colorful boxes. Within a task there are the same number of marbles in boxes of the same color. Boxes of the same color may contain a different number of marbles in a different task. There were 12 tasks in 4 different task types.

[1] Other studies used the data to examine the conceptualization of the variables (e.g. Lenz, 2021).

Table 1: Overview of the tasks.

Task type	Example of the tasks
Type A: “The same?” Two given sets of quantities have to be compared with each other. The content of the boxes is not known and does not need to be determined to answer the question. The boxes can be seen as a variable as an indefinite.	 Task A1: “Does both children have the same amount of marbles? How did you get that?”
Type B: “How many?” The contents of a box must be determined. The amount of marbles asked for can clearly be determined and so appears as an unknown. Exercises B1 and B4 also contain additional boxes (the red ones), which content is not known and does not necessarily have to be determined in order to find a solution.	 Task B4: How many marbles have to be in a green box, so that both children have the same amount of marbles? How did you get that?
Type C: “How many?” Both children have boxes of unknown content. In contrast to the previous type, no specific quantities can be given for them. In order to answer the question, children can state a relationship between the amount of marbles in the boxes. Since the contents of the boxes cannot be clearly determined in comparison to task type B, it can be seen as indefinite.	 Task C1: How many marbles have to be in the boy’s box so that both children have the same amounts of marbles? How did you get that?
Type D: “Make them equal” Both children have the same amounts of marbles. The interviewer makes a transformation by removing or adding a box by one child in the task. Children have to decide what amounts of marbles they have to give to the other child in the task or take away from the child to the interviewer, to make the quantities equal again. Tasks D1 could be answered with a specific number of marbles, while in task D2 a relationship between two indefinite quantities had to be established.	 Task D1: Both children have the same amount of marbles. Now, the boy gives one of his boxes to the interviewer. How much does the girl have to give to the interviewer, so that both children have the same amount of marbles again?

To get insight into children’s ways of thinking and their use of relational thinking, a qualitative survey method using interviews was chosen. The study follows a diagnostic approach and is not to be understood as an intervention. The tasks were dealt with in video-recorded, semi-standardized individual interviews with 80 children in three age groups. 5-6 years old kindergarten children (N = 25), 7-8 years old second-graders (N = 29) and 9-10 years old fourth-graders (N = 26) took part. The children were asked to explain their approach. The transcribed interviews formed the data basis for the subsequent qualitative content analysis (cf. Mayring, 2010) and the method for analyzing interviews according to Schmidt (2005). Categories were formed out of all of the interview-transcripts which described children's approaches to answer the tasks. They were created deductively based on preliminary theoretical considerations and inductively obtained from the data. The categories were recorded in a coding guide. After re-coding all the material, an overview of the categories of the entire data material was given in frequency tables. These were used for further analysis by pointing out possible relationships that need to be checked in individual cases. In a last step, in-depth case analyzes were made (Schmidt, 2005).

Findings

After answering the tasks, the children were asked how they got their answer. Based on the analysis of the interviews, this article focuses on comparing the approaches described by the primary school children. First, the evaluation dimensions are presented and related to the theoretical background. Then insights into three case studies from primary school children are given.

Number-oriented and structure-oriented approaches

The approaches described by the children for processing the tasks can be described across all tasks in a continuum between number-oriented and structure-oriented approaches.

Number-oriented approach

The number-oriented approach focuses on the specific amounts of the marbles. Because the calculation of sums instead of relating quantities predominates, it can be characterized as an arithmetic way of thinking.

Structure-oriented approach

In a structure-oriented approach, children make gestural or linguistically clear that equal subsets are related to each other. The focus is on the quantities themselves and not on their value ("they are the same" instead of naming the specific number). Children take a structural perspective on the task and make connections between sub-structures of the task. According to Molina and Ambrose (2008), this approach can be characterized as relational thinking.

Three case studies

The distinction between number-oriented and structure-oriented approaches is compared using the example of the processing of tasks B4 and C1 (see Table 1) by three children. But they also show the influence of adding another, indefinite variable to exercise C1. It should be noted that the change in task types was not communicated to the children. In task type B, it was possible to answer with specific numerical values. Immediately afterwards, task C1 was set, whereby no specific numerical values could be given. Thus, some problems for the children are to be expected. But the answers to task C1 also reflect the spontaneous approaches of the children without being influenced by learning effects.

Leonie, 4th- grader

In task B4, Leonie states that there must be a marble in each of the red and green boxes. She justifies this with the fact that both children then each have four marbles. When asked whether she needs to know the contents of the red boxes, she seemed unsettled. This shows that in addition to the number-oriented approach described, no structure-oriented approach is conceivable for her, in which the content of the red boxes is not determined.

In task C1, Leonie spontaneously gives numerical values for the two boxes given. The interviewer then names various other numerical values as the contents of the girl's box. Leonie can give the correct amount of marbles for the boy's box. This shows that she does not accept the aforementioned numerical values as fixed actual content, but can imagine different values. She is able to deal with changing numerical values and recognizes the dependency. However, she does not explicitly succeed in generalizing the relationship between the indefinite quantities.

Matteo, 4th-grader

In task B4, Matteo structures subsets as equivalent to one another without having to determine their specific content. Based on the individually lying marbles, he deduces the contents of the green boxes. This approach can be characterized as structural:

Matteo: There must be one marble in a green box, because here (*points to the red boxes*) there are the same numbers and here (*points to a green box on the boy's side and on the girl's side*) ... In order to make this one marble difference (*points to the girl's marble*), one must also be in here (*points to the girl's front green box*).

In task C1 Matteo states that there is a dependency between the indefinite quantities of marbles in the two differently colored boxes. He says correctly that the contents of the boy's box cannot be determined because the content of the girl's box is not known. When asked by the interviewer, Matteo can then state the general relationship between the quantities of marbles in both boxes and refers to the marble lying individually in his argumentation. In addition, a structuring of the given quantities becomes clear:

Matteo: Here (*points to the boy's box*) there is one more marble than here (*points to the girl's box*), because here (*points to the girl's marble*) there is a single marble.

Julius, 2nd grader

In task B4, the second grader Julius names the value of one marble as the content of the green box. He claims to have checked this by calculating subtotals: the contents of the green boxes and the individually lying marbles. He doesn't say anything about the red boxes. He may have excluded these because they contain the same amount of marbles. Although his approach by calculating partial sums is to be regarded as number-oriented, this already represents a transition to the structure-oriented approach. He has recognized partial amounts of equal amount (the red boxes) that will be disregarded for further consideration.

In task C1 Julius succeeds in specifying the relationship between the indefinite quantities:

Interviewer: How many marbles must there be in a green box so that both children have the same amount of marbles?[…]

Julius: Because one thing (*taps the girl's marble*) and then you still have to calculate that here (*taps the girl's box*), there can be one, two or three (*waving his hand rhythmically in the air*) and there would always have to be one more (*taps on the boy's box*) to be in it than in the box (*points to the girl's box*) then it would be right.

Julius example shows impressively that he is able to establish relationships and to support this with gestures. At this point he shows a structure-oriented view of the task.

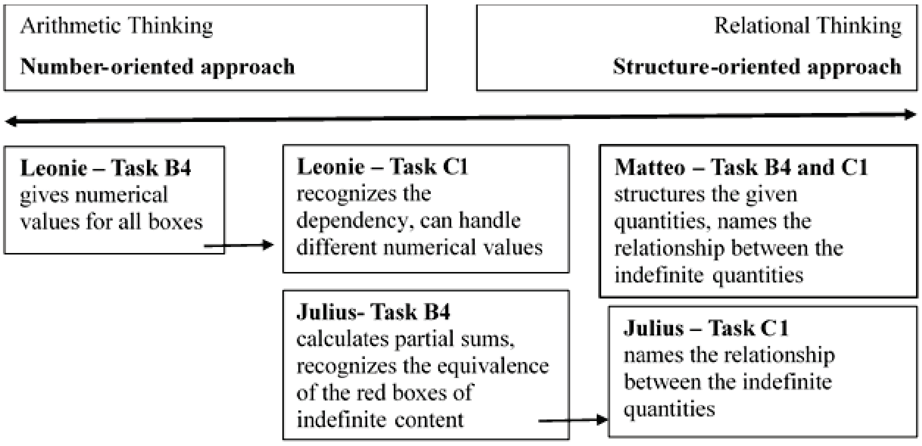

Figure 1: Approaches of the three children in comparison of tasks B4 and C1

Figure 1 shows how Leonie and Julius move from a number-oriented approach to a structure-oriented approach in the transition from task types B to C. This suggests that the task design, and especially task type C, can encourage children to think relationally. Since not all values are given, the children have no way of calculating specific numbers. They are encouraged to take a look at the whole and to establish relationships between the indefinite quantities. Thus, the results of the study by Stephens and Wang (2008) can also be confirmed with regard to the handling of real material and with primary school children.

Conclusion

The analysis of the entire interviews showed that there are children who mainly proceed in a number-oriented approach. To do this, they name numbers for additional boxes in task type B (like the red boxes in task B4) and give arithmetic reasoning. In task type C, these children are primarily tied to numerical values in order to find access to the task. This is shown in the case study of Leonie. However, she already manages to deal with various numerical examples in task C1 but she cannot indicate a static relationship between the indefinite quantities.

In contrast, there are children who show mainly structure-oriented approaches across all of the 12 tasks. Matteo's explanations of tasks B4 and C1 serve as an example. He is able to take a structure-oriented view of the whole from above across all tasks. This can be characterized as relational thinking (e.g. Molina & Ambrose, 2008).

In addition to these cases, however, there are also children who switch approaches. Second grader Julius described in task type B mainly number-oriented procedures. This may be due to the fact that it is possible to operate with specific numerical values. But also in his processing of task B4 it should be noted that he is already on the way to a structure-oriented approach in that he only calculates partial sums instead of the whole sum of marbles, as Leonie did. In task C1, Julius shows that he is able to describe relationships between the sets. The tasks of type C thus stimulated him to move from a number-oriented approach to structure-oriented approach and thus relational thinking.

Discussion

The empirical study shows that relational thinking as a sub-area of algebraic thinking can be stimulated in elementary school children. The study also showed that some kindergarten children are also capable of relational thinking, which, due to the length of this article, could not be taken up. The skills of the kindergarten children are to be regarded as prior knowledge and at the same time the starting point for further mathematical learning with regard to early algebra. With the help of the task design in its non-formal representation, instead of starting from procedures and calculating result values, many children succeed in recognizing relationships between the elements with the help of a look at the whole and using them to find solutions. It is precisely this “view from above” on the elements of a mathematical situation and their relationship to one another that constitutes relational thinking and thus also an essential aspect of algebraic thinking.

In particular, the type C tasks, which contain indefinite quantities, encourage children of primary school age to use relational thinking. This is already indicated by the small insight into the processing by the second grader Julius within the case studies and also corresponds with the explanations of Stephens and Wang (2008). As a result, the inclusion of unknown and indefinite quantities in the sense of a spiral curriculum also appears profitable in elementary school lessons.

The analyses give a little insight into the differences in the approaches of the children. With regard to the use of the task design in school, very different approaches by the children are to be expected. A classroom discussion about children’s ways of thinking used can lead the children to focus on both number-oriented approaches and structure-oriented approaches. The real material can be used to clarify your own ways of thinking to others - in particular the established relationships between the quantities.

Nevertheless, it is important to break away from a real representation and later perceive the variable as a thought object instead of a real object in the form of the box.

The “Sense-Making-Algebra” project for Hungarian seventh graders

Orsolya Dóra Lócska[1] and Zoltán Kovács[2]

[1]University of Debrecen, MTA-ELKH-ELTE Research Group in Mathematics Education, Hungary; locska.orsolya@science.unideb.hu

[2]Eszterházy Károly Catholic University, MTA-ELKH-ELTE Research Group in Mathematics Education, Hungary; kovacs.zoltan@uni-eszterhazy.hu

According to the Hungarian National Curriculum, the systematic study of algebra starts in the seventh grade. In the initial phase, traditional methods focus less on generalization as a cornerstone of algebra and more on algebraic operations. Matched with the traditional syllabus, the authors have incorporated lessons into the teaching process at this early stage of algebra learning that focus on generalization activities and the meaningful use of symbols. The authors investigated how generalization activities manifest themselves during these lessons.

Keywords: Algebraic reasoning, generalizations, using symbols, algebra in the early grades, lower secondary level education.

Introduction

The cognitive ability to abstract is given special attention in the Hungarian National Core Curriculum in grades 7-8 (Government Decree, 2012, rev. 2020). The generalization of experiences and the need to justify relationships are also expected. The curriculum also requires the learner to formalize the mathematical content of everyday problems and use letters to denote unknown quantities. To begin teaching using symbols, a procedural approach based on “letter arithmetic,” i.e., practicing operations with algebraic expressions based on definitions and rules, is a traditional teaching strategy also presented in Hungarian textbooks. However, less emphasis is on generalization and the meaningful use of symbols in that early stage. Discrepancies between development goals and the practice in teaching early algebra were the impetus of our research. Improving this situation requires recognizing that algebraic thinking, which involves the meaningful use of symbols, is a form of mathematical sense-making related to symbolization (Schoenfeld, 2007). Many authors explain the sense-making process of a mathematical concept by connecting it to prior knowledge (Scheiner, 2016). Palatnik & Koichu (2017) found that the criterion for successful implementation of the sense-making process is that students are adequately engaged in the task and that the learning environment, which in their scenario was project work, is supportive. Inspired by these ideas, the authors of this paper added mathematical problem situations to the traditional “letter arithmetic” to support the generalization process and the meaningful use of variables. This paradigm is named the “Sense-Making-Algebra” teaching strategy by the authors of this paper. A rationale behind this teaching strategy is to allow students to see the power of symbolization as early as possible in the algebra learning process. Furthermore, with a problem-oriented teaching approach (Kónya & Kovács, 2021), the authors aimed to create a supportive learning environment.

The authors’ research questions are, (1) how do seventh-grade students’ generalization activities manifest themselves during the “Sense-Making-Algebra” intervention, and (2) what resources do they employ to create their generalization? We hypothesize that most learners can generalize from experience and argue for generalization using natural language or symbols after the teaching unit.

This paper describes a part of the broader experiment: the content and analysis of the first experimental lesson and the related follow-up test. In this lesson, we used the so-called "calendar problem," which has been discussed in various places in the literature, as an effective initiative to encourage generalization (Friedlander & Hershkowitz, 1997; Huang et al., 2014).

The first author performed the action research reported in this paper in her three seventh-grade classes. The second author acted as a critical friend during the teaching experiment. The study provides an example of how to put into practice the sense-making use of variables. Although there are some well-prepared collections on teaching strategies and recommendations on algebra learning (e.g., Friedlander & Arcavi, 2017), these works are focused on equations. The authors found fewer compendiums of a similar style at the pre-equations stage of algebra learning, with generalization and reasoning in focus, which also motivated this research.

Theoretical underpinning

Several scholars attempted to investigate the nature and content of algebraic thinking. There are several perspectives on what defines algebraic thinking, but many agree that generalization, or the ability to discern the general in the specific, is a crucial element (Pittalis & Zacharias, 2019). The present article focuses mainly on generalization, which may be accomplished using natural language and symbols. While outlining the theoretical basis, we emphasize this perspective, and in this regard, the work of Kaput (2007) serves as the theoretical framework for our research.

Freudenthal (1977) made an early attempt to conceptualize school algebra and included algebraic thinking in the subject. Freudenthal highlighted that the ability to describe relations and solve procedures in a general way is part of algebra. In this novel perspective, algebra is seen as a human cognitive activity. Thus, those who conceive algebra as reasoning prefer to examine how students think and speak about it. Arcavi (1994) considers the dichotomy of generalization and symbol usage in school algebra and claims that many students who master algebraic methods often fail to perceive algebra as a tool for comprehending, expressing, conveying generalizations, and constructing mathematical arguments. According to Kieran's (2004) model for conceptualizing algebraic activity, algebra is a multidimensional activity that includes numerous ways of thinking. Algebraic thinking approaches quantitative situations that aim to find relationships and structure using not strictly letters-symbolic approaches. Kaput (2007) emphasizes two core aspects of algebraic reasoning. One of them is generalization, and expressing generalizations in increasingly coherent symbol usage (Core Aspect A). "Increasingly" means that initially, the students use their resources, typically natural language, but later switch to conventional representational forms. Core Aspect B means the syntactically guided action on symbols. Kaput argues that the "Core Aspect B" should come later than the "Core Aspect A" since rule-based actions on symbols depend on knowing the allowed combinations of symbols, particularly which combinations are equivalent to others.

Method

The action research took place from December 2020 till March 2021 in a Hungarian practicing school for teacher training. A total of 68 seventh-grade students aged 13-14 years (hereafter S01-S68) from three classes (hereafter classes b, d, z) participated in the experiment. The groups have three maths lessons a week, each 40 minutes long. The teacher was the same in all three classes. Based on the textbook used in the school, the teacher's syllabus allocated 28 lessons to algebra instruction. The intervention took place in the first teaching unit (Algebraic expressions and operations with algebraic expressions), for which the curriculum allocated 11 lessons. The teacher conducted four experimental lessons in this teaching unit. The authors only report on the first experimental lesson in this paper and the follow-up test relating to it. The authors used the following tools for data collection and analysis: (1) classroom observation through a visiting teacher's field notes; (2) the teacher's research journal; (3) copies of students' written outputs.

The first lesson was inspired by Huang et al. (2014), where the authors report a lesson on investigating patterns in calendars, focusing on improving empirical reasoning towards deductive proof. The planning of lessons followed a problem-oriented teaching approach (Kónya & Kovács, 2021). It means that students: (1) analyzed mathematical problems; (2) were allowed to reflect on their own and their classmates' thinking critically in classroom discussions; (3) were encouraged to explain and justify their thinking.

The plan of the first lesson is as follows. Part 1: pattern finding. Students looked for patterns in the December 2020 calendar during the preparatory phase of the lesson. First, the teacher chose the diagonal 1-9-17-25 (Figure 1, left). Then, after determining that the numbers in the sequence increased by 8, students worked in pairs to explore similar patterns (Figure 1, right). The purpose of the pattern-finding task was to make students aware of the mathematical structure of the calendar, which is already familiar from everyday life.

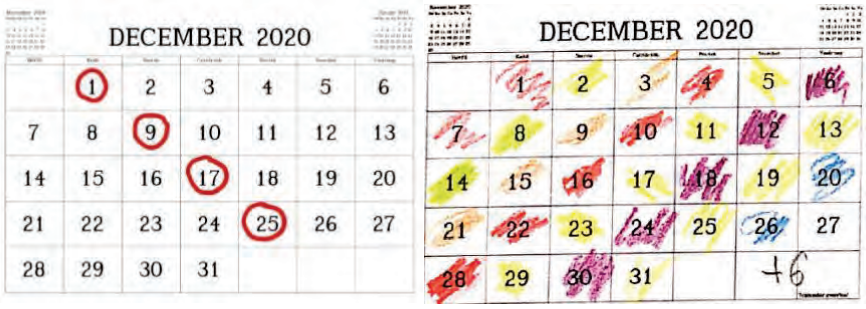

Figure 1. The December 2020 calendar with diagonal patterns

Part 2: magician's trick. The principal part of the lesson was based on a magician's trick. "Choose a number with a top right and a bottom left neighbor. Then, you tell me the sum of the three numbers, and I will guess the chosen number!" The processing of the magician's trick had three stages: (1) Numerical experience. The number said by the student and the number thought of was recorded on the board. (2) Formulating the rule: how did the magician do the calculations? (3) Explanation of the rule. The theoretical consideration behind placing the problem in a playful context was to engage as many students as possible in the task and maintain motivation.

In the follow-up test, two compulsory and one optional assignment were given to the students (Table 1). The first and second problem was close to the calendar task in the lesson. These two tasks were chosen to require generalization and make it easy to argue without using symbols. On the other hand, the third task was assumed to be much more difficult to explain without symbols.

Table 1: The follow-up test (for March calendar)

Task 1. (Compulsory) Nándi selected a number in the calendar and added its left and right neighbors. When he halved the sum, he got exactly the number he had chosen. Do you think this is always true if you choose a number with a left and a right neighbor? Justify!	
Task 2. (Compulsory) Csenge chose a number from the calendar with both a lower and an upper neighbor. She added the two neighbors together and then halved the sum. What has she experienced? Will this always be true if you choose a number that has a lower and an upper neighbor? Justify!	
Task 3. (Optional) Laci had a magician trick. If someone told him the sum of three numbers in the calendar in the shape of a V, he would guess the middle number. (For example, if someone told him that the sum is 22, he would know that the middle number is 12.) However, unfortunately, he forgot how the trick worked. Help him!	

To assess the follow-up test, the authors examined the students’ solutions, for which they created the following code system (Table 2).

Table 2: The coding system to evaluate students’ outcomes

Code	Description	Definition
NA	No Answer	One of the following elements: The student has not submitted a solution. No explanation. The student did not understand the text. The student tries to give reasons but does not give a relevant explanation.
AR	Arithmetic level	The student makes relevant calculations only on some numbers.
ALG	Algebraic level, without symbol	The student argues generally and correctly, using natural language without using symbols.
ALG+	Algebraic level, using a symbol	Three criteria must be fulfilled. (1) A symbol represents a number in the configuration. (2) Student correctly expresses the relationships between the numbers, and (3) student performs algebraic operations.

Findings and analysis

During the pattern-finding task (part 1 of the lesson), students have skillfully formulated the rules in the natural language during classroom discussions. Moreover, the generalization process emerged naturally:

S45: Is what we are talking about a feature unique to December or not?

S32 [Enthusiastically] There are seven numbers next to each other, that is, they are arranged by week, so for each month, it is [true].

While working on the magician's trick (part 2 of the lesson), the experience was written on the whiteboard (Table 3), and the one who figured out the trick could be the next magician.

Table 3: Numerical experience in class *d*

The magician	Teacher	Teacher	Teacher	S31	S31
Sum	33	66	69	73	75
Number thought	11	22	23	"You made a mistake."	25

Finally, students formulated the rule in their own words; they had to divide the sum of three numbers by three to get the number they had chosen.

When questioned why the trick worked, a faulty analogy emerged. Several students suggested that it should be divided by three because three numbers were added. The teacher took advantage of this situation and involved the class in discussing the mistake. The following dialogue is from class *b*, although almost the same happened in class *z*.

Teacher: [Adressing the faulty analogy.] Look at the diagonal patterns in the calendar! [She points to the corresponding pattern, see Figure *1* (right) that she deliberately left on the board at the beginning of the lesson.]

S03: [Uncertainly] The [number] six is the key.

S14: One number is six less and the other six more [than the number one thinks].

T: Let us write what he said! Let, for example, the number thought be 11. Thus $(11-6)+11+(11+6)=3\cdot 11=33$.

T: What if the thought number is not 11?

S: [Unrecognized student from the class] It can be anything

S14: Let it be x!

First, S14 tried to explain the rule with his natural resource, which was the basis of the teacher's general example. They concluded with the deductive proof $(x-6)+x+(x+6)=3\cdot x$. It is worth noting that the students explained the rule of merging starting from the problem situation; this is a point where the advantage of the "Sense-Making Algebra" approach is very apparent.

In class d, after the general examples, S46 proposed denoting the numbers with a, b, c, d, i.e., $a + b + c = d$. Although the need to use letters emerged in the student, she did not express the relationships between the symbols. The student's typical failure provided an appropriate opportunity for the teacher to draw attention to the principle that symbols must express the mathematical relations extracted from the situation.

In two classes, the students wanted to create their own magic tricks. The need for generalization was raised naturally in all three classes: do the series apply in other months, does the magic trick work in other directions, or other months? The use of letters and symbols occurs spontaneously in two of the three classes, with minimal teacher guidance. However, more teacher guidance and questions were needed in the third class.

The result of the coding of the follow-up test is shown in Table 4.

Table 4: Result of the follow-up test

	Task 1	Task 2	Task 3
NA	23	28	61
AR	6	5	0
ALG	25	23	0
ALG+	14	12	7
SUM	68	68	68

39 students gave algebraic level answers (ALG and ALG+) in the first task, i.e., 57% of all students. The result is similar in the second task, 52%, 35 out of 68 students. 21% of all students used symbols to express their reasoning (ALG+) in the first task, while 18% in the second task. The following examples are representative of each category.

NA (Task 1., S12) "Yes, that is true. Because if a number has a left and a right neighbor, both will be odd or even, and if you add two odd or even numbers together and divide by two, you always get an integer." What student writes is true in itself, but it does not explain the experience.

AR (Task 1, S22) See Figure 2. The student refers to only one particular case and concludes that the rule is always valid. (Translation of the text in the figure: "always true").

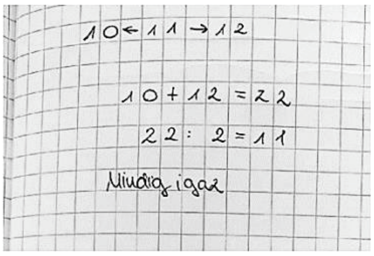

Figure 2: AR solution of Task 1 by S22

ALG (Task 1. S1) "The rule is valid because if you add a number one greater than the number you have chosen and a number one less than the number you have chosen, you will always end up with twice the chosen number.” The student correctly expresses the relationship between numbers in natural language; his reasoning is general, but he does not use symbols.

ALG+ (Task 3. S4) See Figure 3. The student represented the central element of the V-shape by z, correctly determined the other two elements ($z-8, z-6$), and performed the merge correctly ($3z-14$). The number needed is then determined by thinking backward from the sum. Translation of the text: “Add fourteen to the total and divide by three.”

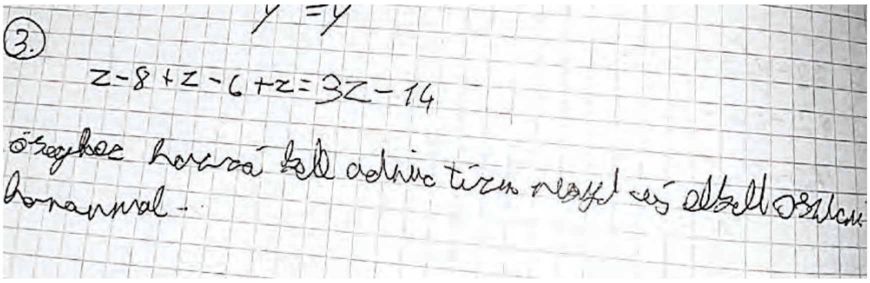

Figure 3: ALG+ solution for Task 3 by S4

The follow-up test also showed an example of an unexpected generalization: S15 wrote: “Conclusion: if you add the neighbors of a number (it can be second neighbors, third neighbors, fourth neighbors), you always get twice the number. It is because both neighbors differ by the same difference from the number.”

Discussion and pedagogical implications

The authors’ first research question was: how do seventh-grade students’ generalization activities manifest themselves during the “Sense-Making-Algebra” intervention? Consistent with Friedlander & Hershkowitz (1997), our research confirmed that students generalize and reason willingly and satisfactorily at the early algebra learning stage. A possible good choice for this process is the “calendar problem,” as presented by Huang et al., (2014). The mathematical structure is simple, based on addition, so it can be used to pose problems accessible to a wide range of learners. Furthermore, we found that making and justifying conjectures occurs naturally using this type of exploration task. Moreover, this study found that the “problem-oriented” teaching approach supported generalization and reasoning activities, providing a good space for classroom discourse (Kónya & Kovács, 2021). Generalization, in many cases, did not occur as an individual activity but as a consequence of group discourse. The starting point for generalization could be the students’ questioning in addition to the teacher’s initiative.

The second research question was: what resources do students employ to create their generalization? Students expressed their ideas verbally in natural language resources in classroom discourse, which facilitated generalization. The predominance of textual formulation remained in written work until the end of the learning cycle. However, about 20% of the students were already confident using symbols in problem situations in our experiment. Although we did not use project work as a learning environment, we saw an identical process described by Palatnik & Koichu (2017), who reported that students developed and justified claims, made generalizations, addressed why-questions, and established coherence among the explored objects.

Recognition of an equation as an algebraic description of contextualised situations by fifth graders

Esperanza López Centella[1], Jana Slezáková[2] and Darina Jirotková[2]

[1]University of Granada, Faculty of Educational Sciences, Granada, Spain; esperanza@ugr.es

[2]Charles University, Faculty of Education, Prague, Czech Republic; jana.slezakova@pedf.cuni.cz, darina.jirotkova@pedf.cuni.cz

In this study we qualitatively explore the conceptual and semantic understanding of equations of elementary school pupils who were introduced to solving basic linear equations. We analyse the individual answers of 38 fifth grade students in a Czech public primary school to a paper-based task consisting of justifying whether the equation 5+2x=13 algebraically describes each one of 5 contextualised situations presented. Under a grounded theory approach, we provide a system of categories of the students' strategies to address this question. Our findings show the students' abilities to deal with the task and to infer true mathematical facts about equations, the wide variety and nature of students' strategies and the apparent dependency of the strategy on the system of representation of the situation.

Keywords: Equations, contextualised situations, elementary students, strategies.

Introduction

Gradually, algebraic activity is finding its place in primary school classrooms, following the guidelines of international organisations of Mathematics Education (National Council of Teachers of Mathematics [NCTM], 2000) and the evidence and conclusions from multiple research works on early algebra (e.g., Kaput, 1999). Getting acquainted with the notions of unknown amounts and variables, establishing dependency relationships between variables, developing functional thinking, representing information in different systems and transferring it from one to another, symbolising and using meaningfully algebraic notation are part of these algebraic activities. In this scenario, equations bring a great chance to deal with several of them at once. In the context of a task involving a linear equation and five contextualised situations verbally and pictorially presented (Figure 1) to elementary students of fifth grade, the aims of this research study are:

(a) Explore the students' abilities to identify and justify the given equation as an algebraic transcription of a particular situation,

(b) Describe the strategies used by students to address this question.

Background and theoretical framework

A branch of research studies in algebraic thinking have focused on epistemological analysis of scholar work with equations and the exploration of different aspects of children's performances when working with them, discerning in such a way a demarcation between arithmetic and algebra. Filloy and Rojano (1989) suggest the terms *arithmetic equations* to refer to equations with an unknown on only one side of the equal sign (so that undoing the operation at hand is enough to know its value), and *algebraic equations* to those where the unknown appears in both sides and therefore must be operated on. Balacheff (2001) understands that the shift from an arithmetic to an algebraic interpretation of equality corresponds to a shift of emphasis in the validation of the problem solution: from a *pragmatic control*, where the solution is validated arithmetically with reference to the initial context of the problem; to a *theoretical control*, where the solution is validated with reference to mathematical principles. Concerning the ways to formulate equations from verbal data, Herscovics (1989) recognises *syntactic* and *semantic translations* as different procedures, referring respectively to direct translation of key words to symbols, and the attempt to express the meaning of the problem. According to Hoch and Dreyfus (2004), "any algebraic expression represents an algebraic structure. The external appearance or shape reveals, or if necessary can be transformed to reveal, an internal order. The internal order is determined by the relationships between the quantities and operations that are the component parts of the structure" (p. 50). In this paper we refer to these notions as *external structure* and *internal structure* of an equation. We say that an equation *algebraically describes* a contextualised situation if there is a correspondence relationship between the equation terms and a set of elements of the context in such a way that the equality established between the relationships of the equation terms is also fulfilled between the homologous relationships of the corresponding elements of the context.

Other works explore the processes of mathematical reasoning of equations in primary mathematics lessons through operations with structures of computing-terms (Nührenbörger & Schwarzkopf, 2016) and how students can come to understand and use the syntactic rules of algebra based on their understanding about relations between quantities (Brizuela & Schliemann, 2014). These studies show that dealing with equations is not beyond ten years old students' mathematical understanding and that much more could be achieved if algebraic activities became part of the daily mathematics classes offered to elementary school children. In this sense, Figueira-Sampaio et al. (2009) propose a constructivist computational tool to assist in learning equations of first degree in primary school, to illustrate the idea of equilibrium and properties of the equality. Otten et al. (2019) report that the algebraic strategies such as restructuring, isolation and substitution that primary school students used when working with a hanging-mobile during their teaching experiment were later used by these students for solving linear equations in new contexts.

Research methodology

This study is part of a larger qualitative and descriptive research project, based on classroom interventions to explore the understanding of elementary students in algebraic activities.

Participants and design of the task

Thirty-eight fifth grade elementary students (10-11 years old) of mixed abilities in mathematics from the same public primary school in the city of Prague (Czech Republic) participated in the study. They were two class groups, both taught by the same teacher. Although equations are included in the second cycle (6-9 grades) of elementary school in the Czech curriculum (VÚP, 2017, pp. 31-34), the participant students had been briefly introduced by their teacher to symbolic letters and solving simple linear equations in the classroom. They had been taught by a method partially inspired in Hejný Method (Hejný, 2012). They had played with numbers and arithmetic operations subject to certain conditions and worked with unknown amounts. They had no prior experience with activities as the involved in our present study.

According to our research aims, we presented to the students the task shown in Figure 1.

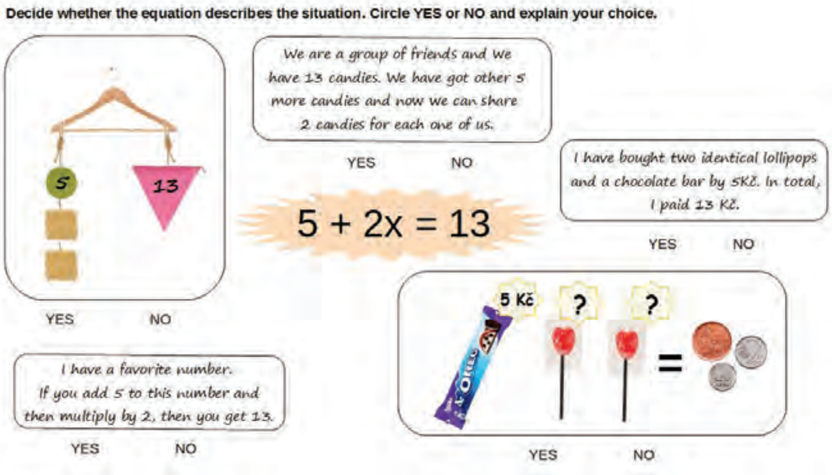

Figure 1: English version of the worksheet presented to the students

The worksheets for them were drafted in Czech language, the students' mother language in which they also wrote down their answers. Table 1 specifies the task variables considered.

Table 1: Task variables and features of the worksheet situations

	Friends	Lollipops	Labels	Number	Hanger
Representation	Verbal	Verbal	Pictorial	Verbal	Pictorial
Unknown	Number of friends	Price of lollipop	Price of lollipop	Favorite number	Weight of square
Order of appear.	13, 5, 2	2, 5, 13	5, 1, 1, 13	5, 2, 13	5, 1, 1, 13
Possible equa.	(13+5)/x=2	2x+5=13	5+x+x=13	(x+5)2=13	5+x+x=13
Described?	No	Yes	Yes	No	Yes

Collection of data and data analysis

The data collection was performed in one session at the beginning of the first semester of the Czech school year 2019-2020, during normal mathematics class time of the participant groups. The worksheets were given and administered by the teacher to the students with the firm instruction of doing the task individually and writing down their explanations with pen on the sheet (and its back if they needed it). During their work, the students did not receive any feedback about the correction of their answers or suitability of their strategies. Upon completion, students' worksheets were delivered to the research team and constitute the data for this qualitative research.

We considered as units of analysis the students' written answers to the different items of the task: selection of yes/no and corresponding explanation for each situation. We transcribed and translated the answers from Czech to English. After thorough reviews, we categorised the data following the principles of Grounded Theory (Corbin & Strauss, 1990). In agreement with our research goals, we establish categories of the focus of their performances and of their strategies, as shown below. Students' anonymity was ensured by assigning each a label: Si, i=1, …,38.

Focus of performance

• Resolution. Ignoring the given equation, the student tries to find a solution for each situation. If the student can solve it, she/he circles “Yes”. Otherwise, she/he circles “No”.

• Discrimination. Considering the given equation, the student decides—based on one or more strategies—whether this algebraically describes each situation. If the student thinks so, she/he circles “Yes”. Otherwise, she/he circles “No”.

Strategies

• Identification. The student establishes a one-to-one correspondence between the contextual elements of the situation and the terms of the given equation.

• Equation solving. ‣ Operational (O). The student follows the algebraic rules and standard solving equation process. ‣ Trial and error (T&E). The student assigns a value to the unknown and checks whether the equality of the equation holds, repeating the process until finding a solution or stopping after some trials. ‣ Memory and mental calculation (MC). The student does not annotate anything about the solving process, using own record of numerical facts and mental calculation.

• Divisibility. The student discusses the existence of solution relying on divisibility arguments.

• Solution checking. The student arithmetically checks whether the solution of the given equation is also a solution for the situation at hand.

• Equations comparison. The student formulates an equation for the situation at hand and compares it—without solving it—with the given equation.

• Solutions comparison. The student formulates an equation for the situation at hand and solves it, numerically comparing its solution with the solution obtained by solving the given equation.

• Analogy. The student recognises a situation as an analogy of another, copying the answer provided in it.

• Numbers comparison. The student compares the numerical data appearing in the statement/picture of the situation at hand with those of the given equation.

Note that, in contrast to the solutions comparison strategy, in the solution checking the student does not formulate any equation of the situation at hand.

Results

Focus of performance

As shown in Table 2, students’ participation in the task was notably high: 186 out of potential 190 answers were provided. More than the half of the students (20 of 38) focused their performances on discrimination—as requested by the task—, while the remaining students (18) did on resolution. Restricting ourselves to the first ones, it is remarkable the high rate of right answers. Interestingly enough, there were those who deliberately circled both “Yes” and “No” for the same situation. This is the case of S_{11} for the Hanger situation:

S_{11}: Yes, since 5+4=9+4=13. No, since 5+?+?=15 [he writes down two 5’s and two arrows from each one of them to each question mark].

He argues similarly in the Labels situation:

S_{11}: Yes, 5+2x=13|-5, 2x=8|:2 [vertical bars are part of his symbolism], 1x=4 [he writes 4 next to each question mark of the lollipop price labels]. No, because the price of lollipop could be 4.50.

After formulating an equation for it, getting its solution and applying the solutions comparison strategy, S_{11} also thinks in a different way: he considers another value for the unknown and checks that the equality of the equation does not hold for that value, what he offers as evidence that the equation might not describe the situation. The answer of S_{37} (focused on resolution) to Friends situation also illustrates this: “Yes: How many people were there? 9 people. No: 1 to 8 people”.

Table 2: Total number of students’ answers of each type

		Friends	Lollipops	Labels	Number	Hanger
Resolution (18)	Yes	12	13	14	4	10
	No	4	4	3	14	6
	Yes & No	2	1	1	0	1
	No answer	0	0	0	0	1
Discrimination (20)	Yes	0	19	18	1	17
	No	19	1	0	17	2
	Yes & No	0	0	1	1	1
	No answer	1	0	1	1	0

The lack of an explicit question in the statements prevented some students to identify an unknown susceptible of being involved in an equation. This is the case of S_{13} in Friends situation:

S_{13}: We do not have any unknowns. It is not a task, because there is no question to answer (it is all information).

Order of operations potentially matters. It turns interesting to analyse the only “Yes” answer in Number situation (restricting to discrimination as focus):

S_{17}: 5+2x=13, 5+2x=13|-5, 2x8=13|:2, x=4 [each step is reproduced as originally written by the student, typos included]. If you add 5 and multiply 2x, you get 13. 13-5=8, 8:2=4.

On one hand, she solves the given equation (getting x=4). On the other hand, she formulates the Number situation in her own words. Then, apparently in order to find the unknown favorite number, she tries to undo the operations that, applied on this number, give 13. She replaces addition by subtraction and multiplication by division, but she does not reverse the application order of the operations (she calculate (13-5):2=4 instead of 13:2-5). In this way she gets 4 as outcome and, comparing the solutions, she circles “Yes”.

Strategies

Table 3 shows the frequencies of use of each strategy by the students who focused their performances on discrimination (20), as requested by the task.

Table 3: Frequencies of the strategies used by students focused on discrimination

	Friends	Lollipops	Labels	Number	Hanger
Identification	0	2	2	0	3
(O, T&E, MC)	(6, 0, 0)	(3, 0, 3)	(6, 0, 0)	(3, 1, 0)	(4, 0, 0)
Divisibility	0	0	0	7	0
Solution checking	0	0	6	1	6
Equations comparison	6	6	1	6	3
Solutions comparison	6	7	3	5	3
Analogy	2	2	9	0	4
Numbers comparison	2	0	0	0	0
Total	22	23	27	23	23

As evidenced by the total number of strategies used in each situation, students often involved more than one strategy in their answers. The frequency of each strategy seems to be influenced by the representation system of each situation. In verbal situations, equations comparison together with solutions comparison and equation solving were the most used strategies, while in pictorial situations the most frequent were analogy and solution checking. Verbal statements awakened the students' need to formulate an equation describing the situation, while pictures let them more easily perceive analogies with other situations and they offered a scenario (the "blanks" of the pieces of cloth and of the lollipops price labels) to implement solution checking. In Friends situation (where the unknown is the number of friends), some students misunderstood the role of the number of candies, as they compared or related it to the value (4) of the unknown for the given equation:

S_{18}: 5 + two x = thirteen → x=4, 13-5=8, 8:2=4 [she solves the given equation]. No. Everybody would have to get 4 c.

S_8: No. This equation shows that one man would get 4 candies [referring to the solution of the given equation].

In the same situation, some students' answers reveal how important the external structure and numerical data were for them, obviating the internal relations:

S_5: No. It will not work because there should be 13 of anything.

S_{33}: No. 13+5=18. This task does not work because it comes out of 18 candies, but we need 13 candies in total.

S_{23}: Yes, because 1,2 [referring to Friends and Lollipops situations] are the same because the numbers are the same.

In contrast, other students referred to mathematical properties when comparing equations. In Lollipops situation, S_{13} alludes to commutativity (involving symbolic letters and numbers):

S_{13}: Yes. This equation would look 2x+5=13, but we can switch 5 and 2x [comparing it with the given equation 2x+5=13].

Both disambiguation and interpretation of the statements also become crucial. For the same situation, S_{10} justifies her negative answer as follows:

S_{10}: I say no, because it says "two identical lollipops and chocolate for 5 Kč" so this all together written "for 5 Kč" and then total costs 13 Kč. It is an illogical task. "My choice".

Some students used the same letter to symbolise different quantities. This is the case of S_{30} in his attempt of syntactic translation of the Number statement:

S_{30}: No because it would be: x+5= x, x·2 = 13 but it is not: 5+2x=13 and also does not happen x·2=13 since 13 is not a divisor of two. [He verbally exchanges multiple by divisor.]

In Hanger situation, this same student does not interpret the need for the numbers in the squares to be equal, but to add up to the difference (8) between the quantities in both sides (13 and 5):

S_{30}: Yes, because the two numbers under 5 can be any way, so there could be 2 times 4, or 5 and 3 etc.

Discussion and conclusions

In this work we show elementary students' abilities to recognise whether a linear equation describes different contextualised situations. We shed light on the individual strategies that fifth grade students newly initiated in solving equations used to discern this. We highlight the wide variety and nature of their strategies as well as the different frequencies of their use depending on the system of representation of the situations. Faced with verbally presented situations, students tended to formulate an equation based on syntactic and semantic translation of the statement, to compare it with the given equation. Faced with pictorially presented situations, their tendency was to allude to an analogy between the situation at hand and another one of the tasks, concluding then the same as they did in the analogous situation. Alternatively, in this case, they also preferred to check whether the solution of the given equation was a solution for the situation at hand. This finding can be used with teaching purposes. It is also remarkable that students used more than one strategy to justify their decisions and that they did not systematise their strategies but adapting them at each situation. This is illustrated by the fact that seven used divisibility arguments to discuss the Number situation.

The students' performances indicate that they were able to infer mathematical truths not explicitly taught to them when briefly introduced to equations in the classroom. Behind their use of solution checking and solutions comparison strategies are the following facts, connected to the internal structure of equations (related to the equivalence of linear equations and uniqueness of solution): (a) If the solution of a linear equation is a solution for a situation, then this equation can algebraically describe that situation; (b) if two linear equations have the same solution, then they can algebraically describe the same situations. In contrast, most of the students who used the equations comparison strategy based their strategy on the external structure of the equations. Although this did not prevent them to get right answers in this task, it is not a safe practice, since two equivalent equations can have different external structures. Another practice that stands out in the students' performances is the frequent mathematical checking of their answers (e.g., S_{18}: 1 lollipop costs 4Kc, 13-5=8, 8:2=4, 4+4+5, 8+5=13). This validation was mostly pragmatic (Balacheff, 2001), although also a few students referred to mathematical rules in their justifications (see S_{13} above). Based on our findings, as many other authors (e.g., Brizuela & Schliemann, 2004), we conclude that algebraic activities and tasks in which the notion of linear equations is implicitly or explicitly involved could be worked at this educational level, serving to enrich students' mathematical thinking.

Proofs without words: focus on argumentation as a tool to investigate the link between visualization and generalization processes enacted by students

The study presented in this paper is based on data collected within a teaching experiment aimed at the implementation of a didactical path focused on proofs without words. Our research aim is to investigate the link between visualization and generalization processes enacted by students during their work on the tasks that constitute the didactical path. To pursue our aim, we analyzed students' argumentative processes, documented within their written protocols and within excerpts from the video-recordings of small group activities and classroom discussions. Through this analysis, developed by means of Radford's theory of objectification and Duval's levels of apprehension, we highlight the role played by visualization in supporting generalization.

Keywords: Argumentation, explanation, generalization, proofs without words, visualization.

Background

A proof without words is a proof that makes use of a graphical artifact, a picture or other visual mean, to reconstruct a deductive process that justifies a given statement or an equation (Nelsen, 1993). There is debate around whether a proof without words really qualify as a proof (Gierdien, 2007, p.1); anyway research in Mathematics Education highlighted the powerful role of proofs without words in learning and teaching mathematics. Hanna (1989) showed that involving students in interpretation and analysis of activities on proofs without words could shift the focus of teaching from proofs that prove to proofs that explain.

In 2019 we designed and implemented a teaching experiment focused on proofs without words. It was a pilot study that involved three 10th grade classes of a scientific high school near Rome, with a total of 66 students. In this paper we will focus on the second stage of this experiment trying to highlight the link between the visualization process and the generalization one through the tool of argumentation. By argumentation we mean, according to Stylianides et al. (2016), the discourse or rhetorical means used by an individual or a group to convince others that a statement is true or false. It may involve exploration of examples, generation or refinement of conjectures, and production of arguments for these conjectures.

Theoretical framework

The analytical framework we refer to is made up of two main components, the apprehension levels described by Duval and the theory of objectification introduced by Radford.

Following Duval (2006, p.107) "Mathematical objects, in contrast to phenomena of astronomy, physics, chemistry, biology, etc., are never accessible by perception or by instruments". He goes on to state that “the only way to have access to them [mathematical objects] and deal with them is using signs and semiotic representations”. This is the reason why “representation and visualization are at the core of understanding in mathematics” (Duval, 1999, p.1). Furthermore visualization, in the Duval framework, is a process that goes over the vision. “Unlike vision, which provides a direct access to the object, visualization is based on the production of a semiotic representation” (Duval, 1999, p.7). A semiotic representation does not show things as they are, it “shows relations or, better, organization of relations between representational units” (Duval, 1999, p.7). In our work students are asked to explain the relations they see between images of proofs. The *perceptual apprehension* refers to the recognition of figures and subfigures; *sequential apprehension*, is used when describing a construction of a figure based on mathematical properties; the ability to recognize such mathematical properties and explain them refers to the *discursive apprehension* while the *operative apprehension* is a process by which students, operating on the figure, identify the solution of a mathematical problem.

Following Radford (2001, p.81), generalization must be considered as “one of the more natural human semiotic process”; looking into the way students “deploy and mobilize signs to accomplish mathematical generalization”, Radford points out three levels of generalization. *Factual generalization*, that is, “a generalization of numerical actions in the form of an operational scheme that remains bound to the numerical level” (p.82), at this level the semiotic tools for the objectification are the perceptual semiosis, the generative functions of language and the operational schemes. The factual generalization is achieved by students by means of rhythm in the utterances, ostensive gestures, adverbs like always, every, etc. and making reference to space and time (i.e. *the next figure*…). The second step in generalization is *contextual generalization*, at this level students are able to write explanations regarding their conjectures and mathematical operations, in these explanations they perform actions on abstract objects (*you take that square…*) but still have a *perspectival view* of mathematical objects. The last level is *symbolic generalization*, it occurs when students talk about mathematical objects in an impersonal way (*the sum of the first n squares…*, *the n-th figure…*) and using a more specific terminology, these aspects show that the symbolic generalization is reached when students succeed in a de-subjectification process.

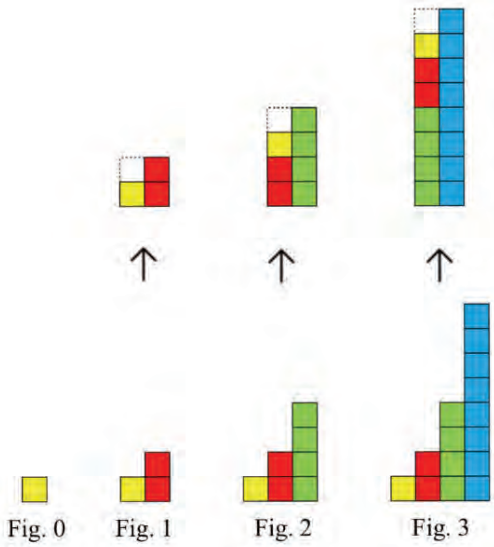
These two theorical frameworks start from different systems of principles since Duval takes constructivism as his point of departure, while Radford’s theory stems from a sociocultural perspective on learning. Nevertheless, we decided to implement a *networking* (Prediger et al., 2008) of the two theories, integrating them locally in order to study the visualization process, by means of the apprehension levels, and the generalization process referring to Radford theory. This decision is motivated by the fact that, beyond the effectiveness of the level of apprehension in analysing the visualization processes, we noticed that students, explaining and justifying on the way they look at the figure, use the figure itself as an artifact of communication and signification. This is in line with the sociocultural perspective that grounded the theory of *semiotic mediation* in the sense of Vygotsky (Cole et al. 1978) and is one of the starting points for Radford’s theory.

Context of the study

The study presented in this paper took place in Spring 2021 (totally 8 hours) and involved a 10^{th} grade class of an Italian high school (26 students). Due to the pandemic period, the presence of students in the classroom was limited to 50%. Half of the students were present in the classroom, while the other half was at home connected using a video-communication service (Google Meet) and a Multimedia Interactive Whiteboard.

The students were divided into 6 non-homogeneous groups, in agreement with their teacher. Each meeting was articulated in an initial phase of small group activity, followed by a classroom discussion. The students were invited to discuss the questions as a group and to write down the answers that would be later collected by the teacher. After the small groups' work, the students were involved by the researchers (the authors of this paper) and by their teacher in a discussion regarding the strategies used by the different groups to deal with the tasks they had to face.

The didactical path was designed as a sequence of worksheets focused on questions based on examples of proofs without words. One of the worksheets is represented in Figure 1.



The number of squares in the previous figures can be represented as follows:

Figure	Number of squares
Fig. 0	$1 = 2^0$
Fig. 1	$1 + 2 = 2^0 + 2^1 = 3$
Fig. 2	$1 + 2 + 4 = 2^0 + 2^1 + 2^2 = 7$
Fig. 3	$1 + 2 + 4 + 8 = 2^0 + 2^1 + 2^2 + 2^3 = \ldots$

1. Imagine to continue the sequence of figures, what will be the number of squares (not considering the dashed one) in Figure 5? And in Figure 9?
2. Explain how to determine the total number of squares in any figure in the previous sequence.
3. Explain which features of the figures helped you in constructing answers to the previous questions.
4. These figures aim to justify a theorem on the sum of the powers of two. Try formulating this theorem.
5. Write a reasoning to justify the theorem you formulated in question 4.

Figure 1: Worksheet 3

All the worksheets included questions about a number sequence, as the one in Figure 1. The students were asked to find some elements of the number sequence under investigation (question 1, Figure 1) and to explain how to find out a generic element of the sequence (question 2, Figure 1). To make them reflect on the visualization processes they enacted, the students were asked to explain which features of the figures helped them in formulating their answers (question 3, Figure 1). Nevertheless we add a table with numbers (see figure 1) to let the students be free to choose the semiotic representation they felt more comfortable with: the picture that recalls a proof without words or the table that recalls a more traditional approach. From the analysis of data collected we could see that only one group preferred the table and did not use the picture in answering questions 1 and 2.

The last two questions aimed to prompt students identify the theorems behind the proofs without words proposed in the worksheets and reflect on the role played by figures in supporting the formulation of conjectures and in proving theorems (questions 4 and 5, Figure 1).

Research questions and methodology

Our research hypothesis is that argumentation could represent an effective tool through which the link between visualization and generalization could be explored. The analysis we developed was aimed at investigating this link. The research question that guided our analysis is: referring to the level of generalization and of apprehension reached by students, what characterizes the link between visualization and generalization when students face activities focused on proofs without words?

In order to answer this question, we collected the protocols written by students during the group work and the audio and video-recordings of all the activities (both face-to-face activities and activities carried out at distance), including group work and classroom discussions. We then analyzed the whole material, transcribing some excerpts we considered as interesting in order to establish a link between visualization and generalization.

For our analysis, we referred to the main components of our theoretical framework: Duval’s levels of apprehension and the generalization categorization proposed by Radford.

In this paper we will analyse the work of only two groups. The reason for this choice is that the students in these groups felt the need to explain in depth their written protocols during the class discussion even if they didn’t grasp the whole solution of the task. This didn’t happen in other groups, probably because students were not used to argumentation neither written nor oral. Sometimes (it is the case of one of the groups of our experiment) the solution of the task was easily grasped, and the visualization process remained implicit.

We follow the evolution of each group along three steps: (1) the discussion in the small group, (2) the students’ written protocols, and (3) the classroom discussion with the teacher and the authors. We chose to focus our analysis on the excerpts regarding questions 2 and 3 of the worksheet in Figure 1, since they enable us to focus on the way students formulate their generalizations (question 2) and explain how they looked at the figures, that is the visualization processes that supported their generalizations (question 3).

Regarding step (2), we should note that the condition under which the experiment was conducted (remote meeting) strongly limited the semiotic potential of the interaction between students. In particular, it was not possible to collect any data about students’ use of gestures or facial expressions during the small group discussions.

The final discussion in class which is reported here was led by one of the authors with the aim to foster students’ explication of their visualization and generalization processes.

Data analysis

Analysis of data taken from group 1

The first excerpt is taken from the discussion of group 1. They are working together during a remote meeting. One of the participants share the screen with the figures of worksheet 3 (Figure 1). The group is trying to answer the number 2 question while they look at the figures on the screen.

20	Giada:	…But…I think I understood that the next figure is always equal to twice the previous figure plus one.
21	Giorgia:	Yes, it’s true.
22	Lea:	Giada, can you repeat what you said?
23	Giada:	So… for instance figure 5 is equal to twice the figure 4 plus 1.
24	Lea:	Ah, ok, I got it, so you suggest writing down this instead of the whole formula?

In line 20 Giada comes up with an idea, “the next figure is always equal to twice the previous figure plus one”, and she shares the idea with the group. The group discusses and they write it in their protocol. From these data it emerges, according to Radford theoretical framework, a *contextual generalization*, it goes over the numerical level; they find out a property that holds for each figure. However, we argue that they still have a *perspectival view* of the mathematical objects, seen in the expression “the next figure …the previous figure”, so the generalization process is not complete, they did not reach to the symbolic level.

In their written answer to question 2, the students wrote: “*The number of squares of the next figure, with respect to the figure we are considering, is doubled plus one*”. And when they are asked to clarify the visualization process (question 3) they discuss and then write: “*Colours that helps to differentiate the different columns, the increasing shape, the figure number*”.

During the discussion in class, we tried to push forward the investigation about the visualization, asking the students for explanations about the written answers. This can be seen in the following excerpt involving one of the authors and a student from group 1.

13	Giorgia:	Given a figure of the sequence, to get the number of squares of the following figure, we doubled the number of squares of the given figure and add 1.
14	Author:	Where did you see it in the figure?
15	Giorgia:	… for instance [*pointing at figure 0 of the worksheet displayed on the whiteboard*] the figure 0… 1 times 2 is 2, plus 1 is 3, and so on…
16	Author:	Did the figure help you in discovering that?
17	Giorgia:	Yes.
18	Author:	How?
19	Giorgia:	It helped us because we saw that … this one [*pointing at the yellow square*]… in order to get to the red one [*pointing at the two red squares*] … we multiply times two and then we add the one that we had before.
20	Author:	Which one?

21	Giorgia:	The yellow one.
22	Author:	And what about the next steps?
23	Giorgia:	… all this stuff [*pointing at figure 1, lower part*] times 2 is 6, the same as 1,2,3,4,5,6… the red and green squares [*pointing at the red and green squares of figure 2, lower part*] plus 1 that is, once again, the yellow one.

We think that, in the previous excerpt, Giorgia has carried out a very peculiar visualization process. Even if she didn't use the hint given by the upper part of the sequence of figures of the worksheet, she is able to perform an advanced process of visualization. She actually doesn't stop herself to the visual perception of the figures, she goes over, seeing the "relations", and the "organization of relations between representational units" (Duval, 1999). In this case the representational units are the squares. She highlighted the relation between the yellow square of figure 0 and the two red squares of figure 1 (the yellow square doubled and "became" the two red squares of figure 1) and did the same for each figure in relation with the next one. Moreover, in line 19, Giorgia describes the construction of any figure of the sequence starting from the previous one (*sequential apprehension*).

Analysis of data taken from group 2

We now move to the analysis of the material of group 2. We will notice that, even if the two groups obtained two different formulas and looked at the figures in two different ways, the characterization of the link between the visualization and the generalization process is similar.

7	Francesco:	…Anyway… these figures…are simply increasing…every next column is one plus the previous one and then…I didn't get why… they … put them on top of each other...
8	Federica:	I think they go like 2 x 2 is 4, next 4 x 2 is 8, the last column, so 8 x 2 I think … so figure 4 will be 16, the last column and so…
9	Francesco:	Are you talking about…the one that has been added?
10	Federica:	Yes, the blue one...
11	Francesco:	Ok, yes, it is multiplied by 2
…		
16	Francesco:	… anyway… the column that has been added is a number… and the other columns equal that number minus 1, so… for instance, in figure 5 they will be 32 plus 31…
17	Federica:	Yes, is it so.

Francesco, in line 16, makes an effort towards generalization. In this moment he is contributing to the work of the group with an idea that goes over the numerical level. After the discussion, the group wrote down their idea in the written answer to question 2 as follows:

Last column times 2, minus 1

We notice that this protocol is different from the formula given by group 1. Even the generalization process is slightly different because group 2 explained how to compute the number of squares of any figure without any reference to the previous figure, so they go over the *perspectival view*. Anyway, the generalization level of group 2 is still a *contextual generalization* because they did not proceed to the *des-embodiment* in their mathematical description; they actually need to know the number of squares of the *last column* in order to compute the number of squares of the whole figure. Since we want to investigate the link between this generalization process and the visualization, we analyze the written answer to question 3 given by group 2. It was:

It helped us the way the squares are arranged in the upper part of the figures.

Therefore, the way students in group 2 look at the figure is also different with respect to group 1; specifically, students of group 2 look at the upper part of the figures while students from group 1 look at the lower part. In the next excerpt, taken from the class discussion with one of the authors, the visualization process fielded by the students in answering question 2 emerges.

41	Francesco:	A way to find the number of squares is taking the last column, multiply such a column times 2 and subtract 1.
42	Author:	What tells you that?
43	Francesco:	We can argue that from the figure here above, i mean … you see that it always misses a square… is this one times 2 minus 1 [*pointing at figure 1*]
44	Author:	Ok
45	Francesco:	…Or this times 2 minus 1 [*pointing at figure 3*]…because…I mean…you can tell it by this figure [*pointing at the upper part of figure 3*]

In line 41 Francesco describes an action on abstract objects (*taking the last column*); this kind of operation, characteristic of the *contextual generalization*, is suggested by the figure, as Francesco explained in line 43. Furthermore, from line 45 we argue that the description of Francesco is indeed the description of the construction of the whole sequence of mathematical figures, as pointed out by Duval describing the *sequential apprehension*.

Conclusions

Generalization and visualization are two essential components of the mathematics learning and teaching process. Often the link between these two components is obscured by many factors. We refer to the attitude of students toward argumentation (as we already discussed) and to the peculiar conditions in which the experiment took place (remote meetings) which affect the social-communicative dimension of the interaction between students. In the small-group activities mediated by screens, students' semiotic assets are restricted. The fact that *implicit and mutual agreement of face-to-face interaction must be replaced by objective elements of social interaction*, according to Radford (2001), guides the activity toward the generalization. Thus, the balance between visualization and generalization it's unlikely to arise. However, the two examples discussed in this paper show that pushing forward the argumentation process is an effective way to clarify the connection between the visualization and the generalization processes fielded by students when they approach a mathematical problem. The link between visualization and generalization process was outlined in other studies (e.g., Barbosa, 2011). The contribution of this paper is to characterize, in terms of level of apprehension, the generalization achieved by 10th grade students who do not succeed in the whole task. In the analysis we outlined that, even if the two groups looked at the figure in different ways and produced different formulas, their contextual generalization was guided by a sequential apprehension. So, in these two cases, the link between the visualization and the generalization process is characterized by the match of sequential apprehension and contextual generalization. It seems to us to be worthy of further study to investigate the visualization process of groups of students that reach a symbolic generalization in solving similar tasks.

The role of generalized arithmetic in the development of early algebraic thinking

Demetra Pitta-Pantazi, Constantinos Christou and Maria Chimoni

University of Cyprus, Department of Education, Cyprus; dpitta@ucy.ac.cy, edchrist@ucy.ac.cy; chimoni.m@cyearn.pi.ac.cy

The purpose of this study is to characterize early algebraic thinking in relation to students' understanding of generalized arithmetic concepts and procedures. The participants of the study were 203 Grade 6 students. Data were collected from two tests which focused on number, operations, equivalence, and equality properties. The first test included arithmetic tasks which could be solved by either strategies based on calculations or strategies based on arithmetic structure, while the second test included algebraic tasks which involved letters-symbolic representations. The results indicate that students who were able to solve arithmetic tasks using arithmetic structure were also able to solve algebraic tasks. The findings imply that generalized arithmetic abilities underpin the syntactical manipulation of algebraic expressions and exemplify why seeing structure is a highly important process of early algebraic thinking.

Keywords: Generalized arithmetic, seeing structure, early algebraic thinking.

Introduction

Generalized arithmetic has been described by Kaput (2008) as a basic algebra content strand in the K-12 curriculum. In the context of early algebra, generalized arithmetic provides students with the opportunity to work with properties that are inherent to number and arithmetic operations and understand that these properties are generalizable (Kieran et al., 2016). This kind of activity entails the process of generalizing, but also the complementary process of seeing structure.

Placing attention on structure means turning attention away from carrying calculations (Hewitt, 2019). Looking for and becoming aware of structure pertains to the manipulation of number and arithmetic operations as objects which could be decomposed and recomposed in various ways (Kieran, 2018). While the process of generalizing has been explored in extend, more research is still needed in respect to the process of seeing structure, especially within generalized arithmetic contexts (Kieran, 2018). This study aims to contribute towards a better understanding of the role of generalized arithmetic and arithmetic structure awareness in the development of early algebraic thinking. Specifically, the study aims to exemplify why and how Grade 6 students' abilities in generalized arithmetic may be related to their understanding of algebra symbolic language and the meaningful manipulation of algebraic expressions.

Literature review

Generalized arithmetic

Generalized arithmetic abilities involve understanding of (a) the properties of numbers, such as odd and even numbers (Bastable & Schifter, 2008), (b) the way operations relate to each other and the use of properties of operations for transforming arithmetic expressions (Britt & Irwin, 2011), and (c) the relational conception of the equals sign, which is not merely a signal for performing operations, but also a signal for presenting the relationship of equivalent expressions and preserving the same value on both sides of an equation (Jones et al., 2012). These abilities could be developed within activities that are abstracted from computations and do not address the use of letters (Kieran et al, 2016). They facilitate the development of structural awareness which in turn enables the interpretation of arithmetic expressions as encoding the operational composition of numbers (Subramaniam & Banerjee, 2011). For example, the number 989 could be decomposed and recomposed into various structures depending on different relations, i.e., $9 \times 109 + 8$ or $9 \times 110 - 1$ or $989 = 9 \times 10^2 + 8 \times 10^1 + 9 \times 10^0$) (Kieran, 2018).

Several studies explored the significance of structural awareness within generalized arithmetic contexts for students' successful engagement in algebraic activity. Warren (2003) indicated that understanding the use of properties of operations, like the commutative and associative property of addition, is critical for interpreting an operation as a general procedure that reflects a specific relationship between quantities, either known or unknown. Similarly, it was found that the use of opposite and inverse relations for simplifying arithmetic expressions enables students to understand that performing calculations in a serial way is not always necessary and that similar procedures could be applied for manipulating algebraic expressions (Linchevski & Livneh, 1999).

Britt and Irwin (2011) also indicated that helping students to understand the relational function of the equals symbol supports their meaningful engagement with algebra as a formal symbolic language. For example, using compensation in addition to transform $27 + 6$ into $30 + 3$ provides a foundation for generalizing that $a + b$ is an equivalent expression to $(a + c) + (b - c)$. Likewise, students can more easily understand that the transformations performed for solving an equation, like $4x - 8 = 3x + 1$, should always preserve the equivalence of the two sides (Knuth et al., 2005).

Another example concerns the result of operations with classes of numbers that have specific properties, like odd and even numbers. This kind of activity was found supportive for developing generalization, since multiple instances are compressed into a single, unitary form (Blanton et al., 2018). At the same time, the process of seeing structure is triggered, since the result of operations with specific classes of numbers is justified by their additive and multiplicative structure. At a later stage, students become able to represent the structure of operations with specific classes of numbers using letters i.e., odd + odd = even as $(2n + 1) + (2m + 1) = 2n + 2m + 2 = 2(n + m + 1)$.

Aim of the study

The current paper aims to extend prior research by providing insight into students' behavior when they confront a variety of generalized arithmetic tasks and whether this behavior influences their abilities in solving algebraic tasks. Therefore, this paper aims to contribute into further characterizing abilities in generalized arithmetic and exemplifying its role in developing early algebraic thinking abilities. Specifically, this paper focuses on describing Grade 6 students' abilities in solving generalized arithmetic tasks that involve (a) properties of operations, (b) equivalence and equality properties, and (c) properties of numbers. Moreover, this paper aims to illustrate why and how these abilities may be related to students' capability for solving respective algebraic tasks.

Method

Participants

A group of 203 6th grade students from 4 urban schools (7 classrooms) participated in the study. The schools were chosen through convenience sampling, but attempt was made to invite schools from various socio-economic backgrounds to participate in our study. All students had received similar instruction in respect to algebra which was based on the content of their mathematics textbooks. Mathematics textbooks are the same for all students and are used at a national and compulsory level. These lessons involved the use of properties of numbers for simplifying calculations and finding the value of numerical expressions, the use of variables for representing unknown quantities, the formulation of algebraic expressions, the concept of equality and equality properties, equation solving (one-step and two-step equations), the concept of function, the use of different representations for representing functional relationships, and modeling problems.

Procedure and materials

Two tests were administered to the students. To distinguish more easily the two tests, we named the first test "arichthmetic" and the second "algebraic". The first test included 10 tasks that involved numbers, whereas the second test included 10 corresponding tasks that involved letter-symbolic representations. By corresponding tasks, we mean that for each task in the first test, there was a corresponding task in the second test which involved the same concept (Table 1). Each test consisted of three categories of tasks: (a) properties of operations (3 tasks), (b) equivalence and equality properties (4 tasks), and (c) properties of numbers (3 tasks). The tasks in the arithmetic test could be solved based entirely on calculation procedures, but they could also be solved through procedures based on the identification of general properties. The tasks in the algebraic test could only be solved through algebraic procedures.

Table 1: Examples from the arithmetica nd algebraic tests

	Arithmetic tasks	Algebraic tasks
Properties of operations	Calculate the result. Show your work. (a) $27 + 89 + 262 - 92 + 92 - 89 =$ (b) $846 \div 28 \cdot 28 \div 2 =$	Vasiliki claims that she can find the value of the following expressions. Do you agree or disagree with Vasiliki. Explain your answer (a) $420 - 3\chi - 4\psi + 3\chi + 3\psi + \psi =$ (b) $35 \cdot 3\chi \div 4\psi \div 3\chi \cdot 4\psi =$
Equivalence and equality properties	Find the missing number. Explain your thinking. $\square + 17 = 15 + 24$	$18 + A = 20 + B$ Based on the above equality, express the relationship between A and B.
Properties of numbers	Name number y, using one of the following labels: odd number, multiple of 10, 2-digit number. $(a)\ y = (10 \times 3) + 8$ $(b)\ y = 246\,779\,568 + 1$ $(c)\ y = 10 \times 1245$	Name number y, using one of the following labels: even number, multiple of 10, odd number. $(a)\ y = 2a$ $(b)\ y = 2b + 1$ $(c)\ y = 10c$

Research questions

To fulfill the general aim of the study, the following research questions were addressed:

(1) Is there a statistically significant difference between students' performance in the arithmetic and algebraic tasks?

(2) Is there a statistically significant difference between students' performance in the tasks concerning (a) properties of operations, (b) equivalence and equality properties, and (c) properties of numbers, when these tasks include only numbers and when they include letters?

(3) Are there any differences in the strategies that low, medium and high achievers employ to respond to these types of tasks?

Analysis

The first step of the analysis was to mark the tests and give 1 point to correct solutions and 0 points to erroneous solutions. The second step was to assess the type of strategy that students used to respond to each task in the first test. Researchers categorized students' strategies as (a) strategy based on claculations, (b) strategy based on arithmetic structure, and (c) no strategy. By "strategy based on calculations" we mean the application of calculation procedures in a serial way or trial and error strategies. By "strategy based on arithmetic structure" we mean the identification of general properties, as these are instantiated as relationships between mathematical objects (Mason et al., 2009). No strategy was used to characterize responses that did not include a description of the way an answer was reached. To ensure reliability of the categorization of students' strategies, a subset of responses was randomly selected and coded by each author individually. Then, the authors compared their coding. Disagreements were resolved through discussion, until consensus was reached. The data analyses were conducted with IBM SPSS Statistics 27. Descriptive analysis was conducted for the variables and paired sample t-test to compare the students' results in the two tests.

Presentation of Results

To respond to the first research question, we analyzed the means and standard deviations of students' responses in the two tests. Students had a mean performance of .777 in the first test and .664 in the second. The difference in the means of these two tests was statistically significant ($p<0.001$).

To respond to the second research question, Table 2 shows the means and standard deviations in the three different categories of tasks and the results of the paired t-tests. The mean performance in all the categories of the arithmetic tasks was always higher than in the respective algebraic tasks. Paired t-test analysis showed that this difference was always statistically significant.

Table 2: Students' performance in the three categories of tasks in the two tests

	n	Mean	SD	t	df	p
Properties of operations (arithmetic test)	203	.757	.202	7.465	202	<0.01
Properties of operations (algebraic test)	203	.654	.241			
Equivalence/equality properties (arithmetic test)	203	.787	.214	8.104	202	<0.01
Equivalence/equality properties (algebraic test)	203	.674	.239			
Properties of numbers (arithmetic test)	203	.789	.293	5.590	202	<0.01
Properties of numbers (algebraic test)	203	.664	.294			

To respond to the third question, we first examined the strategies used by students to solve the arithmetic tasks. Table 3 illustrates examples of students' responses to an arithmetic task that involved the use of opposite and inverse operations. Students' responses to the respective algebraic task are also presented. Christos was one of the students that used a strategy based on calculations for solving the arithmetic task; he performed calculations in a serial way, without noticing the components of the expression and the relationship between them. In the respective algebraic task, he answered that he could not find the value of the expression, because he needed first to know the values of the variables. Dora was one of the students that used a strategy based on arithmetic structure for solving the same arithmetic task. Dora seems to have immediately looked at the arithmetic expression and noticed the relationship between opposite and inverse numbers. She was also successful in solving the algebraic task. As Mason et al. (2009) have highlighted "to decide without any calculation is a form of relational thinking, of appreciating arithmetic structure" (p.21).

Table 3: Examples of students' responses to arithmetic and algebraic tasks

	Arithmetic task	Algebraic task
	Calculate the result. Show your work. $(a)\ 27 + 89 + 262 - 92 + 92 - 89$ $(b)\ 846 \div 28 \cdot 28 \div 2$	Vasiliki claims that she can find the value of the following expressions. Explain your answer. $(a)\ 420 - 3\chi - 4\psi + 3\chi + 3\psi + \psi$ $(b)\ 35 \cdot 3\chi \div 4\psi \div 3\chi \cdot 4\psi$
Arithmetic strategy (Christos)		 *"No, because you first need to know the value of χ and ψ."*
Arithmetic structure strategy (Dora)		 "Yes, it is correct because if you add a number and then subtract it, the number stays the same. The same stands for multiplication and division."

To better understand the profile of students who used each type of strategy, we identified three groups of students, based on students' mean score in the two tests, We labeled as (a) low achievers those with a mean score in the two tests equal or below 0.654 (N=58, 28.6% of the population), (b) middle achievers those with a mean score between 0.655-0.854 (N=88, 43.3% of the population), and (c) high achievers those with a mean score 0.855-1 (N=57, 28.1% of the population). Then, we examined the type of strategy that low, middle, and high achievers used to solve the arithmetic tasks in the first test. Tables 4, 5, and 6 show the percentage of students who used strategies based on arithmetic structure (S.S), strategies based on calculations (S.C), and no strategy (NoS.).

The percentages in Tables 4, 5, and 6 tell the same story. In the three categories of tasks, low achievers, consistently used more strategies based on calculations. High achievers systematically used strategies based on arithmetic structure. Middle achievers used more frequently strategies based on arithmetic structure than the low achievers but less frequently than the high achievers. However, we should note that the percentage of strategies based on arithmetic structure in solving properties of numbers tasks was much smaller in relation to the other two categories.

Table 4: Percentages of different strategies in properties of operations tasks

Item	Concept	Low Achievers N=58 (28.6%)			Middle Achievers N=88 (43.3%)			High Achievers N=57 (28.1%)		
		S.S	S.C	No S.	S.S	S.C	No S.	S.S	S.C	No S.

Discussion and conclusion

The purpose of this study was to characterize students' early algebraic thinking in respect to generalized arithmetic abilities. The results showed that students who were able to manipulate structure within arithmetic expressions were also able to manipulate the syntactical structure of algebraic expressions where calculations are impossible. Therefore, this study offers empirical evidence to theoretical postulations which addressed that seeing structure is significant for the emergence of early algebraic thinking, equally important to generalizing (Kieran, 2018).

The results revealed that some students used strategies based on calcilations for solving the arithmetic tasks, whereas others used strategies based on arithmetic structure. It was found that low achievers more often used strategies based on calculations to solve the arithmetic tasks. In contrast, high achievers did not perform calculations right away, but they analyzed and made use of the embedded structure. In a similar way, they approached respective algebraic tasks. This result shows that to achieve the full potential of generalized arithmetic in enhancing early algebraic thinking, instruction needs to support all students to look for structure.

The tasks in the two tests captured three basic categories of generalized arithmetic, as these were described by previous theoretical and research studies: (a) properties of operations, (b) equivalence and equality properties, and (c) properties of numbers. In each category, students' awareness and use of the embedded properties seem to have enabled the manipulation of both arithmetic and algebraic expressions as objects that can be decomposed and recomposed in flexible ways (Kieran, 2018; Subramaniam & Banerjee, 2011). The fact that the algebraic expressions involved letters did not seem to obscure their manipulation. This finding is also supportive of the idea that understanding of the formal and symbolic language of algebra might be rooted in students' understanding of the irrelevance of performing calculations and the fact that expressions, even if they involve only numbers, could remain uncalculated to declare a kind of relationship between two quantities or more.

Further analysis of the data revealed that the lowest percentage of strategies based on arithmetic structure was applied to tasks that involved properties of numbers, implying that these tasks might be more difficult or less emphasized in schools. This kind of strategies was more requently used in tasks that involved equivalence and equality properties, implying that the number of students in the sample who could understand the equals sign relationally was higher. The highest percentage of strategies based on arithmetic structure was observed in tasks that involved properties of operations. These findings denote that the instruction that these students received might have placed an emphasis on specific generalized arithmetic concepts and procedures and less attention was paid to others.

Summing up, this study illustrates through empirical evidence how and why generalized arithmetic comprises a critical content strand of early algebra lessons. As to how, the results imply that generalized arithmetic offered students the opportunity to decompose and compose arithmetic expressions and transfer this process when the format of an expression changed from numerical to letter-symbolic. As to why, it seems that generalized arithmetic provided a concrete foundation for placing attention to structure and not to calculations. Future research may examine students' behavior through qualitative methods to clearer describe the transfer of working from arithmetic to algebraic contexts and describing pedagogical instructional environments which establish this transfer for all students.

Grade 3 Students' Algebraic Thinking Abilities: An empirically Validated Theoretical Framework

Marios Pittalis[1], Demetra Pitta-Pantazi[1] and Constantinos Christou[1]

[1]University of Cyprus, Department of Education, Nicosia, Cyprus; m.pittalis@ucy.ac.cy, dpitta@ucy.ac.cy, edchrist@ucy.ac.cy

The present study proposed and empirically validated a theoretical framework describing algebraic thinking abilities for Grade 3 students. Four algebraic abilities were incorporated in this framework: 'relational manipulation of equalities/inequalities', 'compose and decompose number and arithmetical expressions', 'functional thinking' and 'representing-modeling'. The study involved 124 students. Analysis showed that the three first constructs compose a general thinking ability that could be considered as an index of Grade 3 students' capacity to respond to a variety of algebraic thinking tasks. This general ability was a strong predictive factor of students' representing-modeling ability.

Keywords: Early-algebra, functional thinking, generalized arithmetic, modeling.

Introduction

Initiatives worldwide have underlined the significance of early algebra in mathematics education and stressed that to meet the goal of developing a fundamental algebraic understanding, students in elementary school should be involved in activities that prepare them for algebra in later grades (National Council of Teachers of Mathematics, 2000; Stephens, et al., 2017). Early algebraic thinking can be coherently conceptualized as a synthesis of different content strands, concepts, processes or forms of reasoning that relate to the ideas of equivalence, properties of numbers and operations, variable, proportional reasoning, modelling, and functional thinking (Chimoni, et al., 2018; Kaput, 2008; Kieran, et al., 2016). Research studies suggest that elementary school children could engage in sophisticated ways of algebraic thinking, such as generalizing, representing, justifying, and reasoning with mathematical structure and relationships (Stephens et al., 2017). However, the existence of different approaches to the notion of algebraic thinking, in terms of content strands, concepts, processes and reasoning forms makes it challenging to provide a coherent description of the nature of algebraic thinking. The relation between young students' algebraic thinking abilities, remains under-researched. In this study, as a first step, we explore Grade 3 students' thinking algebraic abilities to identify their relations based on empirical data.

Theoretical Considerations

Several research efforts concentrated on the analysis of the nature and content of algebraic thinking and provided a list of characteristics of algebraic thinking in all grades (e.g., Blanton et al., 2011). An overarching definition suggested that algebraic thinking is a 'habit of mind' that enables students to identify and express mathematical structure and relationships (Blanton & Kaput, 2005). Researchers claimed that a fundamental element of algebraic thinking is generalization, that is the ability to see the general in the particular (Kaput, 2008; Kieran, 2007). Chimoni et al. (2018) provided a synthesis of the literature, suggesting four basic dimensions in terms of (a) content strands, (b) concepts, (c) processes, and (d) reasoning forms: A number of theoretical frameworks conceptualized algebra in terms of content strands and concepts. For instance, Kaput's (2008) model asserts that generalizing and symbolizing are tightly linked in that symbols allow generalizations to be expressed in a stable and compact form, throughout generalized arithmetic, functional thinking, and modeling languages. Generalized arithmetic entails noticing relationships between numbers, the manipulations of operations and their properties, and the transformation and solution of equations (Chimoni et al., 2018). Functional thinking has generally been defined as the process of building, describing, and reasoning with and about functions (Stephens, et al., 2017). Modeling languages involves the use of symbols for developing models, and re-translating between models and situations. Kaput's framework was empirically validated by Pitta-Pantazi et al. (2020) for grades 8 and 9.

Kieran (2007) conceptualized algebra as a multidimensional activity that encompasses various types of tasks and ways of thinking. She suggested three types of activities: *generational, transformational*, and *global, meta-level*. The generational activities refer to the generation of equations and expressions in various situations and involve exploration of problem situations and numerical and geometrical patterns that lead to the formulation of generalizations, and exploring numerical relations. The transformational activities refer to the transformation of expressions by applying specific rules and involve conceptual understanding of algebraic objects. The global, meta-level activities are not strictly algebraic in nature, but algebraic tools are needed to be investigated and involve general mathematical processes, such as proving, studying functional relations, and identifying structure. Further, Kieran (2007) suggested that the smooth transition from arithmetic to algebra could be achieved by focusing on (a) the relations of numbers and not only on calculations; (b) relations between operations; (c) representation and solution of problems; (d) the use of numbers and letters; (e) the meaning of the equal sign. This list of activities provides a comprehensive lens to examine algebraic thinking in terms of content strands and specific algebraic concepts. In addition, Drijvers et al., (2011) distinguished four strands in algebra teaching: patterns and formulas; restrictions; functions; and language. Patterns and formulas involve searching for regularity, patterns and structures and embeds generalization. Restrictions entail manipulating equations or inequalities, such as finding what value of the unknown variable satisfies the required conditions. Functions reflect algebra as the study of relations and functions. Language concerns algebra as a symbolic system. Driscoll (1999) provided a description of algebraic thinking in terms of habits of mind that fits with the frameworks suggested by Kieran (2007) and Drijvers et al. (2011). He suggested 'doing and undoing mathematical processes', 'identifying and representing functional rules', and 'thinking about computations independently of particular numbers'.

In terms of processes and reasoning forms, a number of research studies proposed noticing, representing, and justifying with mathematical structure and relations as core processes for searching similarities and differences (Blanton et al., 2011; Jeannotte & Kieran, 2017). Abductive, inductive and deductive reasoning were proposed as important types of reasoning forms in algebraic situations (Chimoni et al., 2018). For instance, abductive reasoning is necessary at the stage where individuals develop a prediction about a plausible generalization (Rivera & Becker, 2007), while inductive reasoning is required to grasp a generality through noticing how a local commonality hold across all terms. The variety of the frameworks described above shows the complexity in defining early algebraic thinking by clarifying its differences from arithmetical thinking and defining well-accepted algebraic abilities for young students (Chimoni et al., 2018). Furthermore, to date, these frameworks have not been extensively validated based on empirical data for young students.

The Present Study

The main purpose of the study is to examine, based on a synthesis of well-accepted theoretical frameworks, Grade 3 students' algebraic thinking abilities. We define algebraic thinking abilities as the capacity of the individuals to perform various early algebra tasks and include both relevant knowledge, reasoning skills, and algebraic processes, such as generalizing, representing, justifying and reasoning with mathematical relationships (Blanton et al., 2011). We propose algebraic thinking abilities in an attempt to describe the structure of algebraic thinking by amalgamating various types of algebraic tasks, processes and practices. The proposed framework is based on (a) Kaput's (2008) algebra core content areas, (b) Blanton et al.'s, (2011) description of algebraic processes, (c) Kieran's (2007) algebraic types of activities, (d) Drijvers et al.'s, (2011) algebra strands, and (e) Driscoll's (1999) algebraic habits of mind. The framework (see Figure 1) involves four distinct but correlated factors and defines a measurement model of young student's algebraic thinking abilities. The innovative aspect of the proposed framework is the fact that it integrates aspects of the fore-mentioned frameworks that meet Grade 3 students' early-algebraic experiences and needs. It is grounded on embedding early algebraic processes and practices in specific content areas to define algebraic thinking abilities that Grade 3 students should develop based on well-accepted frameworks, contemporary curricula, and policy documents. The proposed thinking abilities can be used as measurement indicators of Grade 3 algebraic thinking.

The first factor, *relational manipulation of equalities/inequalities*, corresponds to students' capacity to manipulate equations and equalities, find the value of the unknown in equations and inequalities that are represented in the form of an empty box to be filled or in balance scale equalities and inequalities that are suitable for Grade 3. It embeds Driscoll's (1999) idea of doing and undoing mathematical procedures. The second factor, *compose and decompose numbers and arithmetical expressions*, includes students' ability to conceptualize the relations and properties of numbers, relations between operations, to reflect and make predictions about computations and solve problems independently of particular numbers, based on number-property generalizations. In addition, it includes the ability to interpret equalities expressed in different forms (Blanton et al., 2011). Students need to decide as a result of noticing an arithmetic or computational structure, before proceeding to a second action. Conclusively, it conceptualizes students' capacity to make numeric and arithmetical computations, solve numeric related problems, and interpret equivalence expressions by grasping mathematical structure and relations in these situations, abstracting from arithmetic properties and objectifying the generalized properties. The third factor, *functional thinking*, adopts the definition proposed by Pittalis et al. (2020) for young students, suggesting that it encompasses student's capacity to notice, generalize, and abstract relations between covarying quantities/variables, represent these relations through natural language, symbols, and appropriate representations and use the generalized representations in problem solving situations. Finally, *representing-modeling languages*, represents students' capacity to represent word-problem situations that embed relations among quantities using a variety of representations, such as number sentences, literal symbols, and figural models (Kaput, 2008; Kieran et al., 2016). The research questions of the study were: Could different algebraic thinking tasks be categorized on the basis of the factors of the proposed theoretical framework? What is the structure and the relations between the proposed algebraic thinking abilities, as they are projected through Grade 3 students' responses?

Measures

The test items were adopted or developed based on previous research studies (Blanton et al. 2011; Chimoni et al., 2018). The multiple-choice tasks were considered as correct or incorrect, while the open tasks were given partial marks. The first factor, *relational manipulation of equalities/inequalities*, was measured by three types of tasks: completing the missing value in an equity, finding the value of the unknown in an equation that was presented in a balance-scale form, and finding one possible value of an unknow variable in an inequality that was presented in a pictorial form (Drijvers et al., 2011). Variables in balance-scale equations and inequalities were represented by pictorial symbols (see Table 1). The second factor, *compose and decompose numbers and arithmetical expressions*, was measured by four types of tasks. The first type required students to solve number-property problems, such as conceptualizing odd and even numbers. The second type of tasks provided students the result of an addition or subtraction and asked students to find the sum or difference based on the derived facts (Driscoll, 1999). Generalization of the derived fact was necessary to conceptualize the structure of the provided and the given calculations and grasp the differences. The third type required students to predict whether 'big calculations' result to odd or even numbers, without making any calculations but noticing the odd/even property of the numbers and generalizing the result of adding/subtracting odd/even numbers. The fourth type provided students two equalities in the form of balance-scale situation. Student had to find the heaviest toy by interpreting the equalities and making assumptions regarding the relations of the involved objects. The *representing-modeling languages* factor was measured by three types of tasks that required translating a word-problem situation by noticing the relation between the involved quantities. In the first type students had to represent the problem in a number sentence form, in the second one in a model form (Kieran et al., 2016), and the third one in literal symbols. *Functional thinking* was measured by tasks that entail four modes of thinking (Pittalis et al., 2020): recursive patterning (14 tasks), covariational thinking (5 tasks), correspondence-particular (7 tasks), and correspondence-general (7 tasks). Due to space limitations, we do not present the functional thinking tasks.

Participants, Procedure and Data Analysis

Consent forms for students to participate in the study were distributed to two urban primary schools in Cyprus. The schools, teachers and students involved participated voluntarily, thus our sampling was a convenient one. Parents' consent forms were returned for 95% of the students, resulting in a sample of 124 Grade 3, 9-year-old students (65 males and 59 females).

Table 1: Examples of tasks

Factor	Type of task	Example
Relational manipulation of equalities and inequalities	(a) Completing equalities (b) Solving equations in balance scale form (c) Solving inequalities	(a) Fill in the missing number: $12 + 4 = \square + 6$, $3 \times \square = 15$ (b) Find the value of the symbol. (c) Find a possible value for the symbol.  Compose and decompose numbers and arithmetical expressions	(a) Solving number-property problems (b) Make calculations based on derived facts (c) Make predictions based on number-properties (d) Interpret equities	(a) I had in my pocket more than 12, but less than 15 euro. I spent all my money to buy pencils that cost 2 euro each. How much money I had in my pocket? (b) Find the following if you know that 118+8=126. 128+8, 118+18, 118+9, 218+8, 119+18 (c) Does the following give even result (without making calculations)? 122+18, 15+45, 478+222+444, 333-115 (d) Which toy is the heaviest? 
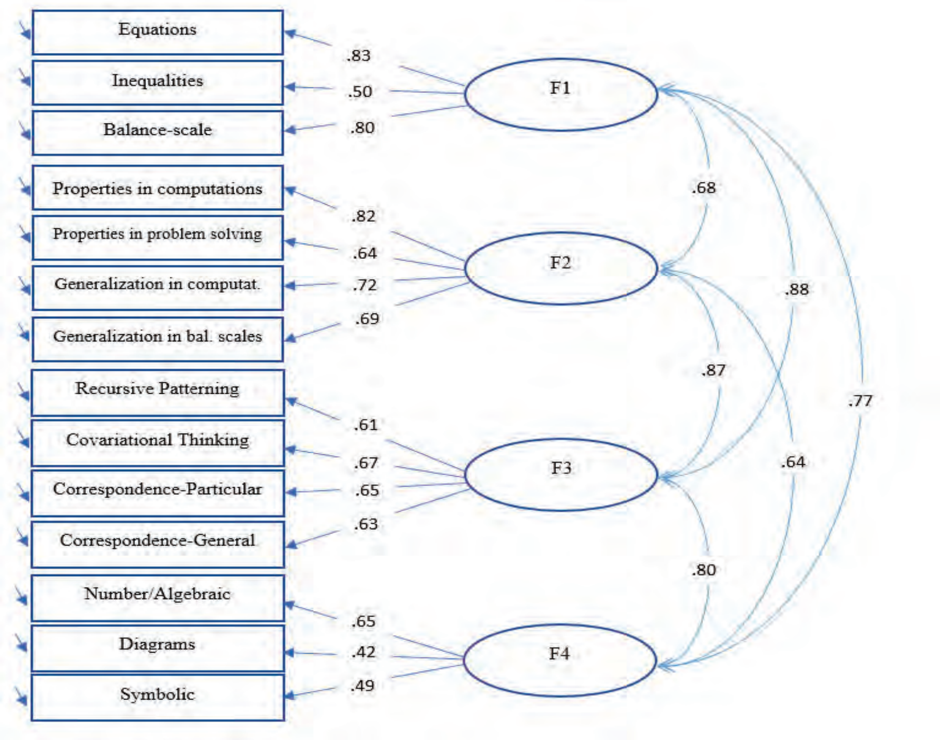
Representing-modeling languages	(a) Number sentence (b) Model (c) Literal Symbols	(a) Which number sentence represents the problem? *I had 4 pencils. I gave 3 pencils to my brother. How many pencils have I got now?* $3 + 3 + 4 = \square$ $3 \times 4 = \square$ $4 + 3 = \square$ $4 - 3 = \square$ (b) Which model represents the situation? *Nick has 5 stamps less than Sophie.*  (c) Which relation represents the situation? *Katy (K) and Lia (L) have altogether 3 stamps less than Mary (M).* $K + L - 3 = M$ $K + L + 3 = M$ $K + L = M + 3$ $K + L + M = 3$

The tasks of the study were split into two parts. Consideration was given to the number of tasks and time required to be approximately the same. Each part was administered in the form of a written test during one school period. The two parts were administered in two successive weeks. The instructions were provided in written and verbal form. Confirmatory factor analysis was used to examine the validity of our proposed, a priori model by using MPLUS 8.0 (Muthén & Muthén, 1998-2007). To evaluate model fit, three widely accepted fit indices were computed: χ^2/df should be <2; the Comparative Fit Index should be >.9; and the root mean-square error of approximation (RMSEA) should be <.08. The Cronbach's alpha index of internal consistency was very good (α=.81).

Results

Confirmatory factor analysis (CFA) was used to evaluate the construct validity of the model. Based on the results, the a-priori model matched the data set of the present study and determined the "goodness of fit" of the hypothesized latent construct. Analysis showed that the fit-indices of the hypothesized model were excellent (χ^2/df=1.27, CFI=.97, and RMSEA=.05), validating empirically the fit of the structure of the model to the empirical data. Figure 1 presents the observed variables (different types of tasks in Table 1), the corresponding factor loadings and the factor correlations. CFA showed that the factor loadings of the tasks were statistically significant and most of them were rather large, ranging from .42 to .83, giving support to the assumption that all latent factors were adequately measured by the observed variables. In accordance with our theoretical assumption, all measures were clustered into four first-order factors in the expected factor-loading pattern. Thus, analysis showed that algebraic thinking consists of four interrelated abilities that is (a) relational manipulation of equalities/inequalities, (b) compose and decompose numbers and arithmetical expressions, (c) functional thinking, and (d) representing-modeling languages. The correlations between the four abilities were significant (see Figure 1) and ranged from .64 to .88.



p<.05, **F1:** Relational Manipulation of Equalities/Inequalities, **F2**: Compose and Decompose Numbers and Arithmetical Expressions, **F3**: Functional thinking, **F4**: Representing-modeling Languages

Figure 1: The standardized solution of the proposed framework

To investigate the relations between the four algebraic thinking abilities, we examined the fit to the data of alternative structural models, hypothesizing a direct sequential path between the four factors or the existence of a higher-order thinking ability. The model that had the best fitting indices (χ^2/df=1.25, CFI=.97, and RMSEA=.04) showed that F1, F2, and F3 compose a higher-order factor, F100, reflecting students' general algebraic ability to manipulate relationally equalities and inequalities, compose and decompose numbers and arithmetic structures, generalize and abstract functional relations (see Figure 2). Analysis showed that F100 could accurately explain students' variances in F1, F2 and F3, suggesting that young students develop these abilities in parallel, their development is interrelated, and they share equally important contribution in building up a general functional thinking ability. F100 could be considered as an index of students' readiness to engage in algebraic thinking situations by noticing, interpreting, abstracting, and effectively using structure in arithmetic situations, number and operations properties, and quantity relations. It is the consequence of the correlations between F1, F2 and F3 that underlies a synthesis of specific arithmetic and algebraic thinking abilities. The regression coefficient of F100 on F4 was 0.76 ($p<0.05$), indicating that F100 is a strong predictive factor of students' modeling languages ability using a variety of representational forms. It could be supported that F100, as a general arithmetic-algebraic ability predicts rather accurately 'representing-modeling languages' that has a salient algebraic-nature.

Figure 2: The relations between algebraic thinking abilities

Discussion

The contribution of the study lies on the empirical evaluation of a proposed model that unpacks the dimensions of Grade 3 students' algebraic thinking. The results of the study showed that Grade 3 students' variances in algebraic situations might be modelled by four distinct and interrelated algebraic thinking abilities; relational manipulation of equalities and inequalities, compose and decompose numbers and arithmetical expressions, functional thinking. and representing-modeling languages. Structural analysis showed that the three abilities, *relational manipulation of equalities and inequalities*, *compose and decompose numbers and arithmetical expressions*, and *functional thinking* compose a general algebraic thinking ability that can be considered as an index of Grade 3 students' capacity to respond adequately in a variety of arithmetic-algebraic thinking tasks (Blanton et al., 2011, Driscoll, 1999). This general ability proved to be a strong predictive factor of students' ability to represent word problems and situations using number sentence, models or symbols. It could be supported that *compose and decompose numbers and arithmetical expressions* facilitates grasping the numerical relations in a problem and conceiving how the quantities set an equivalence or an equation, *functional thinking* contributes in noticing the relations between the involved quantities in the word situation, and *relational manipulation of equalities and inequalities* to discern the known and the unknown in the formed expression. The results of the present study are important in terms of teaching implications. The framework helps teachers to get a better understanding of algebraic thinking and the specific type of abilities that Grade 3 students should develop. Furthermore, the description of algebraic thinking abilities may inform teachers about students' potential difficulties and thinking requirements in a variety of situations.

Early algebra: Simplifying equations

Luis Radford

Laurentian University, Canada; lradford@laurentian.ca

Placed within the early algebra research field (Blanton et al., 2017; Cai & Knuth, 2011; Kieran, 2018; Kilhamn & Säljö, 2019), this article focuses on young students' understanding of basic algebraic ideas around equations. The article seeks to contribute to the field by shedding light on Grade 3 students' meaning-making processes underpinning the simplification of equations and the algebraic operations involved. In the first part, I present a theoretical conception of algebraic thinking. I also describe two non-alphanumeric semiotic systems that played an important role in the students' dealings with algebra. In the second part, I discuss two episodes of students simplifying $ax + b = cx + d$ *equations.*

Keywords: Algebra, equations, isolating the unknown, semiotics.

Algebraic thinking

One of the most enduring problems with which mathematics educators have been confronted is the problem of characterizing algebra and clarifying what makes it different from arithmetic. Two main solutions have been suggested. One consists in equating algebra with the *use of letters*. The other consists in conceiving of algebra as focused on *operations* rather than on results. While the first solution offers a very narrow conception of algebra—impeding teachers from recognizing algebraic thinking in activities based on types of mathematical representations different from letters—the second one offers a very narrow conception of arithmetic, which becomes demoted to simple computation.

In previous work (Radford, 2014) I have suggested three elements to characterize algebraic thinking:

(1) *Indeterminacy of magnitudes*: algebraic thinking involves *indeterminate* magnitudes. These can be unknowns, variables, parameters, etc.

(2) *Denotation*: the indeterminate quantities involved must be named or symbolized. This symbolization can be carried out in several ways. Alphanumeric signs can be used, but not necessarily. The denotation of indeterminate quantities can also be symbolized by means of natural language, gestures, unconventional signs, or even a mixture of them.

3) *Analyticity*: algebraic thinking (a) calculates/operates with indeterminate magnitudes *as if they were known* and (b) treats the mathematical relations featuring determinate and indeterminate magnitudes (equations, formulas, expressions, etc.) in a *deductive* manner.

Simplifying equations

Drawing on the aforementioned conception of algebraic thinking, in what follows, I report on the results of a teaching-learning activity in a Grade 3 class (8-9-year-old students). The activity was based on the use of two non-alphanumeric semiotic systems: a *Concrete Semiotic System* (CSS) and an *Iconic Semiotic System* (ISS) through which students could translate simple word-problems into linear equations.[1] The CSS is comprised of material objects: a) paper envelopes that each contain the same unknown number of cardboard cards; b) cardboard cards, and c) the equal sign. The envelopes played the role of unknowns while the card played the role of concrete numbers (constants). The ISS is derived from the CSS: it replaces concrete objects with iconic drawings {, , =, ↑}. The additional "arrow" sign replaces *actions* performed on concrete cards or envelopes of the CSS during the process of simplifying equations. The students could substitute the arrow by simple lines indicating that a card or envelope (or sets of) are removed. The range of problems that can be formulated in natural language and translated into the CSS and ISS is very limited, but it is enough to ensure that young students have their first encounter with algebraic thinking.

The research question that this paper seeks to address is about the identification of the teacher and students' meaning-making processes underpinning the understanding of algebraic techniques of isolating the unknown in one-unknown linear equations. Following the methodology of the theory of objectification (Radford, 2021), the data analysis involves a multimodal investigation of teaching-learning activity where students work in small groups and participate in collective discussions.

In Grade 2 the students started being familiarized with the isolating-the-unknown procedure using the CSS (Radford, 2017). At the beginning of the teaching-learning activity that I investigate here (which was the first Grade 3 activity on equations), the teacher organized a general discussion around the equation $3 + x = 7$. (Of course, no alphanumeric symbolism, was used in Grades 2 and 3). The students discussed various solving procedures: trial and error, comparison of terms (more on this below), and the isolating-the-unknown procedure. In Grade 3 the isolating-the-unknown procedure was not yet the students' first choice. The teacher had to ask, referring to what they had learned in Grade 2: "What do we mean by isolate? If I tell you, I'd like to isolate the envelope . . . " Cyr, one of the students, answered: "Does that mean like putting it alone?" When the teacher asked Cyr to articulate the idea, Cyr went to the blackboard and removed one card after another from each side of the equation, showing the procedure. The isolating-the-unknown procedure remained *shown* with actions rather than articulated with words. The teacher rephrased Cyr's actions: "If you remove one [card] on this side, what do you do?" Cyr answered: "I remove another one from there (the other side of the equation). Isolating-the-unknown procedure was a key aspect in the systematization of algebra conducted by Arab mathematicians in the 8th and 9th centuries (Al-Khwārizmī and others; see Oaks & Alkhateeb, 2007). It involves operations with known and unknown magnitudes to simplify equations. Mathematicians called these simplifying operations *al-gabr* and *al-muqābala*, and it is from the former that our modern term algebra borrows its name. By working with Cyr and by thematizing actions through language, the teacher strives to enable the students to reach a deeper level of understanding of the ideas underpinning the algebraic procedure. In the next sections, I discuss the work of one small group, focusing on two $ax + b = cx + d$ equations.

[1] Here is an example of a simple word problem: "Sylvain and Chantal have some hockey cards. Chantal has three cards and Sylvain has two cards. Their mother puts some cards in three envelopes and makes sure to put the same number of cards in each envelope. She gives one envelope to Chantal and two to Sylvain. Now the two children have the same number of hockey cards. How many hockey cards are inside each envelope?" (Radford, 2017, p. 18).

The equation $2x + 1 = x + 6$ in the CSS and the ISS

The two equations were given in the ISS. They are translations of a story in which two children have cards and envelopes. Each envelope has the same unknown number of cards, and both children have in total the same number of cards (see footnote 1). The exercise of translating stories of this type into the ISS was done in Grade 2 and continued in Grade 3. In this section I discuss the students' dealings with the equation $2x + 1 = x + 6$ (Figure 1.1) and in the next section I discuss the equation $3x + 1 = 5 + x$ (Figure 1.2).

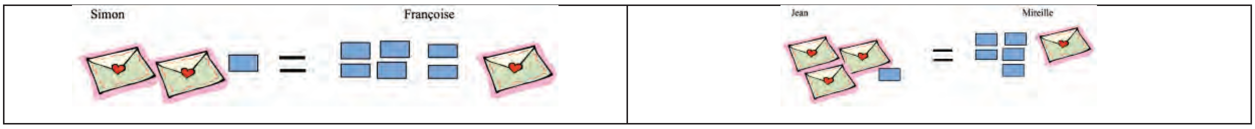

Figure 1. The equations $ax + b = cx + d$ as presented to the students in the ISS

Using a kit of envelopes and cards, the students were asked to make an equation and solve it, then draw their procedure. The idea was, hence, to have the students solve the equation first in the CSS, then using the ISS. The students made the equation in the CSS (Figure 2.1). Then, they drew the equation in the ISS. Elsa says: "We must remove that (*she circled the card on the left side of the equation*) so that there are just envelopes, do you remember? (*Then she removes one card on the other side)* 1, 1." *(Figure 2.2).* The answer is found by the *comparison method* (i.e., the students compare the equal to the equal and associate the remaining parts of the equation: in this case, one envelope on the left side is equal to the envelope on the right; hence, the other envelope is equal to the five remaining cards).

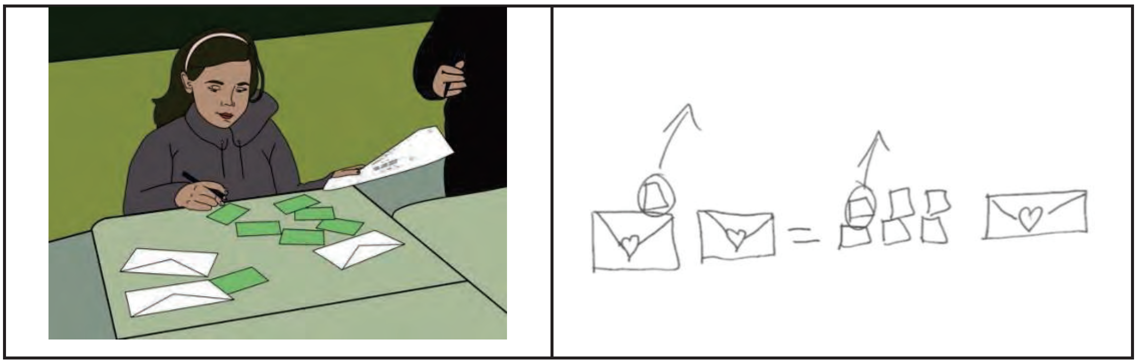

Figure 2. Solving the equation $2x + 1 = 6 + x$ in the CSS and the ISS

The teacher arrives and asks the students to explain their procedure. The students construct again the equation in the CSS. They remove one card from each side of the equation. The teacher says: "You are in the process of isolating! . . . How many envelopes do you want on one side?" Puzzled by the question, the students look at each other. One moment ago, Elsa mentioned the idea of having envelopes on one side. The teacher's intervention pushes the conversation further. On the one hand, the teacher acknowledges that the students are in the process of isolating the unknown. On the other hand, she raises a question that deals with something that has not been considered by the students. It is this unconsidered aspect of the simplification of the equation—a mathematical operation that would lead from $2x = x + 5$ to x equal to something—that puzzled the students.

1 Teacher: You want to know how many cards there are in ONE envelope (*she points to the envelope several times when she says ONE*) . . . First of all, you did this (*she removes a card from*

each side) you removed a card . . . Okay, what happens now? There are 2 envelopes (*pointing to the envelopes on one side of the equation*), then (*pointing to the objects on the other side of the equation*) 1 envelope and 5 cards.

2 Cora: We counted all these (*points to the cards*). It's 5. So, it (*pointing to 1 of the envelopes*) should have 5 too (*see Figure 3.1*).

3 Teacher: How do you know?

4 Elsa: We are going to remove (*she removes 1 envelope from the left side; see Figure 3.2*).

5 Teacher: You're removing 1 envelope?

6 Elsa and Cora: Yes. (*Elsa removes an envelope from the other side as well; Figure 3.3*).

7 Teacher: Why did you choose to do that?

8 Cora: Because this (*the sides of the equation*) must be equal.

9 Elsa: because we must remove; because there must be only 1 envelope left (*she takes the envelope that is left*)

10 Teacher: Is it okay to remove 1 envelope and then 1 envelope? Is your equation still equal?

11 Cora: Yes!

Figure 3. The students and the teacher discussing the equation $2x + 1 = x + 6$

In Line 1 the teacher starts simplifying the equation as the students did. She says: “First of all, you did this” and removes one card from each side. Then, in an encouraging tone, she asks “What happens now?” In Line 2 Cora resorts to the comparison method, but the verbal articulation of ideas leaves important relations unaccounted for. These are the relations that the teacher asks for in Line 3. In Line 4 Elsa starts removing one envelope from each side. The teacher wants to make sure that the students understand the idea behind the “removing” operation. So, in Line 7 she asks for reasons. In Lines 8 and 9 the students offer two answers: Cora’s focuses on the conservation of the equality between both sides of the equation; Elsa’s focuses on the idea of ending up with one envelope. In Line 10 the teacher wants again to make sure that there is a clear understanding of the actions that are carried out to simplify the equation. When the teacher leaves, the students come back to the equation in the ISS and remove one envelope from each side (Figure 3.4).

So far, the isolating-the-unknown procedure has necessitated the application of a key operation: *removing* equal things from both sides of the equation. In the next equation an additional mathematical operation is required. Let’s turn to the students’ investigation of this equation.

The equation $3x + 1 = 5 + x$ in the CSS and the ISS

The students tackle the equation $3x + 1 = 5 + x$. They construct the equation in the CSS and, instead of solving it with the help of concrete materials, they draw the equation.

Cora starts by removing one envelope from each side. After that, she removes one card from each side (Figure 4.1).

12 Elsa: You only removed 1, but there must be only 1 envelope left. That's a problem. (*They think for a while; then Elsa continues*). Four [cards], but there's not another envelope here (*points to the right side of the equation*).

13 Cora: There are 4 cards left, that's 4, we must remove these cards (*she circles the 4 remaining cards on the right side of the equation*) . . . And here (*she points to 1 of the remaining envelopes on the left side of the equation*) there are 0 [cards].

14 Elsa: Yes but look! If there is 0 [cards] in the envelope, this (*pointing to the envelope on the right side of the equation*) will be 4 and this (*pointing to an envelope on the left side*) will be 1 [meaning perhaps 0]. But the 2 [envelopes] must have the same exact (*she points to the drawing*), the 2 [envelopes] must have the same number [of cards].

15 Cora: (*Explaining the idea again*) We removed that (*the 4 cards*).

16 Elsa: Then, there are 0, but there must be some cards [in the envelope].

17 Cora: Why?

18 Elsa: Here you have to remove this, here you remove this (*points with her pen to her drawing*) and you can't remove that [the 4 cards on the right side], because there are not 4 other [cards] here [on the left side] that you can remove . . .

Here, the students find themselves in a new situation. While in the previous problem, removing the same number of cards and envelopes was sufficient to isolate the unknown, in this problem the “removing” operation is not enough. They end up with two envelopes on the left side of the equation and four cards on the right side. They cannot continue removing envelopes for, as Elsa notes in Line 12, there are no more envelopes to remove on the right side. And “That's a problem.” Cora suggests removing the four cards on the left side, which will lead them to zero cards. She then assigns zero cards to one of the two envelopes on the left side, which means that there are four cards in the other envelope. Elsa points out two problems with Cora’s suggestion. First, she argues that all envelopes must have the same number of cards (Line 14). Second, simplifying entails removing the same things *on both sides* of the equation (Line 18). This requirement or condition is violated.

The students reach an impasse. “On est en train de se chicaner pour la réponse” [“We are having an altercation over the response”]. They tried to call the teacher, but she was busy discussing with another group. I was videotaping this group; I removed my headphones and went to talk to the students. I suggested that they use the concrete material (envelopes and cards). The students constructed the equation again and proceeded to remove one card and one envelope on each side.

19 Elsa: There are still 2 envelopes left (*see Figure 4.2*).

20 Mia: Then, there are 2 (*pointing to 2 cards*) here (*pointing to 1 of the envelopes*) and 2 (*pointing to the 2 remaining cards*) here (*pointing to the other envelope; see Figure 4.3*).

21 Cora: There must be 1 envelope!

22 Elsa: (*She removes 1 envelope and moves the cards to the other side of the equation; see Figure 4.4*)

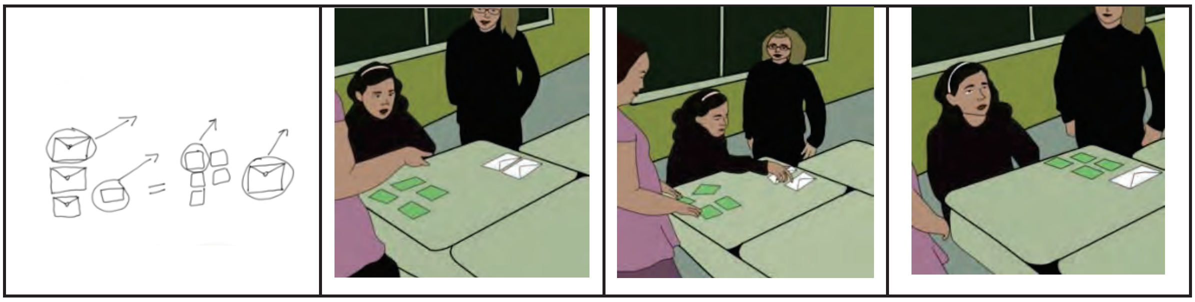

Figure 4. Discussing the solution of $3x + 1 = 5 + x$ in the CSS

In Line 20 Mia suggests an idea. However, the idea is not taken into consideration by the other students. Perhaps because the idea is not framed within the kind of actions that the students recognize as legitimate in solving the equation. Yet, we see in Figure 4.4 that Elsa, in despair, removes one envelope and transfers the cards to the other side of the equation, placing them underneath the envelope, twice breaking the "do the same on both sides" rule. Not finding a convincing way to proceed, Elsa (like Cora in Line 13) steps outside the boundaries of the algebraically thinkable that they have established so far. The situation once again became very tense as we saw in Line 18. Elsa says that they are still altercating and laughs. Cora says: “OK. We’ll do it again!” They remove one card and one envelope from each side of the equation.

23 Elsa: There are 4 [cards]. We must have just 1 envelope remaining. So, we must remove 1 [envelope]; we don’t have a choice (*she removes the envelope*).

24 Cora: Yes, but if we remove 1 … we must remove something else (*she points to the other side of the equation*).

They discuss for a while and come back to the simplified equation ($2x = 4$). After looking attentively at the 4 cards and the 2 envelopes, Elsa says that she has an idea:

25 Elsa: Wait, wait. Here's my idea. Because we have 2 [cards] here (*with each hand, she takes 2 cards from the bunch of 4 cards; then, she slowly moves the 2 hands holding the cards and puts them in front of each of the envelopes; see Figure 5.1. When the cards arrive at their destination, she says*) 2 in each envelope.
She immediately starts the explanation again: she slides the 4 envelopes as she did before, on one side of the equation. She says:

26 Elsa: Separate this [the 4 cards] into 2 (*as she says this, she separates the envelopes; see Figure 5.2. She then slides them in front of each envelope*); there are 2 in each envelope.

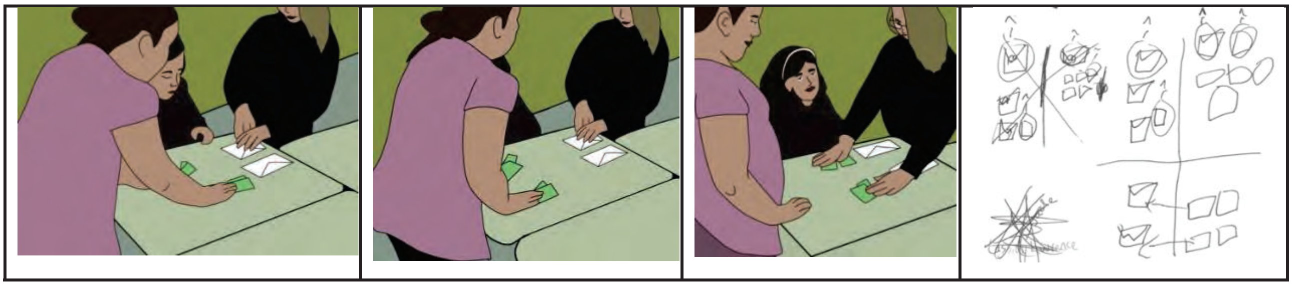

Figure 5. Finding (again) how to solve the $2x = 4$ equation

Elsa’s demonstration is followed by Mia’s reaction:

27 Mia: This is what I said before, but you, you were . . .

28 Elsa: (*completing Mia’s sentence*) . . . altercating!

29 Mia: . . . you said, no, no . . .

30 Elsa: I am sorry, Mia!

Cora makes the equation again and goes through the steps to isolate the unknown. When she reaches the equation $2x = 4$, she says:

31 Cora: We are going to separate . . . (*and slides the 2 cards towards 1 envelope and 2 cards towards the other envelope; see Figure 5.3*).

Mia is right in arguing that she suggested long before (Line 20, Figure 4.3) that each envelope has two cards. However, her suggestion was not articulated in terms of a separation of cards. In Elsa’s case, the solution appears first in an embodied way: “Wait, wait. Here's my idea. Because we have 2 [cards] here . . . 2 in each envelope.” The few uttered words are accompanied by a complex set of grabbing and sliding actions that remain unqualified linguistically. The linguistic articulation appears when she starts again the process of solving the problem. She says: “Separate this into 2, there are 2 in each envelope.” Although the importance of the kinesthetic dimension that accompanied the problem-solving procedure does not disappear, the thematic articulation in language is much more sophisticated. The new mathematical operation is named “to separate.” This new operation is a precursor of what will later be known as the algebraic operation of division. The Arab mathematicians had a term for it: *al-radd*, decreasing the coefficient of the unknown to 1.

In previous research we have found that at the precise moment of learning something, the students undergo a process where mathematical thinking becomes reorganized; what previously took many words and actions becomes reorganized and contracted: the students filter the necessary from the unnecessary and their semiotic activity becomes contracted. There is a *semiotic contraction* (Radford, 2021). Here, we see the opposite process: in Line 26 Elsa adds actions and words to signify the emerging operation. There is a *semiotic expansion* that allows her and her teammates to better notice the operation and endow it with meaning.

The students kept solving with their hands the equation in the CSS several times. It seems that seeing was not enough and that feeling with their hands and their bodies was necessary. Then, they drew their solution in the ISS. The new operation requires a sign to be expressed. Figure 5.4 shows that the students chose an arrow, which is reminiscent of the sliding action that makes the two cards correspond to each envelope. The sign is an icon of the action.

Concluding remarks

This article dealt with the topic of equations in early algebra. It focused on the way Grade 3 students dealt with some of the key algebraic ideas that underpin the simplification of equations. In the first part, I suggested that the characterization of algebra (a) as calculation with letters or (b) as focused on operations rather than on their results are both unsatisfactory. In the first case, the characterization falls short by limiting the scope of algebra; in the second case it fails by downplaying the complexities of arithmetic thinking (which is reduced to trivial calculations). Based on historical-epistemological considerations (Radford, 1995; 2001), I suggested a conception of algebra that stress the authenticity of denotating unknown magnitudes in various ways and emphasizes the analytic-deductive nature that underpins algebraic inquiries. If we know that second degree equations have at most two solutions, it is not because we guessed the solutions, it is because they were *deduced*.

Starting from these premises, the Grade 3 teaching-learning activity was didactically organized around the use of two semiotic systems: the CSS and the ISS. The excerpts analyzed here started with a classroom general discussion around different methods to solve the equation $3 + x = 7$. According to the definition of algebra suggested in the first section of this paper, the solution of equations $ax + b = c$ does not include the operation of the unknown. As a result, in solving those equations the students have not stepped yet into the realm of algebra (Filloy & Rojano, 1987). However, the investigation of the equation $3 + x = 7$ provided the students with an opportunity to continue familiarizing themselves with the isolating-the-unknown procedure that they encountered in Grade 2. In this sense the equation $3 + x = 7$ was envisioned rather as a propaedeutic step towards tackling equations of the type $ax + b = cx + d$ algebraically, something that the students did in the second part of the teaching-learning activity. We can see in Figures 3.2 and 3.3 the moment at which Elsa applies the *al-muquabāla* or removing operation that was previously applied to the constants in solving the equation $3 + x = 7$ to the equation $2x + 1 = x + 6$. The “removing” operation now acquires a new and more developed meaning. It requires seeing the unknown and the equation under a new light. It is this new aspect of the mathematical activity that leads the teacher, in Line 10, to ask two fundamental questions: "Is it okay to remove 1 envelope and then 1 envelope? Is your equation still equal?" More generally, the CSS- and ISS-based teaching-and-learning activity made room for meaning-making processes out of which the Grade 3 students to generate, in their work with the teacher, two important algebraic ideas that underpin the simplification of equations: "removing" (removing equal terms from both sides of the equation) and "separating" (i.e., reducing the coefficient of the unknown to 1), those operational ideas that Arab mathematicians referred to as *al-gabr* / *al-muqābala and al-radd*, respectively (Oaks & Alkhateeb, 2007). The emergence of these sensuous and embodied operations served as foundational blocks for the students' encounter with algebraic alphanumeric symbolism, which happened one year later, when they were in Grade 4.

Calculational and analytical perspectives in introductory algebra: a theoretical contribution

Jorunn Reinhardtsen[1] and Martin Carlsen[2]

[1,2] University of Agder, Faculty of Engineering and Science, Kristiansand, Norway; jorunn.reinhardtsen@uia.no, martin.carlsen@uia.no

In this theoretical paper we discuss what a calculational perspective on mathematical activity entails and discuss its relevance in terms of related speech genres in the introductory algebra classroom. Learning in the introductory algebra classroom is multifaceted because major shifts in form (the algebraic syntax versus arithmetic syntax) and function (analytic rather than calculational) are expected to take place. This theoretical argument is exemplified through student utterances from a Californian 6th grade classroom discussion, in which students' calculational perspective on mathematical activity is apparent. The data reveal traits and intentions from both traditional and alternative instructional genres. Our main argument is that the students' approaches to generalize provided patterns were limited to their perceptual field and thus fail to include a deductive argument, the key feature of algebraic reasoning.

Keywords: Algebraic reasoning, analytic perspective, calculational perspective, introductory algebra, speech genre.

Introduction

This theoretical paper discusses two perspectives on mathematical activity, *calculational* and *analytic*, that are discernible in introductory algebra classrooms. Different frames of reference, or speech genres (Bakhtin, 1986), can present communicational challenges and limit possibilities for algebra learning. We take these two perspectives as points of departure and discuss these in terms of previous research. A calculational perspective is exemplified through discussions of patterning tasks in a US 6th grade classroom.

Hewitt (2019), in a theoretical contribution, suggested that students in school ought to focus on "structure within complex examples" (p. 558) to develop algebraic thinking. Moreover, the students should be encouraged to make their reasoning explicit through expressing what they see rather than performing any mathematical calculations. Montenegro et al. (2018) argued in a similar manner from an empirical point of view. They found that students succeeded in obtaining a functional relationship in a figural pattern when the students turned away from the patterns in numbers and turned towards structure in the figural pattern engaged with. Both Hewitt (2019) and Montenegro et al. (2018) thus argued in favour of an analytic approach over a calculational one.

Although the goal of algebra teaching is for students to engage in analytical thinking, the calculational discourse persists in many classrooms. We argue that research has to acknowledge and investigate the role that this discourse plays in students' participation in algebraic activity. Learning in the introductory algebra classroom is multifaceted because major shifts in form (the algebraic syntax versus arithmetic syntax) and function (analytic rather than calculational) are expected to take place. Sfard (2007) addresses the bewilderment involved in the shift in function of mathematical activity algebra teaching may cause for students through her heading “When the rules of discourse change, but nobody tells you”. We would like to contribute theoretical insights into the characteristics of students’ calculational perspective in introductory algebra classrooms

A sociocultural approach to mathematical thinking

To address students’ perspective on mathematical activity in classroom interactions we draw on Radford (2014) who defines thinking as cultural, embodied and material. Students mathematical thinking is not a separated and ideal internal process but occur as they use cultural artifacts (function table, algebraic syntax, etc.) and other semiotic means in social and goal-oriented activity. The semiotic resources the students use to solve patterning problems, such as gestures, spoken and written words, numbers, function tables and algebraic symbols, shape the form and generality of their mathematical thinking (Radford, 2018). Furthermore, the patterning activity itself and the cultural artifacts employed gain meaning from cultural practices such as algebraic reasoning and schooling, of which language is a prominent aspect (Sfard, 2007).

We draw on Bakhtin’s (1986) notion of *speech genres* when considering the nature of different perspectives on mathematical activity and their role in shaping the classroom discourse. According to Bakhtin, speech genres are extremely heterogeneous, and examples varies from everyday small talk and narratives to sports commentary and different kinds of scientific statements. As an inclusive concept, speech genre is not generally defined. Instead, we conceptualize it in terms of the specific speech genres discussed in this study. For Bakhtin (1986), the utterance, i.e. the unit of language in use and in context, was the basic unit of analysis and he argued that *addressivity* is the key to understanding it. Addressivity refers to the dialogic nature of the utterance, as it is shaped to address a particular listener (real or imagined) foreseeing his response. Furthermore, Bakhtin found our utterances relatively stable in forms of construction and argued that no utterance is given that does not belong to a speech genre, emphasizing that we are not always conscious of it: “[we] speak in diverse genres without suspecting that they exist.” (Bakhtin, 1986, p. 78).

Related speech genres in the introductory algebra classroom

In the introductory algebra classroom, we argue that there are several related speech genres with deep cultural roots at play. A genre form may include linguistically coded intentions and rhetoric that a current speaker may not be aware of (Gerofsky, 1999). Gerofsky argued for the importance of intertextuality between related genres as “a genre which, in its form and addressivity, recalls other familiar genres may bring to consciousness the hidden ground and intentions embedded within [these]” (p. 38). Genres speak to students telling them what to expect and what is expected of them. Radford (2001) argued that algebra as a way of reasoning involves dealing with indeterminate quantities in an analytic and deductive manner with the intensions of explaining and arguing about general relationships and methods for solving problems. Thus, algebra is a specific genre form.

Another speech genre at play is instructional discourse. Mehan (1979) showed that utterances in the classroom (mathematics as well as other subjects) followed a distinct pattern of initiation-reply-evaluation (I-R-E). Thus, it can be seen as a rather standard and rigid speech genre, also found to dominate mathematics teaching in American classrooms (Stigler & Hiebert, 1999).

Experimental studies have developed alternative programs to open up classroom discourse, in which students explore new problems, pose conjectures and argue (Lampert, 1990). Reform documents, such as Standards 2000, aim to bring these ideas into the ordinary classroom (Hiebert, 1999). The speech genre involved shares some ground and intentions with algebraic reasoning since algebra grew out of a sociocultural context of explaining and arguing (Radford, 2001).

Hiebert (1999) explained that the implementation of alternative programs in school districts have not been effective for a simple but unappreciated reason, since it "is hard to change the way we teach" (p. 15). Furthermore, Hiebert argued that there is overwhelming evidence that what students learn in traditional teaching is unsatisfactory and consists of the following: "In most classrooms, students have more opportunities to learn simple calculation procedures, terms, and definitions than to learn more complex procedures and why they work or to engage in mathematical processes other than calculation and memorization" (p. 12). This supports the notion of students developing a calculational perspective on mathematical activity in mathematics classrooms. Furthermore, this genre can be seen to emerge as students' uptake of teachers' intentions in traditional instruction. A genre analysis of classroom interactions can shed new light on the communicational processes that shape the introductory algebra classroom discourse. In this paper we limit the further discussion to explore the nature of a calculational perspective and contrast it to an analytic perspective.

Calculational and analytical perspectives in introductory algebra

We propose a new theoretical stance on student activity in the introductory algebra classroom, i.e. a calculational perspective. Based on previous research on algebra learning, we single out as key demarcations between algebraic and calculational perspectives: (1) ways of interpreting signs and operations; (2) strategies for solving problems; and (3) ways of justifying solutions. This is contrasted to an analytic perspective, which is a central feature of algebraic reasoning (Radford, 2012).

As regards the first demarcation, Booth (1984) and Kieran (1981) found that students working with numbers and their operations tended to interpret the operational signs and the equal sign as signaling types of actions rather than structure. Additionally, Kieran showed that students developed a limited view of what constitutes a mathematical solution and were likely to search for numerical answers (lack of closure). Radford (2018), upon repeatedly observing that 4th, 5th, and 6th grade students included an equal sign in their generalizations (i.e. $n + n = x$), argued that the conceptual challenge for students was not necessarily the alphanumerical symbols themselves, but a need for reconceptualizing numerical operations.

Students holding a calculational perspective are limited to a processual view of signs and operations. In contrast, an analytic perspective includes a structural view of operations: (1) signaling mathematical structures that are relevant and can be used in transformations of expressions (Kieran, 2018); and (2) seeing expressions as objects in themselves that can be operated upon, substituted, or classified (Sfard, 2007). These are interdependent of a developing awareness of mathematical generalities (Kieran, 2018) and an acceptance of indeterminacy, both in operations (operating with indeterminacy as if it were a number) and solutions (Radford, 2018).

Concerning students' problem-solving strategies, the second demarcation, students often use a guess-and-check strategy to solve new algebraic problems, including patterning tasks (Bednarz & Janvier, 1996; Lannin, 2005; Radford, 2018). Bednarz and Janvier (1996) found that students using a guess-and-check strategy were not able to accept indeterminacy and remained dependent on performing calculations on numbers. In contrast, students that used a strategy of determining the underlying structure of the problem (which included the linking of different mathematical structures such as for example additive and multiplicative to determine how many equal parts) were able to explain an algebraic equation when shown such a solution.

Addressing the third demarcation, students' justifications, Lannin (2005) showed that 6th grade students mainly used empirical results to determine and justify their pattern generalizations when left to themselves. They tended to focus on particular values to determine and verify generalizations, rather than a general relation. Radford (2012) argued that algebra is an analytic art. Formulas must be deduced and not guessed for students to engage in algebraic reasoning. They have to come up with a deductive argument. A deductive argument, for example in a patterning activity, includes three components: (1) noticing a commonality between the terms p_1, p_2, p_3, …, p_k; (2) generalizing this to all subsequent terms p_{k+1}, p_{k+2}, p_{k+3}, …; and (3) using the communality to formulate an expression for any term in the sequence, i.e. an explicit strategy to generalize a sequence (Radford, 2008). However, students more often pursue a recursive strategy where each term (p_k) is determined from the previous one (p_{k-1}) (Lannin et al., 2006). Radford (2012) argued that such a generalization is of an arithmetic nature, as opposed to algebraic, as it is limited to include terms within the perceptual field. It does not include the third component of a deductive argument. Nevertheless, guess-and-check and recursive strategies might be helpful in generalizing a pattern. Particularly, a recursive strategy can give insight into the pattern's rate of change, which again can be helpful in developing an explicit expression. However, research shows that students struggle to see the connection between the two ways of generalizing a pattern (Lannin et al., 2006).

Ellis (2007) showed that the processes of generalization and justification were interwoven in students' activity. 7th grade students' generalizing acts were directly linked to the justifications they gave. On the other hand, their view of what counts as an acceptable justification influenced their generalization process and students following a deductive justification scheme developed more sophisticated generalizations from initially limited or unhelpful generalizations.

In sum, a calculational perspective on mathematical activity includes (but is not limited to): 1) viewing numbers as the main objects of activity and other signs and operations as actions to perform; 2) employing strategies rooted in calculational processes in problem solving, and 3) relying on empirical results for justification. These aspects may confirm and reinforce each other as Ellis (2007) pointed out, and they may function as barriers for students' engagement in algebraic, analytic reasoning. The intention of the calculational genre, as opposed to the algebraic genre, is to perform calculations following known procedures to produce correct numerical solutions.

Students' calculational perspective in a 6th grade classroom

To empirically exemplify our theoretical contribution, we draw on data from a Californian 6th grade classroom where students were working with patterning tasks. The background for this paper is an international algebra project called VIDEOMAT (see Kilhamn & Säljö, 2019). An in-depth analysis of students' discourse in classroom patterning activity showed that students across countries pursued similar solving strategies. Reinhardtsen and Givvin (2019) found that students focused on processes of calculations rather than structure and quantitative relationships in their work, i.e. they drew on operations on numbers rather than introduced algebraic ideas and symbols.

The teacher's approach to working with every patterning task involved three main phases of activity, classroom exploration of a pattern, making a function table and developing an explicit generalization from a recursive one when possible, and extending the generalization to all subsequent terms and creating an algebraic expression. The teacher first asked for students' observations and suggestions before proceeding, allowing students to pose conjectures and ideas.

We structure the following section according to the three main characteristics of the calculational perspective outlined above. The first two episodes exemplify students' view of numbers as the main objects of activity and other signs and operations as actions to perform. The third episode exemplify students use of strategies rooted in calculational processes, thus relying on empirical justification.

Explicit and recursive generalizations: "Multiplying by 4 or they're adding 4"

In the first lesson the teacher introduced the metaphor of function machine, emphasizing an explicit relationship between sets of numbers in the second phase of activity. In the first phase of activity the class discussed the numerical sequence 4, 8, 12, 16, __, __, __. Students suggested both recursive generalizations: "Like it's plus 4, 4 plus 4 equals 8, and 8 plus 4 equals 12, and so on", and explicit ones: "I did multiples of 4, 20, 24, 28".

In phase two, the teacher drew a function chart and a function machine and then asked the students to discuss shortly with their seat-partner: "And if I put a 2 in, what's going on in here, so that I get an 8 out. What's happening in this machine that represents this number sequence?". One student, Mara, made a link to the previous discussion and said to her partner: "Multiplying by 4 or they're adding 4". Another student, Ivy, offers a more literal explanation: "And then it came out in a different number, so it's a function machine".

The ideas presented by students in the whole class discussion in the first phase are mainly concerned with how to calculate the terms in the sequence. Mara's uptake of the calculational ideas as presented in phase two shows that these are accessible to other students. However, making sense of the difference between the two generalizations, recursive ($p_k= p_{k-1}+4$) and explicit ($p_k=4k$) and the relationship between them, requires looking at the numbers and operations analytically.

Neither Ivy nor Mara picked up on the significant changes in the perspective that the teacher was emphasizing. Ivy offered a literal interpretation and referred to a transformation of a number, as if by magic. Mara linked the teacher's question to the previous discussion but did not notice that the operation of "adding 4" no longer was appropriate, i.e. the horizontal relationship between numbers in the two columns only corresponds to an explicit generalization of the sequence.

Using letters: "Because you can do *4n* … *n* can be any number, so multiply it"

In the third phase of working with the sequence above after having determined the 10^{th} and 20^{th} terms of the sequence together, the teacher asked the students to discuss the general expression with their seat-partner "How do I show 4 times any number. We're just calling it *n* for right now".

Trace explained his expression to his partner: "*4n*. Because you can do *4n*, yea, *4n*. *n* can be any number, so multiply it, *4 dot n*, *4n*, stuff like that". Trace made sense of his expression on the terms of being able to perform a calculation when replacing *n* with a number: "Because you can do *4n*… *n* can be any number, so multiply it". Thus, Trace was able to respond to the teacher's question of how to show "4 times any number". However, as Küchemann (1978) pointed out, there is a leap between being able to evaluate an expression and using a letter as a variable to express mathematical structures and relationships.

In the third lesson the class worked with a figural pattern. In phase one the whole class discussion centered around rate of change. However, in the second phase of creating a function table guided by the teacher, the students no longer made references to the figures but quickly noticed a familiar (quadratic) relationship between the numbers in the two columns. Luna set up multiple numerical expressions such as $1 \cdot 1=1$, $2 \cdot 2=4$ and $3 \cdot 3=9$, and in the third phase she suggested: "It's called *n* times *n* equals *x*". Her generalization was developed and verified through calculating numerical expressions, and her algebraic expression also resembled these.

Guess-an-check strategy: "I tried the next number which is 6"

The teacher emphasized the relationship between a recursive and an explicit generalization as a strategy to determine the explicit expression throughout the classroom work. However, the students mainly used a guess-and-check strategy when working independently with function charts.

In the third lesson the teacher gave the students a function chart in which the left column included the numbers 1-8, with *x* as the last entry, and the right column included the four first entries: 5, 11, 17, 23. The instructions were to fill in missing numbers, describe patterns and write an expression.

The teacher, in a whole class setting, asked Liam to explain what he noticed. He explained that he first looked at "1 times something gets to 5", deciding this being 5. He then tried the next pair of numbers in the chart (2, 11), but found that $2 \cdot 6 \neq 11$: "So, I realized that you could do, I tried the next number which is 6". He then explained he did minus one to get the number he needed; five. He then tried the sequence of operations regarding the next pair of numbers in the chart (2,11): $6 \cdot \mathbf{2}=12$, $12-1=\mathbf{11}$, and found that it worked. Liam demonstrates how the students approached the number sequences through guess-and-check. Also when working with figural sequences, the students used this strategy. Lisa, in the fourth lesson, explained her approach: "Um, I tried it, I kind of did, um. I don't know how to explain it, but I started with doing multiplying it by 1 and adding 2, but it didn't work. So, I tried multiplying by 2 and subtracting 1". The students working with function charts increasingly made explicit generalizations, but these were mainly based on numerical schemes rather than analytical ones. This finding coincides with Ellis' (2007) argument.

Synthesizes and concluding remarks

In this paper we set out to come up with theoretical insights into the characteristics of students' calculational perspective in introductory algebra classrooms. We have argued that developing algebraic reasoning is a challenging process as previously met calculational perspectives interfere when trying to reason analytically about number patterns and figural patterns. The empirical examples demonstrate that students approach problems in introductory algebra through a calculational perspective. They face difficulties making sense of the difference between a recursive and an explicit generalization (cf. Lannin, 2005; Lannin et al., 2006), they evaluate letters but struggle using them to express structure and generalities (cf. Küchemann, 1978; Radford, 2018), and they use a guess-and-check strategy (cf. Bednarz & Janvier, 1996; Ellis, 2007).

The classroom data reveal traits and intentions from both traditional and alternative instructional genres. Elements such as letting students explore sequences, notice patterns, and suggest ideas invited students to engage in generalization processes. However, the use of a function chart and algebraic notation as a step-by-step process heavily supported by the teacher share traits with the traditional instructional discourse and may have informed students' participation in the activity. Deeply rooted norms (cf. Stigler & Hiebert, 1999) of emphasizing procedures and products (solutions, facts, etc.) rather than mathematical processes (problem solving, generalizing, etc.) came to the fore in the classroom, despite efforts by the teacher to focus on the latter in discussions.

We argue in accordance with Radford (2012) that the students' calculational perspective is of an arithmetic nature, as opposed to an algebraic nature. The students' approaches to generalize the patterns are limited to their perceptual field, and thus fail to include a deductive argument, the key feature of algebraic reasoning (Ellis, 2007; Radford, 2012). Despite the teacher's efforts, the students do not make sense of the shifts in form (the algebraic syntax versus arithmetic syntax) and function (analytic rather than calculational) in this classroom. These expected shifts unfortunately do not take place. More research is needed to investigate the role that the calculational perspective play in students' participation in algebraic activity.

Radford (2018) found that symbolic thinking, in which letters are used to develop a generalization, took a long time for students to develop. Furthermore, it developed in line with an increasingly analytic approach to patterning activity. A genre analysis of the introductory algebra classroom supports this finding. A genre form includes many aspects that reinforce each other, as we have pointed out concerning calculational and analytical genres. Our discussion suggests the importance of addressing the elements of the algebraic genre as a consorted effort.

Using the bar model to ease the transition from transforming arithmetic-numerical to algebraic equations: theoretical considerations and possible obstacles

Anna-Katharina Roos[1] and Leander Kempen[1]

[1]TU Dortmund University, Germany;

aroos@mathematik.tu-dortmund.de, leander.kempen@tu-dortmund.de

We discuss an approach to transforming and solving algebraic equations via the so-called bar model, based on the strategy of transposing. After developing a learning environment, we conducted design experiments to get insights into how students work with it. First, this paper aims to present the core idea of our learning environment. Second, we highlight the following difficulties that students face when working with the bar model: (1) the model itself, with its translation processes between graphical and symbolic representations (such as numbers, variables or operation signs), turned out to be a considerable learning content, (2) the transition from arithmetic-numerical contexts to general algebraic equations in the bar model seems to bear distinct conceptual obstacles which may even lead to misconceptions based on over-generalizations resulting from the bar model. We point to theoretical insights and implications for enhancing our learning environment.

Keywords: Bar model, equations, algebra, design research.

Introduction

In the transition from arithmetic to algebra, students face a variety of difficulties (e.g., Warren, 2003). Especially for low-achieving students, it is important to fill the concepts and procedures introduced in arithmetic-numerical contexts with meaning for transferring them into the field of algebra. One example of such an idea that originates from numerical considerations is the concept of equivalence with its strong connections to the procedure of equivalence transformations regarding solving equations. This process, however, is known to bear several problems for learners. Kieran (2006) gives a short overview of students' errors, like ignoring the minus sign or reduction errors. To work against these procedural errors, a deep understanding of the idea of equivalence could be helpful. The idea of equivalence represents a central part of solving equations in school algebra and can be characterized by three different perspectives (Prediger & Roos, in press): (1) equations are equivalent if they have the same set of solutions, (2) equations are equivalent if there exists an equivalence transformation that transforms one into the other[1], and (3) equations are equivalent if they describe the same situation. While the first and second characterizations stay close to the formal mathematical definition, the third can be used for giving meaning to equivalence transformations in a rather intuitive and visual way. Thus, especially for low-achieving students, this could be a promising approach to build up conceptual understanding for the mathematical procedure of solving equations.

Our focus is on developing a learning environment, i.e. teaching material, to ease the transition from transforming arithmetic-numerical to algebraic equations. With the help of the so-called bar model,

[1] An equivalence transformation can be seen as an application of a bijective function on both sides of the equal sign.

we want to emphasize the meaning of equivalent equations in order to develop the strategy of transposing for solving equations. Firstly, we summarize the theoretical background for creating our learning environment. Secondly, we report results of interview studies used to evaluate the learning environment to derive theoretical and practical conclusions.

Theoretical Background

Regarding the process of solving algebraic equations, Selter et al. (2012) differentiate between two formal strategies: *performing the same operation on both sides* ($B + C = A \Leftrightarrow B + C - C = A - C$) and *transposing* (put an expression on the other side of the equal sign by applying the respective inverse operation: $B + C = A \Leftrightarrow B = A - C$; compare Figure 1) (see also Kieran, 1992). While solving equations by performing the same operation on both sides should depict one main objective (Malle, 1993), especially at the beginning of the learning process, the strategy of transposing is considered more intuitive for students (Mason et al., 2005). Selter et al. (2012) particularly emphasize the close relationship of the idea of transposing to former arithmetical experiences. Therefore, the strategy of transposing can be linked back on the one hand to the concept of equivalent equations as equations describing the same situation and, on the other hand, to experiences that were made in arithmetical contexts. We explain both shortly.

Equivalent equations as describing the same situation – a graphical model

According to Malle (1993), object relationships represented in drawings (such as relationships between line segments) can be used to give variables, expressions, and formulae a meaningful interpretation. Such graphical models can also be used later on for making sense of transposing when solving equations (ibid.; see Figure 1).

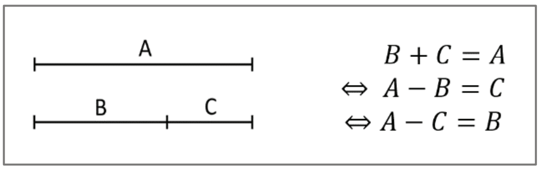

Figure 1: Bar model for representing transposing; based on Malle (1993, p. 220)

The Singapore bar model (e.g., Fong Ng & Lee, 2009) works similar to this approach. This model is used widely among others in Singapore's primary schools (e.g., Kaur, 2019) and discussed as a method for supporting students to get good results in problem solving activities for instance in international assessment studies like TIMSS (e.g., Beckmann, 2004).

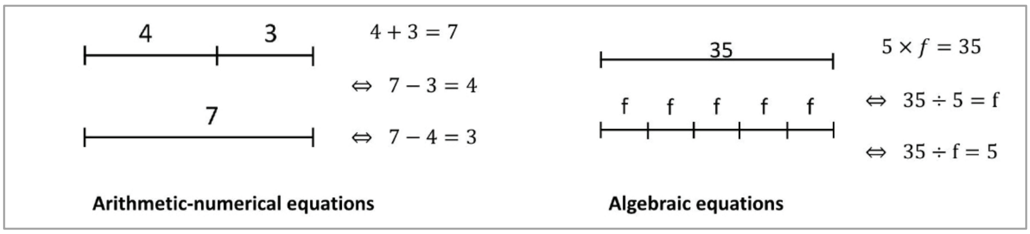

Figure 2: The bar model as a visual representation of equivalent equations

One bar model serves to describe three equations (see Figure 2) and that is why these equations are called equivalent. Following a semiotic point of view, the bar model can be considered a representational system. As with every representational system, working with the bar model presupposes specific knowledge being implicit (see Kempen and Biehler (2020) for a more detailed description) to work with. For example, two numbers are added by placing corresponding line segments next to each other, subtraction by crossing out or erasing. Multiplication is traced back to counting units in this model and is thus done by bundling line segments with equal length (see the five fs in Figure 2); division can be done by laying out a line segment with smaller segments of equal length. The equality of two values, expressions, etc., results from the phenomenon that two resulting line segments are equal. It becomes clear that one needs both an understanding of the mathematical operations and how they are represented or performed in the context of the bar model. To communicate such incidents, a distinct language is required that refers to the operations performed in the bar model and to the model itself. This language is closely related to the meaning-related language needed to describe basic operations (see Table 1).

Linking back the idea of equivalent equations to arithmetical contexts

For the strategy of *transposing* the relationship between the operations – the inverse operation of addition is subtraction etc. – is one key component that must be transmitted from arithmetic to algebra. To accomplish this transmission, it seems helpful to focus on the meanings of the operations involved as well as the related language that comes along with these meanings (see Table 1). The use of such meaning-related language seems also helpful when working with the bar model (see above).

Table 1: meanings and meaning-related language (see also Prediger & Roos, in press)

Meanings of the basic operations	Examples for meaning-related language
• Addition as putting together • Subtraction as taking away or determining the difference	• I have 2 and I **put it together** with 3, then I obtain **in total** 5. • I have 5, and I **take away** 3, so 2 remains. • I have 3, so I **need 2 more to reach** 5.
• Multiplication as counting in units • Division as sharing (partitive model) • Division as measuring (quotative model)	• I count in groups: 3 **groups / sets / units of** 2 are 6. • I **share** 6 **among** 3 people, so everybody gets 2. • 2 fits 3 times into the 6.

The learning environment

Based on the considerations above, we developed a learning environment to prepare the transition from arithmetic to algebra for transforming equations using the bar model (Prediger & Roos, in press). The steps in the learning environment are shown in Figure 3, although the paper focusses on step II and V.

Different representa-tions for equations **(I)**	The bar model in numerical contexts **(II)**	Equivalent equations in numerical contexts **(III)**	The bar model in algebraic contexts **(IV)**	Equivalent equations in algebraic contexts **(V)**

Figure 3: Steps in the learning environment towards transforming algebraic equations

In *step II (The bar model in numerical contexts)*, students get to know the bar model and start working with it. The key component here is the understanding of the bar model itself and how to perform and understand basic (arithmetic) operations in it (see Table 1, Figure 1). Learners need to connect the bar model as a graphical representation of equations with equations represented symbolically, and formulate verbally corresponding relationships. In *step V (Equivalent equations in algebraic contexts),* the objective is to detach the ideas of transforming equations from the use of the bar model so that students can transform equations also in rule-based procedures. Here, abstraction processes and the idea of reverse operation play a decisive role.

Research Question

Our focus is on developing a learning environment to ease the transition from transforming arithmetic-numerical to algebraic equations by using the bar model. The design research project (Gravemeijer & Cobb, 2006) builds and enhances the design based on empirical insights into students' learning processes. In this paper, we focus on the following research question: *Which obstacles become apparent when transforming and solving algebraic equations with the aid of the bar model?*

Methodology

Within the applied design research approach (Gravemeijer & Cobb, 2006), the learning environment created was sequenced into five steps (Figure 3). The target group of our learning environment consists of low-performing students who need a second chance to develop an understanding of the mathematical process of solving equations. The first two design experiment cycles addressed three low-achieving tenth graders in remediating mathematics classes, aiming to pass their Grade ten exam in a prevocational setting (Cycle 1) and three eighth graders of a German comprehensive school (Cycle 2). Data was collected while the students worked on equations in zoom-sessions in addition to their 'normal' math classes during the pandemic in January – May 2021. In total, 960 minutes of video data were collected and partially transcribed.

During the sessions, the design experiment leader watched the student work with the material. Whenever the student's work stayed unclear, she asked the students to explain their approach, thoughts, and solutions. Also, when students needed additional help or had questions, she explained the tasks in more detail.

In our analysis, we watched the videos and selected places where difficulties with the bar model or the transformation of equations occurred. For these places, we took a closer look into the corresponding transcripts. Two of the typical conceptual challenges appear when working in step II and step V of the learning environment. They will now be discussed based on the cases of Vivien and Anno. The problems discussed below can be considered prototypical for our sample in terms of their characteristics.

Tentative Results

Case of Vivien

The case of Vivien was already presented in Prediger & Roos (in press). She is an 18-year old girl in grade 10 participating in a remediating mathematics class. In this episode, the design experiment leader (DEL) talks with Vivien about the task in Figure 4 located in step II of the learning environment.

Three different running programs and their drawings

- John goes running every Saturday to train for a half marathon. He runs 21 km every time.
- Eva runs three times a week 7 km and
- Max runs every day 3 km from his place to his grandparents.

Assign Eva, Max and John's runs to the matching drawings.

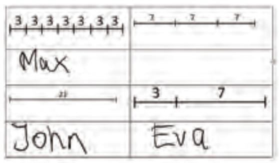

Figure 4: Vivien's solution to the running program task

1 Vivien: And Eva beneath, the one next to it [*refers to the lower right bar*]. Where there is written 3, then the middle line and then 7.
2 DEL: Here?
3 Vivien: Yes.
4 DEL: And can you explain how you came up with that or why?
5 Vivien: Because it says, “Eva runs three times a week 7 km”. And then I would say, the 3 stands for “three times a week” and the 7 for “7 km”.

Vivien focused on the numbers while missing to connect the bar model with the intended mathematical operation. This problem is also mirrored in her explanation: Rather than grasping the additive structure of 3 and 7 in this part of the bar model (e.g., with meaning-related language of addition like “putting together”, see Table 1), she only articulates the numbers, not joint lengths: “Where there is written 3, then the middle line and then 7” (Line 1). Vivien shows difficulties with the distinction of additive and multiplicative structures in connection with the bar model. This is also reflected in her rather simple use of language: “And then” is the only connective between 3 and 7 that she uses, which does not allow her to distinguish an additive structure from a multiplicative structure. Moreover, Vivien fails in realizing the idea of multiplication displayed in the bar model on the upper right. Here, multiplication is shown as counting units. It becomes evident that a learner has to combine two facets of knowledge: First, the conceptual understanding of multiplication as counting units is needed for mathematizing the text on Eva’s run. Second, the representation of this multiplication (as several units consisting of 7 km each) in the context of the bar model has to be realized (three line segments of length seven are meant to represent "3 · 7"). In this sense, the conceptual understanding of multiplication serves as a prerequisite for choosing the adequate bar model. However, based on this conceptual understanding, the corresponding representation in the bar model (the juxtaposition of three line segments [addition] of equal length [leading to multiplication]) has to be understood, too, as a matter of implicit knowledge.

Case of Anno: Anno is a 14-year old German 8th grader with average achievement in mathematics classes at the comprehensive school. In the beginning of his learning process, he displayed a good understanding of the bar model by explaining the meanings of the underlying operations. When talking about the bar model, he finds the correct corresponding symbolic equations and gives a correct explanation (see Figure 5).

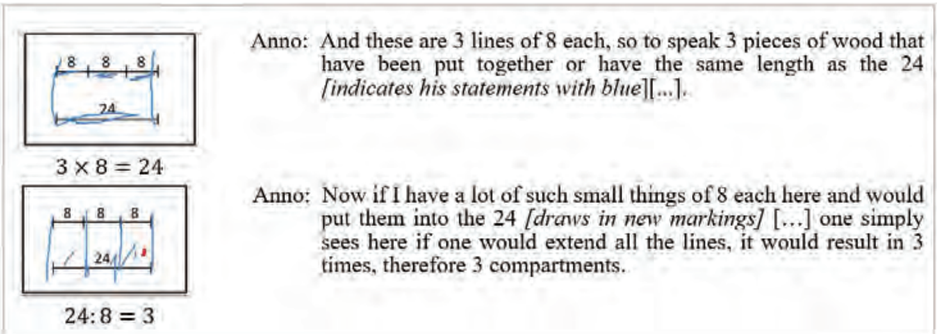

Figure 5: Anno explaining corresponding equations in the bar model

Anno refers directly to the significance of the operations when he speaks of pieces that have been "put together" or of the "three compartments" that have been placed in the 24. Thus, although the bar model is new to him, he seems to have a good intuitive understanding of the operations and the corresponding connections between the bar model and the symbolic representation. In the following episode, the design experiment leader and Anno discuss the task shown in Figure 6 (step V, see Figure 3). This task was designed to initiate a detachment from the bar model with which the students had worked before. Detaching is necessary because the multiplication with the rate r can hardly be visualized as counting in units in the bar model (and scaling up and down is not known by Anno). Therefore, from the tasks, which were solved before with the bar model, the idea of the reverse operation is to be transferred.

You know an example of such a formula from percentage calculation:

$\underbrace{amount}_{a} = \underbrace{rate}_{r} \times \underbrace{base}_{b}$

i) What are the equivalent equations here?

The same is now possible with every formula. So I finally don't have to learn so many by heart…

Figure 6: Anno's task for detaching from the bar model due to other meanings of multiplication

After Anno finds the correct equivalent equations ($a = r \times b; r = a \div b; b = a \div r$) the interviewer asks how he came up with his solutions:

Anno: Yes, because it was always in the beginning [*referring to former tasks in the learning environment*] larger [value] was always calculated by the two smaller ones. If you now assume that somehow these are the two smaller ones, like 3 times 2 or something, the larger value is calculated by these two [*marks the rate and the base*]. This [*referring to a*] you can then divide by the two, by the rate and the base, I suppose.

Also in the following, Anno continues explaining his strategy of transposing equations by using ideas of smaller or bigger numbers. For him, the number or variable that stands alone opposite the multiplication on one side of the equation has to be the largest. If one wants to obtain an equivalent equation, this only makes sense if one divides the larger number by a smaller number. He shows here – similar to Vivien – a non-sufficient focus on the underlying operations with respect to their structures. Although Anno described the meaning of multiplication and division as inverse operations in earlier tasks, he can only superficially exploit this idea when developing a strategy without the bar model. He uses a method that is based on the magnitude of numbers ("if one now assumes […] these are the two smaller […] the larger value is calculated by these two"). This strategy might be considered an over-generalization resulting from the bar model: The one number alone on one side of the equation is always bigger than the two numbers on the other side. In fact, multiplication in the bar model is based on the aspect that at least one of the factors is a natural number. Albeit Anno's strategy can be helpful when working with equations with natural numbers, the strategy fails when multiplying with factors smaller than 1.

Discussion and Conclusion

The insights we gained in our design experiments are the following:

Regarding the understanding of the bar model, some students have considerable difficulties connecting representations (iconic-symbolic-verbal) relying on conceptual understanding of basic operations. For such students, it is hard to use the model to make sense of equivalence transformations of equations. Even the step before, representing one side of the equal sign in the bar model already depicts challenges. These students focus on the given numbers in the model instead of on the underlying mathematical structures. This phenomenon has also been reported in the context of multiplication for grade 5 students (Prediger, 2019). However, our sample consists of students in grade 10. Other students who have acquired an adequate understanding of the meaning of equivalent equations within the bar model are not necessarily able to develop an appropriate strategy (like transposing) when prompted to detach it from the bar model. Especially regarding algebraic equations with a multiplicative structure, the concept of inverse operations should be used, not an idea concerning the magnitude of numbers that are not transmissible to decimal numbers below 1.

Based on these findings regarding students' obstacles when using the bar model for solving equations, we want to highlight the following theoretical implications. First, when working with the bar model, a profound understanding of basic mathematical operations has to be considered essential. This understanding is not only necessary for performing respective operations when solving equations in arithmetical or algebraic contexts; learners need to have an appropriate conceptual understanding to understand which operations are illustrated in the bar model or perform operations in the bar model themselves. Although Koleza (2015) found that third graders already understand multiplication after short instruction with the bar model, our preliminary results show that this does not have to be the case even for students in grade 8. Moreover, the bar model must first be seen as a learning object in its own right before it can aid learning. In this sense, the bar model is neither self-evident nor self-explanatory, as learners need specific knowledge to work with it. Besides, the student's attention must be directed from a focus on the numbers to a focus on the underlying operations (see also Prediger (2019)) and its representation in the bar model. In the case of Anno, the extensive work with the bar model led to an over-generalization of a respective strategy for working with equations. Furthermore, this overgeneralization might be considered a considerable misconception. Accordingly, the idea of inverse operation has to be highlighted in the bar model to focus rather on the operations than on the 'length' in the bar model. Following these theoretical insights, we draw the following related practical implications: (1) Especially for low achieving students, the repetition of the meanings of the basic operations seems necessary. Accordingly, we plan to extend our learning environment with a new part at the beginning to ensure respective prerequisites. (2) The conceptual meanings of the basic operations need to be more closely related to the bar model so that the bar model is brought in more explicitly as an independent object of learning (step II, Figure 3). (3) Tasks must be added that focus on the application of the idea of inverse operations; this idea should be followed throughout the whole learning environment. In addition, tasks have to be incorporated to help students detach from the bar model and thus work against overgeneralizations and misconceptions.

Based on the results of our analysis, we are planning the next cycle of our research project for the end of 2021.

Acknowledgment

Using the graph when talking about functional relations in Grade 1: The importance of terminology

Helén Sterner

Linnaeus University and Dalarna University, Department of Mathematics Education, Sweden; hse@du.se

This study investigates how the graph representation creates opportunities for young students to develop an understanding of functional relationships in pattern generalizations. The empirical data is from an educational teacher-focused classroom design research focusing on generalizations in arithmetical growing patterns in Grade 1. The results show that the students in Grade 1 are given an opportunity to reason mathematically in both recursive- and covariational thinking. The results also show how the teaching provided opportunities for the students to use multiple representations of functional thinking and how oral language is a common representation to describe relationships. However, using a well-thought-out terminology to exploit the potential of the graph representation when discussing functional relationships and generalizations appears to be important.

Keywords: Generalizations, functional relationships, graph representation, elementary school, terminology.

Introduction

The concept of *generalization* is used in various ways and in relation to multiple mathematical contents, for example, generalized arithmetic or generalized relationships between quantities. Generalizing the functional relationship between two variables in growing patterns has been used successfully, even with young students, and research indicates that young students can develop their functional thinking (e.g., Blanton & Kaput, 2004; Blanton et al., 2015; Stephens et al., 2017). However, teachers as well as students have difficulties in working with generalizations and students are often not given opportunities to develop mathematical generalizations (e.g., Stylianides & Silver, 2009). In the Algebraic Thinking Group at CERME, there is an ongoing discussion about figural patterns and how they can support young students' understanding of algebraic generalizations. Nevertheless, what is unsolved is how teaching can contribute to students' shifting their focus "from the visual structure to the algebraic structure" (Chimoni et al., 2019, p. 530) and how teaching can contribute to young students' overcoming the difficulties described by Stylianides and Silver (2009) as a way to support their understanding of functional relationships. In an attempt to contribute insights about teaching functional relationships, an educational teacher-focused classroom design research with three teachers was conducted (Sterner, 2019; 2021). This paper builds on the teaching of one Grade 1 teacher who used graphs to talk about functional relationships and generalizations and includes reflections from the three teachers in the design research (intervention). The research question in the paper is, "In what way does the graph representation support teaching and provide learning opportunities about functional relationships and generalizations in Grade 1?". What is interesting in relation to young students' learning about functional relationships is the teachers' reflections on their challenges.

Background and conceptual frames for the intervention

Functional thinking is a part of algebraic thinking that, focuses on the relationship between two (or more) quantities. The definition central for this study is from Wilkie (2016): "Functional thinking relates to understanding the notion of *change* and how varying quantities (or "variables") relate to each other" (p. 247). Research indicates that teaching functional thinking in elementary school is dominated by identifying recursive patterns, where the relationship between quantities is often missing (Blanton et al., 2015; Carraher et al., 2008). In addition, young students are often introduced to variable notation as a quantity with a "missing value", and thus the relationship between the independent and dependent variables and proportional reasoning is lacking in elementary school (Blanton et al., 2015; Carraher et al., 2008).

In Swedish primary schools (Grades 1–6), it is not common to teach functional relationships; the concepts of "double" and "a half" are used in lower grades when talking about proportional relations. In this study, design principles (DPs) are used as a theoretical frame to focus on generalizations and functional relationships. As can be seen from the Methodology section, the research project is intended as an educational design research. The content of the design principles (DPs) used in this study are formulated based on previous research on generalizations and functional relationships in teaching in elementary school. I interpret these principles as theoretical frames for the intervention as well as a guide for the content of the teachers' teaching, and the following design principles have been used. The second (DP2) is particularly central in this study.

DP1: The students should be given opportunities to identify a pattern, structure the pattern, and generalize the pattern (Mulligan et al., 2013; Stylianides & Silver, 2009).

DP2: The students should be given opportunities to work with algebraic reasoning, including functional thinking and proportional relationships and determining relations between two or more varying quantities (Beckman & Izák, 2015; Blanton et al., 2015; Blanton & Kaput, 2004).

Theoretical frames in the analysis

The analysis was done in three steps. In the first step, the definition from Wilkie (2016) was used in relation to the content of the design principles. The first analysis resulted in the empirical data, including students' and the teachers' discussions about the content of the design principles. In the second step, the second strand of Kaput's (2008) three algebra content strands was used, *Functions, Relations, and Joint Variation*. This strand provided an opportunity to highlight sequences in the empirical material, including functions, relations, and joint variation. In the third and last step of the analysis, I explored how the graph representation supports teaching and young students' learning of functional relationships and generalizations. Based on Kaput's (2008) algebraic thinking and the core aspects, Blanton et al., (2018) and Blanton et al, (2019) worked on generalization and functional thinking. Blanton et al., (2019) suggested four essential algebraic thinking practices: *generalizing, representing, justifying,* and *reasoning with* mathematical structure and relationships. In the last analysis, I used Blanton et al.'s (2019) essential algebraic thinking practices of generalizing as a theoretical frame. The second and the third practices, representing and justifying, became the most central practices to explore how teaching can be formulated to contribute to young students' learning of functional relationships and generalization in arithmetical growing patterns. The combination of representing generalizations and justifying generalizations made visible what opportunities the graph representation provides to students to justify generalizations.

Methodology

The study outlined in this paper is a part of an educational teacher-focused classroom design project inspired by *classroom design with teachers* (Stephan, 2015). One aspect of mathematical reasoning central in this paper is generalizing the functional relationship between two variables. In addition to the author, three mathematics teachers from different schools in Sweden, one from Grade 1 (Jonna) and two from Grade 6 (Clara and Irma), participated and collaborated in three recurring design cycles, an intervention, over a period of nine months (Sterner, 2019). The intervention is guided by design principles (Greeno, 2006; McKenney & Reeves, 2012), which are then used as the theoretical frame for the mathematical content of the intervention and as a guide for the content of the teaching (see "Background and conceptual frames for the intervention" section).

The empirical data in this paper include video recordings from various parts of the design process: five common meetings from the design– and refining phase and three lessons from Grade 1. Other data material includes field notes from the Grade 1 classroom, observations, copies of student work, and tape recordings of reflections with the teacher directly after teaching. Jonna, as well as the other teachers are experienced and development-oriented. The students are 6 or 7 years old, and the study is conducted with half the class (twelve students). The teacher (Jonna) describes functional relationships as a new and unknown way to learn pattern generalization in Grade 1. As mentioned, the design principles served as a theoretical frame for the intervention and teaching, and thus empirical data from both the teaching in the classroom and discussions from the design process were necessary. The empirical data was analyzed in three steps and three different frameworks were used (Blanton et al., 2018; Blanton et al., 2019; Kaput, 2008; Wilkie, 2016).

Ethical considerations

The intention was not to generalize the results but rather to exemplify the opportunities and challenges in teaching functional relationships in Grade 1. In the intervention, it was important to consider the teachers' and the students' participation and the chosen mathematical content.

The intervention in Grade 1

In the intervention, the three teachers (Clara, Irma, and Jonna) designed various tasks to support students in Grade 1 to *identify*, *structure*, and *generalize* different patterns (DP1). In the initial stage of the teaching in Grade 1, the students were given the opportunity to identify and structure different sequences of repeating patterns (e.g., AABAABAAB…) as well as conceptualize the idea of a unit of a repeating pattern.

One task concerning a certain number of dogs and the corresponding number of tails, ears, and legs was used to exemplify direct proportionality and to support functional relationships, as well as the importance of how quantities vary in relation to each other (DP2). This growing pattern task was used in teaching in both Grades 1 and 6 and was taken from an earlier study inspired by Blanton and Kaput (2004) and Mulligan et al. (2013). Students in Grade 1 counted and structured the tails, ears, and legs and represented the data and their functional thinking in different ways, for example, by drawing pictures, putting matches in piles, and making simple tables. The whole class talked about the patterns, for instance, those in the relationship between the number of dogs and the number of tails, ears, and legs (i.e., 1 dog has 2 ears…2 dogs have 4 ears…3 dogs have 6 ears… Each dog has 2 ears, and each dog has 4 legs). In the whole-class discussion, Jonna, the teacher in Grade 1, structured the data in function tables and made a graphical representation in a Cartesian coordinate system. They made graphical representations of the three relationships, where the number of dogs was illustrated as a function of the number of tails, ears, or legs respectively ($y = x,\ y = 2x,$ or $y = 4x$). Finally, Jonna and the students discussed the three different graphs. In the class, questions were asked like the following, "Which of these graphs represent the tails of the dogs and how do you know that?", "How many dogs do we need for 6 tails?", or "How many dogs do we need for 6 ears?" Some of the students counted, and some used the graph to recognize the patterns and the functional relationship.

Result and analysis

Despite that the teachers found it challenging to teach about functional relationships and pattern generalizations in the classroom, it turned out that a significant part of the classroom conversation worked well as an entry to discussing functional relationships. There was a learning potential to work with the graph representation and discuss the relation between quantities in Grade 1.

In the reflection directly after the teaching, Jonna talked about her perceived challenges in the teaching. Jonna talked both about the lack of words to describe the functional relationships and the challenges in explaining generalizations in Grade 1. Similar challenges arose in the discussions in the design process. The transcript below is from the teachers' discussion in the design process after the teaching had been completed, whereby the teachers refer to the previously mentioned tasks with dogs and the number of legs.

Clara: I don't have the words to talk about the functions the relation between dogs and legs. I don't know what questions I should ask the students to give them opportunities to develop generalizations.

Jonna: To be honest… I am not sure what a generalization includes. Is it enough when the students say, "Every time I add 4 more…"?

The transcript highlights two thoughts that often arose in the intervention when the teachers discussed generalizations in patterns and functional thinking. First, the teachers talk about challenges in how to talk about functional relationships. They talk about the lack of words to describe and express how quantities vary in relation to each other. In the intervention, the concept of a functional relationship is new and unknown in relation to pattern generalization the teachers used before ("double" and "a half") when working with relationships in elementary school. Now, the teachers are searching for words to describe and explain, for example, coordinates, independent- and dependent variables, proportional relationships, graphs, functions, and the x- and y-axes. The teachers are searching for the terminology that they have not previously used in their teaching.

Secondly, the teachers expressed uncertainty about when the students' arguments are enough to represent a generalization. In the dialogue, Jonna's reflections about whether it is enough when the students say, "Every time, I add 4 more." This can be interpreted as the student having identified a pattern and is somehow about to generalize the pattern. In the design process, the teachers discuss "When can a generalization be seen as a generalization?" in Grade 1.

At the end of the intervention, the teachers planned activities that would allow the students to identify functional relationships and patterns from what they called the "opposite way". They start from the graph representation, the function, and ask the students to find patterns. They begin an activity like the previously mentioned activity involving functional relationships with discrete numbers, that is the dogs and the relationships between the numbers of tails, ears, or legs ($y = x, y = 2x$ or $y = 4x$). The graph representation creates opportunities to talk about functional relationships in discrete values in Grade 1. However, in the intervention, the participants problematize the graph's visualization of continuous values.

Before the lesson in Grade 1, Jonna expressed worry about explaining and talking about functional relationships to the students. She mentions again the missing terminology for talking about how quantities vary in relation to each other. Jonna starts to give all the students a Cartesian coordinate system with two graphical representations and an empty table. The two graphs (the green and the red graph, see Fig. 1) illustrate the functions $y = x$ and $y = 3x$.

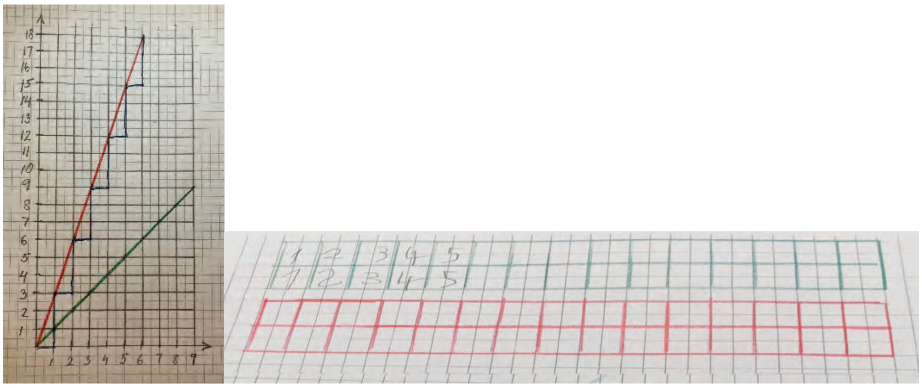

Figure 1: The Cartesian coordinate system and Karim's table,

illustrating the functions $y = x$ and $y = 3x$

The students used the graphs, wrote the independent and the dependent values in the tables, and then identified the pattern. Some of the students had to write many coordinates in the tables before they identified the pattern and tried justifying the pattern with oral language. Some students found the pattern quite fast and tried to express the pattern illustrating the function $y = 3x$ in the classroom. One of the students, Karim, talks to the teacher; he points to the camera stand with three legs and says, "Every time we have a new camera stand, we have three more legs."

In the class discussion, Jonna, the teacher, initiated talks about the identified patterns and used the tables and the graphs to talk about predicting near data. The results show that the teacher-led-class discussions included recursive- and covariational reasoning. The teacher and the students spoke about what emerges in a single sequence, namely, what happed to the dependent value? This short transcript is an example of a conversation in the discussion relating to one of the graphs in Figure 1, that of the "red" graph illustrating, $y = 3x$.

1	Teacher, Jonna:	Can someone describe the identified pattern?
2	Student, Sara:	The pattern increases by 3.
3	Teacher, Jonna:	How do you know that the pattern increases by 3?
4	Student, Ida:	In the table, it is "3–jumps".
5	Teacher, Jonna:	Yes, what can the red graph illustrate?
6	Student, Alex:	A snowman with 3 snowballs.
7	Student, Tanesha:	A tricycle with 3 wheels.
8	Teacher, Jonna:	Yes, how many wheels do we need for 2 tricycles?
9	Student, Frank:	We need 6 wheels.
10	Teacher, Jonna	Tell me, how do you know that?
11	Student, Frank:	3 wheels are needed for each tricycle.

The observed teaching offers several opportunities to represent pattern generalizations in multiple ways, such as using pictures, tables, graphs, or oral language. The students used the Cartesian coordinate system and structured coordinates in a table. The transcript indicates that the students only have their oral language to describe the patterns, as they have no access to variable notation. However, the most common way to talk about generalization and functional relationships was in a recursive pattern, which means describing the variation and the relation in the dependent value, for example, line 2 ("… increases by 3") and line 4 ("… 3-jumps"). It continues like this, and the teacher tries to initiate discussions, including those centered around the relationship between the independent and dependent variables. An initial reasoning, including the covariational relationship, is visible at the end of the transcript in lines 8-11: "3 wheels are needed for each tricycle."

The class discussion continues and the teacher, Jonna, points to the Cartesian coordinate system and asks the students to say something about the green and red functions ($y = x$ and $y = 3x$) . One student notes that "the red line goes straight up compared to the green one." Jonna, the teacher, agrees and asks the students if anyone wants to justify why this may be so. One of the students points to the red graph and shows what he calls the "small tents" [the tent is much bigger in the red graph]. The teacher says, "Yes … that's right … and how can we explain this big and small tent?". In the class, the silence is noticeable before one of the students points to the red graph and says, "The red graph could be the tricycle, 1 tricycle has 3 wheels". The student points to the "tent" in the y-axis and counts "1, 2, 3…". The student then goes on to point to the x-axis and y-axis and the coordinate (2.6) and says, "2 tricycles have 6 wheels…".

The discussion ends with the teacher asking what the green graph could illustrate. Several students recognize the graph and the table from the last lesson about the dogs, and their corresponding tails. Another student connects this to the tricycle and says, "…The green line shows a unicycle."

Discussion

This study sheds light on the role of the graph representation and how it can develop students' functional thinking. The results provide insights about the opportunities the graph representation invites, in terms of both the teachers' and students' reasoning about functional relationships when working with pattern generalizations in Grade 1. Although the graph representation first and foremost invites discussions of recursive reasoning, both the teacher and the students in Grade 1 also succeeded in discussing covariational relationships.

Despite Jonna's worries before the lesson, it seems that functional thinking is visible in the class discussions. For example, Jonna's teaching visualizes one way to try to get closer and talk about how quantities vary in relation to each other, which could be compared to what Wilkie (2016) claims, "the notion of *change* and how varying quantities (or "variables") relate to each other" (p. 247). The graph representation supports the teacher and the students to justify the relationship between independent- and dependent variables in the oral language without variable notations. This suggests that my results show that the graph representation can be seen as a tool to use in elementary school when transforming what Chimoni et al. (2019) call shifting focus "from the visual structure to algebraic structure." However, Jonna and the other teachers in the intervention are still searching for the terminology to talk about functional relationships in elementary school.

The results also indicate what the teacher in the study expresses "I am not sure what a generalization includes. Is it enough when the students say, Every time I add 4 more…?". This phrase is a recursion and could be interpreted as a generalization in Grade 1. One may wonder what else could be done if there was some big number of wheels and one more tricycle was added and in what way would symbols for the unknown number of wheels and tricycles be introduced. Maybe the discussion about functional relationships with the support of the graph representation can be seen as the first step towards variable notations, which does not just support a missing value. This falls in line with both Carraher et al., (2008) and Stephens et al. (2017), who stress the importance of using coordinated changes in quantities when teaching generalizations. However, the study shows the importance of using a well-thought-out terminology to exploit the potential of the graph representation when discussing functional relationships and generalizations. What is interesting in this example is how the teacher's reflections enable the teacher to find new and unknown "ways" to teach generalization.

Elementary algebra has been the bedrock of science and technology for centuries. But taught algebra today is much more a set of formal exercises than a modelling tool. The present study focuses on the notion of formula and how its curricular evolution appears to be a witness and a cause of the degradation of taught algebra as a modelling tool. This examination involves careful analyses of curricular facts that seem not to have attracted the full attention of researchers, such as the vanishing of parameters from algebraic equations. Drawing on the anthropological theory of the didactic (ATD), we outline the perspective of an imperative revitalization of the elementary algebra curriculum. Data used in the study include curriculum materials such as textbooks from different countries and various types of publications on school algebra by authors influential in their time.

Keywords: Curriculum, didactic transposition, elementary algebra, formulas, parameters.

Introduction

The passing of time changes curricular contents. This universal process of "curricular aging" can lead any subject matter to lose a large part of its instrumental value and to deteriorate to the point that its study at school becomes but a rite of passage imposed on the younger generations. In this study, we try to set out conditions favourable to making *elementary algebra*, understood as the algebra taught in secondary schools, an effective tool for understanding many "facts" of both the mathematical and the extra-mathematical world. By studying how the possibilities offered by elementary algebra have been greatly reduced by the evolution of the algebra curriculum over the last century, we will highlight the potential of elementary algebra to become a tool for understanding the world around us. Our research question is: *What key conditions should secondary school algebra meet to become an effective modelling tool for our time?*

On the epistemology and methodology of the study

In the framework of the ATD (Chevallard, 2019, 2020), the modelling of didactic phenomena rests on the notions of *person*, *institution*, and *institutional position*.

All human individuals are persons. Any "instituted" reality is an institution, such as a family, a class, a couple, a school, a ministry, the Norwegian society, and the French society. Any institution is organized into a set of institutional positions: In a classroom, there is the teacher position and the position of student; in mathematics education, there are the positions of textbook author, of teacher educator, of "great mathematician", etc. An institutional position is occupied by persons who thus become "subjects" of the institution. Persons are shaped by the set of institutional positions they occupy and have occupied. Persons are thus singular representatives of a position to which they are subjected. At the same time, persons can change the positions they occupy; there is thus a dialectic between persons and institutions in the making of a society.

Consequently, to study any institutional position, one studies the persons who are or have been its subjects; and, conversely, in order to study a person, one studies the positions he or she occupies or has occupied. Hence, in this study, we have studied persons' publications that allow us to enlighten the historical evolution of the teacher and student positions regarding elementary algebra. This has enabled us to identify conditions and constraints that have determined the current didactic transposition of elementary algebra and, most importantly, the vanishing of parameters from it. Our methodology is essentially that of *didactic transposition analysis* (Chevallard, 1991).

The take-off of algebra: From rules to formulas

We shall first highlight the key points of the changes that have affected the algebra curriculum, in order to identify core requirements for revitalizing secondary school algebra. We will focus on an aspect little considered: the role played (or not played), in the algebra curriculum, by the notion of *formula*, seen both as a symptom and as a cause of the impoverishment of school algebra. Here is a typical rule found on the Internet for how to find the area of a trapezoid (How to Find the Area, n.d., Example Question #1 section): "To find the area of a trapezoid, multiply the sum of the bases (the parallel sides) by the height (the perpendicular distance between the bases), and then divide by 2." Once fully algebraized, this rule becomes a formula: $A=\frac{1}{2}(b_1+b_2)h$, where b_1 and b_2 are the lengths of the parallel sides and h the distance between them.

Parameters: From implicit to explicit

To distinguish between "arithmetical rules" and "algebraic formulas," we must use the essential notion of *parameter*. In the formula $A=l\times b$ for the area of a rectangle with length l and breadth b, the letters l and b are parameters specifying the rectangle. While a rule (in words) contains parameters *implicitly* (like "length" and "breadth"), a formula contains *explicit* parameters. Consider the following rule given by Percival Abbott (1869–1954) in his book *Algebra* (Abbott, 1942/1971):

> The area of a rectangle in square metres is equal to the length in metres multiplied by the breadth in metres. This rule is shortened in Algebra by employing letters as symbols, to represent the quantities… [With the letters l, b, and A representing respectively the length, breadth, and area (in metres and square metres)] the above rule can now be written in the form: $A=l\times b$." (pp. 13–14)

A rule thus expressed is therefore called a formula. With this, a question arises. According to Abbott (p. 13), the "classical" doctrine on the arithmetic-algebra divide consists in the fact that, in arithmetic, one employs *definite numbers*, whereas in algebra, "we are, in the main, concerned with *general expression* and *general results*, in which letters or other symbols represent numbers not named or specified." Now this statement is subtly contradictory to the notion of "arithmetical rule": In the rule for the rectangle, we have, not "definite numbers," but "implicit parameters," the length and the breadth, not represented by *letters*.

How can this seeming discrepancy be explained? A quick answer is: In arithmetic, students are *given* a rule—they only have to *apply* it when the (implicit) parameters in the rule take definite numerical values. *Deriving* a formula (relying on some basic, given rules or formulas) is usually rather easy when done algebraically. In contrast, if you do it "arithmetically," it usually becomes more complex, and beyond the reach of beginners. This can be linked to the notion of *topos* of an institutional position, that is the set of *types of tasks* that persons in that position may have to perform (Chevallard, 2019). Let us repeat: in arithmetic, the teacher provides the rules ready-made, and the students simply apply them to numerical values.

In his *History of Mathematics,* David E. Smith (1925/1958, p. 437) made this comment: "To the student of today, having a good symbolism at his disposal, it seems impossible that the world should ever have been troubled by an equation like $ax+b=0$." Such however was the case. The algebraization of arithmetic was a huge step forward, a game changer for the sciences. But an almost surreptitious drawback happened that greatly reduced the power of the algebra actually taught.

A Pyrrhic victory

The algebraic modelling of arithmetical rules might pertain to the student *topos,* as the exercise set of Abbott's *Algebra* (1942/1971) seems to show. Here are some of Abbott's exercises (pp. 20–21): "Write down expressions for: (1) The number of pence in £x; (2) The number of pounds in n pence… (19) A train travels at v km/h. How far does it go in x hours and how long does it take to go y km?"

The implicit parameters of arithmetical rules are here translated into explicit parameters: n, v, x, and y. However, in the history of elementary algebra, explicit parameters will tend to be replaced by "definite numbers." Here is an example taken from the chapter "Simple Equations" of Abbott's book:

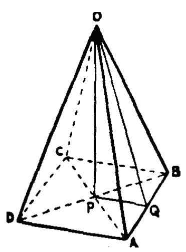
> A motorist travels from town A to town B at an average speed of 64 km/h. On his return journey his average speed is 80 km/h. He takes 9 hours for the double journey (not including stops). How far is it from A to B? (Abbott, 1942/1971, p. 66)

Abbott (1942/1971, p. 76) describes another type of equations "in which the values of the unknown quantities will be found in terms of letters which occur in the equation." He calls them *literal equations* and states that they can be solved by the same methods as simple equations. The examples he gives of literal equations are $5x-a=2x-b$, and $a(x-2)=5x-(a+b)$. The 14 equations in the related exercise set are similar to these: they are quite simple, and nobody knows what they claim to model—they are a mere didactic device, related to the need for tasks for repetitive training. We will come back to this phenomenon in the section "A turning point in the didactic transposition process."

Transformation versus evaluation of formulas: Reaching a demarcation line

The paucity of the material thus presented by Abbott is in striking contrast to the chapter's introduction, which begins with this promising statement (Abbott, 1942/1971):

> One of the most important applications of elementary Algebra is to the use of formulae. In every form of applied science and mathematics… formulae are constantly employed, and their interpretation and manipulation are essential. (p. 69)



The author explains that formulas "involve three operations: (1) Construction; (2) manipulation; (3) evaluation" (p. 69). The construction of a formula does not start from scratch: it relies on formulas previously established, either theoretically or empirically. The first "worked example" given by Abbott is typical: "Find a formula for the total area (A) of the surface of a square pyramid as in Fig. 10 [see figure opposite] when AB$=a$ and OQ$=d$" (p. 70). Here, the use of algebra is genuine but minimalist. By contrast, the second example and all the exercises given by Abbott are just *evaluation* tasks, as this exercise: “The volume of a cone, V, is given by the formula $V=\frac{1}{3}\pi r^2 h$, where r=radius of base, h=height of cone. Find V when $r= 3{\cdot}5$, $h=12$, $\pi=\frac{22}{7}$” (Abbott, 1942/1971, p. 70).

The *manipulation* of formulas is only present in the section entitled “Transformation of Formulae.” About the volume of a cone ($V=\frac{1}{3}\pi r^2 h$), Abbott (1942/1971) writes:

> It may be necessary to express the height of the cone in terms of the volume and the radius of the base. In that case we would write the formula in the form: $h=\frac{3V}{\pi r^2}$, that is, the formula has been transformed. When one quantity is expressed in terms of others, as in $V=\frac{1}{3}\pi r^2 h$, the quantity thus expressed, in this case V, is sometimes called the *subject of the formula*… This process of transformation has been termed by Prof. Sir Percy Nunn *“changing the subject of the formula.”* (pp. 71–72)

About such a change, Abbott (1942/1971) adds this caveat: “The transformation of formulae often requires skill and experience in algebraical manipulation” (p. 72). He then illustrates the “methods” to be followed by five “worked examples.” In one of them (p. 73), he transforms the formula $L=l+\frac{8d^2}{3l}$ to find d in terms of L and l and arrives at $d=\sqrt{\frac{3l(L-l)}{8}}=\sqrt{\frac{3lL-3l^2}{8}}$. Readers are not asked to find the expression of l in terms of L and d—the answers are $l=\frac{L}{2}\pm\sqrt{\frac{L^2}{4}-\frac{8d^2}{3}}$—, which would require solving the *quadratic* equation $l^2 - Ll + \frac{8d^2}{3} = 0$. Here we reach the demarcation line drawn by the traditional didactic transposition of elementary algebra.

This line draws a curricular curiosity. Firstly, the quadratic equations with parameters considered have only one parameter. Secondly, students are not asked to give the expression of their solutions (which, in the general case, would include the parameter), but simply to specify, according to the value of the parameter, when they have 0, 1 or 2 roots. This sudden change of didactic contract (Brousseau, 1997)—an equation is no longer “something to be solved” but to be “studied” or “discussed”—was (and still is) a source of difficulty for students. In spite of this, the question of the “manipulation” and transformation of formulas, alongside their “construction” and “evaluation,” which are much less problematic, is at the heart of what algebra can consist of. In Abbott’s Example 5 (p. 74), readers are asked to find the length l of a simple pendulum in terms of the other quantities when its time of vibration is given by $t=2\pi\sqrt{\frac{l}{g}}$. Exercise 13 (No. 2) is about expressing the radius r of a sphere in terms of its volume V (p. 74). The usefulness of these transformations seems obvious. Now the big problem is that the type of tasks in question— “changing the subject of a formula”—has become marginalized in most secondary curriculums. A study of Norwegian textbooks used in recent decades is a clear testimony to this fact (Strømskag & Chevallard, 2021). In one of the textbooks for Grade 11 (Sandvold et al., 2006, p. 26), the authors consider the formula $v=\frac{d}{t}$ (where v is the speed, d is the distance travelled, and t is the time) and explain how to “solve the formula with respect to the time t" as if the students were complete beginners in elementary algebra. The authors then explain how to solve for c the (fabricated) formula $p=a+\frac{1}{2}bc^2$ to arrive at $c=\pm\sqrt{\frac{2-2a}{b}}$. Then follow tasks that ask to solve for t these formulas: $d=vt$; $d=\frac{1}{2}at^2$; $v=v_0+at$; $d=\frac{(v_0+v)t}{2}$. This is a limited viaticum (e.g., there are no quadratic equations with parameters) for a further journey into elementary algebra. The same phenomenon prevails in French textbooks (Chevallard & Bosch, 2012) and in German textbooks (e.g., Brandt & Reinelt, 2009). The latter is in line with the German Mathematics Standards for the expected level by the end of upper secondary education (Kultusministerkonferenz, 2012), where parameters are present in some of the example tasks but never in equations to be solved.

The pitfalls of didactic transposition

The marginalization of formula transformation

Let us consider the following exercise proposed by Abbott (1942/1971, p. 75): "There is an electrical formula $I=\frac{V}{R}$. Express this (1) as a formula for V and (2) as a formula for R. Find I if $V=2$ and $R=20$." A number of teaching institutions choose to "spare" their subjects the algebraic "work" needed to go from the formula $I=\frac{V}{R}$ to the formulas $V=R\cdot I$ and $R=\frac{V}{I}$. One of the most widespread techniques, it seems, consists in substituting to the algebra needed a graphic "mnemonic trick" which takes the form of a triangle in which the parameters V, I, R are displayed (see example in Figure 1).

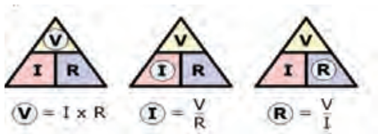


Figure 1: A graphic mnemonic trick (retrieved from Nimar_geek, 2020)

This "triangle technique" is pushed forward by institutions. The institutional enforcement of this technique seems to send the following message: "You don't need to know algebra *at all*."

There is also another, widespread technique, which is implemented more by people—students, in particular—than by institutions. This technique consists in avoiding any literal calculation. Suppose we are given the formula $I=\frac{V}{R}$ and values for I and R, and are asked to calculate V. If $I=1.2$ and $R=20$, the formula gives rise to the equality $1.2=\frac{V}{20}$, which is a linear equation in V that the student can therefore easily solve. This technique consists in first transforming a formula into a "simple" numerical equation.

A turning point in the didactic transposition process

How has this demarcation line been drawn? The answer must involve the conditions and constraints that have historically determined the didactic transposition of elementary algebra. Two influential textbook authors who have taken part in this transpositive work are Abbott and Nunn. About the phrase "Change the subject of a formula," Nunn writes in his book *The Teaching of Algebra* (1914):

He [the author himself] believes that it was used for the first time in his lectures to teachers of mathematics in 1909. It was subsequently adopted in the Report on the Teaching of Algebra by the Committee of the Mathematical Association. (p. 78)

Why did Nunn introduce this way of saying, which was adopted by Abbott and others, when what is required is simply to "solve the equation $A=\pi r^2$ for r?" Nunn seems to have been quite aware of the change he wanted to popularize. Thus, he launches an attack against the position of strength given to equations, which he calls "conundrums" that "the school tradition has not lifted … to a much higher level of intellectual dignity" (Nunn, 1914, p. 77).

Nunn's degradation of equations leads to the coming apart of two distinct topics: equations and formulas. Formulas such as $V = R \cdot I$, which become equations once an unknown has been chosen (we can solve $V = R \cdot I$ for I for example), are indispensable in many fields of science and technology. Paradoxically, they were going to be marginalized by their very "promotion."

This detail of the didactic transposition process is linked to two great constraints. The first constraint is that of *simplicity*: the transposed content must be "simple" enough to offer students a *topos* that they can actually occupy. In France, in the early 1960s, a demanding exercise textbook for Grade 10 still proposed the following, highly artificial exercise (what exactly is it modelling?): "Solve the equation $(a+b)^2x^2 - (a-b)(a^2-b^2)\,x - 2ab(a^2+b^2) = 0$" (Combes, 1961, p. 124). But parameters in equations were officially deemed "undesirable" in 1981 (Chevallard & Bosch, 2012, p. 16). The second constraint is that, for didactic reasons of repetitive training, the teacher must be able to produce *at will* tasks of any type he or she has to teach. However, because of their origin in specific domains (geometry, physics, technology, etc.), it seems that the list of formulas to be "solved" is limited. In order to make it easier to create formula transformation tasks, it is accepted to break the link between a formula and what it models. The constraints mentioned therefore contributed to making the algebra taught a separate field, almost foreign to the other fields of mathematics and science.

Systems and models: Algebra for the future

So, what should elementary algebra consist of? To answer this question, we must first introduce two basic notions of the ATD: the notions of *system* and *model*. A system $\mathcal{S}$ is any entity subject to laws of its own. For example, a (geometric) sphere is a system whose "laws" are generally called the *properties* of the sphere, such as the following: "A great circle… of a sphere is the intersection of the sphere and a plane that passes through the centre point of the sphere" ("Great Circle," 2021). Any formula is a system as well. The formulas for the volume and the surface area of a sphere of radius r, that is, $V=\frac{4}{3}\pi r^3$ and $A=4\pi r^2$, are systems in their own right, which themselves have properties (we have $V=A\times\frac{r}{3}$ or $A=\frac{3V}{r}$ or $3V-rA = 0$, etc.). Given a system $\mathcal{S}$, a system $\mathcal{S}'$ is said to be a model of $\mathcal{S}$ if, by studying $\mathcal{S}'$, one can answer certain questions Q about $\mathcal{S}$. In practice, given a question Q relating to $\mathcal{S}$ which one wants to answer, one tries to build up a model $\mathcal{S}'$ of $\mathcal{S}$ (or choose one already existing) whose study with respect to the question Q is easier, safer, quicker than by a "direct" study of $\mathcal{S}$. For example, if the radius r of a sphere increases by 20%, the new surface area A' will be $4\pi r'^2=4\pi(1.2r)^2=1.44A$, so that the surface area will increase by 44%—a tricky result to obtain experimentally.

The great catastrophe which historically disorganized and denatured elementary algebra resulted from the generalized rupture of the link between the systems $\mathcal{S}$ to be modelled algebraically and their algebraic models $\mathcal{S}'$ relating to some question Q about $\mathcal{S}$. In most textbooks, this link has disappeared entirely. The vanishing of parameters from algebraic expressions goes together with the purely formal existence of algebraic expressions, which consequently lose their functional role, that is, the role of elements of a model of a system.

Conclusion: Conditions for a more authentic algebra curriculum

How can we pave the way towards a curricular reconstruction that revitalizes elementary algebra? The answer rests on two components: 1) the notions of system and model explained above and 2) rescuing the notion of formula and reintroducing expressions in several indeterminates in order to be able to model a diversity of mathematical or extra-mathematical systems. In a mathematics class, it is essential to study triples ($\mathcal{S}$, Q, $\mathcal{S}'$) composed of a mathematical or extra-mathematical system $\mathcal{S}$, a question Q raised about $\mathcal{S}$, and a model $\mathcal{S}'$ (related to $\mathcal{S}$ and Q) which contains mathematical elements that are key to constructing an answer to Q.

Mathematics education is therefore potentially concerned with all situations in which mathematics is or can be used to better understand the situation in question. In this respect, let us remind the reader that, from about 1600 to 1800, mathematics was divided into two branches, that of *pure* mathematics and the widely embracing branch of *mixed* mathematics (see e.g., Bacon, 1605/1901, pp. 172–174).

So, what key conditions should school algebra meet to be an effective modelling tool for our time? By way of a conclusion, we shall sum up the core of a more "authentic" study and use of algebra identified in the course of this inquiry:

> 1) The students start from a system $\mathcal{S}$ and a question Q raised about it, whose adequate treatment seems to involve mathematical elements; 2) These students build up a model $\mathcal{S}'$ of $\mathcal{S}$, relative to the question Q, which will be built with elementary algebra (and will include as many parameters as seems useful); 3) They work on $\mathcal{S}'$ to derive an answer A deemed adequate to the question Q; 4) At the same time, prompted by this process of inquiring about $\mathcal{S}$, they discover the resources of algebra, study or restudy them in order to make an efficient use of the tools thus garnered.

A brief example is in order here. The starting point is the theorem which says that when the sum of three numbers a, b, and c is constant, then the expression $ab+bc+ca$ is maximal when $a=b=c$. What can this result be used for? One answer concerns the prices of diamonds, when assumed to be proportional to the *square* of their weight. If the price of a diamond of weight w is equal to kw^2, where $k>0$, and if a diamond is broken into three pieces of weight a, b, and c, respectively, the price of each of these pieces is ka^2, kb^2, and kc^2 while the price of the original diamond of weight w_0 was $kw_0{}^2=k(a+b+c)^2$. We have: $(a+b+c)^2-(a^2+b^2+c^2)=2(ab+bc+ca)>0$. The price of the original diamond is therefore greater than the sum of the prices of the three diamonds obtained. As a consequence of the equality $3(ab+bc+ca)=(a+b+c)^2-\frac{1}{2}[(a-b)^2+(b-c)^2+(c-a)^2]=w_0{}^2-\frac{1}{2}[(a-b)^2+(b-c)^2+(c-a)^2]$, the loss of value caused by the breaking of the diamond into three parts is maximal when $a=b=c$, that is when the three pieces have the same weight. Here, the system $\mathcal{S}$ is a diamond and its selling price, and a key element of the model $\mathcal{S}'$ is the equality

$3(ab+bc+ca)=(a+b+c)^2-\frac{1}{2}[(a-b)^2+(b-c)^2+(c-a)^2]$ with three parameters. For a more detailed discussion of this example, see Strømskag and Chevallard (2021). The four points listed above outline a research and innovation programme to which the present study is a contribution in order to help develop, in the decade to come, the full collaboration of researchers, teachers, and teacher educators.

Programming tasks as an instrument for helping students make meaning of methods for solving quadratic equations

David Taub

Karlstad University, Department of Mathematics and Computer Science, Sweden; david.taub@kau.se

Keywords: Mathematics education, algebra, programming.

Poster summary

Although there has been a good deal of research into the problems students often encounter when solving and trying to understand first-degree equations, there has been relatively little comparable research involving quadratic equations. A number of authors have identified difficulties with quadratic equations which overlap with those known for first-degree equations. For example, some students were unable to solve quadratic equations because of difficulties with working with fractions, negative numbers and basic computational skills, as well as difficulties with understanding the concept of variable (e.g., Didiş & Erbas, 2015; Hu et al., 2021; O'Connor & Norton, 2016). However, a number of problems specific to solving quadratic equations have also been identified, including using the quadratic formula, completing the square, factoring second-degree polynomials, and understanding the zero product property (e.g., Hu et al., 2021; O'Connor & Norton, 2016; Tall et al., 2014).

Research into how programming can help students understand algebra has been rather limited so far. Most of the connections to algebra that have been looked at are related to built-in features of the chosen programming environment, such as coordinate systems and variables (e.g., Germia & Panorkou, 2020). Much recent research has focused on using Scratch to introduce programming to younger students, both with the goal of teaching computational thinking as well as teaching concepts within mathematics (e.g., Benton et al., 2016).

Although the zero product property is unlikely to be useful for solving an arbitrary quadratic equation, since it is unlikely to be factorable (Bossé & Nandakumar, 2005), it has clear uses within the context of school mathematics, as well as being important for understanding more advanced mathematics such as the roots of polynomials and the partial fraction method of integration. Therefore, this poster aimed to initiate a discussion in the TWG3 about the use of programming tasks as an instrument to teach and develop algebraic thinking, in particular with regard to using the zero product property to solve quadratic equations. In addition to background information, the poster includes information about the intended design of the project as well as example tasks.

In cooperation with secondary school teachers, pairs of students will be given a series of programming tasks designed to elicit a deeper understanding of the zero product property and how to apply it when solving quadratic equations. The tasks will be developed together with the teachers, tapping into their knowledge of their own students' current understanding of mathematics. The students will be recorded while working on the tasks and interviewed afterwards in order to gain insight into the effectiveness of the programming tasks. The tasks and results will be designed and analyzed using the theoretical framework Abstraction in Context (AiC), which builds on the works of Freudenthal and Davydov and combines both cognitive and sociocultural ideas (Dreyfus et al., 2015; Dreyfus & Kidron, 2014). AiC relies on a detailed analysis of student discussions during the tasks as well as their interview responses in order to identify the formation of new mathematical constructs. This method of analysis does not depend on comparing the results of a pre-test and post-test.

This poster presents the research project in a graphical format in order to more clearly show how the various phases fit together.

Diagnostic test tool based on a praxeological reference model to examine students' technical and theoretical algebra knowledge

Pia Tonnesen

University of Copenhagen, Denmark; pia.tonnesen@ind.ku.dk

The main aim of this paper is theoretical and methodological: to show how The Antropological Theory of the Didactics – in particular, the construction of a praxeological reference model – can be used as a foundation for developing a diagnostic test tool which examines students technical and theoretical knowledge of basic algebra (and related arithmetical knowledge on which initial algebra is based). The point is to provide explicit control on what is being tested, for instance, in relation to a given national curriculum, and in relation to teaching interventions.

Keywords: Anthropological theory of the didactics, school algebra, praxeological reference model, diagnostic test.

School algebra

In secondary school, basic algebra is a crucial bridge between arithmetic and more advanced subjects involving functions and analytic geometry. To set up algebraic models, it is necessary to master arithmetic and algebraic techniques by hand, at to know associated theory like the distributive law. But it is a longstanding and widespread problem that large groups of students seem to get stuck at this bridge between arithmetic and algebra (Herscovics & Linchevski, 1994). This has major personal and societal consequences because basic algebra as taught in lower secondary school plays a crucial role in upper secondary mathematics and hence for access to attractive higher education programmes. In that way school algebra is often described as a central gatekeeper (Loveless, 2013).

The last decades of algebra research has given more attention to the theoretical foundations of students' work. Algebraic transformations are not viewed only as procedures, but also as theoretical entities (Kieran, 2007). Kieran divides research in algebraic transformations into theoretical, technical, and practical elements. These elements are closely connected, and different institutions within the educational system manage them in subtly different ways. Early research on school algebra tended to make a sharp distinction among procedural and conceptual approaches. This dichotomy is currently challenged, and the potential of new theoretical and methodological approaches become essential to investigate the crucial *connections* between techniques and theory (Schneider & Stern, 2010). The Anthropological Theory of the Didactic offers, in particular, a promising new approach to this task.

To investigate the transition from arithmetic to algebra and to gain knowledge about what algebraic techniques and theory are particularly problematic for students in Danish lower secondary school, we ask the research question: "How can the Anthropological Theory of the Didactics (ATD) and the construction of a praxeological reference model (PRM) be used as foundation for developing a diagnostic test tool, to examine students technical and theoretical algebra knowledge?"

This paper will concentrate on the construction of the PRM and the derived diagnostic test tool with preliminary results from the pilot test. The PRM and the results of the diagnostic test will be used in a latter study to select research-based resources and design teaching interventions to support teachers teaching basic algebra.

ATD as theoretical foundation

The Anthropological Theory of Didactics, subsequently noted as ATD, has emerged as a theory of mathematics education. A central feature in ATD is the use of praxeology to model school mathematics activity. A praxeology compromise types of task, techniques, technologies, and theories (Bosch, 2015). The "practical block" or *praxis* is formed by the types of task and by the techniques used to solve them (Barbé et al., 2005). The "theoretical block" or *logos* consists of technology (discourse on techniques) and theory (more general discourse, based on deductive reasoning from definitions and the like). This means the techniques for carrying out tasks are explained and justified by a 'discourse on the technique' called technology; taking this discourse to a more abstract level yields mathematical theory, to validate the technological discourse and to connect entire praxeologies (Bosch, 2015).

The use of praxeology to analyse school algebra has been particularly successful, since the birth of ATD as a theoretical foundation for mathematics education research (Bosch, 2015). Bosch argues that the explicit reference praxeological models (PRM) concerning school algebra provides opportunities to ask research questions that go beyond the assumptions held by the school institution itself. At the international level, ATD research has led to significant new insights on the algebra problem, including the frequent disconnectedness of praxeologies taught and learnt.

According to Chevallard (2019), praxeologies are not static, but a dynamic system of institutionally situated activities. The explicit construction of a PRM will enable us to analyse what arithmetic and algebraic praxeologies are currently taught in the Danish lower secondary school according to curriculum, textbook material, and written examination. The PRM will also form the foundation for developing a diagnostic test tool, which can "diagnose" what algebraic techniques and theory are problematic for students (in our case, Danish grade 7). The result of the diagnostic test is analysed in terms of the PRM and may lead to revise the tool (e.g., if unexpected techniques appear). In a later study the diagnostic tool and the associated PRM will be used to design the intervention based on resources and to analyze the effects of the interventions. Thus, the model is the researchers' explicit reference throughout the four-step research process shown in Figure 1.

Methods to construct the praxeological reference model

In Denmark, the so-called "common goals" for mathematics (Danish Ministry of Education, 2019), constitute the official directives for all primary and lower secondary school. They are divided into four parts: competences, number and algebra, geometry and measurement, statistics, and probability. The overall goal for algebra is that "the student can apply real numbers and algebraic expressions in mathematical investigations". It is up to textbook authors and teachers to transpose the common goals into teaching practice; in addition to the official goals, they can also find some direction in the exercises appearing the national exam after grade 9.

Our first step in building the PRM was to identify types of tasks appearing in the 2019 national exam (Prøvebanken, 2021) and in the textbook series Kontext+ grade 7-9 (Lindhardt et al., 2021). We began by identifying the tasks in the material associated to arithmetic and algebra, understood as tasks solely focused on operations, equations and order relations involving numbers (arithmetic), or numbers and literal symbols (algebra). At the level of theory, operations are in these two cases obeying the axioms of ordered integral domains or fields. In this paper, we do not consider the use of CAS tools and instrumented techniques.
